Each steam generator is treated separately with each steam generator's four narrow range level signals being input to two 2-out-of-4 logic matrices in the DEFAS Cabinet 2C410. DEFAS-1 trip signals for EFW initiation to steam generator 1 (SG-1) are output from the two SG-1 2-out-of-4 logic matrices with trip signals being transmitted to each half of the EFAS-1 circuitry in Auxiliary Relay Cabinet A (2C39) and trip signals being transmitted to each half of the EFAS-1 circuitry in Auxiliary Relay Cabinet B (2C40). Likewise, DEFAS-2 trip signals for EFW initiation to steam generator 2 (SG-2) are output from the two SG-2 2-out-of-4 logic matrices with trip signals being transmitted to each half of the EFAS-2 circuitry in Auxiliary Relay Cabinet A (2C39) and trip signals being transmitted to each half of the EFAS-2 circuitry in Auxiliary Relay Cabinet B (2C40). The DEFAS cabinet output trip signals are only transmitted to the Auxiliary Relay Cabinets if a DSS actuation has occurred, indicating the existence of an ATWS event.

DEFAS interfaces with the safety related steam generator narrow range level instrument loops and the EFAS circuitry in the Auxiliary Relay Cabinets are accomplished via safety related fiber optic isolators.

The DEFAS 2-out-of-4 logic system outputs are actually configured as a 2-out-of-2 logic system which interfaces with each half of the EFAS actuation logic circuitry. A DEFAS trip signal generated in one trip path will only result in a half leg trip. The DEFAS logic in the Auxiliary Relay Cabinets is designed such that the loss of both trip paths is needed to de-energize the subgroup relays, resulting in EFW initiation.

The DEFAS design consists of the following requirements:

- DEFAS initiates emergency feedwater flow for conditions indicative of an ATWS where the EFAS has failed.

- The DEFAS is not required to provide mitigation of an accident such as isolating feedwater flow to a ruptured steam generator.

- DEFAS will stop feedwater flow to the affected steam generator after reaching a pre-determined level setpoint at about 30 minutes after actuation; thereafter, manual operator intervention will control the system.

- DEFAS utilizes a 2-out-of-4 logic system with steam generator water level as the parameter indicative of the need for EFAS actuation.

- DEFAS interfaces with the actuated components via the Auxiliary Relay Cabinet relays. These relays are considered to be the final actuation devices and therefore they are not required to be diverse from the reactor trip system.

- DEFAS is blocked by the EFAS to prevent control/safety interactions and to disable DEFAS when the EFAS actuates.

- DEFAS is blocked by a main steam isolation signal to prevent control/safety interactions and to disable the DEFAS when conditions for MSIS exist.

- DEFAS is enabled by a signal from the DSS indicating DSS actuation due to an ATWS event.

- DEFAS includes capabilities to allow testing at power.

- DEFAS includes features that provide alarms, plant computer data, and other operator interfaces to indicate system status and meet operability requirements.

- Manual initiation of DEFAS is provided for each steam generator via control room panel switches.

- DEFAS setpoints and response times are coordinated with the existing PPS setpoints and response times so that a competing condition between the PPS and DEFAS is prevented.

- DEFAS interfaces with existing Class 1E sensors and output devices by a fiber optic isolation technique which has been approved by the NRC for nuclear plant safety related system application. The DEFAS is physically and electrically separated from the existing RTS. It does not degrade the existing separation criteria of the RTS.

- DEFAS equipment is qualified for its environment due to Anticipated Operational Occurrences.

- DEFAS is designed under suitable Quality Assurance procedures consistent with the requirements and clarification of 10 CFR 50.62 contained in NRC Generic Letter 85-06.

- DEFAS logic power is separate and independent from the existing PPS power and is capable of providing uninterruptible power for up to one hour following the loss of its power source.

- The DEFAS is not required to be sealed-in, or locked-out, at the system level due to EFAS and MSIS control interactions. However, the 2-out-of-4 logic channels are sealed in upon receipt of a valid low steam generator level signal until a DEFAS high level setpoint is obtained.

- DEFAS uses a micro-computer with solid state I/O modules as contrasted with the PPS which uses analog bistable trip units. The DEFAS is an energize-to-actuate system while the PPS/EFAS is a de-energize-to-actuate system.

- The DEFAS is placed in service during Mode 1 operating conditions. However, the system may be taken out of service during Mode 1 for corrective maintenance or surveillance testing purposes.

In summary, the DEFAS is a highly reliable system designed to mitigate ATWS event consequences by providing a diverse means to initiate emergency feedwater, thereby minimizing the potential for a common mode failure affecting both the reactor trip system and the existing emergency feedwater actuation system.

7.7.2 ANALYSIS

The plant control systems and equipment are designed to provide high reliability during steady state operation and anticipated transient conditions.

The RPS analysis of Section 7.2.2 encompasses the failure modes of these control systems and demonstrates that these systems are not required for safety.

The accident analyses of Chapter 15 do not require these systems to remain functional.

Table 7.2-1

REACTOR PROTECTIVE SYSTEM BYPASSES

Title	Function	Initiated By	Removed By	Notes
DNBR and Local Power Density Bypass	Disable Low DNBR and High Local Power Density Trips	Key-Operated Switch (1 per channel) if power is < 10^{-2}%	Automatic if power is ≥ 10^{-2}%	Allows low power testing
RPS/ESFAS Low Pressurizer Pressure/ Low RWT Level Bypass	Disables Low Pressurizer Pressure Trip, SIAS, and RAS	Spring Return Switch (1 per channel) if pressure is below bypass permissive (< 400 psia)	Automatic if Pressure is ≥ 500 psia	Allows plant cool down and depressurization
High Log Power Level Bypass	Disables High Logarithmic Power Level Trip	Pushbutton (1 per channel) if power is > 10^{-4}%	Automatic if power is ≤ 10^{-4}%	Bypassed during reactor startup
Trip Channel Bypass	Disables any given Trip Channel	Manually by Controlled Access Switch	Same Switch	Interlocks allow only one channel for any type trip to be bypassed at one time.
RPS/ESFAS Steam Generator High/Low Level Bypass	Disables High/Low Steam Generator Level Trips and Emergency Feedwater Actuation	Spring Return Switch (1 per channel) if RCS Temperature is < 200 °F	Automatic if RCS Temperature is ≥ 200 °F	Allows testing at low power. High Steam Generator Level Bypass does not affect ESFAS

Table 7.2-4

REACTOR PROTECTIVE SYSTEM INSTRUMENT RANGES AND MARGINS TO TRIP

Reactor Trip	Instrument Range	Trip Setpoint	Full Power Nominal Value	Margin To Trip
High Logarithmic Power Level	10^{-8} - 200% Power	≤ 0.75% Power	N/A	N/A
High Linear Power Level	0 - 200% Power	≤ 110% Power	100% Power	10% Power
High Pressurizer Pressure	1500 - 2500 psia	≤ 2362 psia	2200 psia	162 psid
Low Pressurizer Pressure	0 - 3000 psia	≥ 1650 psia [2]	2200 psia	550 psid
High Steam Generator Level [4,5]	0 - 100% [1]	≤ 85.8% [1]	70% [1]	15.8%
Low Steam Generator Level [5]	0 - 100% [1]	≥ 22.2% [1]	70% [1]	47.8%
Low Steam Generator Pressure	0 - 1200 psia	≥ 751 psia [2]	943.9 psia	192.9 psid
High Containment Pressure	0 - 27 psia	≤ 18.3 psia	15 psia	3.3 psid
Low DNBR	See Section 7.2.1.1.2.5	≥ 1.25 [3]	1.65	0.40
High Local Power Density	See Section 7.2.1.1.2.5	≤ 21.0	≤ 12.1	≥ 8.9

*These are the setpoints required by the ANO-2 Technical Specifications.

(1) Percentage of the distance between steam generator upper and lower level instrument nozzles.

(2) These setpoints can be decreased manually as pressure is reduced and increase automatically as pressure is increased. The low pressurizer pressure trip can be manually bypassed below the bypass permissive, (< 400 psia). The bypass is automatically removed before pressure increases to 500 psia.

(3) The CPC system calculated value of DNBR assures trip considering all sensor and processing time delays and inaccuracies (see Section 7.2.1.1.2.5 for additional information). It also accounts for the difference between the thermal hydraulic model, CHF correlations, and DNBR limit used in the reload design analysis and that used in the CPC System.

(4) Not required for safety. This trip is equipment protective only.

(5) The steam generator high/low trips can be manually bypassed when RCS temperature is below 200 °F. The bypass is automatically removed if RCS temperature increases to 200 °F.

TABLE 7.2-5

PLANT PROTECTION SYSTEM
FAILURE MODES AND EFFECTS ANALYSIS

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Measurement Channel	Reactor Flux	FMEA Diagrams 1 & 2A		
1)	Ex-Core Flux Monitor (68)	Low - all detectors (low, mid, and high)	Loss of H.V. power supply.	Loss of data, erroneous data. Affects local power density (LPD), departure from nucleate boiling ratio (DNBR) and calibrated nuclear power calculations. LPD and DNBR channel trips due to Nuclear Instrument System (NIS) trouble contacts.	Annunciating. Trip alarms on HI LPD and LOW DNBR. Nuclear instrument inoperative alarm. CPC sensor failure alarm. 3-channel comparison. Periodic manual test.	3-channel redundancy (4th channel bypassed). Nuclear instrument trouble bistable channel trip.	Makes reactor trip logic for LO DNBR and HI LPD 1-out-of 2 coincidence. Makes reactor trip logic for HI LOG PWR and HI LIN PWR 2-out-of- 2 coincidence.	Reactor trip logic for HI LOG PWR, LO DNBR, HI LPD, and HI LIN PWR trips must be converted to 1-out-of-2 by placing appropriate bistables in affected channel in the tripped state.
		Low - one detector.	Breakdown in insulation resistance. Cable break.	Loss of data, erroneous data. Affects local power density (LPD), departure from nucleate boiling ratio (DNBR) and calibrated nuclear power calculations. Possible LPD and DNBR channel trips.	Annunciating. Pre-trip and trip alarms on HI LPD and LO DNBR. 3-channel comparison. Periodic manual test.	3-channel redundancy (4th channel bypassed). Channel trip.	Makes reactor trip logic for LO DNBR and HI LPD 1-out-of 2 coincidence. Makes reactor trip logic for HI LIN PWR and HI LOG PWR (mid detector only) 2-out-of-2 coincidence.	Reactor trip logic for HI LOG PWR (mid detector only), HI LIN PWR, LO DNBR, and HI LPD trips must be converted to 1-out-of-2 by placing appropriate bistables in affected channel in the tripped state.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Measurement Channel	Reactor Flux	FMEA Diagrams 1 & 2A		
1)	Ex-Core Flux Monitor (68) (cont)	High	Detector shorts, continuous ionization.	Erroneous data. Affects LPD, DNBR, and calibrated nuclear power calculations. LPD, DNBR, and possible HI Linear PWR channel trips. For mid detector, possible additional HI LOG PWR channel trip.	Annunciating. Pre-trip and trip alarms on LPD, DNBR, HI LIN PWR, and HI LOG PWR (mid detector only). Possible Log rate alarm (mid detector only). CPC sensor failure alarm. 3-channel comparison. Periodic manual test.	3-channel redundancy (4th channel bypassed). Channel trip.	Makes reactor trip logic for HI LIN PWR, LO DNBR, HI LOG PWR (mid detector only), and HI LPD 1-out-of-2 coincidence.	Reactor trip logic for HI LOG PWR (mid detector only), HI LIN PWR, LO DNBR, and HI LPD trips must be maintained in 1-out-of-2 by placing appropriate bistables in affected channel in the tripped state.
2)	Ex-core Power Level (69)	Low Linear and Log outputs.	Loss of Low Voltage power supply.	Loss of data, erroneous data. Affects LPD, DNBR, Log and calibrated nuclear power calculations. LPD and DNBR channel trips due to NIS trouble alarm contacts.	Annunciating. Trip alarms on HI LPD and LOW DNBR. Nuclear instrument inoperative alarm. CPC sensor failure alarm. 3-channel comparison. Periodic manual test.	3-channel redundancy (4th channel bypassed) Nuclear instrument trouble bistable causes DNBR/LPD auxiliary channel trip.	Makes reactor trip logic for LO DNBR and HI LPD 1-out-of 2 coincidence. Makes reactor trip logic for HI LOG PWR and HI LIN PWR 2-out-of 2 coincidence.	Reactor trip logic for HI LOG PWR, LO DNBR, HI LPD, and HI LIN PWR trips must be converted to 1-out-of-2 by placing appropriate bistables in affected channel in the tripped state.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Measurement Channel	Reactor Flux	FMEA Diagram 1		
2)	Ex-core Power Level (69) (cont)	Low Linear output.	Amplifier failure - Linear section.	Loss of data, erroneous data. Affects LPD, DNBR, and calibrated nuclear power calculations. Possible LPD and DNBR channel trips.	Annunciating. CPC sensor failure alarm. Pre-trip and trip alarms on HI LPD and LOW DNBR. 3-channel comparison. Periodic manual test.	3-channel redundancy (4th channel bypassed) Channel trip.	Makes reactor trip logic for LO DNBR and HI LPD 1-out-of-2 coincidence. Makes reactor trip logic for HI LIN PWR 2-out-of 2 coincidence.	Reactor trip logic for HI LIN PWR, LO DNBR, and HI LPD trips must be converted to 1-out-of-2 by placing appropriate bistables in affected channel in the tripped state.
		Low Log Output.	Amplifier failure - Log section.	Loss of data, erroneous data.	3-channel comparison. Periodic manual test.	3-channel redundancy (4th channel bypassed)	Makes reactor trip logic for HI LOG PWR 2-out-of-2 coincidence.	Reactor trip logic for HI LOG PWR trip must be converted to 1-out-of-2 by placing appropriate bistable in affected channel in the tripped state.
		High Linear Output.	Amplifier failure - Linear section.	Erroneous data. Affects LPD, DNBR, and calibrated nuclear power calculations. Possible LPD, DNBR, HI Linear PWR channel trips.	Annunciating. Pre-trip and trip alarms on LPD, DNBR and HI LIN PWR. CPC sensor failure alarm. Auto sensor validity test. 3-channel comparison. Periodic manual test.	3-channel redundancy (4th channel bypassed) Channel trip.	Makes reactor trip logic for HI LIN PWR, HI LPD, and LO DNBR 1-out-of-2.	Reactor trip logic for HI LIN PWR, LO DNBR, and H LPD trips must be maintained in 1-out-of-2 by placing appropriate bistables in affected channel in tripped state.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Measurement Channel	Reactor Flux	FMEA Diagram 1		
2)	Ex-core Power Level (69) (cont)	High Log output.	Amplifier failure - Log section.	Erroneous data. Possible HI LOG PWR channel trip.	Annunciating. Possible pre-trip and trip HI LOG PWR alarms. Possible Log Rate alarm. 3-channel comparison. Periodic manual test.	3-channel redundancy (4th channel bypassed). Channel trip.	Makes reactor trip logic for HI LOG PWR 1-out-of-2.	Reactor trip logic for HI LOG PWR trip must be maintained in 1-out-of-2 by placing appropriate bistable in affected channel in the tripped state.
				Measurement Channel	CPC Inputs	FMEA Diagram 1		
3)	Core Outlet Temp-erature T_{hot} (80)	Low	Power supply failure. Shorted RTD or cable. Temperature transmitter failure. Resistor short. I/I isolator failure.	Erroneous data. Reduces ΔT power calculation. Affects Quality Margin, LPD, DNBR, and RCS flow calculations.	Annunciating. Automatic sensor validity test (CPC sensor failure alarm). 3-channel comparison. Two T_{hot} measurements per channel.	3-channel redundancy (4th channel bypassed). CPC selects higher of neutron flux power and ΔT power for calculation of DNBR and LPD.	Makes reactor trip logic for LO DNBR and HI LPD 2-out-of-2.	Reactor trip logic for HI LPD and LO DNBR trips must be maintained in 1-out-of-2 by placing appropriate bistables in affected channel in tripped state.
		High	Open RTD or cable. Temperature transmitter failure. Resistor failure.	Erroneous data. Increases ΔT power calculation. Affects Quality Margin, LPD, DNBR, and RCS flow calculations. LO DNBR, HI LPD channel trips. Auxiliary LO DNBR, HI LPD channel trips due to Low Quality Margin.	Annunciating. Trip alarms on LO DNBR, HI LPD. Automatic sensor validity test (CPC sensor failure alarm). 3 chan-nel comparison. Two T_{hot} measurements per channel.	3-channel redundancy (4th channel bypassed). Channel trip due to CPC auxiliary trip on Low Quality Margin.	Makes reactor trip logic for LO DNBR and HI LPD 1-out-of-2.	Reactor trip logic for HI LPD & LO DNBR trips must be maintained in 1-out-of-2 by placing appropriate bistables in affected channel in tripped state. CPC aux trips do not generate pre-trip alarms.

4)	Core Inlet Temp-erature T_{cold} (82)	Low	Power supply failure. Shorted RTD or cable. Shorted resistor Temperature transmitter failure. I/I isolator failure.	Erroneous data. Increases ΔT power and calibrated neutron flux power. The higher of these two affects LPD and DNBR calculations. LO DNBR, HI LPD channel auxiliary trips due to T_{cold} sensor input outside normal range.	Annunciating. Trip alarms on LO DNBR, HI LPD. Automatic sensor validity test (CPC sensor failure alarm). 3-channel comparison. Two T_{cold} measurements per channel.	3-channel redundancy (4th channel bypassed) Channel trip due to CPC LO DNBR, HI LPD auxiliary trip on T_{cold} outside normal range.	Makes reactor trip logic for LO DNBR and HI LPD 1-out-of-2.	Reactor trip logic for HI LPD and LO DNBR trips must be maintained in 1-out-of-2 by placing appropriate bistables in affected channel in the tripped state.
		High	Open RTD or cable. Temperature transmitter failure. Resistor failure.	Erroneous data. Decreases ΔT power and DNBR calculations. Affects LPD calculation. LO DNBR, HI LPD auxiliary trips due to T_{cold} sensor input outside normal range.	Annunciating. Trip alarms on LO DNBR, HI LPD. CPC sensor failure alarm. Auto sensor validity test. 3 channel comparison. Two T_{cold} measurements per channel.	3-channel redundancy (4th channel bypassed) Channel trip due to CPC auxiliary trip on T_{cold} outside normal range.	Makes reactor trip logic for LO DNBR and HI LPD 1-out-of-2.	Reactor trip logic for HI LPD and LO DNBR trips must be maintained in 1-out-of-2 by placing appropriate bistables in affected channel in the tripped state.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Measurement Channel	CPC Inputs	FMEA Diagram 1		
5)	Reactor coolant pump flow (84)	Loss of signal.	Power supply, speed transmitter, or signal processor failure. Mechanical damage to sensor.	Loss of data. Reduces DNBR calculation. LO DNBR channel trip.	Annunciating. Pre-trip and trip alarms on LO DNBR. Automatic sensor validity test (CPC sensor failure alarm).	3-channel redundancy (4th channel bypassed) Channel trip.	Makes reactor trip logic for LO DNBR 1-out-of-2.	Reactor trip logic for LO DNBR trip must be maintained in 1-out-of-2 by placing appropriate bistables in affected channel in the tripped state.
6)	Non-target CEA position (149)	Other than actual position.	Shorted resistor. Power supply malfunction. Shorted reed switches.	Erroneous data input to one CEA calculator (CEAC). Possible penalty factor added to DNBR and LPD calculation in each CPC channel.	Annunciating. CEA deviation alarm. CWP alarm. Comparison with redundant CEAC.	Redundant CEAC.	Possible penalty factor will be applied to each CPC channel. DNBR and LPD operating margins will be reduced. Possible LO DNBR, HI LPD reactor trip.	One CEA calculator (CEAC) will detect CEA deviation and apply penalty to all CPCs.
		Excessive rate of change high or low.	Shorted resistor, power supply malfunction.	Erroneous data input to one CEAC.	Annunciating. Automatic sensor validity test (CEAC sensor failure alarm). Comparison with redundant CEAC.	CEAC uses last valid position if sensor failure is detected. Redundant CEAC.	None	One CEAC will detect CEA sensor failure based on rate of change of indicated position.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Measurement Channel	CPC Inputs	FMEA Diagram 1		
6)	Non-target CEA position (149) (cont)	Off scale.	Broken wire, open reed switch, open resistor, electrical short, power supply malfunction.	Loss of data input to one CEAC.	Annunciating. Automatic sensor validity test (CEAC sensor failure alarm). Comparison with redundant CEAC.	CEAC uses last valid position if sensor failure is detected. Redundant CEAC.	None	One CEAC will detect CEA sensor failure based on rate of change of indicated position and/or input out of range.
				Measurement Channel	CPC Inputs	FMEA Diagram 1		
7)		Other than actual position - Low	Shorted resistor. Power supply malfunction. Shorted reed switches.	Erroneous data input to one CPC channel and one CEAC. Out of sequence or sub group deviation penalties applied to DNBR and LPD calculations (except for lead reg group CEA). LO DNBR and HI LPD channel trips.	Annunciating. Pre-trip and trip alarms on LO DNBR and HI LPD. Automatic sensor validity test (CEAC sensor failure alarm). 3-channel comparison.	3-channel redundancy (4th channel bypassed) Channel trip.	Makes reactor trip logic for LO DNBR and HI LPD 1-out-of-2.	Reactor trip logic for HI LPD and LO DNBR trips must be maintained in 1-out-of-2 by placing appropriate bistables in affected channel in the tripped state.
		Other than actual position - High	Shorted resistor. Power supply malfunction. Shorted reed switches.	Erroneous data input to one CPC channel and one CEAC.	Annunciating. Automatic sensor validity test (CEAC sensor failure alarm). 3-channel comparison.	3-channel redundancy (4th channel bypassed)	None	At power rod positions are normally all rods out (ARO). For other conditions, effects may be the same as for the Low failure mode.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Measurement Channel	CPC Inputs	FMEA Diagram 1		
7)		Off scale	Broken wire, open reed switch, open resistor, electrical short, power supply malfunction.	Loss of data to one CPC channel and one CEAC. Possible Out of sequence or sub group deviation penalties applied to DNBR and LPD calculations (except for lead reg group CEA). Possible LO DNBR and HI LPD channel trips.	Annunciating. Automatic sensor validity test (CEAC sensor failure alarm and CPC sensor failure alarm). Possible pre-trip and trip alarms on LO DNBR and HI LPD. 3-channel comparison.	3-channel redundancy (4th channel bypassed) Possible channel trip.	Possibly makes reactor trip logic for LO DNBR and HI LPD 1-out-of-2.	Effects are similar to Low and High failure modes with the addition of a CPC sensor failure alarm.
8)	Control Element Assembly Calculator (88)	No data output	Loss of ac power, input/output failure. Data link failure. Arithmetic, logic, or memory failure.	Loss of one CEAC penalty factor inputs to each CPC channel. Loss of CEA position display from failed CEAC.	Annunciating. CEAC trouble alarm. Comparison of CEA position displays.	CPCs use either the output of the redundant CEAC or the last previous penalty factor from the failed CEAC, which ever is most conservative.	None	CEAC diagnostic routine or loss of data link sends failure flag to CPCs.
		Erroneous data output.	CEA position sensor failure, input/output failure. Data link failure. Arithmetic, logic, or memory failure.	Erroneous CEAC penalty factors applied to CPCs. Possible LO DNBR and HI LPD trips.	Annunciating. CEAC trouble alarm. Comparison of CEA position displays.	CPCs use the largest penalty factor from the two CEACs.	Possible LO DNBR and HI LPD reactor trip.	Assumes CEAC failure flag not generated. CPCs compare CEAC outputs and annunciate on significant difference.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Measurement Channel	CPC Inputs	FMEA Diagram 1		
9)	Core Protection Calculator (89)	Tripped	Loss of ac power. Input/output failure. Arithmetic, logic, or memory failure. Sensor failure	Erroneus calculated results. Loss of CPC remote operator module display. CPC internal self testing and watchdog timer trip outputs on fault.	Annunciating. Pre-trip and trip alarms on LO DNBR and HI LPD. CPC failure alarm. 3-channel comparisons.	3-channel redundancy (4th channel bypassed) Channel trip.	Makes reactor trip logic for LO DNBR and HI LPD 1-out-of-2.	Computer shuts down in orderly sequence on loss of ac power and resumes normal operation with restoration of power. Reactor trip logic for HI LPD and LO DNBR trips must be maintained in 1-out-of-2 by placing appropriate bistables in affected channel in the tripped state.
		Stays in un-tripped state	Input/output failure. Arithmetic, logic or memory failure. Sensor failure.	Erroneous calculated results.	Non-Annunciating. 3 channel comparison. Periodic test.	3-channel redundancy (4th channel bypassed)	Makes reactor trip logic for LO DNBR and HI LPD 2-out-of-2.	Reactor trip logic for HI LPD and LO DNBR trips must be converted to 1-out-of-2 by placing appropriate bistables in affected channel in the tripped state.

TABLE 7.2-5 (continued)

				Measurement Channel	S/G Water Level	FMEA Diagram 1		
10)	SG No. 2 Level Signal (51) SG No. 1 Level Signal (55)	Low	Sensor failure, dc power supply failure, I/I isolator failure, open circuit, resistor failure, junction box failure.	Loss of data. Erroneous data. Low SG-1(2) level signal to associated channel bistables. SG-1(2) LO LVL bistable trips. SG-1(2) HI LVL bistable disabled.	Annunciating. Pre-trip and trip alarms on SG-1(2) LO LVL. 3-channel comparison.	3-channel redundancy (4th channel bypassed) Channel trip on SG-1(2) LO LVL.	Makes reactor trip and EFAS logic for SG-1(2) LO LVL 1-out-of-2 coincidence. Makes reactor trip logic for SG-1(2) HI LVL 2-out-of-2 coincidence.	Reactor trip and EFAS logic for SG LVL functions must be converted to 1-out-of-2 by placing the appropriate bistables in affected channel in the tripped state. Same response for SG-1 and SG-2.
		High	Sensor failure, I/I isolator failure. Resistor failure. Cable failure. Junction box failure.	Erroneous data. High SG-1(2) level signal to associated channel bistables. SG-1(2) HI LVL bistable trips. SG-1(2) LO LVL bistable disabled.	Annunciating. Pre-trip and trip alarms on SG-1(2) HI LVL. 3-channel comparison. Periodic test.	3-channel redundancy (4th channel bypassed) Channel trip on SG-1(2) HI LVL.	Makes reactor trip and EFAS logic for SG-1(2) LO LVL 2-out-of-2 coincidence. Makes reactor trip logic for SG-1(2) HI LVL 1-out-of-2 coincidence.	Reactor trip and EFAS logic for SG-1(2) LVL functions must be converted to 1-out-of-2 by placing the appropriate bistables in affected channel in the tripped state.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				RPS Operating Bypass	S/G Water Level	FMEA Diagram 1		
11)	SG-1&2 HI/LO LEVEL Operating Bypass Permissive (222)	Off	RTD open, temperature transmitter failure, bistable comparator failure, auxiliary relay card failure, Operating trip bypass switch failure.	Unable to bypass SG LVL trip functions in affected channel when T_{hot} < 200 °F or if bypass was previously in, it will be removed. SG LVL reactor trip and EFAS-1/2 channel functions remain or become active.	Periodic test. Bypass and/or Permissive lights on Remote Operator Module (ROM) go out. Possible pre-trip and trip alarms on one or more SG LVL functions during startup.	3-channel redundancy (4th channel bypassed) SG LVL HI/LOW channel trips are enabled.	Possibly makes reactor trip logic for one or more SG LVL functions 1-out-of-2 coincidence depending on plant conditions.	This bypass permits CEA testing during cold shutdown. T_{hot} signal faults can also produce consequences described for Item No. 3). For detailed component failure modes see items 20, 21, 22, and 23 (identical hardware).
		On	Bistable comparator failure (no trip). Auxiliary relay card failure (stuck closed contacts). Operating trip bypass switch failure.	SG LVL reactor trip and EFAS-1/2 channel functions for affected channel disabled.	Possible bypass annunciator. Bypass light and possibly permissive light on ROM. Periodic test.	3-channel redundancy (4th channel bypassed)	Makes reactor trip and EFAS logic for SG LVL functions 2-out-of-2 coincidence.	Operator may be able to remove bypass manually at ROM, otherwise, reactor trip and EFAS logic for SG LVL functions must be converted to 1-out-of-2 by placing the appropriate bistables in affected channel in the tripped state.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				RPS Operating Bypass	S/G Water Level	FMEA Diagram 1		
11a)	SG-1&2 HI/LO LEVEL Operating Bypass	Off	Loss of permissive (Item 11), auxiliary relay (AK-26) or driver, trip bypass opto-isolator failure.	SG LEVEL reactor trip and EFAS-1/2 channel functions remain or become enabled.	3-channel comparison ROM Bypass light off. Periodic test. Possible trip alarm(s) on HI or LO SG LEVEL depending on plant conditions.	3-channel redundancy (4th channel bypassed) Affected channel trip and EFAS functions are enabled.	Possibly makes HI/LO SG LEVEL reactor trip and EFAS-1/2 functions 1-out-of-2 coincidence depending on plant conditions.	Loss of permissive fault also produces consequences described for Item 11).
		On	Auxiliary relay (AK-26) or driver failure.	SG LEVEL reactor trip and EFAS-1/2 channel functions will be disabled.	Possible Bypass alarm. 3-channel comparison. ROM bypass light on. Periodic test.	3-channel redundancy (4th channel bypassed)	Makes SG LEVEL reactor trip and EFAS-1/2 functions 2-out-of-2 coincidence.	Logic for SG LEVEL reactor trip and EFAS-1/2 functions must be converted to 1-out-of-2 by placing the appropriate bistables in affected channel in the tripped state.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Measurement Channel	PZR Pressure	FMEA Diagram 1		
12)	Wide Range PZR Pressure Signal (61)	High	Sensor failure, I/I isolator failure. Resistor failure. Junction box failure.	Erroneous data. High PZR press. signal to LO PZR PRESS bistable. LO PZR PRESS bistable disabled. Affects reactor trip, SIAS, CCAS, and CSAS functions.	3-channel comparisons. Periodic test.	3-channel redundancy (4th channel bypassed)	Makes reactor trip, CSAS enable, CCAS, and SIAS logic for LO PZR PRESS 2-out-of-2 coincidence.	Reactor trip and ESFAS logic for LO PZR PRESS must be converted to 1-out-of-2 by placing the appropriate bistable in affected channel in the tripped state.
		Low	Sensor failure, I/I isolator failure, dc power supply failure, open circuit. Resistor failure. Junction box failure.	Loss of data. Erroneous data. Low PZR press. signal to LO PZR PRESS bistable. LO PZR PRESS bistable trips. Causes channel trips on reactor trip, SIAS and CCAS functions. CSAS function is affected.	Annunciating. Pre-trip and trip alarms on LO PZR PRESS. 3-channel comparisons.	3-channel redundancy (4th channel bypassed) Channel trip.	Makes reactor trip, CSAS enable, CCAS, and SIAS logic for LO PZR PRESS 1-out-of-2 coincidence.	Reactor trip and ESFAS logic for LO PZR PRESS must be maintained in 1-out-of-2 by placing the appropriate affected channel bistable in the tripped state.
13)	Narrow Range PZR Pressure Signal (91)	High	Sensor failure, I/I isolator failure. Resistor failure. Junction box failure.	Erroneous data. High PZR press. Signal to HI PZR PRESS bistable and CPC. HI PZR PRESS bistable trips. CPC LO DNBR and HI LPD auxiliary channel trips due to PZR press. Sensor input outside operating range. CWP channel trip.	Annunciating. Pre-trip and trip alarm on HI PZR PRESS. Trip alarms on LO DNBR, HI LPD. CWP alarm. CPC sensor failure alarm. 3 channel comparison.	3-channel redundancy (4th channel bypassed) Automatic sensor validity test. Channel trips on HI PZR PRESS, LO DNBR, HI LPD.	Makes CWP and reactor trip logic for HI PZR PRESS, LO DNBR and HI LPD 1-out-of-2 coincidence.	Rx trip logic for HI PZR PRESS, HI LPD, & LO DNBR trips must be maintained in 1-out-of-2 by placing appropriate bistables in affected channel in tripped state.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Measurement Channel	PZR Pressure	FMEA Diagram 1		
13)	Narrow Range PZR Pressure Signal (91) (cont)	Low	Sensor failure, I/I isolator failure, dc power supply failure, open circuit, resistor failure, junction box failure.	Loss of data. Erroneous data. Low PZR press. Signal to HI PZR PRESS bistable and CPC. HI PZR PRESS bistable disabled. CPC LO DNBR and HI LPD auxiliary channel trips due to PZR press. Sensor input outside operating range.	Annunciating. Trip alarms on LO DNBR, HI LPD. CPC sensor failure alarm. 3 channel comparison.	3-channel redundancy (4th channel bypassed) Automatic sensor validity test. Channel trips on LO DNBR, HI LPD.	Makes reactor trip logic for HI PZR PRESS 2-out-of-2. Makes reactor trip logic for LO DNBR and HI LPD 1-out-of-2 coincidence.	Reactor trip logic for HI PZR PRESS, HI LPD, and LO DNBR trips must be converted to 1-out-of-2 by placing appropriate bistables in affected channel in the tripped state.
				Measurement Channel	S/G Pressure	FMEA Diagram 1		
14)	SG No. 2 Pressure Signal (27) SG No. 1 Pressure Signal (42)	Low	Sensor failure, I/I isolator failure, dc power supply failure, open circuit, resistor failure, junction box failure.	Loss of data. Erroneous data. Low SG-1(2) press. signal to associated channel bistables. SG-1(2) LO PRESS and SG-2>SG-1 (SG-1>SG-2) PRESS bistables trip. Channel trip for reactor trip, and MSIS actuation. Affects EFAS-1(2) function.	Annunciating. Pre-trip and trip alarms on SG-1(2) LO PRESS and SG-2>SG-1 (SG-1>SG-2) PRESS. 3-channel comparison.	3-channel redundancy (4th channel bypassed) Channel trip for reactor trip and MSIS. Two steam generators.	Makes reactor trip and MSIS logic for SG-1(2) LO PRESS 1-out-of-2 coincidence. Makes EFAS-1(2) logic 2-out-of-2 coincidence for initiation to an operable SG.	Reactor trip and ESFAS logic for SG-1(2) LO PRESS and SG-2>SG-1 (SG-1>SG-2) PRESS must be converted to 1-out-of-2 by placing the appropriate bistables in affected channel in the tripped state.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
14)	SG No. 2 Pressure Signal (27) SG No. 1 Pressure Signal (42) (cont)	High	Sensor failure, I/I isolator failure, resistor failure, junction box failure.	Erroneous data. High SG-1(2) press. signal to associated channel bistables. SG-1(2) LO PRESS disabled. SG-1>SG-2 (SG-2>SG-1) PRESS bistable trips. Affects reactor trip, MSIS, and EFAS functions.	Annunciating. Pre-trip and trip alarms on SG-1>SG-2 (SG-2>SG-1) PRESS. 3-channel comparison.	3-channel redundancy (4th channel bypassed)	Makes reactor trip and MSIS logic for SG-1(2) LO PRESS 2-out-of-2 coincidence. Makes EFAS-1(2) logic 2-out-of-2 coincidence for preventing initiation to a damaged SG.	Reactor trip and ESFAS logic for SG-1(2) LO PRESS and SG-2>SG-1 (SG-1>SG-2) PRESS must be converted to 1-out-of-2 by placing the appropriate bistables in affected channel in the tripped state.
				Measurement Channel	Containment Press	FMEA Diagram 1		
15)	Contain-ment Pressure Signal (6)	High	Instrument loop component failure.	Erroneous data. High containment press. signal to HI CONT PRESS reactor trip and ESFAS channel bistables and to HI-HI CONT PRESS channel bistable. Reactor trip, ESFAS HI CONT PRESS, and HI-HI CONT PRESS bistables trip. Affects reactor trip, CIAS, SIAS, CCAS, and CSAS functions.	Annunciating. Pre-trip and trip alarms on RPS and ESFAS HI CONT PRESS and on HI-HI CONT PRESS. 3-channel comparison.	3-channel redundancy (4th channel bypassed) Channel trips initiated. 2-out-of-3 logic prevents inadvertent actuation of containment spray on a single channel failure.	Makes CSAS logic 1-out-of-2 coincidence. Makes reactor trip, CIAS, SIAS, and CCAS logic for HI CONT PRESS 1-out-of-2 coincidence.	Reactor trip and ESFAS logic for HI CONT PRESS and CSAS logic for HI-HI CONT PRESS must be maintained in 1-out-of-2 by placing the appropriate bistables in affected channel in the tripped state.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Measurement Channel	Containment Press	FMEA Diagram 1		
15)	Contain-ment Pressure Signal (6) (cont)	Low	Instrument loop component failure.	Loss of data. Erroneous data. Low containment press. signal to associated channel bistables. Reactor trip and ESFAS HI CONT PRESS bistables disabled. HI-HI CONT PRESS bistable disabled. Affects reactor trip, CIAS, SIAS, CCAS, and CSAS functions.	3-channel comparison. Periodic Test.	3-channel redundancy (4th channel bypassed)	Makes CSAS logic 2-out-of-2 coincidence. Makes reactor trip, CIAS, SIAS, and CCAS logic for HI CONT PRESS 2-out-of-2 coincidence.	Reactor trip and ESFAS logic for HI and HI-HI CONT PRESS must be converted to 1-out-of-2 by placing the appropriate bistables in affected channel in the tripped state.
16)	(221) [Deleted]							
				Measurement Channel	RWT Level	FMEA Diagram 1		
17)	Refueling Water Tank Level Signal (1)	Low	Instrument loop component failure.	Loss of data. Erroneous data. Low RWT level signal to REFUEL TANK LO LEVEL bistable. REFUEL TANK LO LEVEL bistable trips. Affects RAS function.	Annunciating. Pre-trip and trip alarm on REFUEL TANK LO LEVEL. 3-channel comparison.	3-channel redundancy (4th channel bypassed) Channel trip initiated.	Makes RAS logic 1-out-of-2 coincidence.	RAS logic must be maintained in 1-out-of-2 by placing the appropriate bistables in affected channel in the tripped state.
		High	Instrument loop component failure.	Erroneous data. High RWT level signal to REFUEL TANK LO LEVEL bistable. REFUEL TANK LO LEVEL bistable disabled. Affects RAS function.	3-channel comparison. Periodic Test.	3-channel redundancy (4th channel bypassed)	Makes RAS logic 2-out-of-2 coincidence.	RAS logic must be converted to 1-out-of-2 by placing the appropriate affected channel bistable in the tripped state.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				PPS Operating Bypass	RWT Lvl/PZR Press	FMEA Diagram 1		
18)	LO RWT LEVEL/LO PZR PRESS Operating Bypass Permissive (59)	Off	WR PZR press. Signal failure high, bistable comparator (A25) failure, auxiliary relay (AK-21) or driver failure, loss of auxiliary logic power supply.	Unable to bypass LO RWT LEVEL RAS function and LO PZR PRESS reactor trip, SIAS, CCAS and CSAS functions in affected channel when P_{PZR} < 400 psi. If bypass was previously in, it will be removed. LO RWT LEVEL RAS function and LO PZR PRESS reactor trip, SIAS, CCAS and CSAS functions remain or become enabled.	3-channel comparison. ROM permissive light off. Periodic test. PPS trouble alarm if fault due to power supply failure. Possible trip alarm(s) on LO RWT LEVEL and/or LO PZR PRESS depending on plant conditions.	3-channel redundancy (4^{th} channel bypassed) Affected channel trip and ESFAS functions are enabled.	Possibly makes LO RWT LEVEL RAS function and LO PZR PRESS reactor trip, SIAS, CCAS, & CSAS functions 1-out-of-2 coincidence depending on plant conditions.	This bypass permits CEA testing during cold shutdown. WR P_{PZR} signal faults also produce consequences described for Item 12).
		On	WR PZR press. Signal failure low, open circuit, bistable comparator(A25) failure, auxiliary relay (AK-21) or driver failure.	Permissive will be present when plant conditions do not warrant it. During plant startup, bypass will not be automatically removed. Possible to have channel protective functions bypassed when still required.	3-channel comparison. ROM permissive light on. Periodic test.	3-channel redundancy (4^{th} channel bypassed) Manual operator action required to activate bypass.	During startup, makes LO RWT LEVEL RAS function and LO PZR PRESS reactor trip, SIAS, CCAS &CSAS functions 2-out-of-2 coincidence.	During startup, operator can manually remove bypass and restore PPS to 2-out-of-3. If fault occurs at power, there is no effect on PPS logic.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				PPS Operating Bypass	RWT Lvl/PZR Press	FMEA Diagram 1		
19)	LO RWT LEVEL/LO PZR PRESS Operating Bypass (60)	Off	Loss of permissive (Item 18), auxiliary relay (AK-22) or driver, trip bypass opto isolator failure.	LO RWT LEVEL RAS function and/or LO PZR PRESS reactor trip, SIAS, CCAS and CSAS channel functions remain or become enabled.	3-channel comparison. ROM bypass light off. Periodic test. Possible trip alarm(s) on LO RWT LEVEL and/or LO PZR PRESS depending on plant conditions.	3-channel redundancy (4th channel bypassed) Affected channel trip and ESFAS functions are enabled.	Possibly makes LO RWT LEVEL RAS function and LO PZR PRESS reactor trip, SIAS, CCAS and CSAS functions 1-out-of-2 coincidence depending on plant conditions.	Opto-isolator fault will affect either LO RWT LEVEL or LO PZR PRESS functions, not both. Loss of permissive fault also produces consequences described for Item 18).
		On	Auxiliary relay (AK-22) or driver.	LO RWT LEVEL RAS, LO PZR PRESS reactor trip, SIAS, CSAS, and CIAS channel functions will be disabled.	Possible Bypass alarm. 3-channel comparison. ROM bypass light on. Periodic test.	3-channel redundancy (4th channel bypassed)	Makes LO RWT LEVEL RAS function and LO PZR PRESS reactor trip, SIAS, CCAS and CSAS functions 2-out-of-2 coincidence.	Logic for LO RWT LEVEL RAS function and LO PZR PRESS reactor trip, SIAS, CCAS and CSAS functions must be converted to 1-out-of-2 by placing the appropriate bistables in affected channel in the tripped state.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				PPS Operating Bypass	RWT Lvl/PZR Press	FMEA Diagram 1		
20)	Pressurizer Pressure Auxiliary Bistable (BS-25)	Output energized	Failure of Input signal buffer, trip setpoint comparator, or setpoint power supply.	Energizes auxilary relay AK-21. Generates permissive to LO RWT LEVEL/LO PZR PRESS operating bypass circuit. Same effect as Item No.18) On	Same as Item No.18) On.	Same as Item No.18) On.	Same as Item No.18) On.	Same as Item No.18) On.
		Output de-energized	Failure of Input signal buffer, trip setpoint comparator, setpoint power supply, DC/DC converter, trip output opto-isolator.	Deenergizes auxiliary relay AK-21. Removes permissive to LO RWT LEVEL/LO PZR PRESS operating bypass circuit. Same effect as Item No.18) Off.	3-channel comparison. ROM permissive light off. Periodic test. Possible trip alarm(s) on LO RWT LEVEL and/or LO PZR PRESS depending on plant conditions.	Same as Item No.18) Off.	Same effect as Item No.18) Off.	
21)	Aux Relay Card 24	AK-21 (K101) Coil open	Sustained overvoltage	Removes +12V from AK-22 and permissive light. Removes permissive to LO RWT LEVEL/LO PZR PRESS operating bypass circuit. Same effect as Item No. 18) Off.	Same as Item No. 20) Output Deenergized.	Same as Item No.18) Off.	Same effect as Item No. 18) Off.	
		AK-21 (K101) Coil short	Deterioration of insulation	Generation of permissive from aux bistable card BS-25 at <400 psi will cause AK-21 to draw excessive current & place a severe load on the relay driver. This may cause the relay coil to open or the driver to short or open. Loss of permissive signal. Same effect as Item No. 18) Off.	Same as Item No. 20) Output Deenergized.	Same as Item No. 18) Off.	Same as Item No. 18) Off.	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				PPS Operating Bypass	RWT Lvl/PZR Press	FMEA Diagram 1		
21)	Aux Relay Card 24 (cont)	AK-21 (K101) Contact open	Deterioration of contact	Same as open coil.	Same as open coil.	Same as open coil.	Same as open coil.	AK-21 uses one NO contact to provide +12V source to AK-22 (Aux relay card 23) and the ROM permissive light.
		AK-21 (K101) Contact short	Welded contact, stuck contact.	Generates permissive to LO RWT LEVEL/LO PZR PRESS operating bypass circuit. Same effect as Item No.18) On.	Same as Item No.18) On.	Same as Item No.18) On.	Same as Item No.18) On.	
		AK-21 Relay Driver (Q101) Off	Open transistor junction.	Deenergizes AK-21 coil. Loss of permissive. Same effect as Item No.18) Off.	Same as Item No. 20) Output Deenergized.	Same as Item No.18) Off.	Same as Item No.18) Off.	
		AK-21 Relay Driver (Q101) On	Emitter to collector short.	Energizes AK-21 coil. Generates permissive to LO RWT LEVEL/LO PZR PRESS operating bypass circuit. Same effect as Item No.18) On.	Same as Item No.18) On.	Same as Item No.18) On.	Same as Item No.18) On.	Shorted transistor may open due to increased current flow.
22)	Aux Relay Card 23	AK-22 (K101) Coil Open	Sustained overvoltage	Removes operating bypass from LO RWT LEVEL and LO PZR PRESS bistables. Removes +12V from ROM Bypass light applies it to Normal light. Opens contact to Bypass annunciator. Same effect as Item 19) Off.	Same as Item 19) Off.	Same as Item 19) Off.	Same as Item 19) Off.	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				PPS Operating Bypass	RWT Lvl/PZR Press	FMEA Diagram 1		
22)	Aux Relay Card 23 (cont)	AK-22 (K101) Coil short	Deterioration of insulation	Attempting to insert LO RWT/LO PZR PRESS operating bypass with permissive present will cause AK-22 to draw excessive current and place a severe load on the relay driver. This may cause the relay coil to open or the driver to short or open. Loss of bypass function. Same effect as Item No. 19) Off.	Same as Item No. 19) Off.	Same as Item No. 19) Off.	Same as Item No. 19) Off.	
		AK-22 (K101) Open contact to opto-isolators	Deterioration of contact, stuck contact.	Removal of +12V to trip bypass opto-isolators for LO RWT LEVEL and LO PZR PRESS bistables. LO RWT LEVEL RAS channel function and LO PZR PRESS reactor trip, SIAS, CCAS and CSAS channel functions remain or become enabled.	Periodic test. Possible trip alarm(s) on LO RWT LEVEL and/or LO PZR PRESS depending on plant conditions.	Same as Item 19) Off.	Same as Item 19) Off.	AK-22 uses 3 sets of contacts. Normal light remains lit. Bypass annunciator remains on.
		AK-22 (K101) Shorted contact to opto-isolators	Welded or stuck contact.	Applies +12V to trip bypass opto-isolators for LO RWT LEVEL and LO PZR PRESS bistables and to the ROM Bypass light. LO RWT LEVEL RAS channel function and LO PZR PRESS reactor trip, SIAS, CSAS, and CCAS channel functions become disabled.	3-channel comparison. ROM bypass light on. Periodic test.	Same as Item 19) On.	Same as Item 19) On.	Same as Item 19) On.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				PPS Operating Bypass	RWT Lvl/PZR Press	FMEA Diagram 1		
22)	Aux Relay Card 23 (cont)	AK-22 (K101) Open contact to ROM Normal Light	Deterioration of contact, stuck contact.	ROM Normal light does not come on when Bypass light goes out. No effect on LO RWT/LO PZR PRESS operating bypass operability.	3-channel comparison. ROM Normal light off.	3-channel redundancy (4th channel bypassed)	None	
		AK-22 (K101) Shorted contact to ROM Normal Light	Welded, stuck contact.	ROM Normal light stays on when Bypass light comes on. No effect on LO RWT/LO PZR PRESS operating bypass operability.	3-channel comparison. ROM Normal and Bypass lights on simultaneously.	3-channel redundancy (4th channel bypassed)	None	
		AK-22 (K101) Open contact to Bypass Annun-ciator	Deterioration of contact, stuck contact.	Bypass Annunciator does not actuate when channel is placed in bypass.	3-channel comparison. ROM Bypass light on with annunciator off. Periodic test.	3-channel redundancy (4th channel bypassed) ROM Bypass light uses separate contact.	None	
		AK-22 (K101) Shorted contact to Bypass Annun-ciator	Welded or stuck contact.	Bypass annunciator continuously actuated.	3-channel comparison. ROM Bypass light off with annunciator on. Periodic test.	3-channel redundancy (4th channel bypassed) ROM Bypass light uses separate contact.	None	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				PPS Operating Bypass	RWT Lvl/PZR Press	FMEA Diagram 1		
22)	Aux Relay Card 23 (cont)	AK-22 Relay Driver (Q101) Off	Open transistor junction.	Deenergizes AK-22 coil. Loss of LO RWT LEVEL/LO PZR PRESS bypass capability. Same effect as Item 19) Off.	Same as Item 19) Off.	Same as Item 19) Off.	Same as Item 19) Off.	
		AK-22 Relay Driver (Q101) On	Emitter to collector short.	If permissive is present, energizes AK-22 coil. Generates LO RWT LEVEL/LO PZR PRESS bypass without operator action.	Annunciating. Bypass alarm. 3-channel comparison. ROM Bypass light on. Periodic test.	3-channel redundancy (4th channel bypassed) Bypass will automatically be removed when LO PZR PRESS permissive is removed.	None.	Shorted transistor may open due to increased current flow.
23)	LO RWT LEVEL/LO PZR PRESS ROM Bypass Switch	Short in bypass position	Mechanical failure.	If permissive is present, generates LO RWT LEVEL/LO PZR PRESS bypass without operator action.	Annunciating. Bypass alarm. 3-channel comparison. ROM Bypass light on. Periodic test.	3-channel redundancy (4th channel bypassed) Bypass will automatically be removed when LO PZR PRESS permissive is removed.	None.	
		Open in bypass position	Mechanical failure.	Loss of LO RWT LEVEL/LO PZR PRESS bypass capability. Same effect as Item 19) Off.	Unable to bypass. ROM Bypass light not lit. Periodic test.	Same as Item 19) Off.	Same as Item 19) Off.	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				RPS Operating Bypass	Hi Log Power	FMEA Diagram 1		
24)	HI LOG POWER Operating Bypass Permissive (70)	Off	Log power signal failure low, NI Safety Channel bistable fails off, NI Safety Channel bistable relay failure, auxiliary relay AK-27 or driver failure, auxiliary logic power supply failure.	Unable to bypass HI LOG PWR reactor trip when power is above the Log Power Bistable Setpoint for the affected channel. If bypass was previously in, it will be removed. HI LOG PWR channel trip remains or becomes enabled.	Unable to bypass. 3-channel comparison. ROM Permissive light off. Periodic test. PPS trouble alarm if fault due to power supply failure. Possible trip alarm on HI LOG PWR depending on plant conditions.	3-channel redundancy (4th channel bypassed) Affected channel trip function enabled.	Possibly makes HI LOG PWR reactor trip logic 1-out-of-2 coincidence depending on plant conditions.	Log power signal failure will also produce consequences described for Items 1) and 2).
		On	Log power signal failure high, NI Safety Channel bistable fails on, NI Safety Channel bistable relay failure, auxiliary relay AK-27 or driver failure.	Permissive will be present when plant conditions do not warrant it. During plant shutdown, bypass will not be automatically removed. Possible to have channel HI LOG PWR reactor trip bypassed when it is required (below the Log Power Bistable Reset Point).	3-channel comparison. Periodic test. Hi Log Pwr Permissive alarm if bypass was not already inserted.	3-channel redundancy (4th channel bypassed) Bypasses are not automatically activated.	When shutting down, makes HI LOG PWR reactor trip logic 2-out-of-2 coincidence.	Bypass can be manually removed to restore HI LOG PWR reactor trip logic to 2-out-of-3.
25)	HI LOG POWER Operating Bypass (71)	Off	Loss of permissive (Item 24), ROM latching solenoid failure, ROM DC/DC convertor failure, HI LOG PWR bistable trip bypass opto-isolator failure.	Affected channel HI LOG PWR reactor trip function remains or becomes enabled.	Annunciating. Pre-trip and trip alarm on HI LOG PWR if reactor power is >0.75%. Possible Hi Log Pwr Permissive alarm. 3-channel comparison. ROM bypass light off. Periodic test. Unable to bypass.	3-channel redundancy (4th channel bypassed) Affected channel trip function is enabled.	If reactor power is > 0.75%, makes HI LOG PWR reactor trip logic 1-out-of-2 coincidence.	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				RPS Operating Bypass	Hi Log Power	FMEA Diagram 1		
25)	HI LOG POWER Operating Bypass (71) (cont)	On	High Log Power Bypass Switch stuck contact.	Affected channel HI LOG PWR reactor trip function is automatically bypassed when reactor power increases above the Log Power Bistable Setpoint. This effectively defeats the channel HI LOG PWR trip function at 1% power.	Annunciating. HI LOG PWR pre-trip alarm. 3-channel comparison. ROM bypass light on. Periodic test.	3-channel redundancy (4th channel bypassed)	During startup, makes reactor trip logic for HI LOG PWR 2-out-of-2 coincidence.	Reactor trip logic for HI LOG PWR must be converted to 1-out-of-2 by placing the appropriate bistable in the affected channel in the tripped state.
26)	HI LOG POWER Permissive Relay AK-27	Coil open	Sustained overvoltage.	Same as Item 24) Off.	Unable to bypass. 3-channel comparison. ROM Permissive light off. Periodic test. Possible trip alarm on HI LOG PWR depending on plant conditions.	Same as Item 24) Off.	Same as Item 24) Off.	
		Coil short	Deterioration of insulation.	Generation of permissive from NI safety channel above the Log Power Bistable Setpoint will cause AK-27 to draw excessive current and place a severe load on the relay driver. This may cause the relay coil to open or the driver to short or open. Loss of permissive signal results. Same effect as Item 24) Off.	Unable to bypass. 3-channel comparison. ROM Permissive light off. Periodic test. Possible trip alarm on HI LOG PWR depending on plant conditions.	Same as Item 24) Off.	Same as Item 24) Off.	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				RPS Operating Bypass	Hi Log Power	FMEA Diagram 1		
26)	HI LOG POWER Permissive Relay AK-27 (cont)	N.O. contact in bypass circuit open	Deterioration of contact, stuck contact.	Same as Item 24) Off.	Same as open coil.	Same as Item 24) Off.	Same as Item 24) Off.	
		N.O. contact in bypass circuit shorted	Welded or stuck contact.	Same as Item 24) On.	3-channel comparison. ROM bypass light remains on when permissive clears.	Same as Item 24) On.	Same as Item 24) On.	
		N.C. contact in Off light circuit shorted	Welded or stuck contact.	ROM HI LOG PWR Bypass Off light will not go out when bypass is actuated. No effect on bypass operability.	ROM Off light remains on concurrent with Bypass light. 3-channel comparison. Periodic test.	Affects indication only.	None	
		N.C. contact in Off light circuit open	Deterioration of contact, stuck contact.	If ROM HI LOG PWR bypass button is depressed without permissive present the Off light will go out until the button is released.	Periodic test.	Affects indication only.	None.	
		N.C. contact in annun-ciator circuit shorted	Welded or stuck contact.	When the HI LOG PWR permissive is generated, it will not be annunciated.	Periodic test.	Affects indication only. 3-channel redundancy (4th channel bypassed)	None.	
		N.C. contact in annun-ciator circuit open	Deterioration of contact, stuck contact.	HI LOG PWR Bypass Permissive annunciator will be on when actual permissive is not present.	Annunciating. Periodic test.	Affects indication only.	None.	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				RPS Operating Bypass	Hi Log Power	FMEA Diagram 1		
27)	High Log Power Manual Bypass Switch	Solenoid open	Mechanical failure of wire, sustained overvoltage.	HI LOG PWR Trip Bypass pushbutton will not latch in the ON position.	Attempting to place the affected channel in bypass.	Channel trip remains enabled.	If reactor power is increased >1%, bistable will trip making HI LOG PWR reactor trip logic 1-out-of-2 coincidence. (4th channel bypassed)	Channel can be bypassed by continuously holding in the HI LOG PWR Bypass pushbutton.
		Solenoid short	Deterioration of insulation.	Attempting to bypass the HI LOG PWR trip in the affected channel will reduce the output voltage of the auxiliary logic power supply and possibly produce associated faults. Bypass will not be actuated.	Attempting to place the affected channel in bypass. Possible PPS Trouble alarm.		If reactor power is increased >1%, bistable will trip making HI LOG PWR reactor trip logic 1-out-of-2 coincidence. (4th channel bypassed)	When pushbutton is released, power supply output should recover. See DC Power Distribution Failure of Auxiliary Logic Power Supply.
		N.O. contact in trip bypass circuit open	Mechanical failure, contact deterioration.	Same as Item 25) Off.	Same as Item 25) Off.	Same as Item 25) Off.	Same as Item 25) Off.	
		N.O. contact in trip bypass circuit shorted	Mechanical failure, welded contact.	Same as Item 25) On.	Same as Item 25) On.	Same as Item 25) On.	Same as Item 25) On.	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				RPS Operating Bypass	Hi Log Power	FMEA Diagram 1		
27)	High Log Power Manual Bypass Switch (cont)	N.C. contact in Bypass Off light circuit shorted	Mechanical failure, welded contact.	ROM HI LOG PWR Bypass Off light will not go out when bypass is actuated. No effect on bypass operability.	ROM Off light remains on concurrent with Bypass light. 3-channel comparison. Periodic test.	Affects indication only.	None.	
		N.C. contact in Bypass Off light circuit open.	Mechanical failure, contact deterioration.	ROM HI LOG PWR Bypass Off light goes out when permissive is generated. No effect on bypass operability.	ROM Off light goes off before bypass is actuated. 3-channel comparison. Periodic test.	Affects indication only.	None.	
		N.O. contact in annunciator circuit open	Mechanical failure, contact deterioration.	HI LOG PWR Bypass Permissive annunciator will not clear when bypass is actuated.	When bypass is actuated, permissive annunciator does not clear. Periodic test.	Affects indication only.	None.	
		N.O. contact in annunciator circuit shorted	Mechanical failure, welded contact.	HI LOG PWR Bypass Permissive annunciator will not alarm for the affected channel.	3-channel comparison. Periodic test.	Affects indication only.	None.	
		N.O. contact in pre-trip annunciator circuit open	Mechanical failure, contact deterioration.	HI LOG PWR pre-trip annunciator remains enabled. If power > pre-trip setpoint, alarm will be generated.	3-channel comparison. Periodic test.	Affects indication only.	None.	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				RPS Operating Bypass	Hi Log Power	FMEA Diagram 1		
27)	High Log Power Manual Bypass Switch (cont)	N.O. contact in pre-trip annunciator circuit shorted	Mechanical failure, welded contact.	HI LOG PWR pre-trip annunciator disabled at all times. If power > pre-trip setpoint with no bypass, alarm will not be generated.	3-channel comparison. Periodic test.	Affects indication only.	None.	
		DC/DC Converter failure.	Open, component failure.	Same as Item 25) Off.	Same as Item 25) Off.	Same as Item 25) Off.	Same as Item 25) Off.	
				RPS Operating Bypass	CPCs	FMEA Diagram 1		
28)	CPC Operating Bypass Permissive	Off	Log power signal failure high, NI Safety Channel bistable failure on, bistable relay failure, auxiliary relay AK-20 or driver failure.	Unable to bypass LO DNBR and HI LPD reactor trips when power is below the Log Power Bistable Reset Point for the affected channel. If bypass was previously in, it will be removed. LO DNBR and HI LPD channel trips remain or become enabled.	Unable to bypass. 3-channel comparison. Possible trip and pre-trip alarms on LO DNBR and HI LPD depending on plant conditions. Periodic test.	3-channel redundancy (4th channel bypassed) Affected channel trip functions enabled.	Below the Log Power Bistable reset point, may make LO DNBR & HI LPD trip logic 1-out-of-2 coincidence depending on plant conditions. Above the Log Power Bistable setpoint, no effect.	Log power signal failure will also produce consequences described for Items 1) and 2). This bypass permits CEA testing during shutdown. For detailed relay failures see Item 26).
		On	Log power signal failure low, NI Safety Channel bistable failure off, bistable relay failure, auxiliary relay AK-20 failure.	Permissive present when power above Log Power Bistable setpoint for the affected channel. During plant startup, bypass will not automatically remove. Possible to have LO DNBR & HI LPD trips bypassed when they are required.	3-channel comparison. Periodic test.	3-channel redundancy (4th channel bypassed) Bypasses do not activate automatically.	During reactor startup, makes LO DNBR and HI LPD reactor trip logic 2-out-of -2 coincidence.	Bypass can be manually removed at CPC Operator Module to restore LO DNBR & HI LPD Rx trip logic to 2-out-of-3. For detailed relay failures see Item 26).

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				CWP Automatic Bypass		FMEA Diagram 1		
29)	CWP Automatic Bypass	Off	Same as Item 28) Off.	CPC CWP signal for the affected channel will be enabled when power is below the Log Power Bistable Setpoint.	3-channel comparison. Periodic test.	3-channel redundancy (4th channel bypassed). Not required for protection.	None.	This function is not credited in the safety analysis. Generated from same circuit as the CPC manual bypass permissive.
		On	Same as Item 28) On.	CPC CWP signal for the affected channel will be always be disabled.	3-channel comparison. Periodic test.	3-channel redundancy (4th channel bypassed) Not required for protection.	None.	
				Trip Channel Bypass	Channel A (Typical)			
30)	Trip Channel Bypass - Channel A (Typical)	Contact AXKB6-7 or AXK1-4 open	Deterioration of contact, stuck contact.	Bypasses of the affected function will not be indicated on the Remote Operator Module (ROM) or on the PPS Bistable Control Panel (BCP).	3-channel comparison. Periodic testing or when bypassing during operation.		No effect on logic matrices.	Contact used for annunciation only. AXK1 represents RPS only application. AXKB6 represents RPS and ESFAS application.
		Contact AXKB6-7 or AXK1-4 short	Welded contact, stuck contact.	Bypasses of the affected function will be continuously indicated on the ROM and on the BCP.	ROM and BCP bypass lights lit. Periodic testing.		No effect on logic matrices.	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Channel Bypass	Channel A (Typical)			
30)	Trip Channel Bypass – Channel A (Typical) (cont)	Contact AXKA6-5 or AXK1-5 open	Deterioration of contact, stuck contact.	Plant annunciator will indicate a bypass condition on the affected channel function at all times.	Annunciating. Affected channel function bypass alarm.		No effect on logic matrices.	Contact used for plant annunciation only.
		Contact AXKA6-5 or AXK1-5 short	Welded contact, stuck contact.	Plant annunciator will never indicate a bypass condition on the affected channel function.	Periodic test.		No effect on logic matrices.	
		Relay coil AXKA6 (AXKB6) open	Sustained overvoltage, mechanical failure.	Affected channel bistable cannot be bypassed for the RPS (ESFAS) function.	Periodic testing or when attempting to bypass.	Associated trip function remains or becomes enabled.	If the associated bistable is tripped, makes affected RPS (ESFAS) trip logic 1-out-of-3 coincidence.	ESFAS (RPS) function is not affected as a different relay bypasses the bistable contacts in the ESFAS (RPS) matrices.
		Relay coil AXKA6 (AXKB6) short	Deterioration of insulation.	No symptoms until an attempt is made to bypass the affected bistable. Excessive current will reduce the supply voltage possibly causing all bypasses in affected channel to be removed.	Periodic testing or when attempting to bypass.	Removal of bypass(es) enables associated trip function(s).	Removal of trip channel bypasses may result in channel trips for one or more functions depending on plant conditions.	
	Trip Channel Bypass (Typical)	Bypass switch AXS-1 Contact S1 in normally off position	Mechanical failure, contact deterioration.	Channel bistable cannot be bypassed for the affected function.	Periodic testing or when attempting to bypass.	Channel trip function is enabled.	If bistable is tripped, makes affected RPS or ESFAS trip logic 1-out-of-3 coincidence.	Same effect for BXS-1 Contact S2, CXS-1 Contact S3, and DXS-1 Contact S4.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Channel Bypass	Channel A (Typical)			
30)	Trip Channel Bypass – Channel A (Typical) (cont)	Bypass switch AXS-1 Contact S1 in normally on position	Mechanical failure, contact welded.	Channel bistable is bypassed regardless of the position of the switch.	Annunciating. Trip channel bypass alarm. ROM and BCP bypass lights. Periodic testing.	If an attempt is made to bypass the same function in another channel, both bypasses will be removed.	Makes affected RPS or ESFAS trip logic 2-out-of-3 coincidence.	
		Bypass switch AXS-1 Contact S2 (S3,S4) in normally off position	Mechanical failure, contact deterioration.	Will not be able to bypass the affected function in channel B (C,D).	Periodic testing or when attempting to bypass.	Channel trip function is enabled.	If bistable in channel B (C,D) is tripped, makes the affected RPS or ESFAS trip logic 1-out-of-3 coincidence.	Similar effect for BXS-1 Contacts S1, S3, & S4; CXS-1 Contacts S1, S2, & S4; or DXS-1 Contacts S1, S2, & S3.
		Bypass switch AXS-1 Contact S2 (S3,S4) in normally on position	Mechanical failure, contact welded.	Permissive for bistable 1 in channel B (C,D) bypass will be present even though channel A bistable 1 is in bypass. The circuit, however, will still not allow 2 channels in bypass simultaneously.	Periodic test.	A bypass on bistable 1 in channel B (C,D) will remove a bypass on bistable 1 in channel A.	None.	
				Bistable Circuits, RPS				
31)	RPS Bistable for: HI CONT PRESS(24), SG-1 HI LVL (135), SG-2 HI LVL (134), HI LIN PWR (72), HI LOG PWR (75)	Trip output de-energized (off)	Open circuit, Failure of: ± 15V power supply, Trip voltage comparator, Setpoint voltage supply, Trip setpoint potentiometer, Trip opto-isolator.	Bistable relays in RPS logic deenergize. Places a half trip in 3 coincidence logic matrices for the associated function.	Annunciating. Trip alarm on associated function. Periodic test.	3-channel redundancy (4th channel bypasses) Channel trip.	Makes the affected reactor trip logic 1-out-of-2 coincidence.	Affected reactor trip logic must be maintained in 1-out-of-2 by placing the appropriate bistable in the tripped state.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Bistable Circuits, RPS				
31)	RPS Bistable for: HI CONT PRESS(24), SG-1 HI LVL (135), SG-2 HI LVL (134), HI LIN PWR (72), HI LOG PWR (75)	Trip output energized (on)	Failure of: ± 15V power supply, Trip voltage comparator, Setpoint voltage supply, Trip setpoint potentiometer, Trip opto-isolator.	Bistable relays in RPS logic will remain energized. Affected channel function is inoperative.	Periodic testing.	3-channel redundancy (4th channel bypasses)	Makes the affected reactor trip logic 2-out-of-2 coincidence.	Affected reactor trip logic must be converted to 1-out-of-2 by placing the appropriate bistable in the tripped state.
		Trip relay driver open	Open transistor.	One trip relay is deenergized. Places a half trip in one coincidence logic matrix.	Annunciating. Trip alarm on associated function. Periodic test.	3-channel redundancy (4th channel bypasses)	1 of 3 logic matrices is half tripped for the affected function. Makes reactor trip logic 1-out-of-2 using the affected channel and 2-out-of-3 using the unaffected channels.	Channel trip outputs to the other two logic matrices are unaffected.
		Trip relay driver short	Shorted transistor.	Trip relay does not deenergize on a trip condition. Effectively bypasses one logic matrix. If excessive current is drawn, may result in associated DC power supply failure. See DC power distribution faults.	Periodic test.	3-channel redundancy (4th channel bypasses)	1 of 3 logic matrices is disabled for the affected function. Makes trip logic 2-out-of-2 using the affected channel and 2-out-of-3 using the unaffected channels.	Affected reactor trip logic must be converted to 1-out-of-2 by placing the associated bistable in the tripped state.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Bistable Circuits, RPS		FMEA Diagram 1		
31)	RPS Bistable for: HI CONT PRESS(24), SG-1 HI LVL (135), SG-2 HI LVL (134), HI LIN PWR (72), HI LOG PWR (75) (cont)	Trip relay coil shorted	Deterioration of insulation.	May cause relay driver to fail, as described above, due to excessive current. Relay contacts will not pick up, same effect as open coil.				
		Trip relay coil open	Sustained overvoltage, broken wire.	One bistable relay is in tripped condition. Same effect as open relay driver.	Same effect as open relay driver.	Same as open relay driver.	Same as open relay driver.	Same as open relay driver.
		Pre-trip output de-energized (off)	Open circuit, Failure of: ± 15V power supply, Pretrip voltage comparator, Setpoint voltage supply, Pretrip setpoint potentiometer, Pre-trip opto-isolator.	Pre-trip relays are deenergized.	Annunciating. Pre-trip alarm for affected function. Periodic test.		None. Indication only.	
		Pre-trip output energized (on)	Failure of: ± 15V power supply, Pre-trip voltage comparator, Setpoint voltage supply, Pre-trip setpoint poten-tiometer, Pre-trip opto-isolator.	Pre-trip relays do not deenergize on a pre-trip condition. No pre-trip annunciation for affected channel function.	Periodic test.		None. Indication only.	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Bistable Circuits, RPS		FMEA Diagram 1		
31)	RPS Bistable for: HI CONT PRESS(24), SG-1 HI LVL (135), SG-2 HI LVL (134), HI LIN PWR (72), HI LOG PWR (75) (cont)	Pre-trip output energized (on)	Failure of: ± 15V power supply, Pre-trip voltage comparator, Setpoint voltage supply, Pre-trip setpoint potentiometer, Pre-trip opto-isolator.	Pre-trip relays do not deenergize on a pre-trip condition. No pre-trip annunciation for affected channel function.	Periodic test.		None. Indication only.	
		Pre-trip relay driver open	Open transistor.	Pre-trip relay deenergizes. Pre-trip annunciation on affected channel function.	Annunciating. Pre-trip alarm for affected function.		None. Indication only.	
		Pre-trip relay driver short	Shorted transistor.	Pre-trip relay does not deenergize on a pre-trip condition.	Periodic test.		None. Indication only.	
		Pre-trip relay coil open	Sustained overvoltage, broken wire.	Same as open relay driver.	Same as open relay driver.		None. Indication only.	
		Pre-trip relay coil short	Deterioration of insulation.	May cause relay driver to fail, as described above, due to excessive current. Relay contacts will not pick up, same effect as open coil.				

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Bistable, RPS/CWP		FMEA Diagram 1		
32)	RPS/CWP Bistable for HI PZR PRESS (65)	Trip output deenergized (off)	Same as Item 31)	Bistable relays in RPS and CWP logic deenergize. Places a half trip in 3 RPS logic matrices for HI PZR PRESS. Places a half trip in the CWP matrix.	Annunciating. HI PZR PRESS trip alarm. Periodic test.	3-channel redundancy (4th channel bypassed) Channel trip.	Makes the reactor trip and CWP logic for HI PZR PRESS 1-out-of-2 coincidence.	Reactor trip logic for HI PZR PRESS must be maintained in 1-out-of-2 by placing the appropriate bistable in the affected channel in the tripped state. CWP function is not credited in the safety analysis.
		Trip output energized (on)	Same as Item 31)	Bistable relays in RPS and CWP logic will remain energized. Affected channel reactor trip and CWP functions are inoperable.	Periodic testing.	3-channel redundancy (4th channel bypassed)	Makes the reactor trip and CWP logic for HI PZR PRESS 2-out-of-2 coincidence.	Reactor trip logic for HI PZR PRESS must be converted to 1-out-of-2 by placing the appropriate bistable in the affected channel in the tripped state.
		Trip relay, pre-trip relay, and relay driver faults	Same as Item 31)	Same as Item 31)	Same as Item 31)	Same as Item 31)	Same as Item 31)	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Bistable, RPS/EFAS		FMEA Diagram 1		
33)	RPS/EFAS Bistable for LO SG-1 LVL (59) and LO SG-2 LVL (52)	Trip output deenergized (off)	Same as Item 31)	Bistable relays in RPS and EFAS-1(2) logic deenergize. Places a half trip in 3 RPS logic matrices for LO SG-1(2) LVL. Provides a channel EFAS-1(2) initiation signal if associated SG is not ruptured.	Annunciating. Trip alarm on LO SG-1(2) LVL. Periodic test.	3-channel redundancy (4th channel bypassed) Channel trip.	Makes the reactor trip and EFAS-1(2) logic for LO SG-1(2) LVL 1-out-of-2 coincidence.	Reactor trip and EFAS-1(2) logic for LO SG-1(2) LVL must be maintained in 1-out-of-2 by placing the appropriate bistable in the affected channel in the tripped state.
		Trip output energized (on)	Same as Item 31)	Bistable relays in RPS and EFAS-1(2) logic will remain energized. Affected channel reactor trip and EFAS-1(2) functions are inoperable.	Periodic test.	3-channel redundancy (4th channel bypassed)	Makes the reactor trip and EFAS-1(2) logic for LO SG-1(2) LVL 2-out-of-2 coincidence.	Reactor trip and EFAS-1(2) logic for LO SG-1(2) LVL must be converted to 1-out-of-2 by placing the appropriate bistable in the affected channel in the tripped state.
		Trip relay, pre-trip relay, and relay driver faults	Same as Item 31)	Same as Item 31)	Same as Item 31)	Same as Item 31)	Same as Item 31)	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Bistable, ESFAS		FMEA Diagram 1		
34)	ESFAS Bistable for HI CONT PRESS (13)	Trip output deenergized (off)	Same as Item 31)	Bistable relays in ESFAS logic matrices deenergize. Places a half trip in 3 ESFAS logic matrices for HI CONT PRESS SIAS/CCAS, CIAS and CSAS actuation.	Annunciating. Trip alarm on HI CONT PRESS. Periodic test.	3-channel redundancy (4th channel bypassed) Channel trip. CSAS actuation requires coincident HI-HI CONT PRESS trip.	Makes the actuation logic for SIAS/CCAS, CSAS and CIAS on HI CONT PRESS 1-out-of-2 coincidence.	SIAS/CCAS, CSAS and CIAS actuation logic for HI CONT PRESS must be maintained in 1-out-of-2 by placing the appropriate bistable in the affected channel in the tripped state.
		Trip output energized (on)	Same as Item 31)	Bistable relays in ESFAS logic matrices remain energized. Effectively disables 3 ESFAS logic matrices for HI CONT PRESS actuation of SIAS/CCAS, CSAS and CIAS.	Periodic test.	3-channel redundancy (4th channel bypassed)	Makes the actuation logic for SIAS/CCAS, CSAS and CIAS on HI CONT PRESS 2-out-of-2 coincidence.	SIAS/CCAS, CSAS and CIAS actuation logic for HI CONT PRESS must be converted to 1-out-of-2 by placing the appropriate bistable in the affected channel in the tripped state.
		Trip relay, pre-trip relay, and relay driver faults	Same as Item 31)	Same as Item 31)	Same as Item 31)	Same as Item 31)	Same as Item 31)	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Bistable, ESFAS		FMEA Diagram 1		
35)	ESFAS Bistable for HI-HI CONT PRESS (7)	Trip output deenergized (off)	Same as Item 31)	Bistable relays in ESFAS logic matrices deenergize. Places a half trip in 3 ESFAS logic matrices for HI-HI CONT PRESS actuation of CSAS.	Annunciating. Trip alarm on HI-HI CONT PRESS. Periodic test.	3-channel redundancy (4th channel bypassed) Channel trip. Concurrent automatic SIAS/CCAS signal is required to initiate the CSAS function.	Makes the actuation logic for CSAS 1-out-of-2 coincidence.	CSAS logic must be maintained in 1-out-of-2 by placing the appropriate bistable in the affected channel in the tripped state.
		Trip output energized (on)	Same as Item 31)	Bistable relays in CSAS logic matrices remain energized. Effectively disables 3 CSAS logic matrices.	Periodic test.	3-channel redundancy (4th channel bypassed)	Makes the actuation logic for CSAS 2-out-of-2 coincidence.	CSAS logic must be converted to 1-out-of-2 by placing the appropriate bistable in the affected channel in the tripped state.
		Trip relay, pre-trip relay, and relay driver faults	Same as Item 31)	Same as Item 31)	Same as Item 31)	Same as Item 31)	Same as Item 31)	
36)	ESFAS Bistable for REFUEL TANK LO LEVEL (2)	Trip output deenergized (off)	Same as Item 31)	Bistable relays in RAS logic matrices deenergize. Places a half trip in 3 RAS logic matrices.	Annunciating. Trip alarm on REFUEL TANK LO LEVEL. Periodic test.	3-channel redundancy (4th channel bypassed) Channel trip.	Makes the actuation logic for RAS 1-out-of-2 coincidence.	RAS logic must be maintained in 1-out-of-2 by placing the appropriate bistable in the affected channel in the tripped state.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Bistable, ESFAS		FMEA Diagram 1		
36)	ESFAS Bistable for REFUEL TANK LO LEVEL (2) (cont)	Trip output energized (on)	Same as Item 31)	Bistable relays in RAS logic matrices remain energized. Effectively disables 3 RAS logic matrices.	Periodic test.	3-channel redundancy (4th channel bypassed)	Makes the actuation logic for RAS 2-out-of-2 coincidence.	RAS logic must be converted to 1-out-of-2 by placing the appropriate bistable in the affected channel in the tripped state.
		Trip relay, pre-trip relay, and relay driver faults	Same as Item 31)	Same as Item 31)	Same as Item 31)	Same as Item 31	Same as Item 31)	
37)	ESFAS Differential Bistable for SG-1 > SG-2 PRESS (48) or SG-2 > SG-1 PRESS (39)	Trip output deenergized (off)	Open circuit, Failure of: ± 15V power supply, Trip comparator, -10V setpoint supply, Trip setpoint potentiometer, Trip opto-isolator, Signal A buffer, Signal B buffer.	Deenergizes bistable relay in EFAS-1(2) actuation logic circuit for the affected channel. Provides permissive for channel EFAS-1(2) initiation on SG LO LVL regardless of SG operability.	Annunciating. Trip alarm on SG-1>SG-2 (SG-2>SG-1) PRESS. Periodic test.	3-channel redundancy (4th channel bypassed)	Makes EFAS-1(2) logic 2-out-of-2 coincidence for Feed Only Good Generator (FOGG) feature. Makes EFAS-1(2) logic 1-out-of-2 coincidence for allowing initiation to an operable SG on SG-1(2) LO LVL.	The tripped state of this bistable is preferred since it allows EFAS initiation. Since, however, both states of this bistable are used for safety-related functions, either the bypassed channel or the fault channel should be returned to service as soon as possible. Trip relay, pre-trip relay and relay driver faults result in the same effects described here. See Item 31) for fault details.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Differential Bistable, ESFAS		FMEA Diagram 1		
37)	ESFAS Differential Bistable for SG-1>SG-2 PRESS (48) or SG-2 > SG-1 PRESS (39) (cont)	Trip output energized (on)	Failure of: ± 15V power supply, Trip comparator, -10V setpoint supply, Trip setpoint potentiometer, Trip opto-isolator, Signal A buffer, Signal B buffer.	Bistable relay in EFAS-1(2) actuation logic circuit for the affected channel remains energized. Channel EFAS-1(2) initiation will be disabled whenever SG-1(2) LO PRESS bistable is tripped.	Periodic test.	3-channel redundancy (4th channel bypassed)	Makes EFAS-1(2) logic 2-out-of-2 coincidence for allowing initiation to an operable SG. Makes EFAS-1(2) logic 1-out-of-2 coincidence for Feed Only Good Generator (FOGG) feature.	Placing the affected bistable in the tripped state is prefered since it allows EFAS initiation. Since, however, both states of this bistable are used for safety-related functions, either the bypassed channel or the fault channel should be returned to service as soon as possible. Trip relay, pre-trip relay and relay driver faults result in the same effects described here. See Item 31) for fault details.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Variable Setpoint Bistable	S/G Pressure	FMEA Diagram 1		
38)	Variable Setpoint Bistable for SG-1 LO PRESS (45) and SG-2 LO PRESS (30)	Trip output deenergized (off)	Open circuit, Failure of bistable comparator (see Item 31), Failure of: Peak detector, step, min, or max adjust circuits, Subtractor/limiter circuit, trip setpoint output buffer, low setpoint comparator, reset circuit, DC/DC Converter.	Bistable relays in RPS, EFAS-1(2), and MSIS logic deenergize. Places a half trip in 3 RPS and 3 MSIS logic matrices for SG-1(2) LO PRESS. Channel EFAS-1(2) initiation will be disabled whenever SG-1>SG-2 (SG-2>SG-1) PRESS channel bistable is not tripped.	Annunciating. Trip alarm on SG-1(2) LO PRESS. Possible low variable setpoint alarm. Periodic test.	3-channel redundancy (4th channel bypassed)	Makes reactor trip and MSIS logic for SG-1(2) LO PRESS 1-out-of-2 coincidence. Makes EFAS-1(2) logic 2-out-of-2 coincidence for allowing initiation to an operable SG. Makes EFAS-1(2) logic 1-out-of-2 coincidence for FOGG.	Reactor trip and MSIS logic for SG-1(2) LO PRESS must be maintained in 1-out-of-2. EFAS trip logic for initiation must be converted to 1-out-of-2 by tripping the SG-1>SG-2 (SG-2>SG-1) bistable in the affected channel. See Item 37).
		Trip output energized (on)	Failure of bistable comparator (see Item 31), Failure of: Peak detector, step, min, or max adjust circuits, Subtractor/limiter circuit, trip setpoint output buffer, low setpoint comparator, reset circuit, DC/DC Converter.	Bistable relays in RPS, EFAS-1(2), and MSIS logic remain energized. Effectively disables 3 RPS and 3 MSIS logic matrices. Allows channel EFAS-1(2) initiation on SG-1(2) LO LVL regardless of SG pressure.	Periodic test.	3-channel redundancy (4th channel bypassed)	Makes reactor trip and MSIS logic for SG-1(2) LO PRESS 2-out-of-2 coincidence. Makes EFAS-1(2) logic 1-out-of-2 coincidence for allowing initiation to an operable SG. Makes EFAS-1(2) logic 2-out-of-2 coincidence for Feed Only Good Generator (FOGG).	Reactor trip and MSIS logic for SG-1(2) LO PRESS must be converted to 1-out-of-2 by placing the affected bistable in the tripped state. EFAS trip logic for initiation must be converted to 1-out-of-2 by tripping the SG-1>SG-2 (SG-2>SG-1) bistable in the affected channel. See Item 37).

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				EFAS Channel Initiation		FMEA Diagram 1		
39)	EFAS-1 Channel Initiation Permissive Circuit (29)(35) EFAS-2 Channel Initiation Permissive Circuit (28)(34)	Off	SG-1(2) press. signal failure low, SG-1(2) LO PRESS bistable A11(A12) failed off, SG-1>SG-2 (SG-2>SG-1) PRESS bistable A19(A20) failed on, bistable relay/relay driver A11(12)-6 or A19(20)-6 failure.	The 3 EFAS-1(2) matrix relays in the affected channel remain energized in the presence of a SG-1(2) LO LVL bistable trip. This effectively disables the affected channel EFAS-1(2) function.	Periodic test.	3-channel redundancy (4th channel bypassed)	Makes EFAS-1(2) logic 2-out-of-2 coincidence for allowing initiation to an operable SG. Makes EFAS-1(2) logic 1-out-of-2 coincidence for FOGG.	For SG-1(2) press. signal faults see Item 14). For SG-1(2) LO PRESS bistable faults see Item 38). For SG-1>SG-2 (SG-2>SG-1) PRESS bistable faults see Item 37) For bistable relay related faults, see below.
		On	SG-1(2) press. signal failure high, SG-1(2) LO PRESS bistable A11(A12) failed on, SG-1>SG-2 (SG-2>SG-1) PRESS bistable A19(A20) failed off, bistable relay/relay driver A11(12)-6 or A19(20)-6 failure.	The 3 EFAS-1(2) matrix relays in the affected channel will deenergize in the presence of a SG-1(2) LO LVL bistable trip regardless of SG operability. This effectively disables the affected channel Feed Only Good Generator (FOGG) EFAS-1(2) function.	Periodic test.	3-channel redundancy (4th channel bypassed)	Makes EFAS-1(2) logic 1-out-of-2 coincidence for allowing initiation to an operable SG. Makes EFAS-1(2) logic 2-out-of-2 coincidence for Feed Only Good Generator (FOGG).	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				EFAS Channel Initiation		FMEA Diagram 1		
40)	EFAS-1 Channel Initiation Circuit (86) EFAS-2 Channel Initiation Circuit (85)	Off	Loss of permissive (Item 39), SG-1(2) level signal failure high, SG-1(2) LO LVL bistable A7(A8) failed on, bistable relay/relay driver A7(8)-6, A19-1, A19-2, A19-3 failure.	This effectively disables the affected channel EFAS-1(2) function.	Periodic test.	3-channel redundancy (4th channel bypassed)	Makes EFAS-1(2) logic 2-out-of-2 coincidence.	EFAS-1(2) logic must be converted to 1-out-of-2. For failed level signal, see Item 10). For failed bistable, see Item 33). For failed relays see below.
		On	SG-1(2) level signal failure low, SG-1(2) LO LVL bistable A7(A8) failed off, bistable relay/relay driver A7(8)-6, A19-1, A19-2, A19-3 failure.	With permissive present, channel EFAS-1(2) function will be initiated regardless of actual SG level.	Periodic test.	3-channel redundancy (4th channel bypassed)	Makes EFAS-1(2) logic 1-out-of-2 coincidence.	EFAS-1(2) logic must be maintained in 1-out-of-2 by tripping the affected channel.
41)	EFAS-1(2) SG-1(2) LO PRESS Bistable Relay A11(12)-6	N.C. contact closed	Stuck or welded contact, relay coil open or shorted, relay driver open.	EFAS-1(2) matrix relays in the affected channel will remain energized whenever the SG-1>SG-2 (SG-2>SG-1) PRESS channel bistable is not tripped. This would effectively disable the channel EFAS-1(2) initiation when both SGs are operable.	Periodic test.	3-channel redundancy (4th channel bypassed)	Makes EFAS-1(2) logic 2-out-of-2 coincidence for two operable SGs.	The EFAS-1(2) logic must be converted to 1-out-of-2 by tripping the SG-1>SG-2 (SG-2>SG-1) bistable in the affected channel. This also changes EFAS-1(2) FOGG feature to 2-out-of-2. See Item 37).

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				EFAS Channel Initiation		FMEA Diagram 1		
41)	EFAS-1(2) SG-1(2) LO PRESS Bistable Relay A11(12)-6 (cont)	N.C. contact open	Stuck or deteriorated contact, relay driver shorted.	EFAS-1(2) matrix relays in the affected channel will deenergize whenever the SG-1(2) LO LVL channel bistable trips. Allows channel EFAS-1(2) initiation on SG-1(2) LO LVL regardless of SG pressure.	Periodic test.	3-channel redundancy (4th channel bypassed)	Makes EFAS-1(2) logic 1-out-of-2 coincidence for allowing initiation to an operable SG. Makes EFAS-1(2) logic 2-out-of-2 coincidence for FOGG feature.	EFAS trip logic for initiation must be maintained in 1-out-of-2 by tripping the SG-1>SG-2 (SG-2>SG-1) bistable in the affected channel. See Item 37).
42)	EFAS-1(2) SG-1>SG-2 (SG-2>SG-1) PRESS Bistable Relay A19(20)-6	N.O. contact open	Stuck or deteriorated contact, relay coil open or shorted, relay driver open.	EFAS-1(2) matrix relays in the affected channel will deenergize whenever the SG-1(2) LO LVL channel bistable trips. Allows channel EFAS-1(2) initiation on SG-1(2) LO LVL regardless of SG pressure.	Periodic test.	3-channel redundancy (4th channel bypassed)	Makes EFAS-1(2) logic 1-out-of-2 coincidence for allowing initiation to an operable SG. Makes EFAS-1(2) logic 2-out-of-2 coincidence for FOGG feature.	EFAS trip logic for initiation must be maintained in 1-out-of-2 by tripping the SG-1>SG-2 (SG-2>SG-1) bistable in the affected channel.
		N.O. contact closed	Stuck or welded contact, relay driver shorted.	EFAS-1(2) matrix relays in the affected channel will remain energized whenever the SG-1(2) LO PRESS channel bistable is tripped. This would disable the channel EFAS-1(2) initiation only when SG-1(2) pressure was low due to a rupture on the opposite SG.	Periodic test.	3-channel redundancy (4th channel bypassed)	FOGG circuit makes EFAS-1(2) logic 2-out-of-2 coincidence for initiation when the opposite SG is ruptured. With both SGs operable, EFAS-1(2) logic remains in 2-out-of-3.	EFAS-1(2) logic must be converted to 1-out-of-2 by tripping either the affected channel matrix relays or the bypassed channel.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				EFAS Channel Initiation		FMEA Diagram 1		
43)	EFAS-1(2) SG-1(2) LO LVL Bistable Relay A7(8)-6	N.O. contact open	Stuck or deteriorated contact, relay coil open or shorted, relay driver open.	EFAS-1(2) matrix relays in the affected channel will deenergize whenever the SG is operable. EFAS-1(2) channel initiation regardless of actual SG level.	Annunciating. Trip alarm. Periodic test.	3-channel redundancy (4th channel bypassed)	Makes EFAS-1(2) logic 1-out-of-2 coincidence. FOGG feature remains in 2-out-of-3.	EFAS logic for must be maintained in 1-out-of-2 by tripping the SG-1(2) LO LVL bistable in the affected channel.
		N.O. contact closed	Stuck or welded contact, relay driver shorted.	EFAS-1(2) matrix relays in the affected channel will remain energized. EFAS-1(2) channel is disabled from feeding an operable SG with low water level.	Periodic test.	3-channel redundancy (4th channel bypassed)	Makes EFAS-1(2) logic 2-out-of-2 coincidence.	EFAS-1(2) logic must be converted to 1-out-of-2 by tripping either the affected channel matrix relays or the bypassed channel.
				Variable Setpoint Bistable,	PZR Press.,	FMEA Diagram 1		
44)	Variable Setpoint Bistable for LO PZR PRESS (62)	Trip output de-energized (off)	Same as SG LO PRESS bistable, Item 38)	Affected channel bistable relays in RPS, CSAS, and SIAS/CCAS coincidence logic deenergize. Places a half trip in 3 RPS, 3 CSAS, and 3 SIAS/CCAS matrices for LO PZR PRESS.	Annunciating. Trip alarm on LO PZR PRESS. Possible low variable setpoint alarm. Periodic test.	3-channel redundancy (4th channel bypassed) Channel trip.	Makes reactor trip, CSAS, and SIAS/CCAS logic for LO PZR PRESS 1-out-of-2 coincidence.	Reactor trip, CSAS, and SIAS/CCAS logic for LO PZR PRESS must be maintained in 1-out-of-2 by tripping the bistable in the affected channel.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Variable Setpoint Bistable	PZR Press	FMEA Diagram 1		
44)	Variable Setpoint Bistable for LO PZR PRESS (62) (cont)	Trip output energized (on)	Same as SG LO PRESS bistable, Item 38)	Affected channel bistable relays in RPS, CSAS, and SIAS/CCAS coincidence logic remain energized. Effectively disables 3 RPS, 3 CSAS, and 3 SIAS/CCAS matrices for LO PZR PRESS.	Periodic test.	3-channel redundancy (4th channel bypassed) HI CONT PRESS also actuates SIAS/CCAS, and provides permissive for CSAS.	Makes reactor trip, CSAS, and SIAS/CCAS logic for LO PZR PRESS 2-out-of-2 coincidence.	Reactor trip, CSAS, and SIAS/ CCAS logic for LO PZR PRESS must be converted to 1-out-of-2 by tripping the bistable in the affected channel.
				CPC/RPS Trip Circui		FMEA Diagram 1		
45)	LO DNBR Trip Circuit (92) HI LPD Trip Circuit (96)	Trip circuit open	Broken wire, CPC LO DNBR (HI LPD) trip contact failed open, NIS trouble trip circuit fault.	Channel bistable relays in RPS coincidence logic deenergize. Places a half trip in 3 RPS coincidence logic matrices for LO DNBR (HI LPD).	Annunciating. Trip alarm on LO DNBR (HI LPD). Periodic test.	3-channel redundancy (4th channel bypassed) Channel trip.	Makes reactor trip logic for LO DNBR (HI LPD) 1-out-of-2 coincidence.	Reactor trip logic for the affected function must be maintained in 1-out-of-2 by tripping the channel via the power trip test interlock. Note: this trips both the LO DNBR and HI LPD functions simultaneously.
		Trip circuit closed	CPC LO DNBR (HI LPD) trip contact failed closed, NIS trouble trip circuit fault.	Channel bistable relays in RPS coincidence logic remain energized for a trip condition. Affected channel function is inoperative.	Periodic test.	3-channel redundancy (4th channel bypassed)	Makes reactor trip logic for LO DNBR (HI LPD) 2-out-of-2 coincidence.	Reactor trip logic for the affected function must be converted to 1-out-of-2 by tripping the channel via the power trip test interlock. Note: this trips both the LO DNBR and HI LPD functions simultaneously.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				2-out-of-4 Coincidence Logic	Reactor Trip	FMEA Diagrams 1, 13		
46)	2/4 RPS Coincidence Logic for: SG-2 LO PRESS (41) SG-1 LO PRESS (50) HI CONT PRESS (26) SG-2 HI LVL (43) SG-1 HI LVL (44) SG-2 LO LVL (54) SG-1 LO LVL (58) LO PZR PRESS (64) HI PZR PRESS (67) HI LIN PWR (74) HI LOG PWR (77) LO DNBR (94) HI LPD (98)	Logic Matrix Off (e.g., AB Matrix)	Component failure, power supply pair failure.	All 4 matrix relays in the AB matrix deenergize. Opens all 4 RPS trip paths. All 8 reactor trip breakers open. Reactor trip occurs.	Annunciating. PPS trip alarm. Matrix power supply trouble alarm (for power supply faults only)		Reactor protective system trip.	Requires failure of two independent relay contacts or redundant power supplies in the affected matrix.
		Logic Matrix On (e.g., AB Matrix)	Component failure; one set of contacts failed closed.	The AB matrix relays will not deenergize when a reactor trip condition is sensed in the A and B channels. PPS will not initiate a reactor trip for signals originating only from A and B channels.	Periodic test.	Reactor trip conditions sensed in the A&C channels or the B&C channels, will trip the reactor via the AC or BC matrices. (Channel D assumed bypassed).	Makes reactor trip logic for affected parameter a selective 2-out-of-3 coincidence.	RPS trip logic can be converted to 1-out-of-3 by tripping the bypassed channel or trip logic can be converted to 2-out-of-3 by removing the bypass from the bypassed channel and bypassing the affected channel.
47)	Matrix relay e.g. 6AB-1 or 6AB-2 or 6AB-3 or 6AB-4	Open coil	Sustained overvoltage.	Trip path with associated relay contact will deenergize. 2 of 8 reactor trip breakers will open. CEDMs will not deenergize.	Annunciating. RPS actuation alarm. PPS status panel indication.	RPS trip path logic is selective 2-out-of-4 coincidence.	The system has 1 of 2 parallel actuation paths open. Remaining RPS trip paths are unaffected.	Each trip path is formed by one set of contacts from each set of logic matrix relays.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				2-out-of-4 Coincidence Logic	Reactor Trip	FMEA Diagrams 1, 13		
47)	Matrix relay e.g. 6AB-1 or 6AB-2 or 6AB-3 or 6AB-4 (cont)	Shorted coil	Deterioration of insulation	The shorted coil may cause the relay driver to fail open or short. If the driver fails open, the symptoms will be the same as the open coil fault. If the driver fails short, the power supply will be shorted producing the same symptoms as loss of the power supply. See Item 165).				
48)	Matrix Relay Driver	On	Emitter to collector short.	One RPS trip path will not deenergize when a trip condition is detected by the associated 2/4 matrix.	Periodic test.	Selective 2-out-of-4 trip paths. Remaining matrix relays/trip paths are unaffected.	System will still respond to a valid trip condition.	The matrix relays in the other 2 unbypassed logic matrices are unaffected. A trip in either of these will cause a trip in all four trip paths.
		Off	Open transistor junction.	Same effect as open relay coil, Item 47).				
49)	Bypass Relay Contact (e.g. AB matrix, AXK1-1 or BXK1-1	Contact short	Stuck or welded contact.	The AB logic matrix is not responsive to a concurrent trip of the A1 and B1 bistables.	Periodic test.	Reactor trip conditions sensed in the A&C channels or the B&C channels will trip the reactor via the AC or BC matrices. (Channel D assumed bypassed).	Makes reactor trip logic for affected parameter a selective 2-out-of-3 coincidence.	RPS trip logic can be converted to 1-out-of-3 by tripping the bypassed channel or trip logic can be converted to 2-out-of-3 by removing the bypass from the bypassed channel and bypassing the affected channel.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				2-out-of-4 Coincidence Logic	Reactor Trip	FMEA Diagrams 1, 13		
49)	Bypass Relay Contact (e.g. AB matrix, AXK1-1 or BXK1-1 (cont)	Contact open	Deterioration of contact, stuck contact.	It is not possible to bypass the contact of bistable A1 (B1) in one of three matrices. During PPS testing, the AB matrix will be half tripped when the affected bistable is tripped.	Periodic test.	Within a coincidence matrix, both channel contacts for a given trip are required to open to initiate a reactor trip.	During testing, makes reactor trip logic for the affected parameter a selective 1-out-of-3. If coincident channel is tripped, testing will cause a reactor trip.	No effect when channel is unbypassed. For bypass relay coil faults see Item 30), Trip Channel Bypass faults.
50)	Bistable Relay Contact (e.g. AB matrix, A1-1 or B1-1)	N.O. contact fails closed/N. C. contact fails open. (Form C contact)	Welded contact, stuck contact.	The AB matrix relays will not deenergize when the affected function trips in the A and B channels. AB trip path is inoperable for the affected function. Bistable Control Panel (BCP) LED will not light.	Periodic test.	The AC and BC matrices are still capable of deenergizing all four trip paths and tripping the reactor. (Channel D assumed bypassed)	Makes reactor trip logic for affected parameter a selective 2-out-of-3 coincidence.	RPS trip logic can be converted to 1-out-of-3 by tripping the bypassed channel or trip logic can be converted to 2-out-of-3 by removing the bypass from the bypassed channel and bypassing the affected channel.
		N.O. contact fails open/N.C. contact fails closed (Form C contact)	Welded contact, stuck contact.	The AB matrix is half tripped. If complementary bistable trips, a reactor trip will occur via all four trip paths. Bistable Control Panel (BCP) LED will be lit continuosly.	Periodic test.	2-out-of-3 trip coincidence (4th channel bypassed). Matrix half trip.	Makes reactor trip logic for affected parameter a selective 1-out-of-3. (4th channel bypassed)	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				2-out-of-4 Coincidence Logic	Reactor Trip	FMEA Diagrams 1, 13		
50)	Bistable Relay Contact (e.g. AB matrix, A1-1 or B1-1) (cont)	N.O. contact fails open - high resistance.	Deterioration of contact.	The AB matrix is half tripped. If complementary bistable trips, a reactor trip will occur via all four trip paths.	Troubleshooting. This fault will not be detected until a reactor trip is inadvertently generated by tripping the complementary bistable individually.	2-out-of-3 trip coincidence (4th channel bypassed). Matrix half trip.	Makes reactor trip logic for affected parameter a selective 1-out-of-3. (4th channel bypassed)	PPS testing will not detect this fault as the N.C. contact used for the BCP LED will still function. For bistable relay coil faults see Item 31), RPS bistable circuit faults.
				2-out-of-4 Coincidence Logic	CSAS, SIAS, CCAS, and CIAS	FMEA Diagrams 1, 13, & 16		
51)	HI CONT PRESS 2/4 Coincidence Logic (15)	Logic matrix Off (e.g. AB matrix)	Multiple component failures.	Spurious actuation of SIAS, CCAS, and CIAS. Permissive available for actuation of CSAS on 2-out-of-3 HI-HI CONT PRESS (4th channel bypassed).	Annunciating. CIAS, SIAS, and CCAS alarms.		SIAS, CIAS, and CCAS actuation.	Requires failure of two parallel, redundant components in the logic matrix.
		Logic matrix On (e.g. AB matrix)	Component failure; one set of contacts failed closed.	AB logic matrix for HI CONT PRESS will not respond to a valid trip signal coincidence in the A and B channels. PPS will not initiate SIAS, CCAS, and CIAS for signals originating only from channels A and B.	Periodic test.	AC and BC coincidence matrices remain available to initiate SIAS, CIAS, and CCAS. (Channel D assumed bypassed).	Makes SIAS, CCAS, and CIAS logic for HI CONT PRESS a selective 2-out-of-3 coincidence.	SIAS, CCAS, and CIAS logic can be converted to 1-out-of-3 by tripping the bypassed channel or the logic can be converted to 2-out-of-3 by removing the bypass from the bypassed channel and bypassing the affected channel.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				2-out-of-4 Coincidence Logic	CSAS, SIAS, CCAS, and CIAS	FMEA Diagrams 1, 13, & 16		
52)	LO PZR PRESS 2/4 Coincidence Logic (127)	Logic matrix Off (e.g. AB matrix)	Multiple component failures.	Spurious actuation of SIAS and CCAS. Permissive available for actuation of CSAS on 2-out-of-3 HI-HI CONT PRESS (4th channel bypassed).	Annunciating. CCAS and SIAS alarms.		SIAS and CCAS actuation.	Requires failure of two parallel, redundant components in the logic matrix.
		Logic matrix On (e.g. AB matrix)	Component failure; one set of contacts failed closed.	AB logic matrix for LO PZR PRESS will not respond to a valid trip signal coincidence in the A and B channels. PPS will not initiate SIAS and CCAS for signals originating only from channels A and B.	Periodic test.	AC and BC coincidence matrices remain available to initiate SIAS and CCAS. (Channel D assumed bypassed).	Makes SIAS and CCAS logic for LO PZR PRESS a selective 2-out-of-3 coincidence.	SIAS and CCAS logic can be converted to 1-out-of-3 by tripping the bypassed channel or the logic can be converted to 2-out-of-3 by removing the bypass from the bypassed channel and bypassing the affected channel.
53)	HI-HI CONT PRESS 2/4 Coincidence Logic (9)	Logic matrix Off (e.g. AB matrix)	Multiple component failures.	All 4 CSAS trip paths open. If SIAS signal is present, containment spray will occur.	Periodic test. If fault is concurrent with SIAS signal, CSAS alarm will occur.	Containment spray requires concurrent SIAS signal.	CSAS actuation signal in all 4 trip paths.	Requires failure of two parallel, redundant components in the logic matrix.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				2-out-of-4 Coincidence Logic	CSAS	FMEA Diagrams 1, 13, & 16		
53)	HI-HI CONT PRESS 2/4 Coincidence Logic (9) (cont)	Logic matrix On (e.g. AB matrix)	Component failure; one set of contacts failed closed.	AB logic matrix for CSAS will not respond to a valid HI-HI CONT PRESS condition. PPS will not initiate CSAS for signals originating only from channels A and B.	Periodic test.	AC and BC coincidence matrices remain available to initiate CSAS. (Channel D assumed bypassed).	Makes CSAS logic a selective 2-out-of-3 coincidence.	CSAS logic can be converted to 1-out-of-3 by tripping the bypassed channel or the logic can be converted to 2-out-of-3 by removing the bypass from the bypassed channel and bypassing the affected channel.
				2-out-of-4 Coincidence Logic	MSIS	FMEA Diagrams 1, 13, & 15		
54)	2/4 Coincidence Logic for: SG-2 LO PRESS (32) or SG-1 LO PRESS (47)	Logic matrix Off (e.g. AB matrix)	Multiple component failures.	All 4 MSIS trip paths open. Spurious actuation of MSIS occurs.	Annunciating. MSIS alarm.		MSIS actuation.	Requires failure of two parallel, redundant components in the logic matrix.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				2-out-of-4 Coincidence Logic	MSIS	FMEA Diagrams 1, 13, & 15		
54)	2/4 Coincidence Logic for: SG-2 LO PRESS (32) or SG-1 LO PRESS (47) (cont)	Logic matrix On (e.g. AB matrix)	Component failure; one set of contacts failed closed.	AB logic matrix for MSIS will not respond to a valid SG-1(2) LOW PRESS condition. PPS will not initiate MSIS for signals originating only from channels A and B.	Periodic test.	AC and BC coincidence matrices remain available to initiate MSIS. (Channel D assumed bypassed).	Makes MSIS logic a selective 2-out-of-3 coincidence.	MSIS logic can be converted to 1-out-of-3 by tripping the bypassed channel or the logic can be converted to 2-out-of-3 by removing the bypass from the bypassed channel and bypassing the affected channel.
				2-out-of-4 Coincidence Logic	RAS	FMEA Diagrams 1, 13, & 15		
55)	REFUEL TANK LO LEVEL 2/4 Coincidence Logic (4)	Logic matrix Off (e.g. AB matrix)	Multiple component failures.	All 4 RAS trip paths open. Spurious actuation of RAS occurs.	Annunciating. RAS alarm.		RAS actuation.	Requires failure of two parallel, redundant components in the logic matrix.
		Logic matrix On (e.g. AB matrix)	Component failure; one set of contacts failed closed.	AB logic matrix for RAS will not respond to a valid RWT LO LEVEL condition. PPS will not initiate RAS for signals originating only from channels A and B.	Periodic test.	AC and BC coincidence matrices remain available to initiate RAS. (Channel D assumed bypassed).	Makes RAS logic a selective 2-out-of-3 coincidence.	RAS logic can be converted to 1-out-of-3 by tripping the bypassed channel or the logic can be converted to 2-out-of-3 by removing the bypass from the bypassed channel and bypassing the affected channel.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				2-out-of-4 Coincidence Logic	EFAS	FMEA Diagrams 1, 13, & 15		
56)	2/4 Coincidence Logic for: EFAS-1 (129) or EFAS-2 (128)	Logic matrix Off (e.g. AB matrix)	Multiple component failures.	All 4 EFAS-1(2) trip paths open. Spurious actuation of EFAS-1(2) occurs.	Annunciating. EFAS-1(2) alarm.	Feedwater Control System will compensate for excess feedwater.	EFAS-1(2) actuation.	Requires failure of two parallel, redundant components in the logic matrix.
		Logic matrix On (e.g. AB matrix)	Component failure; one set of contacts failed closed.	AB logic matrix for EFAS-1(2) will not respond to a valid condition. PPS will not initiate EFAS-1(2) for signals originating only from channels A and B.	Periodic test.	AC and BC coincidence matrices remain available to initiate EFAS-1(2). (Channel D assumed bypassed).	Makes EFAS-1(2) logic a selective 2-out-of-3 coincidence.	EFAS-1(2) logic can be converted to 1-out-of-3 by tripping the bypassed channel or the logic can be converted to 2-out-of-3 by removing the bypass from the bypassed channel and bypassing the affected channel.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				2-out-of-4 Coincidence Logic	CSAS, RAS, EFAS, AB (Typical)	FMEA Diagrams 13, 15, & 16		
57)	Logic Matrix Relay Contact CSAS A17-1 or B17-1	N.O. contact fails closed/N.C contact fails open	Welded, stuck contact.	Same as Item 53), Item 55), or Item 56) Logic On fault. BCP LED will not light.	Same as Item 53), Item 55), or Item 56) Logic On fault.	Same as Item 53), Item 55), or Item 56) Logic On fault.	Same as Item 53), Item 55), or Item 56) Logic On fault.	2/4 Coincident logic matrices use Form C contacts.
	RAS A18-1 or B18-1 EFAS-1 A19-1 or B19-1	N.O. contact fails open/N.C. contact fails closed	Welded, stuck contact.	The AB matrix is half tripped. If complementary bistable trips, the associated ESFAS function will occur via all four trip paths. BCP LED will be lit continuously.	Periodic test.	2-out-of-3 trip coincidence (4th channel bypassed). Matrix half trip.	Makes affected ESFAS function logic a selective 1-out-of-3. (4th channel bypassed)	
	EFAS-2 A20-1 or B20-1	N.O. contact fails open - high resistance.	Deterioration of contact.	The AB matrix is half tripped. If complementary bistable trips, the associated ESFAS function will occur via all four trip paths.	Troubleshooting. This fault will not be detected until the ESFAS function is inadvertently actuated by tripping the complementary bistable individually.	2-out-of-3 trip coincidence (4th channel bypassed). Matrix half trip.	Makes affected ESFAS function logic a selective 1-out-of-3. (4th channel bypassed)	PPS testing will not detect this fault as the N.C. contact used for the BCP LED will still function.
58)	Logic Matrix Relay Bypass Contact CSAS AXK17-1 or BXK17-1 RAS AXK18-1 or BXK18-1 EFAS-1 AXK19-1 or BXK19-1 EFAS-2 AXK20-1 or BXK20-1	Contact shorts	Welded or stuck contact.	The AB logic matrix is not responsive to a concurrent trip of the A and B channel bistables.	Periodic test.	ESFAS trip conditions sensed in the A&C channels or the B&C channels can still initiate the affected ESFAS function via the AC or BC matrices. (Channel D assumed bypassed).	Makes logic for affected ESFAS function a selective 2-out-of-3 coincidence.	Affected ESFAS logic can be converted to 1-out-of-3 by tripping the bypassed channel or trip logic can be converted to 2-out-of-3 by removing the bypass from the bypassed channel and bypassing the affected channel.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				2-out-of-4 Coincidence Logic	CSAS, RAS, EFAS, AB (Typical)	FMEA Diagrams 13, 15, & 16		
58)	Logic Matrix Relay Bypass Contact CSAS AXK17-1 or BXK17-1 RAS AXK18-1 or BXK18-1 EFAS-1 AXK19-1 or BXK19-1 EFAS-2 AXK20-1 or BXK20-1 (cont)	Contact opens	Deterioration of contact, stuck contact.	It is not possible to bypass the contact of associated channel A or B bistable in one of three matrices. During PPS testing, the AB matrix will be half tripped when the affected bistable is tripped.	Periodic test.	Within a coincidence matrix, both channel contacts for a given trip are required to open to initiate an ESFAS function.	During testing, makes affected ESFAS logic a selective 1-out-of-3. If coincident channel is tripped, testing will cause the affected function to actuate.	No effect when channel is unbypassed. For bypass relay coil faults see Item 30), Trip Channel Bypass faults.
59)	Logic Matrix Relay Contact CCAS/SIAS A6-9 or B6-9 A16-1 or B16-1 CIAS A16-1 or B16-1	N.O. contact fails close/N.C. fails open	Welded or stuck contact.	Same as Item 51) or Item 52) Logic On fault. BCP LED will not light.	Same as Item 51) or Item 52) Logic On fault.	Same as Item 51) or Item 52) Logic On fault.	Same as Item 51) or Item 52) Logic On fault.	2/4 Coincident logic matrices use Form C contacts.
		N.O. contact fails open/N.C. contact fails closed	Welded or stuck contact.	The AB matrix is half tripped. If complementary bistable trips, the associated ESFAS function will occur via all four trip paths. BCP LED will be lit continuously.	Periodic test.	2-out-of-3 trip coincidence (4th channel bypassed). Matrix half trip.	Makes affected ESFAS function logic a selective 1-out-of-3. (4th channel bypassed)	
		N.O. contact fails open - high resistance	Deterioration of contact.	The AB matrix is half tripped. If complementary bistable trips, the associated ESFAS function will occur via all four trip paths.	Trblshtng. Fault will not be detected until the ESFAS function is inadvertently actuated by tripping the complementary bistable individually.	2-out-of-3 trip coincidence (4th channel bypassed). Matrix half trip.	Makes affected ESFAS function logic a selective 1-out-of-3. (4th channel bypassed)	PPS testing will not detect this fault as the N.C. contact used for the BCP LED will still function.

	A11-9 or B11-9	N.O. contact fails open/N.C. contact fails closed	Welded or stuck contact.	The AB matrix is half tripped. If complementary bistable trips, MSIS will actuate via all four trip paths. BCP LED will be lit continuously.	Periodic test.	2-out-of-3 trip coincidence (4th channel bypassed). Matrix half trip.	Makes MSIS logic for affected SG a selective 1-out-of-3. (4th channel bypassed)	
	A12-9 or B12-9	N.O. contact fails open - high resistance	Deterioration of contact.	The AB matrix is half tripped. If complementary bistable trips, MSIS will actuate via all four trip paths.	Troubleshooting. This fault will not be detected until the MSIS function is inadvertently actuated by tripping the complementary bistable individually.	2-out-of-3 trip coincidence (4th channel bypassed). Matrix half trip.	Makes MSIS logic for affected SG a selective 1-out-of-3. (4th channel bypassed)	PPS testing will not detect this fault as the N.C. contact used for the BCP LED will still function.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				2-out-of-4 Coincidence Logic	MSIS, AB (Typical)	FMEA Diagrams 13, 15		
63)	Logic Matrix Bypass Relay Contact AXKB11-9 or BXKB11-9 AXKB12-9 or BXKB12-9	Contact shorts	Welded or stuck contact.	The AB logic matrix is not responsive to a concurrent trip of the A and B channel bistables.	Periodic test.	SG-1(2) LO PRESS sensed in the A&C channels or the B&C channels can still actuate MSIS via the AC or BC matrices. (Channel D assumed bypassed).	Makes MSIS logic for the affected SG a selective 2-out-of-3 coincidence.	MSIS logic can be converted to 1-out-of-3 by tripping the bypassed channel or trip logic can be converted to 2-out-of-3 by removing the bypass from the bypassed channel and bypassing the affected channel.
		Contact opens	Deterioration of contact, stuck contact.	It is not possible to bypass the contact of associated channel A or B bistable in one of three matrices. During PPS testing, the AB matrix will be half tripped when the affected bistable is tripped.	Periodic test.	Within a coincidence matrix, both channel contacts for a given trip are required to open to actuate MSIS.	During testing, makes MSIS logic a selective 1-out-of-3. If coincident channel is tripped, testing will cause MSIS to actuate.	No effect when channel is un-bypassed. For bypass relay coil faults see Item 30), Trip Channel Bypass faults.
				2-out-of-4 Coincidence Logic	MSIS, AB (Typical)	FMEA Diagrams 1, 15		
64)	SG-1/SG-2 LO PRESS OR function (33)	Logic Off Logic On	Multiple component failures. Component failure.	The SG-1/SG-2 LO PRESS OR function consists of a series connection of N.O. contacts from SG-1/SG-2 LO PRESS bistables. See Items 62) & 63) for failure modes & effects.				

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				2-out-of-4 Coincidence Logic	CSAS, EFAS, MSIS CIAS, CCAS/SIAS, AB (Typical)	FMEA Diagrams 13, 15, 16		
65)	Logic Matrix Relay Drivers (Transistors and associated components driving AB matrix relay coils)	On	Transistor short, emmitter to collector.	Matrix relay will not deenergize when A & B channels trip. One ESFAS trip path will not deenergize when a trip occurs in only the A & B channels.	Periodic test.	Trip paths operate a selective 2-out-of-4 ESFAS actuation logic circuit.	Makes ESFAS actuation logic a selective 2-out-of-3 trip paths.	The matrix relays in the other 2 un-bypassed matrices are unaffected. A trip in either of these will cause a trip in all four trip paths. 4th channel bypassed.
		Off	Transistor junction open.	One of the four matrix relays will be deenergized causing the associated trip path to deenergize.	Annunciating. Trip path actuation alarm. Periodic test.	Trip paths operate a selective 2-out-of-4 ESFAS actuation logic circuit.	Makes ESFAS actuation logic a selective 1-out-of-3 trip paths.	ESFAS function will still actuate on 2-out-of-3 coincidence for any parameter.
66)	Logic Matrix Relays CSAS 3AB-1,2,3,4 RAS 4AB-1,2,3,4 EFAS-1 7AB-1,2,3,4 EFAS-2 8AB-1,2,3,4 MSIS 5AB-1,2,3,4 CIAS 1AB-1,2,3,4 CCAS/SIAS 2AB-1,2,3,4	Open coil	Sustained overvoltage. Mechanical break in coil winding.	Same as open relay driver, Item 65).				
		Shorted coil	Insulation breakdown.	The shorted coil may cause the relay driver to fail open or short. If the driver fails open, the symptoms will be the same as the open coil fault. If the driver fails short, the power supply will be shorted producing the same symptoms as loss of the power supply See Item 164).				

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				2-out-of-4 Coincidence Logic	CEA Withdrawl Prohibit (CWP)	FMEA Diagram 1		
67)	Core Protection Calculator CWP 2/4 Coincidence Logic (121)	Logic matrix On Logic matrix Off	Multiple component failures. Multiple component failures.	CPC CWP function is inoperative. CWP occurs. Inability to raise CEAs in any mode other than Manual Individual.	Periodic test. Annunciating. CWP alarm.	CWP function is not required for plant safety.	Loss of CPC CWP function. Actuation of CWP.	Either the logic on or logic off fault requires failure of two parallel, redundant components in the 2/4 logic matrix.
68)	HI PZR PRESS CWP 2/4 Coincidence Logic (150)	Logic matrix On Logic matrix Off	Multiple component failures. Multiple component failures.	HI PZR PRESS CWP function is inoperative. CWP occurs. Inability to raise CEAs in any mode other than Manual Individual.	Periodic test. Annunciating. CWP alarm.	CWP function is not required for plant safety.	Loss of HI PZR PRESS CWP function. Actuation of CWP.	Either the logic on or logic off fault requires failure of two parallel, redundant components in the 2/4 logic matrix.
69)	CWP OR Function (151)			The OR function for CWP consists of a series connection of the CPC CWP 2/4 relay matrix and the HI PZR PRESS CWP 2/4 relay matrix. See Items 67) and 68) for failure modes and effects for these matrices.				

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				1-out-of-4 Coincidence Logic	PPS Alarms	FMEA Diagram 1		
70)	Trip Alarm (114), Pre-trip Alarm (115),(113) and Plant Computer (117),(116) for: Refuel Tank LO Level (3), SG-2(1) LO Press (31) (46),HI-HI Cont Press (8) HI Cont Press (14), (25), SG-2>SG-1 Press (40), SG-1>SG-2 Press (49), SG-2(1) HI LVL (136) ,(137), SG-2(1) LO LVL (53),(57), LO PZR Press (63), HI PZR Press (66), HI LIN PWR (73), HI LOG PWR (76),LO DNBR (93), HI LPD (97)	Off	Relay coil or contact failure. Relay driver failure.	Trip, pre-trip, or plant computer input activated.	Audible and visual PPS alarm in control room. Comparison with other plant indications.		None.	
		On	Relay contact failure. Relay driver failure.	Loss of alarm signal for a single channel. If protective action occurs, alarm will be generated via redundant channels.	Periodic test.	Redundant channels.	Makes alarm logic 1-out-of-2 (4th channel bypassed). No effect on PPS logic.	
71)	Relay Contact 6AB-1 or 6BC-1 or 6BD-1 or 6AC-1 or 6CD-1 or 6AD-1	Shorted	Welded or stuck contact.	A trip of the logic matrix associated with the failed contact will not cause deenergization of the affected trip path.	Periodic test.	Trip paths operate a selective 2-out-of-4 reactor trip circuit.	Makes reactor trip circuit logic a selective 2-out-of-3 for the affected matrix. For other matrices, the trip paths remain selective 2-out-of-4.	All four trip paths will deenergize if either of the other 2 un-bypassed 2/4 coincidence matrices trip. (4th channel assumed bypassed).

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path	RPS, Channel 1 (Typical)			
71)	Contact 6AB-1 or 6BC-1 or 6BD-1 or 6AC-1 or 6CD-1 or 6AD-1 (cont)	Open	Deterioration of contact, stuck contact.	One of the four RPS trip paths deenergize.	Annunciating. RPS actuation alarm.	Trip paths operate a selective 2-out-of-4 reactor trip circuit.	Makes reactor trip circuit logic a selective 1-out-of-3 or any 2-out-of-3 trip paths.	2-out-of-3 coincidence of the appropriate bistables is still required to produce a reactor trip. (4th channel bypassed).
72)	Either Vital Bus Circuit Breaker	Open, either or both contacts	Deterioration of contact, stuck contact.	Relay K-1 deenergizes which will cause one pair of UV coils to deenergize and one pair of shunt trip coils to energize. This causes one parallel pair of reactor trip breakers to open.	Annunciating. RPS actuation alarm. PPS status panel. PPS ROM.	CEDM power supplied through selective 2-out-of-4 reactor trip circuit.	Makes reactor trip circuit logic a selective 1-out-of-3 or any 2-out-of-3 trip paths.	2-out-of-3 coincidence of the appropriate bistables is still required to produce a reactor trip. (4th channel bypassed).
		Short both contacts Short one contact	Welded contacts, mechanical failure. Welded contact	The circuit breaker will not open should a fault occur in the AC portion of the trip path. Would cause associated vital bus AC power distribution breaker to open. None.	Periodic test.		No effect. No effect.	
73)	Resistor 2K ohms R1 or R3 R2 or R4	Open	Overvoltage, environmental effects.	The Bistable Control Panel (BCP) will fail to indicate the opening of one of the solid state relays in the RPS trip path.	Periodic test.		No effect upon the functional operation of the system.	Indication only.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path	RPS, Channel 1 (Typical)			
73)	Resistor 2K ohms R1 or R3 R2 or R4 (cont)	Decrease in resistance	Overvoltage, environmental effects.	Indicator may be brighter than usual.		There are two equal value resistors in the circuit. The operating range of the indicator is such that it will operate indefinitely even with one of the resistors shorted out.	No effect upon the functional operation of the system.	Indication only.
		Increase in resistance	Overvoltage, environmental effects.	Indicator will be dimmer than usual.	Periodic test.		No effect upon the functional operation of the system.	Indication only.
74)	Fuses	Open	Transient overcurrent condition.	Trip path deenergizes.	Annunciating. RPS actuation alarm. PPS status panel. PPS ROM.	Trip paths operate a selective 2-out-of-4 reactor trip circuit.	Makes reactor trip circuit logic a selective 1-out-of-3 or any 2-out-of-3 trip paths.	2-out-of-3 coincidence of the appropriate bistables is still required to produce a reactor trip. (4th channel bypassed).
75)	SSR 3 or SSR 4	Input open	Voltage transient.	Output of SSR will open circuit and cause same effects as Item 72), Circuit Breaker Open.				
		Input short	Voltage transient.	The fuses in the trip path will open producing the effects described for Item 74), open fuse. It is possible the short could momentarily load the trip path power supply enough to cause other PPS trip paths using that power supply to deenergize.				

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path	RPS, Channel 1 (Typical)			
75)	SSR 3 or SSR 4 (cont)	Output short	Voltage transient overload.	One side of the current circuit to trip relay K-1 will not interrupt when the trip path trips. Will not prevent trip relay K-1 from functioning properly.	Periodic test.	There are two SSRs in the circuit. Either one can open the circuit that provides a trip to the selective 2-out-of-4 reactor trip circuit.	No affect on functional operation of the system.	
		Output open	Voltage transient overload.	Relay K-1 deenergizes which will cause one pair of UV coils to deenergize and one pair of shunt trip coils to energize. This causes one parallel pair of reactor trip breakers to open.	Annunciating. RPS actuation alarm. PPS status panel. PPS ROM.	CEDM power supplied through selective 2-out-of-4 reactor trip circuit.	Makes reactor trip circuit logic a selective 1-out-of-3 or any 2-out-of-3 trip paths.	2-out-of-3 coincidence of the appropriate bistables is still required to produce a reactor trip. (4th channel bypassed).
76)	250 ohm Resistor R5 or R6	Decrease in resistance	Overvoltage, environmental effects.	None.	Bench check.	There are two equal resistors in the series circuit. The operating range of the SSR is such that it will operate indefinitely even with one of the resistors shorted.	No effect on functional operation of the system.	
		Open	Overvoltage, environmental effects.	The PPS status panel will indicate that the trip path is deenergized even when it is not.	Periodic test.		No effect on functional operation of the system.	Indication only.
		Increase in resistance	Overvoltage, environmental effects.	No symptoms until the resistor has increased in value to about 2 K ohms. Above this value, the effects could be the same as those for an open resistor, above.				

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path	RPS, Channel 1 (Typical)			
77)	SSR 1 Remote Indication	Output open/ input open	Voltage transient overload.	The PPS status panel will indicate that the trip path is deenergized even when it is not.	Periodic test.		No effect on functional operation of the system.	Indication only.
		Input short	Voltage transient.	SSR output will probably open circuit (see effect for output open). R5 and R6 may limit current sufficiently to preclude blowing the trip path power supply fuses. If fuse does blow, effects of Item 74) apply.		Current limiting resistors R5 and R6.		
		Output short	Voltage transient.	The PPS status panel will not indicate a trip of the trip path channel.	Periodic test.		No effect on functional operation of the system.	Indication only.
78)	250 ohm Resistor R7 or R8	Decrease in resistance	Overvoltage, environmental effects.	No symptoms	Bench check.	There are two equal resistors in the series circuit. The operating range of the SSR is such that it will operate indefinitely even with one of the resistors shorted.		
		Open	Overvoltage, environmental effects.	The actuation reset indicator will be flashing when the PPS is in the test mode. Erroneous indication of trip path deenergization.	Periodic test.		No effect on functional operation of the system.	Indication only.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path	RPS, Channel 1 (Typical)			
78)	250 ohm Resistor R7 or R8 (cont)	Increase in resistance	Overvoltage, environmental effects.	There will be no symptoms until the resistor has increased in value to about 2 K ohms. Above this value, the effects could be the same as those for an open resistor, above.				
79)	SSR 2 Test Reset Indicator	Output open, input open	Voltage transient overload.	The actuation reset indicator will be flashing when the PPS is in the test mode. Erroneous indication of trip path deenergization.	Periodic test.		No effect on functional operation of the system.	Indication only.
		Input short	Voltage transient.	SSR output will probably open circuit (see effect for output open). R7 and R8 may limit current sufficiently to preclude blowing the trip path power supply fuses. If fuse does blow, effects of Item 74) apply.		Current limiting resistors R7 and R8.	No effect on functional operation of the system.	Indication only.
		Output short	Voltage transient overload.	An RPS trip in the affected channel will not cause the PPS actuation reset indicator to flash when the test mode is selected.	Periodic test.		No effect on functional operation of the system.	Indication only.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path, Engineered Safety Features	CIAS-RAS-MSIS-EFAS (Typical)	FMEA Diagram 15		
80)	Relay Contact AB contact (typical) (FMEA Diagram 13 & 15) CIAS-1 AB-1 RAS-4AB-1 MSIS-5 AB-1 EFAS-1-7AB-1 EFAS-2-8AB-1	Shorted	Welded contact	A trip of the logic matrix with the failed component will not cause de-energization of the trip path with the shorted contact.	Periodic PPS testing	The other three trip paths are not affected. In the affected trip path any of the other un-bypassed matrices will still de-energize the trip path upon receipt of a bona-fide trip.	One trip path is inoperative for that particular logic matrix. The other two un-bypassed matrices will still de-energize all four trip paths upon receipt of a bona-fide trip.	All four trip paths will deenergize if either of the other two un-bypassed 2/4 coincidence matricies trip. (4th channel assumed bypassed.)
		Open	Deterioration of contact	The trip path will be de-energized	Trip is annunciated on the plant annunciator	The other three trip paths are not affected	Selective 2-out-of-4 Actuation logic converts to 1 out-of-2 (opposite leg) or any 2-out-of-3	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables
81)	Fuse	Open	Transient overcurrent condition	The trip path will be de-energized	Trip is annunciated on the plant annunciator	The other three trip paths are not affected	Selective 2-out-of-4 Actuation logic converts to 1 out-of-2 (opposite leg) or any 2-out-of-3	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables
82)	Test SSR	Output open, input open, Input short	Overload, voltage transient	The actuation reset indicator will be flashing when the PPS is in the test mode, indicating that a trip path has been de-energized	Periodic PPS testing	Current limiting resistors R5 and R6 prevent malfunctioning of this component from affecting the functional operation of this circuit.	None	Safety function of circuit not impaired.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path, Engineered Safety Features	CIAS-RAS-MSIS-EFAS (Typical)	FMEA Diagram 15		
82)	Test SSR (cont)	Output short	Voltage transient overload	The actuation reset indicator on the PPS will not flash when the trip path with the faulty component is exercised.	Periodic PPS testing		None	Safety function of circuit not impaired.
83)	Latching Circuit SSR (n/a for EFAS-1, EFAS-2)	Output open, Input open, Input short	Overload Voltage transient	The trip path will be de-energized.	Trip is annunciated on the plant annunciator.	The other three trip paths are not affected.	Selective 2-out-of-4 Actuation logic converts to 1-out-of-2 (opposite leg) or any 2-out-of-3.	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
	Latching Circuit SSR (n/a for EFAS-1, EFAS-2) (cont)	Output shorted	Voltage transient Overload	The trip circuit will not lock out and will track the state of the trip path contact string de-energizing whenever one or more of the contacts is open and energizing when they are all closed.	Periodic PPS testing		The trip circuit will not remain in the tripped condition but will follow the action of the series string of matrix relay contacts.	The Actuation circuits should not follow any fluctuating condition of a single trip path circuit. Under a trip condition with a channel in bypass all four trip paths will be de-energized & three will be latched in that state. The selective 2-out-of-4 actuation circuits will have three of their four contacts latched open with the fourth fluctuating between open and closed states.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path, Engineered Safety Features	CIAS-RAS-MSIS-EFAS (Typical)	FMEA Diagram 15		
84)	250 ohm resistor R1 or R2 (latching ckt) (n/a for EFAS-1, EFAS-2)	Open	Environmental effects	The trip path will be de-energized.	Trip is annunciated on the plant annunciator.	The other three trip paths are not affected.	Selective 2-out-of-4 Actuation logic converts to 1-out-of-2 (opposite leg) or any 2-out-of-3.	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
		Decrease in resistance	Environmental effects	No symptoms	Bench check	Two equal resistors in the series circuit. The operating range of the SSR is such that it is still within limits if one of the resistors is shorted.	None	Safety function of circuit is not impaired.
		Increase in resistance	Environmental effects	There will be no symptoms until resistor has increased in value to about 2K OHMS. Values exceeding that will cause problems similar to those listed for the failed open mode.	For resistance equal to or greater than 2K a trip is annunciated.	The other three trip paths are not affected.	For resistance equal to or greater than 2K OHMS the Selective 2-out-of-4 actuation logic converts to 1-out-of-2 (opposite leg) or any 2-out-of-3.	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
85)	250 ohm resistor R3 or R4 (indicator ckt.)	Decrease in resistance	Environmental effects	No symptoms	Bench check	Two equal resistors in the series circuit. The operating range of the SSR is such that it is still within limits if one of the resistors is shorted.	None	Safety function of circuit is not impaired.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path, Engineered Safety Features	CIAS-RAS-MSIS-EFAS (Typical)	FMEA Diagram 15		
85)	250 ohm resistor R3 or R4 (indicator ckt.) (cont)	Open	Mechanical failure	The PPS status panel and PPS remote module will indicate a trip for the affected function.	Periodic PPS testing		None	Safety function of circuit is not impaired.
		Increase in resistance	Environmental effects	There will be no symptoms until resistor has increased in value to about 2K OHMS. Values exceeding that will cause problems similar to those listed for the failed open mode.			None	Safety function of circuit is not impaired.
86)	250 ohm resistor R5 or R6 (test ckt.)	Decrease in resistance	Environmental effects	No symptoms	Bench check	Two equal resistors in the series circuit. The operating range of the SSR is such that it is still within limits if one of the resistors is shorted.	None	Safety function of circuit not impaired.
		Open	Mechanical failure	The actuation reset indicator will be flashing when the PPS is in the test mode indicating that a trip path has been de-energized.	Periodic PPS testing		None	Safety function of circuit not impaired.
		Increase in resistance	Environmental effects	There will be no symptoms until resistor has increased in value to about 2K OHMS. Values exceeding that will cause problems similar to those listed for the failed open mode.			None	Safety function of circuit not impaired.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path, Engineered Safety Features	CIAS-RAS-MSIS-EFAS (Typical)	FMEA Diagram 15		
87)	Indicator SSR	Output open, Input open	Voltage transient	The PPS status panel and PPS remote module will indicate a trip for the affected function.	Periodic PPS testing		None	Safety function of circuit not impaired.
		Input fails Short	Voltage transient	The PPS status panel and PPS remote module will indicate a trip for the affected function.	Periodic PPS testing	Resistors in the input of the SSR limit the current that the SSR may draw from the circuit should the input of the SSR short.	None	Safety function of circuit not impaired.
		Output fails Short	Voltage transient	A bona fide trip for the function and channel affected will not be indicated on the PPS status panel and the PPS remote module.	Periodic PPS testing		None	Safety function of circuit not impaired.
88)	Remote Manual Trip Path P/B (n/a for RAS) (Reference items 132, 134, 136, and 138 for specific P/Bs)	Open	Mechanical Failure, deterioration of contact.	The trip path will be de-energized.	Trip is annunciated on the plant computer.	The other three trip paths are not affected.	Selective 2-out-of-4 Actuation logic converts to 1-out-of-2 (opposite leg) or any 2-out-of-3.	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path, Engineered Safety Features	CIAS-RAS-MSIS-EFAS (Typical)	FMEA Diagram 15		
88)	Remote Manual Trip Path P/B (n/a for RAS) (Reference items 132, 134, 136, and 138 for specific P/Bs)	Short	Mechanical failure	The trip path cannot be manually tripped.	Periodic PPS testing or when attempting to manually trip.	The other three trip paths are not affected.	The trip path is inoperative for that particular remote manual pushbutton and actuation is dependent upon a selective 2-out-of the remaining three trip paths from their respective remote manual pushbuttons	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables. All four trip paths will still de-energize upon receipt of a bona-fide trip from the matrix circuits.
89)	Lockout Reset P/B (n/a for EFAS-1, EFAS-2)	Open	Mechanical failure, deterioration of contact	Once tripped, the affected trip path cannot be manually reset.	Periodic PPS testing or when attempting to reset a trip path. Trip path de-energized remains annunciated.	The other three trip paths are not affected.	Once tripped, the trip path cannot be manually reset. Selective 2-out-of-4 Actuation logic remains 1-out-of-2 (opposite leg) or any 2-out-of-3 after bistables have reset.	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path, Engineered Safety Features	CIAS-RAS-MSIS-EFAS (Typical)	FMEA Diagram 15		
89)	Lockout Reset P/B (n/a for EFAS-1, EFAS-2) (cont)	Short	Mechanical failure	The trip circuit will not lock out and will track the state of the trip path contact string de-energizing whenever one or more of the contacts is open and energizing when they are all closed.	Periodic PPS testing.		The trip circuit will not remain in the tripped condition but will follow the action of the series string of matrix relay contacts.	The Actuation circuits should not follow any fluctuating condition of a single trip path circuit. Under a trip condition with a channel in bypass all four trip paths will be de-energized and three will be latched in that state. The selective 2-out-of-4 actuation circuits will have three of their four contacts latched open with the fourth fluctuating between open and closed states.
				Trip Path, Engineered Safety Features	SIAS-CCAS-CSAS (Typical)	FMEA Diagram 16		
90)	Relay contact AB contact (typical) (FMEA diagram 13 & 16) SIAS/CCAS 2AB-1	Shorted	Welded contact	A trip of the logic matrix with the failed component will not cause de-energization of the trip path with the shorted contact.	Periodic PPS testing	The other three trip paths are not affected. In the affected trip path any of the other un-bypassed matrices will still de-energize the trip path upon receipt of a bona-fide trip.	One trip path is inoperative for that particular logic matrix. The other two un-bypassed matrices will still de-energize all four trip paths for the affected functions upon receipt of a bona-fide trip.	All four trip paths will deenergize if either of the other two un-bypassed 2/4 coincidence matricies trip. (4th channel assumed bypassed).

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path, Engineered Safety Features	SIAS-CCAS-CSAS (Typical)	FMEA Diagram 16		
90)	Relay contact AB contact (typical) (FMEA diagram 13 & 16) SIAS/CCAS 2AB-1	Open	Deterioration of contact	The trip path will be de-energized for SIAS and CCAS. The trip path for CSAS will be enabled but not tripped.	Trip is annunciated.	The other three trip paths are not affected.	Selective 2-out-of-4 Actuation logic converts to 1 out-of-2 (opposite leg) or any 2-out-of-3 for SIAS and CCAS. Affected trip path of CSAS has a permissive signal.	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
91)	Relay contact AB contact (typical) (FMEA diagram 13 & 16) CSAS 3AB-1	Shorted	Welded contact	A trip of the logic matrix with the failed component will not cause de-energization of the trip path with the shorted contact.	Periodic PPS testing	The other three trip paths are not affected. In the affected trip path any of the other un-bypassed matrices will still de-energize the trip path upon receipt of a bona-fide trip.	One trip path is inoperative for that particular logic matrix. The other two un-bypassed matrices will still de-energize all four trip paths for CSAS upon receipt of a bona-fide trip.	All four trip paths will deenergize if either of the other two un-bypassed 2/4 coincidence matricies trip. (4th channel assumed bypassed).
		Open	Deterioration of contact	For the affected CSAS trip path one of the two conditions for de-energizing will be present.	Periodic PPS testing.	The other three trip paths are not affected.	No effect unless an SIAS trip is also present. If SIAS is present Actuation logic for CSAS converts to 1-out-of-2 (opposite leg) or any 2-out-of-3.	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables and the presence of an SIAS trip.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path, Engineered Safety Features	SIAS-CCAS-CSAS (Typical)	FMEA Diagram 16		
92)	SIAS Auxiliary Relay (10)	Open coil	Sustained overvoltage	For the affected CSAS trip path one of the two conditions for de-energizing will be present.	Periodic PPS testing.	The other three trip paths are not affected.	No effect unless a CSAS trip is also present. If CSAS trip is also present, a trip will be present in the affected CSAS trip path.	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables and the presence of an SIAS trip.
		Shorted coil	Deterioration of insulation	A shorted coil will cause the fuse(s) supplying the SIAS and CCAS trip paths in the affected channel to open. This will result in a trip in the SIAS and CCAS trip paths. For the affected CSAS trip path one of the two conditions for de-energizing will be present.	Trips are annunciated.	The other three trip paths are not affected.	For SIAS and CCAS the selective 2-out-of-4 Actuation logic converts to 1-out-of-2 (opposite leg) or any 2-out-of-3. If CSAS trip is also present, a trip will be present in the affected CSAS trip path.	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables and the presence of an SIAS trip.
93)	SIAS Auxiliary Relay Contact	Open	Deterioration of contact	For the affected CSAS trip path one of the two conditions for de-energizing will be present.	Periodic PPS testing.		No effect unless a CSAS trip is also present. If CSAS trip is also present, a trip will be present in the affected CSAS trip path	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables and the presence of an SIAS trip.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path, Engineered Safety Features	SIAS-CCAS-CSAS (Typical)	FMEA Diagram 16		
93)	SIAS Auxiliary Relay Contact	Shorted	Welded contact	The CSAS trip path with the affected component will not respond to a trip from the logic matrix in which the faulty component is located.	Periodic PPS testing.		One CSAS trip path is inoperative. Actuation is dependent upon a selective 2-out-of-the remaining three trip paths for CSAS.	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables and the presence of an SIAS trip.
94)	Fuse	open	Transient overcurrent condition	The trip path will be de-energized.	Trip is annunciated.	The other three trip paths are not affected.	Selective 2-out-of-4 Actuation logic converts to 1 out-of-2 (opposite leg) or any 2-out-of-3 for SIAS and CCAS. Affective trip path of CSAS has a permissive signal.	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
95)	Test SSR	Output open, input open, input short	Overload, voltage transient	The actuation reset indicator will be flashing when the PPS is in the test mode, indicating that a trip path has been de-energized.	Periodic PPS testing	Current limiting resistors R5& R6 or R11 & R12 or R17 & R18 prevent malfunctioning of this component from affecting the functional operation of this circuit.	None	Safety function of circuit not impaired.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path, Engineered Safety Features	SIAS-CCAS-CSAS (Typical)	FMEA Diagram 16		
95)	Test SSR	Output shorted	Voltage transient, overload	The actuation reset indicator on the PPS will not flash when the trip path with the faulty component is exercised.	Periodic PPS testing.		None	Safety function of circuit is not impaired.
96)	Latching circuit SSR	Output open, input open, input short	Overload voltage transient	The trip path will be de-energized.	Trip is annunciated.	The other three trip paths are not affected.	Selective 2-out-of-4 Actuation logic converts to 1-out-of-2 (opposite leg) or any 2-out-of-3.	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
		Output shorted		The affected trip circuit will not lock out and will track the state of the trip path contact string de-energizing whenever one or more of the contacts is open and energizing when they are all closed.	Periodic PPS testing	The other three trip paths are not affected.	The affected trip circuit will not remain in the tripped condition but will follow the action of the series string of matrix relay contacts for the affected function (SIAS CCAS, or CSAS permissive).	The Actuation circuits should not follow any fluctuating condition of a single trip path circuit. Under a trip condition with a channel in bypass all 4 trip paths will be de-energized and three will be latched in that state for the affected function. The selective 2-out-of-4 actuation circuits will have three of their four contacts latched open with the 4th fluctuating between open and closed states.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path, Engineered Safety Features	SIAS-CCAS-CSAS (Typical)	FMEA Diagram 16		
97)	250 ohm resistor (latching SSR) R1 or R2 or R7 or R8 or R13 or R14	Open	Mechanical failure	The trip path containing the affected component will be de-energized.	Trip is annunciated.	The other three trip paths are not affected.	Selective 2-out-of-4 Actuation logic converts to 1-out-of-2 (opposite leg) or any 2-out-of-3	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
		Decrease in resistance	Environmental effects	No symptoms	Bench check	Two equal resistors in the series circuit. The operating range of the SSR is such that it is still within limits if one of the resistors is shorted.	None	Safety function of circuit is not impaired.
		Increase in resistance	Environmental effects	There will be no symptoms until resistor has increased in value to about 2K ohms. Values exceeding that will cause problems similar to those listed for the failed open mode.	For resistance equal to or greater than 2K OHMS a trip is annunciated on the plant computer.		For resistance ≥ 2K OHMS the Selective 2-out-of-4 Actuation logic converts to 1-out-of-2 (opposite leg) or any 2-out-of-3.	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
98)	250 ohm resistor (test SSR) R5 or R6 or R11 or R12 or R17 or R18	Open	Mechanical failure	The actuation reset indicator will be flashing when the PPS is in the test mode, indicating that a trip path has been de-energized.	Periodic PPS testing.		None	Safety function of circuit not impaired.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path, Engineered Safety Features	SIAS-CCAS-CSAS (Typical)	FMEA Diagram 16		
98)	250 ohm resistor (test SSR) R5 or R6 or R11 or R12 or R17 or R18 (cont)	Decrease in resistance	Environmental effects	No Symptoms	Bench check	There are two equal resistors in the series circuit. The operating range of the SSR is broad enough to tolerate a short in one of the resistors.	None	Safety function of circuit not impaired.
		Increase in resistance	Environmental effects	There will be no symptoms until resistor has increased in value to about 2K ohms. Values exceeding that will cause problems similar to those listed for the failed open mode.			None	Safety function of circuit not impaired.
99)	250 ohm resistor (Indicator SSR) R3 or R4 or R9 or R10 or R15 or R16	Open	Mechanical failure	The PPS status panel and PPS remote module will indicate a trip for the affected function.	Periodic PPS testing.		None	Safety function of circuit not impaired.
		Decrease in resistance	Environmental effects	No symptoms	Bench check	There are two equal resistors in the series circuit. The operating range of the SSR is broad enough to tolerate a short in one of the resistors.	None	Safety function of circuit not impaired.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path, Engineered Safety Features	SIAS-CCAS-CSAS (Typical)	FMEA Diagram 16		
99)	250 ohm resistor (Indicator SSR) R3 or R4 or R9 or R10 or R15 or R16 (cont)	Increase in resistance	Environmental effects	There will be no symptoms until resistor has increased in value to about 2K ohms. Values exceeding that will cause problems similar to those listed for the failed open mode.			None	Safety function of circuit not impaired.
100)	Indicator SSR	Output open, input open	Voltage transient	The PPS status panel and PPS remote module will indicate a trip for the affected function.	Periodic PPS testing.		None	Safety function of circuit not impaired.
		Input fails short	Voltage transient	The PPS status panel and PPS remote module will indicate a trip for the affected function.	Periodic PPS Testing	Resistors in the input of the SSR limit the current that the SSR may draw from the circuit should the input of the SSR short.	None	Safety function of circuit not impaired.
		Output fails	Voltage transient	A bona fide trip for the function and channel affected will not be indicated on the PPS status panel and the PPS remote module.	Periodic PPS testing.		None	Safety function of circuit not impaired.
101)	Remote Manual Trip Path P/B (Reference items 126, 128, and 130 for specific P/Bs).	Open	Mechanical failure, deterioration of contact	The affected trip path will be de-energized.	Trip is annunciated.	The other three trip paths are not affected.	Selective 2-out-of-4 Actuation logic converts to 1-out-of-2 (opposite leg) or any 2-out-of-3.	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Trip Path, Engineered Safety Features	SIAS-CCAS-CSAS (Typical)	FMEA Diagram 16		
101)	Remote Manual Trip Path P/B (Reference items 126, 128, and 130 for specific P/Bs). (cont)	Short	Mechanical failure	The trip path cannot be manually tripped.	Periodic PPS testing or when attempting to manually trip.	The other three trip paths are not affected.	The trip path is inoperative for that particular remote manual pushbutton and actuation is dependent upon a selective 2-out-of the remaining three trip paths from their respective remote manual pushbuttons.	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables. All four trip paths will still de-energize upon receipt of a bona-fide trip from the matrix circuits.
102)	Lockout reset P/B	Open	Mechanical failure, deterioration of contact	It will not be possible to reset the affected trip path once it is de-energized.	Periodic PPS testing or when attempting to reset the affected trip path. Trip path de-energized remains annunciated.		Once tripped, the trip path cannot be manually reset. Actuation logic remains 1-out-of-2 (opposite leg) or any 2-out-of-3 after bistables have reset.	Actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Actuators, RPS Trip	Path No.1 (Typical)	FMEA Diagram 1		
102)	Lockout reset P/B (cont)	Short	Mechanical failure	The affected trip circuit will not remain in the tripped condition but will follow the action of the series string of matrix relay contacts for the affected function (SIAS, CCAS, or CSAS (with permissive)).	Periodic PPS testing.		None	The Actuation circuits should not follow any fluctuating condition of a single trip path circuit. Under a trip condition with a channel in bypass all 4 trip paths will be de-energized and three will be latched in that state for the affected function. The selective 2-out-of-4 actuation circuits will have three of their four contacts latched open with the 4th fluctuating between open and closed states.
103)	CEA Drop (111)	One CEA fails to drop	CEA mechanical failure		CEA position indication		Logic becomes 1-out-of-3.	
		Inadvertent CEA drop	CRDM coil failure	Possible change in calculated DNBR and local power density margins.	Annunciated. CEA deviation alarm, CEA position indication, dropped CEA indicator.		Reduced operating margins.	
		Inadvertent drop of four symmetric CEAs	CEDMCS logic element failure	Possible change in calculated DNBR and local power density margins.	CEA position indication, dropped CEA indicator.		Reduced operating margins.	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Actuators, RPS Trip	Path No.1 (Typical)	FMEA Diagram 1		
104)	Open CEDM Power Supply (108)	No single failure modes.	One CEDM MG set, Trip circuit breaker or trip path actuates or fails to actuate.	A single failure of MG set or TCB will not initiate or prevent a reactor trip during routine operations. A single failure of DSS contactor or DSS bypass breaker will not initiate or prevent a reactor trip during routine operations.	Plant annunciation and status indicator lights for circuit breakers and phase current.	Redundant MG set, TCB's and trip paths.	None	May initiate reactor trip, turbine trip; or block steam bypass (if Tave is low). If single failure occurs during testing.*
105)	CEDM Bus Under-voltage (107)	Off	Shorted or opened UV relay coil.	Reduces turbine trip to 1/3 logic and steam bypass block to 1/3 logic.	Annunciated. UV indicator lights.		Logic becomes 1-out-of-3.	
		On	Mechanically jammed relay.	Turbine trip and steam bypass logic becomes 2/3 logic.	Not annunciated. Periodic testing.		Logic becomes 2-out-of-3.	
		Off	Shorted or opened UV relay coil while testing another UV relay	Initiates turbine trip and steam bypass block.	Plant reactor trip annunciator and UV indicator lights.			Steam bypass blocked only if T(ave) is low.
106)	Manual Trip (105)	No trip output	Mechanically jammed switch	Failure to open the two associated reactor trip circuit breakers (TCBs) when actuated.	Not annunciated. Periodic testing.	There are two sets of two pushbuttons.	Actuation logic converts to selective 2-out-of-3 for manual trip pushbuttons.	Redundant pair of manual trip pushbuttons available.
		Trip output	Wiring open or shorted.	The two associated TCBs open.	Annunciated. Breaker indication lights and phase current lights.	The other three trip paths are not affected.	Actuation logic converts to 1-out-of-2 (redundant pair of manual trip pushbuttons) or any 2-out-of-3.	A channel in bypass has no effect on the manual trip pushbuttons.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Actuators, RPS Trip	Path No.1 (Typical)	FMEA Diagram 1		
107)	Actuation Relay (K1-K4) (FMEA diagram No. 14)	Coil open	Broken wire, sustained overvoltage	One trip circuit breaker opens in each of the two selective 2-out-of-4 Actuation circuits.	Annunciated. Breaker indication lights and phase current monitors.	Redundant trip paths	Both selective 2-out-of-4 actuation logics convert to 1-out-of-2 (opposite leg) or any 2-out-of-3.	With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
		Coil short	Deterioration of insulation.	One trip circuit breaker opens in each of the two selective 2-out-of-4 Actuation circuits.	Annunciated. Breaker indication lights and phase current monitors.	Redundant trip paths	Both selective 2-out-of-4 actuation logics convert to 1-out-of-2 (opposite leg) or any 2-out-of-3.	With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
		Output contact to under-voltage trip coil open.	Broken wire, contact failure	One trip circuit breaker opens in the affected selective 2-out-of-4 Actuation circuit.	Annunciated. Breaker indication lights and phase current monitors.	Redundant trip paths	The affected selective 2-out-of-4 actuation logic converts to 1-out-of-2 (opposite leg) or any 2-out-of-3.	With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
	Actuation Relay (K1-K4) (FMEA diagram No. 14) (cont)	Output contact to shunt trip coil closed	Contact failure, shorted contact	One trip circuit breaker opens in the affected selective 2-out-of-4 Actuation circuit.	Annunciated. Breaker indication lights and phase current monitors.	Redundant trip paths	The affected selective 2-out-of-4 actuation logic converts to 1-out-of-2 (opposite leg) or any 2-out-of-3.	With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Actuators, RPS Trip	Path No.1 (Typical)	FMEA Diagram 1		
107)	Actuation Relay (K1-K4) (FMEA diagram No. 14) (cont)	Output contact to under-voltage trip coil closed	Shorted contact, contact failure	The undervoltage trip coils will fail to open one trip circuit breaker in the affected selective 2-out-of-4 Actuation circuit when required, but the shunt trip coils will open the same trip circuit breakers.	Periodic testing	Channel has redundant trip path to shunt trip coils.	Logic for the affected RPS undervoltage trip converts to 2-out-of-3 selective. Logic for RPS shunt remains selective 2-out-of-4.	With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
		Output contact to shunt trip coil open	Contact failure, broken wire.	The shunt trip coils will fail to open one trip circuit breaker in the affected selective 2-out-of-4 Actuation circuit when required, but the undervoltage trip coils will open the same trip circuit breakers.	Periodic testing	Channel has redundant trip path to undervoltage trip coil.	Logic for the affected RPS shunt trip converts to 2-out-of three selective. Logic for RPS undervoltage trip remains selective 2-out-of-4.	With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
108)	Manual Trip (1 or 2)	Contact to under-voltage trip coil open	Contact failure, broken wire	One trip circuit breaker opens in the affected selective 2-out-of-4 Actuation circuit.	Annunciated Breaker indication lights and phase current monitors.	Redundant manual trip pushbuttons. Automatic RPS selective 2-out-of-4 not affected.	With one TCB open the affected actuation logic for RPS trip converts to 1-out-of-2 (opposite leg) or any 2-out-of-3.	With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Actuators, RPS Trip	Path No.1 (Typical)	FMEA Diagram 1		
108)	Manual Trip (1 or 2) (cont)	Contact to shunt trip coil closed.	Contact failure, shorted contact	One trip circuit breaker opens in the affected selective 2-out-of-4 Actuation circuit.	Annunciated Breaker indication lights and phase current monitors.	Redundant manual trip pushbuttons. Automatic RPS selective 2-out-of-4 not affected.	With one TCB open the affected actuation logic for RPS trip converts to 1-out-of-2 (opposite leg) or any 2-out-of-3.	With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
		Contact to under-voltage trip coil closed	Contact failure, Shorted contact	The undervoltage trip coils will fail to open one trip circuit breaker in the affected selective 2-out-of-4 Actuation circuit when required, but the shunt trip coils will open the same trip circuit breakers.	Periodic testing.	Redundant manual trip pushbuttons. Manual trip of shunt coils not affected. Automatic RPS selective 2-out-of-4 not affected.	Logic for RPS undervoltage trip converts to 2-out-of 3 selective. Logic for RPS shunt trip remains selective 2-out-of-4.	With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
	Manual Trip (1 or 2) (cont)	Contact to shunt trip coil open	Contact failure, broken wire	The shunt trip coils will fail to open one trip circuit breaker in the affected selective 2-out-of-4 Actuation circuit when required, but the undervoltage trip coils will open the same trip circuit breakers.	Periodic testing.	Redundant manual trip pushbuttons. Manual trip of undervoltage coils not affected. Automatic RPS selective 2-out-of-4 not affected.	Logic for RPS shunt trip converts to 2-out-of-three selective. Logic for RPS undervoltage trip remains selective 2-out-of-4.	With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
108A)	HS/TEST Shunt trip/UV trip bypass Switch	Under-voltage Bypass Contact 4 Of HS/TEST Closed	Contact Failure, Shorted Contact	The undervoltage trip coils will fail to open one trip circuit breaker in the affected selective 2-out-of-4 actuation circuit when required, but shunt trip coils will open the same circuit breakers.	Testing sequence	Shunt trip not affected. Automatic RPS selective 2-out-of-4 not affected.	Logic for RPS undervoltage trip converts 2-out-of-3 selective. Logic for RPS shunt trip remains selective 2-out-of-4.	With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Actuators, RPS Trip	Path No.1 (Typical)	FMEA Diagram 1		
108A)	HS/TEST Shunt trip/UV trip bypass Switch	Shunt Bypass Contact 1 of HS/TEST Open	Contact Failure to the open state	The shunt trip coils will fail to open one trip circuit breaker in the affected selective 2-out-of-4 actuation circuit when required, but the undervoltage trip coils will open the same trip circuit breaker when demanded by PPS.	Periodic Testing	Undervoltage coil Trip not affected	Logic for RPS shunt trip converts to 2-out-of-3 selective. Logic for RPS undervoltage trip remains selective 2-out-of-4.	With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
		Shunt Bypass Contact 3 of HS/TEST Open	Contact Failure to the open state	The shunt trip coils will fail to open one trip circuit breaker in the affected selective 2-out-of-4 actuation circuit when required from manual pushbutton, but the undervoltage trip coils will open the same trip circuit breaker when demanded by pushbuttons.	Periodic Testing	Redundant manual trip pushbutton manual trip of undervoltage coil trip not affected. Automatic RPS selective 2-out-of-4 not affected.	Logic for RPS shunt trip converts to 2-out-of-3 selective. Logic for RPS undervoltage trip remains selective 2-out-of-4.	With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
109)	Under-voltage trip coil	Coil opens	broken wire, sustained overvoltage	One trip circuit breaker opens in the affected selective 2-out-of-4 Actuation circuit.	Annunciated. Breaker indication lights and phase current monitors.	Redundant trip paths.	Logic for the affected RPS selective 2-out-of-4 converts to 1-out-of-2 (opposite leg) or any 2-out-of-3.	With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
		Coil short	Deterioration of insulation	One trip circuit breaker opens in the affected selective 2-out-of-4 Actuation circuit.	Annunciated. Breaker indication lights and phase current monitors.	Redundant trip paths.	Logic for the affected RPS selective 2-out-of-4 converts to 1-out-of-2 (opposite leg) or any 2-out-of-3.	With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Actuators, RPS Trip	Path No.1 (Typical)	FMEA Diagram 1		
110)	Shunt trip coil	Coil open	Broken wire. Sustained overvoltage.	Local shunt coil trips	Periodic testing	Undervoltage trip coil.	None	
		Coil short	Deterioration of insulation	Shorted coil will cause breakers supplying 125 VDC to trip in turn causing undervoltage trip coil to lose voltage.	Annunciated. Breaker indication lights and phase current monitors.		Logic for the affected RPS selective 2-out-of-4 converts to 1-out-of-2 (opposite leg) or any 2-out-of-3.	With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
111)	125V DC BUS (1-4)	Low	Open, short, blown fuse	One trip circuit breaker opens in each of the two selective 2-out-of-4 Actuation circuits.	Annunciated. Breaker indication lights and phase current monitors.	None	Logic for RPS selective 2-out-of-4 converts to 1-out-of-2 (opposite leg) or any 2-out-of-3.	With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
112	480V AC 3 Phase Bus (1,2)	Low	Open, short, open input breaker	MG from unaffected bus has an increase in load.	Annunciated. Breaker indication lights, MG set voltage and current.	None	None	There are two MG sets for plant availability and they will have no effect on the RPS trip system.
113)	M (1,2) MG (1,2) 29-1/DSS 29-2/DSS 52-1/DSS 52-2/DSS	Output low	Motor or generator failure, MCB breaker failure, DSS bypass breaker or contactor failure.	Increased load on the unaffected MG.	Annunciated. Breaker indication lights, MG set voltage and current. DSS contactor and bypass breaker indication lights.		None

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Actuators, RPS Trip	Path No.1 (Typical)	FMEA Diagram 1		
113)	M (1,2) MG (1,2) 29-1/DSS 29-2/DSS 52-1/DSS 52-2/DSS (cont)		Shorted output lines.	Increased load on the unaffected MG.	Annunciated. Breaker indication lights, MG set voltage and current. DSS contactor and bypass breaker indication lights.		None	Possible reactor shutdown if the short results in a loss of both MG sets.
114)	TCB (1-8) Main Breaker contacts	Closed	Mechanical short.	One trip circuit breaker in one RPS selective 2-out-of-4 will fail to open when required.	Periodic testing	Redundant selective 2-out-of-4 actuation logic.	RPS Actuation logic converts to selective 2-out-of-3 for the logic set with the failed trip circuit breaker.	With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
		Open	Mechanical short, broken wire	One trip circuit breaker in one RPS selective 2-out-of-4 will open.	Annunciated. Breaker indication lights and phase current monitors.		RPS Actuation logic converts to selective 1-out-of-2 (opposite leg) or any 2-out-of-3 for the logic set with the failed trip circuit breaker.	With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
115)	Bus Tie TCB-9	Open	Mechanical short, broken wire.	None	Periodic testing		None	
		Closed	Mechanical short.	None	Annunciated, breaker indication, lights.		None	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Actuators, RPS Trip	Path No.1 (Typical)	FMEA Diagram 1		
116)	CEDM power supply under-voltage relays	Open	Shorted undervoltage relay or (open coil or contact).	Unwarranted channel trip for turbine trip and steam bypass block.	Annunciated. Indicating lights.		Logic for turbine trip and steam bypass block is 1-out-of-3 selective or 2-out-of-3.	
		Closed	Mechanically failed	Failure to initiate channel trip for turbine trip and steam bypass block when required.	Periodic testing	Redundant channel trip	Logic for turbine trip and steam bypass block is 2-out-of-3.	
117)	Current Monitoring	Low	Open or shorted sensor	None	Indicating light	None	None	
118)	Turbine controls (109)	Trips turbine	Electrical or hydraulic failure	Loss of Load trip has been deleted. Eventual reactor trip on High Pzr Pressure or Low SG Level.	Turbine trip is annunciated.		None	The loss of Load trip has been deleted from the RPS.
		Full open	Failed control system	Reactor power excursion, low T(ave), low pressure.	Annunciated. Low T(ave)-T(ref) alarm		Possible reactor trip	
		Fails to trip on reactor trip.	Failure of master relay to energize.	Low steam generator pressures resulting in MSIS, turbine output voltage.	Periodic testing	Manual turbine trip	None	
119)	SDBCS Steam Bypass System (110)	Off	Electrical power or air supply failure	Loss of steam bypass capability	Not annunciating. Periodic testing.			
		Fails to inhibit steam bypass	Logic relay failure	Quick opening of bypass valve(s) not inhibited when desired to reduce reactor transients.	Annunciated. Full open bypass valve indication.			

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Actuators, RPS Trip	Path No.1 (Typical)	FMEA Diagram 1		
119)	SDBCS Steam Bypass System (110) (cont)	Inadverten t steam bypass	Shorting of relay contact logic	Opens a steam bypass valve, increase in reactor power level.	Steam bypass valve position indicator.		Possible trip Lo S.G. pressure.	
120)	CEA Deviation Alarm (112)	Off	Shorted Input	Failure to annunciate when required.	Not annunciating, Periodic test	Redundant channel		Operator will be unaware of CEA deviation alarm failure until test.
		On	Open input	Unwarranted annunciation	Audible and visual PPS alarm in control room.		Nuisance	Operator must check system to determine if bone-fide condition exists or if there is a failure in the alarm circuit.
121)	Power Recorder (118)	High	Component failure	High recorder trace, EX-CORE vs calibrated power deviation alarm.	Deviation alarm.	redundant channels.	None-all output data from PPS buffered.	
		Low	Component failure	Low recorder trace, EX-CORE vs calibrated power deviation alarm.	Deviation alarm.	redundant channels.	None-all output data from PPS buffered.	
122)	CWP (119)	Off	Shorted control leads to CEA control system.	Failure to prohibit CEA motion when required.	Periodic tests.		None.	RPS trip is back-up.
		On	Open control leads to CEA control system.	Unwarrented CWP	CWP annunciation w/o input parameters alarming. Inability to move CEA's out		None	RPS trip is back-up.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				Actuators, RPS Trip	Path No.1 (Typical)	FMEA Diagram 1		
123)	Plant Computer (117) (Reference item No. 70).	Off	Loss of CPU, Loss of AC power.	No effect to PPS. All input/ output data transmission is isolated. No credible failure can prevent the PPS from performing its intended function.	Annunciating. Plant computer.		None	
124)	RAS (5) Initiation relay	Short (Fail on)	Relay Failure, electrical short	Unable to de-energize a single RAS trip path in one train, when required.	Not annunciating. Indication lights. Periodic testing.	Two relays must fail to prevent a RAS trip path from de-energizing.	RAS selective 2-out-of-4 Actuation logic converts to a selective 2-out-of-3 for the train with the failed relay. The other train remains selective 2-out-of-4.	Two solid state relays per trip path. A single relay failing does not prevent required actuation. With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.
		Open (Fail off)	Relay failure, loss of relay driver	Unwarranted RAS trip path actuation in one train.	Plant annunciation Indication lights. Periodic testing.	RAS actuation logic is selective 2-out-of-4.	RAS selective 2-out-of-4 Actuation logic converts to 1-out-of-2 (opposite leg) or any 2-out-of-3 for the train with the failed relay. The other train remains selective 2-out-of-4.	A single relay failing does not trip either A or B train. It only trips one of the four trip paths to a train. With a channel in bypass actuation still requires a 2-out-of-3 coincidence of the appropriate bistables.

			Actuators	ESF Selective 2-out-of-4	(typical)	FMEA Diagram 18		
139)	SSR-1 (contact 1A Train A) SSR-2 (contact 1B Train B) for CCAS (219), CSAS (204), RAS (200), SIAS (206), CIAS (208),	Contact open	Overload, broken wires, voltage transient	Unwarranted trip path actuation in one train.	Annunciated.	Redundant trip paths.	Selective 2-out-of-4 actuation logic converts to 1-out-of-2 (opposite leg) or any 2-out-of-3 for the train with the failed relay contact. Other train remains selective 2-out-of-4.	With a channel in bypass a 2-out-of-3 coincidence of the appropriate bistables is still required to obtain an actuation.
		Contact short	Voltage transient, overload.	Failure to initiate a trip of a single trip path in one train when required.	Non-annunciated. Periodic testing.	Redundant trip paths.	Selective 2-out-of-4 actuation logic converts to selective 2-out-of-3 for the train with the failed relay contact. The other train remains 2-out-of-4 selective.	With a channel in bypass a 2-out-of-3 coincidence of the appropriate bistables is still required to obtain an actuation.
		Both contacts open	Component failure in trip path.	Unwarranted trip path actuation in both trains	Annunciated.	Redundant trip paths	Selective 2-out-of-4 actuation logic converts to 1-out-of-2 (opposite leg) or any 2-out-of-3 for both trains.	With a channel in bypass a 2-out-of-3 coincidence of the appropriate bistables is still required to obtain an actuation.
		Both contacts short	Component failure in trip path.	Failure to initiate a trip of a single trip path in both trains when required.	Non-annunciated. Periodic testing.	Redundant trip paths	Selective 2-out-of-4 actuation logic converts to selective 2-out-of-3 for both trains.	With a channel in bypass a 2-out-of-3 coincidence of the appropriate bistables is still required to obtain an actuation.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
			Actuators	ESF Selective 2-out-of-4	(typical)	FMEA Diagram 18		
140)	120 VAC Vital Bus circuit breaker for ARCs	Low	Breaker fails open	Loss of two D.C. power supplies in one ESFAS cabinet, each of which is auctioneered to a redundant D.C. power supply.	Annunciation.	Redundant D.C. power supply.	None	
		Fails closed	Breaker fails closed	No impact on normal operation. Loss of overcurrent protection for one 28 VDC power supply. Power supply may be overstressed and fail open.	Periodic test Power supply failure is annunciated.	Redundant D.C. power supply	None	
141)	28 VDC power supply	Fails off	Component failure	Loss of one of two redundant power supplies for one set of component actuation relays.	Annunciation	Redundant D.C. power supply.	None	
142)	Power supply annunciation relay	Open coil	Sustained overvoltage, broken wire	Spurious annunciation of power supply failure.	Annunciation		None	
		Shorted coil	Deterioration of insulation.	Output of one 28 VDC power supply will be shorted. Power supply will be overstressed and will probably fail off.	Annunciation of power supply failure.	Redundant D.C. power supply.	None	
143)	Auctioneering diode	Fails open	Overstress, open circuit, mechanical failure	Loss of one of two redundant power supplies for one set of component actuation relays.	Annunciation	Redundant D.C. power supply.	None	
		Fails shorted	Overstress, internal failure	Loss of isolation between two 28 VDC power supplies.	Periodic test		None	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
			Actuators	ESF Selective 2-out-of-4	(typical)	FMEA Diagram 18		
144)	Manual Actuation Pushbutton	Fails open	Mechanical damage, open circuit, contact deterioration	One leg of the Actuation circuit for the ESF function will open up. Power for actuation relays will be supplied via opposite leg of circuit.	Annunciation	Opposite leg of actuation circuit will supply power to actuation relays.	Manual ESF actuation becomes 1-of-1. Selective 2-out-of-4 actuation logic converts to 1-out-of-2 (opposite leg).	With a channel in bypass a 2-out-of-3 coincidence of the appropriate bistables is still required to obtain an actuation.
		Fails closed	Contact welded, mechanical damage	The manual actuation pushbutton will not open one leg of the actuation circuit when required.	Periodic test		Manual actuation of the ESF function will not be possible from the ESF cabinets. Manual actuation from the trip path pushbuttons not affected. Automatic actuation not affected.	
145)	Annunciation diodes	Fail open	Overstress, Open lead, Mechanical damage	One leg of the Actuation circuit for the ESF function will open up. Power for actuation relays will be supplied via opposite leg of circuit.	Annunciation	Opposite leg of actuation circuit will supply power to actuation relays.	Manual ESF actuation becomes 1-of-1. Selective 2-out-of-4 actuation logic converts to 1-out-of-2 (opposite leg).	With a channel in bypass a 2-out-of-3 coincidence of the appropriate bistables is still required to obtain an actuation.
		Fail short	Overstress, internal failure	Voltage drop across diodes goes to zero, spurious annunciation of one actuation circuit leg opening up.	Annunciation		None	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
			Actuators	ESF Selective 2-out-of-4	(typical)	FMEA Diagram 18		
146)	Actuator circuit indicator lamp	Fails off	Filament burnout, mechanical failure	Spurious visual indication that one leg of the actuator circuit has opened up.	Indication		None	
147)	Lockout reset pushbutton	Fails open	Contact deterioration, mechanical damage, open circuit	Unable to reset one leg of the actuation circuit after test or an actuation. Other leg can still be reset, which will reenergize lockout relay in affected leg.	Indication	Reset pushbutton in other leg of actuation circuit.	None	
		Fails closed	Contact welded, mechanical failure	No impact during normal operation, after auto actuation. If actuation is caused by using manual actuation pushbutton, actuation relays will automatically reset.	Periodic test	Automatic actuation and manual initiation capabilities not affected.	The ESF function cannot be manually actuated from the ESF cabinet of the affected train.	Automatic ESF actuation and manual ESF initiation from the initiation circuit not affected.
148)	Lockout relay coil	Fails open	Open winding mechanical damage	One leg of the Actuation circuit for the ESF function will open up. Power for actuation relays will be supplied via opposite leg of circuit.	Annunciation	Opposite leg of actuation circuit will supply power to actuation relays.	Manual ESF actuation becomes 1-of-1. Selective 2-out-of-4 actuation logic converts to 1-out-of-2 (opposite leg).	With a channel in bypass a 2-out-of-3 coincidence of the appropriate bistables is still required to obtain an actuation.
		Fails shorted	Insulation breakdown, mechanical failure	One group of actuation relays will be shorted out and will deenergize. The circuit breaker for the affected group will probably open on high current.	Annunciation	Only one of the two groups of actuation relays will be deenergized. The full ESF function will not be actuated.	Partial ESF actuation in the affected train.	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
			Actuators	ESF Selective 2-out-of-4	(typical)	FMEA Diagram 18		
149)	Lockout relay surge protection diode	Fails shorted	Overstress, internal failure	Same as above	Same as above	Same as above	Same as above	
		Fails open	Broken wire, diode failure	Loss of surge protection for lockout relay. Possible damage to relay due to inductive kick when relay de-energizes. Relay may fail open.			None	
150)	Lockout relay N.O. contacts	Fails open	Open circuit, contact deterioration	One leg of the Actuation circuit for the ESF function will open up. Power for actuation relays will be supplied via opposite leg of circuit.	Annunciation	Opposite leg of actuation circuit will supply power to actuation relays.	Manual ESF actuation becomes 1-of-1. Selective 2-out-of-4 actuation logic converts to 1-out-of-2 (opposite leg).	With a channel in bypass a 2-out-of-3 coincidence of the appropriate bistables is still required to obtain an actuation.
		Fails closed	Contact welded, mechanical damage	No impact during normal operation, after auto actuation. If actuation is caused by using manual actuation pushbutton, actuation relays will automatically reset.	Periodic test	Automatic actuation and manual initiation capabilities not affected.	The ESF function cannot be manually actuated from the ESF cabinet of the affected train.	Automatic ESF actuation and manual ESF initiation from the initiation circuit not affected.
151)	One Actuation Relay Fails RAS (201), CSAS (205), CCAS (220), SIAS (207), CIAS (209)	Coil open	Open lead, open winding, mechanical damage	The equipment controlled by the actuation relay will be actuated in the train with the failed relay.	Status indicator for affected equipment		Only the equipment controlled by a single actuation relay will be actuated. A full ESF actuation will not occur.	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
			Actuators	ESF Selective 2-out-of-4	(typical)	FMEA Diagram 18		
151)	One Actuation Relay Fails RAS (201), CSAS (205), CCAS (220), SIAS (207), CIAS (209)	Coil shorted	Insulation failure, mechanical short	Will cause circuit breaker supplying power to actuating relays associated with either the pump or valve group to be tripped.	Annunciation. Indicating lights status indicators for affected equipment.		All equipment controlled by that group of actuation relays will be actuated. A full ESF actuation will not occur. Actuation logic for selective 2-out-of-4 converts to 1-out-of-2 (opposite leg).	
152)	Actuation relay surge protection diode	Fails open	Broken wire, diode failure	Loss of surge protection to actuation relay. Possible damage to relay due to inductive kick when relay deenergizes. Relay may fail open.			None	
		Fails shorted	Overstress Internal failure	Same as item 148 (shorted)	Same as item 148 (shorted)	Same as item 148(shorted)	Same as item 148 (shorted)	
153)	Test relay	Coil open or short	Coil failure, broken wire, short across coil	Failure to test the affected actuation relay (and equipment controlled by it) when required.	Periodic testing		None.	
		Contact open	Contact failure, broken wire	Unwarranted trip of the affected actuation relay.	Indicating lights.	Partial actuation of one train of the ESF function.	Only the equipment controlled by a single actuation relay will be actuated. A full ESF actuation will not occur.

			Actuators	ESF Selective 2-out-of-4	(typical)	FMEA Diagram 18		
153)	Test relay (cont)	Contact shorted	Contact failure, short	Failure to test the affected actuation relay (and equipment controlled by it) when required.	Periodic testing		None.	
154)	Circuit breaker in D.C. path	Fails short	Welded contact, mechanical failure	Loss of overcurrent protection for one leg of one train of actuation.	Bench tests		None	
		Fails open	Deterioration of contact, mechanical failure	Power return line for one group of actuation relays (pump or valve group) in one train opens up. The equipment associated with the actuation relays is energized.	Annunciation. Indicating lights.	Partial actuation of the ESF.	All of the equipment controlled by that group of actuation relays will be actuated. A full ESF actuation will not occur. Actuation logic for selective 2-out-of-4 converts to 1-out-of-2 (opposite leg).	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
			Actuators	ESF Selective 2-out-of-4	Interposing Relays, DEFAS-1 & 2 Trip Relay contacts & DEFAS-1 & 2 Bypass Switches	MSIS, EFAS-1, EFAS-2	(Note 1) Dwg. 6600-M2001-M3-7 Sht. 1 shows interposing relays for MSIS, EFAS-1 & EFAS-2 and the DEFAS 1 & 2 interface For EFAS-1 & 2	
155)	SSR contact 1A, 2A, 3A, 4A, 1B, 2B, 3B, or 4B (Note 1)	Contact open	Overload, broken wires, voltage transient	Unwarranted trip path actuation in one train.	Annunciated.		Selective 2-out-of-4 actuation logic converts to 1-out-of-2 (opposite leg) or any 2-out-of-3 for the train with the failed relay contact. Interposing relays cycle with 1-out-of-2 logic for the train with the failed open contact. The other train remains selective 2-out-of-4.	
		Contact short	Voltage transient, overload	Failure to initiate a trip of a single trip path in one train when required.	Non-annunciated. Periodic testing.	Redundant trip paths Redundant trains	Selective 2-out-of-4 actuation logic converts to selective 2-out-of-3 for the train with the failed relay contact. The interposing relays actuate, cycle open, with selective 2-out-of-3 logic. The interposing relays actuate, cycle closed, with 1-out-of-1 logic for the faulted trip leg, or 2-out-of-2 logic with the non-faulted leg. The other train remains selective 2-out-of-4.	For a bona-fide trip the other three channels will cause actuation of the components controlled by the selective 2-out-of-3. There are two trains of actuation for each ESF function and the other train will cause a full actuation of the ESF function.

TABLE 7.2-5 (continued)

			Actuators	ESF Selective 2-out-of-4	Interposing Relays, DEFAS-1 & 2 Trip Relay contacts & DEFAS-1 & 2 Bypass Switches	MSIS, EFAS-1, EFAS-2	(Note 1) Dwg. 6600-M2001-M3-7 Sht. 1 FMEA Diagram 1 EFAS-1 & 2 and the DEFAS 1 & 2 interface For EFAS-1 & 2	
157)	Auxiliary Logic Actuation Relay (interposing relay) MSIS, EFAS-1 (213), EFAS-2 (212) (Note 1)	Coil opens	Broken wire, mechanical damage.		Indication Annunciated on plant annunciator.		The interposing relay de-energizes causing the equipment controlled by it to actuate.	
		Coil shorts – lead to lead	Breakdown of insulation.	Will cause circuit breaker supplying power to actuating relays associated with either the pump or valve group and one interposing relay to be tripped.	Annunciation. Indicating lights. Status indicators for affected equipment.		All of the equipment controlled by the interposing relay and the group of actuation relays will be actuated. A full ESF actuation will not occur. Actuation logic for selective 2-out-of-4 converts to 1-out-of-2 (opposite leg).	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
			Actuators	ESF Selective 2-out-of-4	Interposing Relays, DEFAS-1 & 2 Trip Relay contacts & DEFAS-1 & 2 Bypass Switches	MSIS, EFAS-1, EFAS-2	(Note 1) Dwg. 6600-M2001-M3-7 Sht. 1 shows interposing relays for MSIS, EFAS-1 & 2 and the DEFAS 1 & 2 interface For EFAS-1 & 2	
158)	DEFAS-1 contacts (K528-2,10) (K728-2,10) in EFAS-1 logic (Note 1)	Contact open	Broken wire mechanical failure	2-out-of-2 DEFAS-1 actuation logic is half tripped.	Indication Annunciation		DEFAS actuation logic converts to 1-out-of-1 (opposite leg) for the train with the failed relay contact. The actuation logic for the other train remains unaffected.	EFAS1 remains functional.
		Contact shorted	Mechanical failure	Not annunciated		Redundant trains	Contact in affected trip leg will not open when required by DEFAS-1 logic. The affected train of EFAS-1 will not fully actuate. The second train will fully actuate when required by the DEFAS-1 logic.	
159)	DEFAS-2 contacts (K628-2,10) (K828-2,10) in EFAS-2 logic (Note 1)	Contact open	Broken wire, mechanical failure	2-out-of-2 DEFAS-2 Actuation logic is half tripped.	Indication Annunciation		Same as item 158 for contact open failure mode.	Same as item 158 for contact open failure mode.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
			Actuators	ESF Selective 2-out-of-4	Interposing Relays, DEFAS-1 & 2 Trip Relay contacts & DEFAS-1 & 2 Bypass Switches	MSIS, EFAS-1, EFAS-2	(Note 1) Dwg. 6600-M2001-M3-7 Sht. 1 shows interposing relays for MSIS, EFAS-1 & 2 and the DEFAS 1 & 2 interface For EFAS-1 & 2	
159)	DEFAS-2 contacts (K628-2,10) (K828-2,10) in EFAS-2 logic (Note 1) (cont)	Contact shorted	Mechanical failure	Not annunciated		Redundant trains	Contact in affected trip leg will not open when required by DEFAS-2 logic. The affected train of EFAS-2 will actuate. The second train will fully actuate when required by the DEFAS-2 logic.	
160)	DEFAS-1 Bypass switch contact (S52B-NO2, C2), (S82B-NO2, C2) (Note 1)	Fails open	Mechanical failure			Redundant trip legs	Cannot bypass DEFAS-1 logic in affected trip leg. The bypass in the other trip leg will prevent any EFAS-1 actuation relays from de-energizing.	The bypassing of an RPS or ESF measurement channel has no effect on the DEFAS-1 logic.
		Fails closed	Mechanical failure			Redundant trains	DEFAS-1 trip contact in affected trip leg will be bypassed by the shorted contact of the bypass switch. The DEFAS-1 logic will not cause a trip of EFAS-1 in the affected train. The second train will trip when required by the DEFAS-1 logic.	The bypassing of an RPS or ESF measurement channel has no effect on the DEFAS-1 logic.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				DC Power Distribution, PPS Cabinet	Bistable Annunciatior Power Supply	FMEA Diagrams 19 & 19A		
160A)	Channel Bistable Annunciator Power Supply (PS-C)	No output	Failure internal to supply, open fuse to power supply.	Pre-trip, trip, and bypass indicators on PPS Bistable Control Panel (BCP) and the Remote Operators Module will fail to indicated condition of bistable for that channel.	Annunciating. PPS Trouble alarm. Periodic test.		None.	Indication only.
		Low output voltage	Failure internal to supply.	Symptoms will depend upon the severity of the undervoltage. The system may operate normally or may exhibit the same symptoms as for no output.	Same as loss of output, if undervoltage is severe enough.		None.	Indication only.
		High output voltage	Failure internal to supply.	Symptoms will depend upon the severity of the overvoltage. The system may operate normally or component failures may be induced that result in an erroneous display.	If errors are induced in the display, periodic testing will detect the problem.		None.	Indication only.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
			Actuators	ESF Selective 2-out-of-4	Interposing Relays, DEFAS-1 & 2 Trip Relay contacts & DEFAS-1 & 2 Bypass Switches	MSIS, EFAS-1, EFAS-2	(Note 1) Dwg. 6600-M2001-M3-7 Sht. 1 shows interposing relays for MSIS, EFAS-1 & 2 and the DEFAS 1 & 2 interface For EFAS-1 & 2	
161)	DEFAS-2 Bypass switch contact (S53B-NO2,C2) (S83B-NO2,C2) (Note 1)	Fails open	Mechanical failure			Redundant trip legs	Cannot bypass DEFAS-2 logic in affected trip leg. The bypass in the other trip leg will prevent any EFAS-2 actuation relays from de-energizing.	The bypassing of an RPS or ESF measurement channel has no effect on the DEFAS-2 logic.
		Fails closed	Mechanical failure			Redundant trains	DEFAS-2 trip contact in affected trip leg will be bypassed by the shorted contact of the bypass switch. The DEFAS-2 logic will not cause a trip of EFAS-2 in the affected train. The second train will trip when required by the DEFAS-2 logic.	The bypassing of an RPS or ESF measurement channel has no effect on the DEFAS-2 logic.
				DC Power Distribution, PPS Cabinet	Bistable Bypass Power Supplies	FMEA Diagrams 19 & 19A		
161A)	Trip Channel Bypass Power Supply (PS-D or PS-E)	No Output	Failure internal to supply, open fuse to power supply.	No operational symptoms.	Annunciating. PPS trouble alarm. Periodic test.	2 power supplies (D&E), one in the affected channel & one in an adjacent channel are auctioneered. Either power supply is capable of supplying the entire load.	None.	Bypass circuits in the affected channel are dependent upon the continued operation of the remaining supply.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				DC Power Distribution, PPS Cabinet	Bistable Bypass Power Supplies	FMEA Diagrams 19 & 19A		
	Trip Channel Bypass Power Supply (PS-D or PS-E) (cont)	Low output voltage	Failure internal to supply.	No operational symptoms. The auctioneered power supply will pick up and maintain load.	Periodic test.	Auctioneered power supplies.	None.	Bypass circuits in the affected channel are dependent upon the continued operation of the remaining supply.
		High output voltage	Failure internal to supply.	Symptoms will depend upon the ability of the components to tolerate the overvoltage. Two possibilities exist:				If an active bypass is lost, channel trip symptoms may occur.
				a. One or more supplied components fails open, making it impossible to bypass the affected function(s).	Periodic test.		Unable to trip channel, bypass the affected function.	
				b. Two or more supplied components fails short. This would reduce the supply voltage to essentially zero, making it impossible to bypass any bistables in the affected channel.	Periodic test.		Unable to bypass any bistables in the affected channel.	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				DC Power Distribution, PPS Cabinet	Channel Auxiliary Logic Power Supplies	FMEA Diagrams 19 & 19A		
162	Channel Aux Logic Power Supply (PS-F)	No output.	Failure internal to supply, open fuse to power supply.	The CEA withdrawl prohibit (CWP) matrix is partially enabled. In the affected channel, it will not be possible to generate the following operating bypasses: a. LO RWT LEVEL/LO PZR PRESS b. HI LOG POWER c. CPC d. SG LEVEL (T_{HOT}) The Power Trip Test circuit will generate channel trips for LO DNBR and HI LPD.	Annunciating. PPS trouble alarm, trip alarms on LO DNBR and HI LPD.	3 Channel redundancy. (4th channel bypassed) Channel trips enabled.	Makes reactor trip logic for LO DNBR and HI LPD 1-out-of-2 coincidence. Makes CWP logic 1-out-of-2 coincidence.	The loss of operating bypasses may result in additional channel trips depending on plant conditions. Operating bypasses in other channels are unaffected thus inhibiting any trip action for the function(s) in question.
		Low output voltage.	Failure internal to supply.	Symptoms will depend upon the severity of the undervoltage. The system may operate normally or may exhibit the same symptoms as for no output.	Same as loss of output if undervoltage is severe enough, otherwise, periodic test.			
		High output voltage.	Failure internal to supply.	Symptoms will depend on the ability of the supplied components to tolerate the overvoltage condition. Depending on how many components fail, one or more bypass functions in the affected channel may be disabled.	Periodic test.	3 Channel redundancy. (4th channel bypassed) Channel trips enabled.	One or more operating bypasses in the affected channel are disabled.	

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				DC Power Distribution, PPS Cabinet	Trip Path Power Supplies	FMEA Diagrams 19 & 19A		
163)	Trip Path Power Supply (PS-H)	No output	Failure internal to supply, open fuse to power supply.	The trip paths for the RPS and all ESFAS functions will deenergize in the affected channel. This will open one side of all the selective 2-out-of-4 actuation and reactor trip circuits.	Annunciating. Trip path actuation alarms. PPS trouble alarm.	Selective 2-out-of-4 actuation circuits.	Makes ESFAS actuation and RPS trip circuits a selective 1-out-of-3 or any 2-out-of-3 trip path coincidence.	A 2-out-of-3 channel coincidence is still required to actuate remaining trip paths. (4th channel bypassed)
		Low output voltage	Failure internal to supply.	Symptoms will depend upon the severity of the undervoltage. The system may operate normally or may exhibit the same symptoms as for no output. Undervoltage could only affect some of the trip paths.	Annunciating. Actuation alarms for any deenergized trip paths. Periodic test.	Selective 2-out-of-4 actuation circuits.	If undervoltage is severe enough, makes the affected trip circuits a selective 1-out-of-3 or any 2-out-of-3 trip path coincidence.	
		High output voltage	Failure internal to supply.	Symptoms will depend on the ability of the supplied components to tolerate the overvoltage condition. Could cause the inputs of some of the trip path SSRs to fail. See entries for ESFAS and RPS trip paths.	Periodic test.	Selective 2-out-of-4 actuation circuits.		Failure of the input side of the solid state relay can only result in the opening of the output side. This is the trip condition.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				DC Power Distribution, PPS Cabinet	ESF 2-out-of-4 Coincidence Logic Power Supplies	FMEA Diagrams 19 & 19A		
164)	ESF Matrix Power Supplies (PS-M or PS-N or PS-P)	No output	Failure internal to supply, open fuse to power supply. Diode in output of supply open.	One half of the matrix relays for all ESF functions in the affected 2/4 matrix (e.g. AB) will be deenergized. Two trip paths for each ESF function will be deenergized, opening one leg of each ESF selective 2-out-of-4 actuation logic circuit.	Annunciating. Trip path actuation alarm, PPS trouble alarm. Open diode fault will generate only the trip path actuation alarm.	2/4 coincidence matrix relays are divided into two groups of two relays. Each group of two is powered from a different power supply. Selective 2-out-of-4 actuation logic.	Two trip paths for all ESF functions will be tripped. Both trip paths affect the same leg of the selective 2-out-of-4 actuation logic. Makes ESF actuation logic 1-out-of-2 of the remaining trip paths.	A 2-out-of-3 channel coincidence is still required to actuate remaining trip paths. (4th channel bypassed)
		Low output voltage	Failure internal to supply.	Symptoms will depend upon the severity of the undervoltage. The system may operate normally or may exhibit the same symptoms as for no output.	If any trip paths are deenergized, trip path actuation alarms will result. Periodic test.	Trip condition will cause voltage to be removed from matrix relay coils.	One or more ESF functions may have half-tripped actuation circuits.	A 2-out-of-3 channel coincidence is still required to actuate remaining trip paths. (4th channel bypassed)
		High output voltage	Failure internal to supply.	Symptoms will depend on the ability of supplied components to tolerate the overvoltage condition. Symptoms may be: a. Normal operation. b. Causes one or more matrix relay drivers to fail shorted, resulting in inability to deenergize the affected matrix relay on a trip. c. Causes one or more of the matrix relay drivers or matrix relays to fail open. This will cause a trip in each associated trip paths.	Periodic test. Annunciating. Trip path actuation alarm(s).	Selective 2-out-of-4 actuation logic. Because of the arrangement of the matrix relays into two groups of two, a maximum of two trip paths for any function can be actuated.	For the affected ESF function(s), makes actuation logic a selective 2-out-of-3. For the affected ESF function(s), makes actuation logic either a 1-out-of-2 coincidence or a selective 1-out-of-3 depending on the number of faults.	A 2-out-of-3 channel coincidence is still required to actuate remaining trip paths. (4th channel bypassed)

				DC Power Distribution, PPS Cabinet	RPS 2-out-of-4 Coincidence Logic Power Supplies	FMEA Diagrams 19 & 19A		
165)	RPS Matrix Power Supplies (PS-J or PS-K or PS-L)	No output	Failure internal to supply, open fuse to power supply. Diode in output of supply open.	One half of the matrix relays in the affected RPS 2/4 matrix (e.g. AB) will be deenergized. Two RPS trip paths will be deenergized, opening one leg of the selective 2-out-of-4 RPS trip actuation circuit.	Annunciating. Trip path actuation alarm, PPS trouble alarm. Open diode fault will generate only the trip path actuation alarm.	2/4 coincidence matrix relays are divided into two groups of two relays. Each group of two is powered from a different power supply. Selective 2-out-of-4 actuation logic.	Two trip paths will be tripped. Both trip paths affect the same leg of the selective 2-out-of-4. Makes RPS actuation logic 1-out-of-2 of the remaining trip paths.	A 2-out-of-3 channel coincidence is still required to actuate remaining trip paths. (4th channel bypassed)
		Low output voltage	Failure internal to supply.	Symptoms will depend upon the severity of the undervoltage. The system may operate normally or may exhibit the same symptoms as for no output.	If any trip paths are denergized, trip path actuation alarms will result. Periodic test.	Trip condition will cause voltage to be removed from matrix relay coils.	RPS actuation logic may be half tripped.	A 2-out-of-3 channel coincidence is still required to actuate remaining trip paths. (4th channel bypassed)
	RPS Matrix Power Supplies (PS-J or PS-K or PS-L) (cont)	High output voltage.	Failure internal to supply.	Symptoms will depend on the ability of supplied components to tolerate the overvoltage condition. Symptoms may be: a. Normal operation. b. Causes one or two matrix relay drivers to fail shorted, resulting in inability to deenergize the affected matrix relay on a trip. c. Causes one or two of the matrix relay drivers or matrix relays to fail open. This will cause a trip in each associated trip paths.	Periodic test. Annunciating. Trip path actuation alarm(s).	Selective 2-out-of-4 actuation logic. Because of the arrangement of the matrix relays into two groups of two, a maximum of two trip paths can be actuated.	Makes RPS actuation logic a selective 2-out-of-3. Makes the RPS actuation logic either a 1-out-of-2 coincidence or a selective 1-out-of-3 depending on the number of faults.	A 2-out-of-3 channel coincidence is still required to actuate remaining trip paths. (4th channel bypassed)

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				DC Power Distribution, PPS Cabinet	Bistable Power Supplies	FMEA Diagrams 19 & 19A		
166)		Low output voltage.	Failure internal to supply.	No operation symptoms.	If the undervoltage is servere enough, PPS trouble alarm. Periodic test.	Auctioneered power supplies for Channel B and C only.	None.	
		High output voltage	Failure internal to supply.	Symptoms will depend on the ability of the supplied components to tolerate the overvoltage condition. Symptoms may be:		Channel A or D could trip.		
				a. Normal operation.				
				b. One or more bistables or bistable relays fail in the non-tripped state.	Periodic test.	3 channel redundancy. (4th channel bypassed)	Makes RPS and/or ESFAS function logic for the affected parameter(s) 2-out-of-2 coincidence.	Affected reactor trip and/or ESFAS logic function logic must be converted to 1-out-of-2 by placing the appropriate bistable(s) in the tripped state.
				c. One or more bistables or bistable relays fail in the tripped state.	Annunciating. Pre-trip and trip alarms.	3 channel redundancy. (4th channel bypassed) Channel trip.	Makes RPS and/or ESFAS function logic for the affected parameter(s) 1-out-of-2 coincidence.	Affected reactor trip and/or ESFAS logic function logic must be maintained in 1-out-of-2 by placing the appropriate bistable(s) in the tripped state.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				DC Power Distribution, PPS Cabinet	Bistable Power Supplies	FMEA Diagrams 19 & 19A		
166A)	Channel B or C Bistable Power Supplies (Ch B or D - PS-A) or (Ch A or D - PS-B)	No output	Failure internal to supply, open fuse to power supply. Diode in output of supply open. De-energization of vital bus (1 and 3) for 2D01 fault or (2 and 4) for 2D02 fault.	No operational symptoms. Channel B or C functions with increasing signal setpoint rendered inoperable if signal source power supply is de-energized.	Annunciating. PPS trouble alarm. Annunciating. PPS trouble alarm.	Two power supplies, one in the same channel as the bistables and one in the adjacent channel, are auctioneered. Either power supply is capable of supplying the entire load. Channel A and D bistable power supplies are not auctoneered to provide safe failure states for de-energization of vital bus (1 and 3) or (2 and 4). 3-Channel redundancy (4th channel bypassed)	None. De-energization of vital bus (1 and 3) or (2 and 4) places RAS in 1-out-of-2 logic, EFAS/FOGG logic in 1-out-of-1 logic, and trips RPS and other ESFAS functions with decreasing signal by AC or BD matrix. ESFAS functions with increasing signal setpoints half trip with 1-out-of-1 logic.	Bistables and bistable relays in the affected channel are dependent upon the continued operation of the remaining supply. ESFAS channel B and C measurement channel inputs for RWT level have auctioneered power supplies. For EFAS/FOGG, the DC bus failure scenario causes either channel A or D to fail to the EFW position and either channel B or C to fail to the FOGG position.

TABLE 7.2-5 (continued)

No.	Name	Failure Mode	Cause	Symptoms and Local Effects Including Dependent Failures	Method of Detection	Inherent Compensating Provision	Effect Upon PPS	Remarks and Other Effects
				DC Power Distribution, PPS Cabinet	Bistable Power Supplies	FMEA Diagrams 19 & 19A		
166B)	Channel A or D Bistable Power Supplies (PS-A)	No output	Failure internal to supply, open fuse to power supply. Diode in output of supply open. De-energization of vital bus channel A or D.	Channel A or D bistable relays in PPS logic matrices de-energize. Places a half trip in 3 PPS logic matrices for all functions.	Annunciating. PPS trouble alarm.	Channel A and D bistable power supplies are not auctioneered to provide safe failure states for de-energization of vital bus (1 and 3) or (2 and 4). 3-Channel redundancy (4th channel bypassed).	De-energization of vital bus (1 and 3) or (2 and 4) places RAS in 1- out- of-2 logic, EFAS/FOGG logic in 1-out-of-1 logic, and trips RPS and other ESFAS functions with decreasing signal by AC or BD matrix. ESFAS functions with increasing signal setpoints half trip with 1-out-of-1 logic.	Bistables and bistable relays in the affected channel are dependent upon the continued operation of the remaining supply. ESFAS channel B and C measurement channel inputs for RWT level have auctioneered power supplies.

* CLARIFYING REMARK: Related entries (i.e. #104, #112, #113) governing context is single failure directly related to CEDM power opening (or low output) based on supporting the safety function of removing power / dropping CEAs / tripping. Beyond said governing context, it is acknowledged that OE has evidenced single failure vulnerability (but with trip result noted as already bounded in FMEA Table) for initiating trip from MG high output scenarios, which can unload unaffected MG with it tripping on low output along with affected MG subsequently failing on high output resulting in simultaneous loss of both MGs and inadvertent/initiated trip (noting no single failure vulnerability relative to supporting the safety function).

Table 7.2-12

OPERATOR'S MODULE DIGITAL METER DISPLAY PARAMETERS

<u>Inputs</u>

Reactor Coolant Pump Speeds, Hot Leg Temperatures, Cold Leg Temperatures, Primary Pressure, Ex-Core Neutron Flux Signals, CEA Positions

<u>Calculated Values</u>

Compensated DNBR, Static DNBR, Reactor Core Max Flow Rate, Compensated Cold Leg Temperatures, Local Power Density, Calibrated Neutron Flux Power, Maximum Peaking Factor, Integral Radial Peaking Factor, Penalty Factors, Total Thermal Power, CEA Deviation

<u>Addressable Constants</u>

Azimuthal Tilt Constant, Calculation Constants for ΔT Power Determination, Reactor Coolant Flow Calculation Constants

<u>Specific Operator's Module Displays as follows:</u>

10 (ten) points to allow the operator to check/verify the current values of addressable constants (all values on the display screen).

Technical specification check - simultaneous display of 6 points which must presently be done once per hour per channel.

Displays of CEAC rod positions (CEAC OM display only).

Auto restart and sensor failure log displays. The displays will give the failed sensor number/PID and some descriptive information for the PID.

CPC - There are 9 PIDs associated with auto restart which correspond to flags and status words giving the restart codes. There are 4 PIDs corresponding to sensor failure status words whose values indicate failed sensors.

CEAC -There are 5 PIDs associated with auto-restart and failed sensors.

A display screen providing the capability of changing the values of addressable constants.

A display screen providing the capability of displaying the values of pre-selected PIDs (default PIDs) i.e,, more than one value would be displayed on the screen.

A display screen providing the capability of defining a group of PIDs whose values are to be displayed on a single screen i.e., a User Group set of PIDs.

An alarm/status screen to pinpoint specific CPC/CEAC problems when the corresponding CPC/CEAC Trouble Light is lit.

The capability of choosing displays via a master menu to specific screens will be provided. Values on the screen being displayed will be updated at a constant rate.

Table 7.2-13

CEAC SINGLE FAILURE ANALYSIS

Single Failure	Results
1. CEAC failure - loss of power, failure detected by on-line diagnostics	Each of the four CPCs uses the most conservative value of either the output of the redundant CEAC or the previous penalty factor from the failed CEAC.
2. CEAC failure - erroneous data (penalty factor too low).	Each of the four CPCs uses the largest penalty factor from the operable CEAC and each CPC annunciates any discrepancy between CEACs.
3. CEAC failure - erroneous data (penalty factor too high)	Each of the four CPCs uses the erroneous high penalty factor which causes an approach to the trip setpoint; each CPC annunciates the discrepancy between CEACs.
4. CEAC failure - "in-test" bit stuck "on".	Each of the four CPCs uses the penalty factor from the other CEAC which is correct; each CPC annunciates the "in test" condition from the failed CEAC.
5. CEAC position transmitter failure	Possible erroneous data from one CEAC which produces results as in 2 or 3 above; CEAC annunciates sensor failure.
6. CEAC failure producing short circuit, open circuit or application of maximum credible potential at sending end of two data links.	Optical isolators prevent failure from propagating to other calculators; data failures and results fall under one of categories 1, 2, 3 or 4 above.
7. CPC failure producing short circuit, open circuit or application of maximum credible potential at receiving end of two data links.	Optical isolators prevent failure from propagating to CEACs or other CPCs; both CEACs and three CPCs remain intact and perform all safety functions.
8. Catastrophic failure (e.g., fire) in Channel B (or Channel C) causing destruction of both CPC & CEAC.	Physical isolation (including fire-proof barriers) and optical isolators prevent catastrophic failure from propagating to other channels; one CEAC and three CPCs(or two CPCs if one of the remaining channels is bypassed) remain intact ensuring a trip if required. Data failures from CEAC which failed and results fall under one of Categories 1, 2, 3 or4 above.

Table 7.5-1 (continued)

* Indicates Post-Accident Monitoring Instrumentation

(1)Indicates display instrumentation which is available to monitor Limiting Conditions for Operations (LCO) in addition to the bases defined in Section 7.5.2.1.

(2)As a result of redundancy provided for this instrumentation, Technical Specifications permit operations with some channels inoperable.

(3)Value displayed is the average of two loop T_{avg} channels.

<u>**Qualification of Circuitry</u>

1 - Completely Class 1E

2 - Channels A and B completely Class 1E
Channels C and D non-Class 1E

3 - Non-Class 1E

<u>**Qualification of Indicating Instrumentation</u>

A - Instrument Class 1C - Environmentally Class 1 for control room environment.
Seismically Class 1 for DBE except only required to operate after DBE, not during.

B - Instrument Class 1C - Same as above except required to operate <u>during</u> and after DBE.

C - Instrument Class 2B - Environmentally similar to 1C above, but documentation not required.
Seismically required to operate during and after DBE.

D - Instrument Class 3 - Standard commercial instrument.

Table 7.5-2

ENGINEERED SAFETY FEATURE SYSTEMS MONITORING

Parameter	Type of Readout (Control Room)	Number of Channels	Range
Containment Isolation			
Containment Isolation Valve Position	Indicating Lights	1 pair/valve	Open/Closed

Table 7.5-3 (continued)

R.G. 1.97 POST ACCIDENT MONITORING VARIABLES

NOTE 1: Parameter not required during events involving > 5% clad failure. Relief from maintaining a post accident sampling system (PASS) was obtained in ANO-2 Technical Specification Amendment 218 (2CNA080005). As part of the relief approval, RG 1.97 and NUREG 0737 requirements concerning PASS capability are no longer applicable. However, sampling capability must continue to be maintained for those fuel accident events involving ≤ 5% clad failure. This capability exists via non-PASS sampling locations and systems. Contingency plans must also be maintained to support RCS and containment atmosphere sampling efforts under post-accident conditions, assuming sample location dose rates are such that samples can be safely obtained and analyzed. These contingency plans are contained within various Emergency Plan, Chemistry, Radiological, and Operating procedures, including the Severe Accident Management Guidelines. It should be noted, however, that sampling intended to support fuel damage assessment is no longer required for RCS chlorides, RCS oxygen, RCS dissolved hydrogen (total gas), or containment atmosphere oxygen content.

NOTE 2: Containment building isolation valves listed in Table 6.2-26 of the ANO-2 SAR were evaluated. This evaluation excluded check valves, locked closed manual valves which are part of a passive boundary and valves which are locked closed and administratively controlled shut. Redundancy is satisfied by GDC 55, 56, or 57.

NOTE 3: Category 3 instrument for beyond design basis accidents only (reference October 2003 revision to 10 CFR 50.44, ANO Commitment #17975)

NOTE 4: Each Super Particulate Iodine Noble Gas (SPING) monitor which inputs to the Radiological Dose Assessment Computer System has the capability to measure halogen and particulate activity as it is accumulated on a sample media. The SPING microcomputer then calculates the gross radiohalogen and particulate sample concentration based on the rate of increase of activity on the filter media. If necessary to further define the analysis or to extend the range, an isotopic analysis of the filter media can be performed by plant radiochemistry personnel.

NOTE 5: DELETED

NOTE 6: DELETED

NOTE 7: Only two of the four indicators are fully Reg. Guide 1.97 qualified devices.

Table 7.7-1

COLSS MONITORED PLANT VARIABLES

Monitored Parameters	COLSS Sensors	Numbers of Sensors	Sensor Range
Core Volumetric Flow	RCP Rotational Speed	2 per pump	0 - 1000 rpm
	RCP Differential Pressure	2 per pump	0 - 130 psid
Core Power			
Primary Calorimetric	Cold Leg Temperature	1 per cold leg	465 – 615 °F
	Hot Leg Temperature	1 per hot leg	525 – 675 °F
Secondary Calorimetric	Feedwater Flow*	2 per generator	0 – 7.6 X 10^6 lbm
	Steam Flow*	2 per generator	0 – 7.6 X 10^6 lbm
	Feedwater Pressure	1 per generator	0 - 3000 psig
	Feedwater Temperature	2 per generator	0 – 550 °F
	Blowdown Flow	1 per generator	0 – 300 gpm
	S/G Pressure	4 per generator	0 – 1200 psia
Core Power Distribution	In-Core Monitoring System	42 In-Core assemblies each containing 5 axially stacked detectors	0 - 10^{14} nv
	CEA Position	1 per CEA	0 - 150 inches
Reactor Coolant Pressure	Pressurizer Pressure	2 (on pressurizer)	1500-2500 psia
Turbine Power	Turbine First Stage Pressure	2 (on Turbine)	0 - 800 psia

* For feedwater flow-based secondary calorimetric, steam flow is a derived input parameter based on feedwater and blowdown flow rates. For steam flow-based secondary calorimetric, feedwater flow is a derived input parameter based on steam and blowdown flow rates.

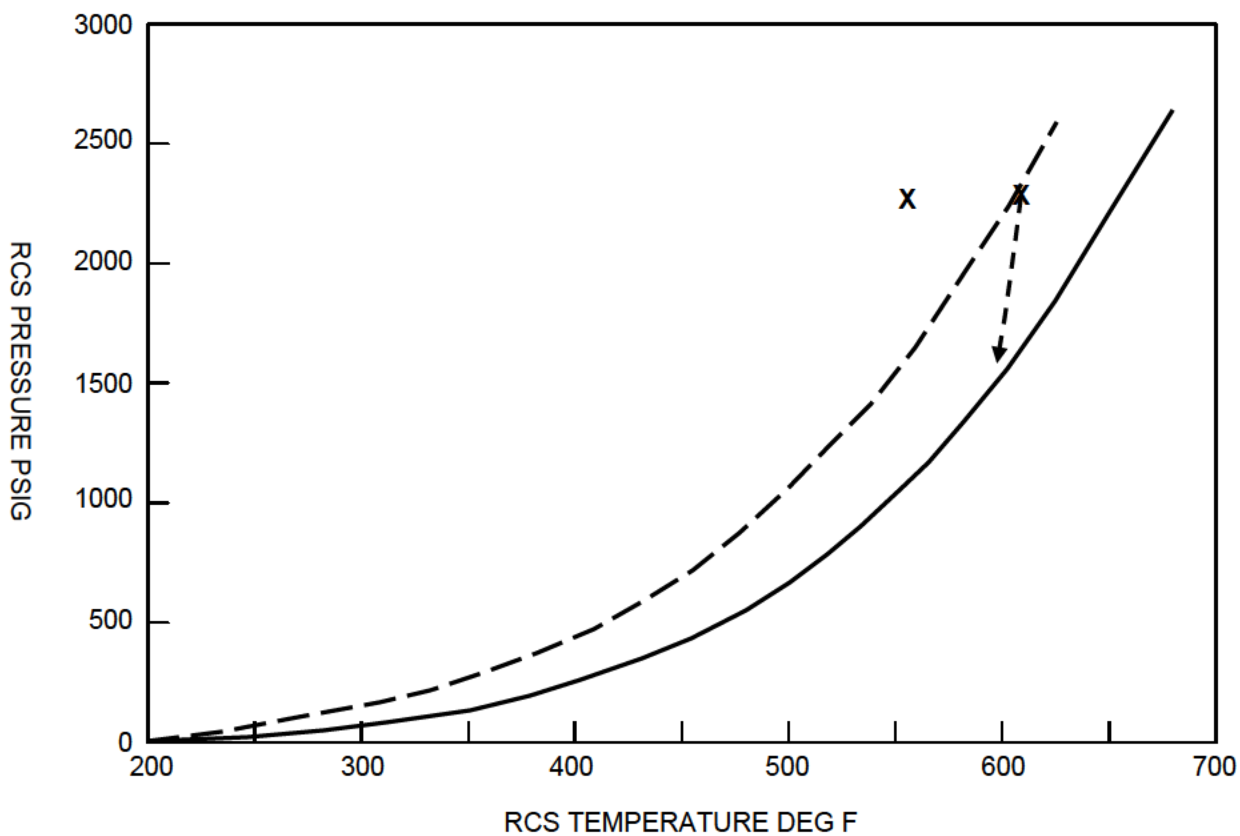
TYPICAL POST TRIP RESPONSE

DRAWING NO	SHEET	REV.



Inadequate Subcooling Margin: T_{hot} is not progressing toward its target values; in fact, it has rapidly dropped through the subcooled margin line. This condition is diagnosed as loss of adequate primary inventory subcooling, or simply “inadequate subcooling margin.”

SAR FIGURE NO. 7.6-4

AMENDMENT 20

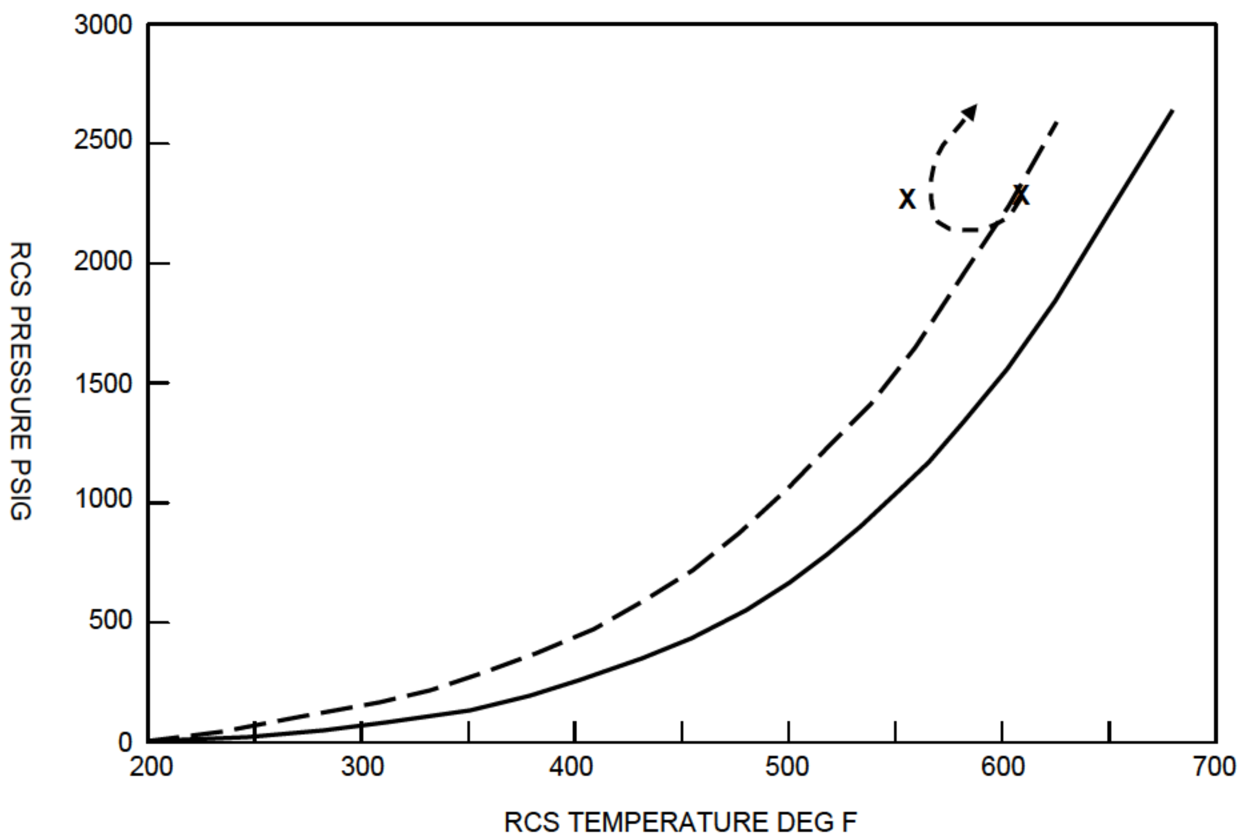
		DRAWN:	ENTERGY
		DESIGN:	ENTERGY
		CAD NO:	N/A
INADEQUATE SUBCOOLING MARGIN	DRAWING NO	SHEET	REV.



Loss of Primary-to-Secondary Heat Transfer: T_{hot} is increasing as steam generator T_{sat} is decreasing. The ΔT between the two is growing larger. The secondary is no longer removing heat and has lost coupling with the primary. This condition is diagnosed and treated as loss of (inadequate) primary-to-secondary heat transfer.

SAR FIGURE NO. 7.6-5

AMENDMENT 20

ARKANSAS NUCLEAR ONE UNIT 2 RUSSELLVILLE, ARKANSAS	Entergy	SCALE:	NONE

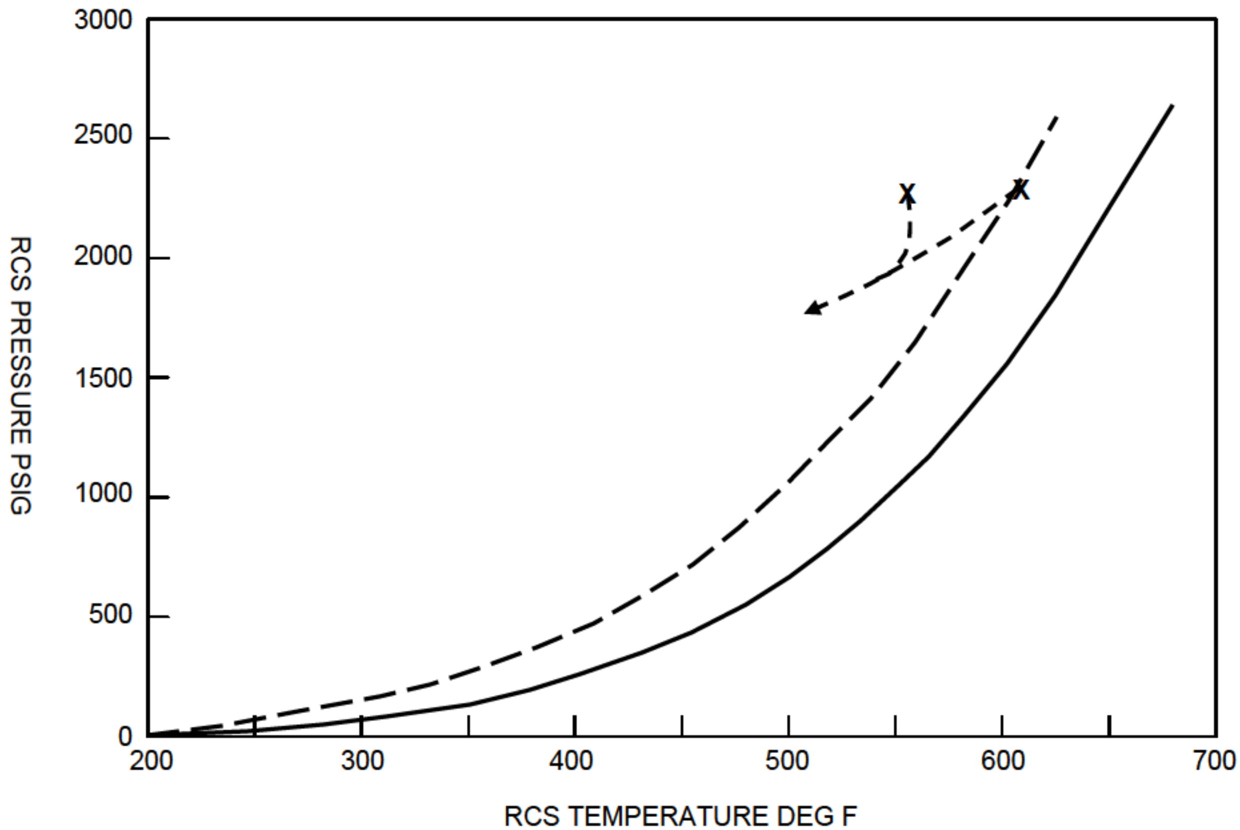
		DESIGN:	ENTERGY
		CAD NO:	N/A
LOSS OF PRIMARY TO SECONDARY HEAT TRANSFER	DRAWING NO	SHEET	REV.



Excessive Primary-to-Secondary Heat Transfer: Steam generator T_{sat} has decreased below its established limit. T_{hot} and T_{cold} have reached equal values, but both have gone out of the post-trip window following steam generator T_{sat}. This condition is diagnosed and treated as excessive primary-to-secondary heat transfer.

8 ELECTRIC POWER

8.1 INTRODUCTION

The off-site transmission system, the transmission switching station, and the onsite distribution system are designed to provide electric power to the necessary plant electric equipment under all foreseeable combinations of plant operation and electric power source availability. The electrical system for Arkansas Nuclear One - Unit 2 is designed to be electrically independent of Unit 1, except as described in Section 8.1.4.F, and to provide adequately reliable power sources for all electrical equipment for startup, normal operation, safe shutdown and all emergency situations.

8.1.1 UTILITY GRID AND ITS INTERCONNECTIONS

The electric system for Entergy Arkansas, Inc. (formerly Arkansas Power & Light Company) extends over an area that provides service to over 610,000 customers in 62 of Arkansas' 75 counties. The system consists of over 4,690 miles of transmission lines ranging from 115 to 500 kV. The grid configuration for Arkansas Power & Light, as of December 31, 1976, is depicted in Figure 8.1-1. The current system configuration for Entergy Arkansas, Inc. is similar.

Entergy Arkansas, Inc. is a wholly owned subsidiary of the Entergy system (formerly Middle South Utilities), which operates as an entity with a highly integrated system consisting of hydro, fossil-fired, and nuclear fueled generating plants. Figure 8.1-2 depicts the Middle South Utilities system as of January 1, 1978. The current Entergy transmission system is similar.

Entergy Arkansas, Inc. benefits from over 50 points of interconnection either directly or through the Entergy system. At the time Unit 2 was licensed, these points of interconnection were with the following systems: Oklahoma Gas & Electric Company; Southwestern Electric Power Company; Gulf States Utilities Company; Central Louisiana Electric Company; Mississippi Power Company; Union Electric Company; Empire District Electric Company; Missouri Utilities; Tennessee Valley Authority; Southwestern Power Administration; Arkansas Electric Cooperative Corporation; and Associated Electric Cooperatives, Inc. This configuration is depicted in Figure 8.1-3, the Southwest Power Pool as of December 31, 1972. The current Entergy interconnections with the grid are similar although the names of the interconnecting systems may have changed.

8.1.2 ONSITE ELECTRIC SYSTEM

Figure 8.3-1 shows the single line diagram arrangement of the station. ANO-2 generates electrical power at 22 kV which is fed through an isolated phase bus to the Unit 2 main transformer bank. The main transformer bank, consisting of three single-phase transformers, steps the output voltage up to 500 kV at which level it is delivered to the station switchyard. The 500 kV switchyard is a 2-bus design consisting of two breakers each for Unit 1 and Unit 2 generators and a breaker and one-half for each line. The 500 kV station switchyard includes three outgoing lines: one line to the Mabelvale substation, one line to the Fort Smith substation, and one line to the Pleasant Hill substation (see Figure 8.3-1).

A bus tie autotransformer bank consisting of three single phase autotransformers interconnects the 500 kV and 161 kV systems in the station switchyard. The 161kV switchyard at the generating station is also of ring bus design and includes one line to the Russellville East 161 kV substation and one line to the Pleasant Hill 161 kV substation. The 22 kV tertiary winding of the autotransformer bank supplies Startup Transformer 3 which is identical to the unit auxiliary transformer. Startup Transformer 2, which serves both units, is supplied from the 161 kV ring bus.

Auxiliary power for normal plant operation is supplied by the main generator through the unit auxiliary transformer. Auxiliary power for main generator startup and shutdown can be supplied by either of the two startup transformers. In the event of non-availability of these two power sources, power to the ESF buses can be furnished by the two fully redundant emergency diesel generator sets. A 120-volt uninterruptible AC power system has been provided for reactor protection and Engineered Safety Feature (ESF) control channels. This consists of six inverters and four distribution panels; one designated for each of the four redundant protective channels.

Three banks of 125-volt batteries, two Class 1E and one non-Class 1E along with their own battery chargers and control panels, provide the necessary DC power sources for the plant.

8.1.3 REACTOR PROTECTION AND ENGINEERED SAFETY FEATURE LOADS

The ESF loads are shown on Table 8.3-1. The ride-through M-G sets and the reactor trip switchgear associated with the Reactor Protective System (RPS) are covered in Section 8.3.

8.1.4 DESIGN BASES FOR SAFETY-RELATED ELECTRIC SYSTEMS

The electrical system for ANO-2 has been designed to be electrically independent of Unit 1 and provide adequately reliable power sources for all electrical equipment for startup, normal operation, safe shutdown, and handling of all emergency situations. Any special design bases that are applicable to specific components are included in the appropriate sections of the SAR. The following criteria, guides and standards have been used in the system and equipment design.

A. Components of the system have been sized for operation under normal and emergency conditions.

B. No single component failure will prevent operation of the required ESF.

C. Redundant sources of power have been provided to ensure satisfactory operation of equipment as required under normal and emergency conditions.

D. The system has been arranged in such a manner as to make it possible to test all safety-related equipment.

E. Electrical and physical separation of cables and equipment associated with redundant elements of the safety-related circuits has been provided.

F. The electrical system of Unit 2 is independent of Unit 1, with the exception of Startup Transformer 2, which is common, and the Alternate AC Generator, which is shared by both Units (see Section 8.1.2). The backup power supplies for 120-volt AC to the switchyard are provided from Unit 1.

G. Class 1E electrical equipment has been seismically qualified in accordance with IEEE344-1971, 1975, or 1987.

H. All components of the electrical power distribution system have been designed using the applicable sections of ANSI, NEMA, IEEE and the National Electric Code as a guide.

I. General Design Criteria 17 and 18 of Appendix A to 10CFR50 have been complied with.*

J. Regulatory Guide 1.6 (dated 3/10/71) - Independence Between Redundant Standby (Onsite) Power Sources and Between Their Distribution Systems; Regulatory Guide 1.9 (dated 3/10/71 - Selection of Diesel Generator Set Capacity for Standby Power Supplies; and Regulatory Guide 1.32 (dated 8/11/72) - Use of IEEE 308-1971 "Criteria for Class IE Electrical Systems for Nuclear Power Generating Stations" have been complied with.*

K. IEEE 279-1971 - Criteria for Protection Systems for Nuclear Power Generating Stations has been complied with.

L. IEEE 308-1971 - Criteria for Class 1E Electric Systems for Nuclear Power Generating Stations have been complied with.

M. IEEE 336-1971 - Installation, Inspection and Testing Requirements for Instrumentation & Electric Equipment During the Construction of Nuclear Power Generating Stations has been complied with.

N. IEEE 379-1972 - Trial-Use Guide for the Application of the Single-Failure Criterion to Nuclear Power Generating Station Protection Systems has been complied with.

O. The electrical system is provided with Grid Undervoltage Protection (Millstone 2 Event).

P. 10 CFR 50.63, Regulatory Guide 1.155, and associated Alternate AC Power Source Guidelines and requirements of NUMARC 87-00, Revision 1, have been complied with regarding Station Blackout. See Section 8.3.3 for supplemental information.

* A discussion of the foregoing criteria and regulatory guides is included in Sections 8.3.1.2 and 8.3.2.2.

Additionally, monitoring of certain parameters of the electrical power system is designed to conform to Regulatory Guide 1.97.

8.2 OFF-SITE POWER SYSTEM

8.2.1 DESCRIPTION

Unit 2 generates electrical power at 22 kV which is fed through an isolated phase bus to the Unit 2 main transformer bank, consisting of three single-phase transformers, where it is stepped up to 500 kV transmission voltage and delivered to the station switchyard. The 500 kV switchyard is a 2-bus design consisting of two breakers each for Unit 1 and Unit 2 generators and a breaker and one-half for each line. The 500 kV station switchyard includes three outgoing 500 kV lines; one 500 kV line 86.74 miles in length, to the Mabelvale EHV Substation, one 500 kV line 93.82 miles in length, to the Fort Smith O.G. & E. EHV Substation and one 500 kV line 32.62 miles in length, to the Pleasant Hill EHV Substation (see Figure 8.2-1).

A bus tie autotransformer bank consisting of three single phase autotransformers interconnects the 500 kV and 161 kV systems in the station switchyard. The 161 kV switchyard at the generating station is a ring bus design and includes one line to the Russellville East 161 kV Substation and one line to the Pleasant Hill 161 kV Substation. The 22 kV tertiary of the autotransformer bank supplies Startup Transformer 3 which is identical to the unit auxiliary transformer. Startup Transformer 2, which is capable of serving both units, is supplied from the 161 kV ring bus. When in Mode 5 or Mode 6, the Unit Auxiliary Transformer can be aligned to supply offsite power by removing isophase bus disconnects and backfeeding through the main transformers. ANO has also committed to make this backfeed available within approximately 24 hours of the unit being off-line and a loss of the primary offsite power source during an NRC approved 30-day maintenance AOT for Startup #2 (Reference 0CAN119904 and 0CNA040011). This could require a backfeed in Modes 3 or 4 until the unit could be placed safely in cold shutdown or the primary offsite source is restored.

8.2.1.1 Single Line Diagrams

Figures 8.2-2, 8.2-3, 8.3-1, and 8.3-6 are single-line diagrams of the switchyard, station buses and circuits.

8.2.1.2 Transmission Lines

The extra high voltage and high voltage transmission system which connects to the switchyard and to the plant involves:

A. Approximately 24 miles of two parallel 500 kV single circuit lines with triple-bundle phase conductors on metal towers from the ANO EHV Substation, south to a junction with the existing Mabelvale-O.G. & E. 500 kV line at a point four miles east of Danville, Arkansas, including crossings of the McClellan-Kerr Arkansas River Navigation System. The two lines are parallel to each other and separated by 140 feet on common 320-foot wide right-of-way, except at the Arkansas River crossing where the parallel lines are separated by 220 feet due to the 190-foot tall river crossing structures.

B. Approximately 32.62 miles of 500 kV single circuit line with triple-bundle phase conductors on metal towers on 180-foot wide right-of-way from the ANO EHV Substation, southeast to the Pleasant Hill Substation north of Morrilton, Arkansas.

C. Approximately 12 miles of single circuit shielded 161 kV line on Steel towers and wood H-frame structures on 100-foot wide right-of-way from the ANO EHV Substation, southeast to the existing Russellville East 161 kV Substation, east of Russellville, Arkansas. The 1.83 mile steel tower portion is constructed on double circuit structures together with "D." below.

D. Approximately 34 miles of single circuit shielded 161 kV line on steel towers and wood H-frame structures on 100-foot wide right-of-way from the ANO EHV Substation east to the Pleasant Hill Substation.

E. One span (622 feet) of single circuit shielded 500 kV tie line with triple-bundle phase conductors on metal towers from the 500 kV switchyard to the plant transformer yard for Unit 1. The conductor is a three-bundle 954 MCM 45/7 strand ACSR and the shield wire 7 #7 alumoweld cable.

F. Two spans (920 feet) of single circuit shielded 500 kV tie line with triple-bundle phase conductors on metal towers from the 500 kV switchyard to the plant transformer yard for Unit 2. The conductor is a three-bundle 954 MCM 45/7 strand ACSR and the shield wire 7 #7 alumoweld cable.

G. Five spans (1,237 feet) of single circuit shielded 161 kV tie line on steel single pole structures from the 161 kV switchyard to the plant transformer yard. The conductor is a 336.4 MCM 26/7 strand ACSR and the shield wire 3/8-inch steel cable.

Single circuit metal towers of the two parallel Arkansas Nuclear One-Jct. Mabelvale-O.G. & E. 500 kV lines on the same right-of-way will afford the advantages of added reliability, least overall height, quicker restoration in event of failure and safer conditions during maintenance. Self supporting steel structures of the single circuit 500 kV design are installed in both lines north of McClellan-Kerr Arkansas River Navigation System. Guyed aluminum towers of the single circuit 500 kV design are installed south from the McClellan-Kerr Arkansas River Navigation System to the point of interconnection with the Mabelvale-O.G. & E. 500 kV line. The conductor is three bundle 954 MCM 45/7 strand ACSR and the shield wire 7 #7 alumoweld cable. The land traversed by the lines varies from flat, rolling hills to rugged terrain in the vicinity of Spring Mountain.

The ANO-Pleasant Hill 500 kV line parallels the other two 500 kV lines immediately north of the plant switchyard on common 460-foot wide right-of-way for a distance of 1.51 miles and parallels the ANO-Pleasant Hill 161 kV line north of Russellville for a distance of 4.44 miles. The two lines are separated by 110 feet on common 250-foot wide right-of-way. Self-supporting steel structures of the single circuit 500 kV design are installed in the paralleled section of the line. Guyed aluminum towers of the single circuit 500 kV design are installed on the remaining section. The conductor is a three-bundle 954 MCM 45/7 strand ACSR and the shield wire 7 #7 alumoweld cable. The land traversed by the line varies from flat, rolling hills to semi-rugged terrain in the vicinity of Crow Mountain.

The two 161 kV lines are double-circuited on a common single steel tower line north from the ANO switchyard a distance of 1.83 miles. The two lines then separate toward their respective destinations.

The southernmost ANO-Russellville East 161 kV line extends east 10.17 miles to the existing Russellville East Substation where the line connects to the 161 kV system. The structures of the 161 kV line beyond the double circuited section are of wood H-frame design. The conductor is 1534 MCM 42/19 ACAR and the shield wire is 3/8-inch 7-strand galvanized steel.

The northernmost ANO-Pleasant Hill 161 kV line, leaving the double-circuited steel tower line north of the ANO switchyard, traverses a distance of 32.02 miles east to the site of the Pleasant Hill 161 kV substation where the line interconnects with AP&L's 161 kV system. The structures are wood H-frame. The conductor is 1024 MCM 24/13 strand ACAR and the shield wire 3/8 inch galvanized steel strand.

The right-of-way of the 500 kV and 161 kV transmission lines, immediately north of the plant, are not common and do not cross. They are separated by a distance, at the closest point of approach, that will ensure a single structural failure on any of the three 500 kV lines in this section would not affect operation of the 161 kV circuits. A single structural failure on either or both of the 161 kV lines in this section would not affect operation of the 500 kV circuits.

The ANO-Pleasant Hill 500 kV line crosses over the ANO-Pleasant Hill 161 kV line northeast of Russellville. A single structural failure on the ANO-Pleasant Hill 500 kV line at this crossover would cause an outage on both lines due to high speed clearing of faults by breaker action, but would not affect operation of the two parallel 500 kV lines or the remaining 161 kV line to Russellville.

Operating problems on the 500 kV lines out of the plant switchyard, due to rugged terrain, vibration or galloping conductor problems, icing or heavy load conditions, and high thunderstorm occurrence rates were all considered in design of the lines. The 500 kV structures exceed requirements of the National Electrical Safety Code heavy loading conditions with the appropriate safety factors, in that the structures are also designed for 100 mile per hour winds with a 1.10 safety factor and 1-inch radial ice on conductors with a 1.10 safety factor. Additional torsional or stringing loads are also included in the structure design. The regional isokeraunic level (thunderstorm-days per year) is approximately 57. No outages due to lightning had been recorded on the 86.74 mile long ANO-Mabelvale 500 kV line since it was energized in 1972, and only one outage due to lightning (April 27, 1973) was recorded on the 93.82 mile long ANO-Fort Smith (O.G. & E.) 500 kV line up to the time of licensing. Field tests have verified that no vibration or conductor problems exist on either 500 kV circuit.

AP&L had 413.75 miles of 500 kV line in operation at the time of licensing. The ANO-Pleasant Hill and the Pleasant Hill to Mayflower 500 kV lines add an additional 61.08 miles to the 500 kV system.

8.2.1.2.1 Crossovers

Figure 8.2-1 shows six specific incidents of transmission lines crossing other transmission lines that connect directly to the ANO plant switchyard. Five of these transmission lines are owned and operated by Entergy Arkansas, Inc. and one by Southwestern Power Administration. Three of these crossings involve lines owned and operated by Entergy Arkansas, Inc. and Southwestern Power Administration and three of these crossings involve lines owned and operated wholly by Entergy Arkansas, Inc. These crossings are discussed as follows:

A. The Southwestern Power Administration double circuit 161 kV line crosses over the ANO-Russellville East 161 kV line northeast of ANO (see Figure 8.2-4, Detail 1A). A shield wire, conductor or structure failure on the Southwestern Power Administration line in this vicinity could cause an outage to this off-site power source, however, four alternate sources would still be in service to feed the ANO switchyard.

B. The Southwestern Power Administration double circuit 161 kV line crosses over the ANO-Pleasant Hill 161 kV line northeast of ANO (see Figure 8.2-4, Detail 2A). A shield wire, conductor or structure failure on the Southwestern Power Administration line in this vicinity could cause an outage to this off-site power source, however, four alternate sources would still be in service to feed the ANO switchyard.

C. The Southwestern Power Administration double circuit 161 kV line crosses under the ANO-Pleasant Hill 500 kV line northeast of ANO (see Figure 8.2-4, Detail 3A). A shield wire, conductor or structure failure on the Southwestern Power Administration line in this vicinity would not cause an outage to this off-site power source.

D. The ANO-Pleasant Hill 500 kV line crosses over the ANO-Pleasant Hill 161 kV line northeast of Russellville (see Figure 8.2-4, Detail 4A). A shield wire, conductor or structure failure on the 500 kV line in the vicinity of this crossing probably would cause an outage to both of these off-site power sources. However, there would still be three off-site power sources in service to feed the ANO switchyard.

E. The two parallel ANO-Jct. Mabelvale-O.G. & E. 500 kV lines cross over the Dardanelle Dam-Dardanelle-Danville 161 kV line northeast of Danville, Arkansas (see Figure 8.2-4, Detail 5A). A shield wire, conductor or structure failure on either of the 500 kV lines at this crossing would operate switches at Dardanelle Dam and Danville substations, thereby isolating the loss of service to the 161 kV system and, assuming that the parallel 500 kV circuit was intact, there would be four off-site power sources in service to feed the ANO switchyard.

F. The Pleasant Hill-Mayflower 500 kV line crosses over the ANO-Pleasant Hill 161 kV line north of Morrilton (see Figure 8.2-4, Detail 4A). A shield wire, conductor, or structure failure on the 500 kV line in the vicinity of this crossing probably would cause an outage to this 161 kV off-site power source, however, four alternative sources would still be in service to feed the ANO switchyard.

8.2.1.2.2 <u>Shared Rights-of-Way</u>

There are three separate examples where two off-site lines are parallel to each other on separate structures sharing the same right-of-way. These examples are individually discussed below:

A. The 24 miles of two parallel 500 kV single circuit transmission lines on metal towers exit the ANO switchyard north, then turn west and south to a point northeast of Danville, Arkansas. The two lines are parallel to each other and separated by 140 feet on common 320-foot wide right-of-way except at the Arkansas River crossing where separation is 220 feet and right-of-way is 460 feet wide due to the 190-foot tall structures. Both circuits of the approximately 5.57 mile parallel section north of the river are composed of steel structures which vary in height from 70 to 110 feet. Structures are placed essentially opposite each other with a maximum differential elevation at the base of approximately 36 feet. Should one of these parallel lines go down it would not effect either the towers or conductors of the parallel line. On the 17.67-mile parallel section south of the river, guyed aluminum towers are installed on 140-foot separation. Tower heights vary from 75 to 115 feet on both circuits. The towers are offset slightly longitudinally. Four guy cables on each structure extend toward the parallel line and toward the edge of right-of-way. Failure in the anchorage, guy cables or loss due to vandalism could result in structural failure to either line and

could cause a structure to fall into the structure guys or conductors of the parallel line. This could result in an outage to both of these parallel off-site power sources. However, there would still be three off-site power sources to feed the ANO switchyard.

B. The ANO-Pleasant Hill 500 KV single circuit transmission line exits the plant north on metal towers and parallel the twin lines of the ANO-Jct. Mabelvale-O.G. & E. 500 kV line, a distance of 1.51 miles. Towers will vary in height from 70 to 110 feet with a maximum differential elevation at the base of approximately 46 feet. Tower separation will be 140 feet east of the more easterly of the twin lines now exiting the plant. Structures will be essentially opposite structures of the east twin line. In the event of a structure failure, only one circuit would be damaged leaving four off-site power sources in service feeding the ANO switchyard.

C. The ANO-Pleasant Hill 500 kV line parallels the ANO-Pleasant Hill 161 kV line northeast of Russellville, Arkansas. These lines are parallel on 250-foot common right-of-way with a line separation of 110 feet for a distance of approximately 4.44 miles. The 500 kV line is on metal towers with a phase-to-phase separation of 30 feet, 3 inches and varies in height from 70 to 150 feet. The 161 kV line is on wooden structures with a phase-to-phase separation of 14 feet, 6 inches and poles vary in height from 55 to 85 feet. A total of 37 wooden structures and 23 metal structures are involved in this parallel section. A structure failure on the wooden 161 kV line would not cause an outage on the 500 kV line, but a structural failure on the 500 kV line could cause an outage to both circuits. In this event three off-site power sources would still be in service to feed the ANO steam electric station switchyard.

8.2.1.3 Switchyard

The ANO switchyard consists of a 500 kV yard and a 161 kV yard connected by a 600 MVA autotransformer bank with a 22 kV tertiary winding.

The 500 kV portion of the yard has two main buses. Both generators are connected to the main buses by double breaker bays. The three 500 kV transmission lines and the autotransformer are connected to the main buses by two breaker-and-a-half bays. Mabelvale and Ft. Smith transmission lines are on one bay and Pleasant Hill and the autotransformer are on the other bay.

The 161 kV portion of the switchyard is a 4-element ring bus. The four elements connected to this 161kV ring bus include the ANO-Russellville East 161 kV transmission line, the ANO-Pleasant Hill 161 kV transmission line, the ANO 500/161 kV autotransformer, and the 161 kV line which feeds an automatic voltage regulator in the switchyard which then feeds Start-up Transformer 2 in the plant. The ring bus is arranged so the autotransformer and the lines to Startup Transformer 2 are not connected to a common 161 kV breaker. Likewise the two 161 kV transmission lines are not connected to a common 161 kV breaker.

The 22 kV tertiary winding of the autotransformer is connected to two 22 kV breakers. One breaker feeds an automatic voltage regulator in the switchyard which then feeds Startup Transformer 1 in the plant via underground 22 kV cable. The other breaker feeds an automatic voltage regulator in the switchyard which then feeds Startup Transformer 3 in the plant also via underground 22 kV cable.

The 161 kV yard is separated from the autotransformer by two 161 kV circuit breakers. Therefore, the failure of any one of the 161 kV breakers will trip the adjacent breakers and interrupt only one of the plant off-site power sources. The 500 kV lines and the autotransformer will remain available. Conversely, the failure of a 500 kV breaker which feeds the autotransformer will trip the two 161 kV breaker connected to the autotransformer, but will not interrupt the 161 kV circuit to the plant.

Each breaker in the switchyard has a separate control circuit and a failure of one circuit to operate properly will not affect any other breaker control circuit.

Protective relaying on the autotransformer consists of a primary and a backup relaying scheme. The primary relaying scheme uses transformer differential relays. The backup relaying scheme uses two sets of distance and directional ground overcurrent relays. One set looks into the autotransformer from the 161 kV side. The other set looks into the autotransformer from the 500 kV side. The primary and backup schemes do not have in common any components such as protective relays, current transformers, potential transformers, trip coils, or DC thermal breakers. Therefore, the failure of one scheme to operate properly will not affect the operation of the other scheme. Both schemes initiate the local breaker failure scheme.

Protective relaying on the 161 kV circuit to the plant also consists of a primary and a backup relaying scheme. The primary scheme uses bus differential relays and the backup scheme uses distance and directional ground overcurrent relays. Again, the two schemes do not have any components in common, so that a failure in one scheme will not affect the operation of the other scheme. Both schemes initiate the local breaker failure scheme. Additional protective relaying on the 161 kV circuit to the plant includes overvoltage protection and sudden pressure relaying for the 161 kV automatic voltage regulator. All of these protective relaying schemes on the 161 kV circuit to the plant operate lockout relays in the switchyard which operate Startup Transformer 2 lockout relays in the plant. This results in the opening of the 161 kV breakers to de-energize the Startup Transformer 2 circuit to the plant and results in the automatic transfer of plant auxiliary loads from Startup Transformer 2 to Startup Transformer 3, if the plant auxiliary loads were being served from Startup Transformer 2.

The control power for the 500 kV and 161 kV switchyard breakers is supplied from two 125 volt DC battery banks and their respective battery chargers located in the switchyard control building. Manual switches are provided to allow either battery bank to carry the entire switchyard load if the other battery is unavailable. The battery charger for Battery Bank #2 is also a battery eliminator and can carry the entire switchyard load if either or both battery banks are unavailable. Three sources of AC power are available for the battery chargers. These are: (1) the auxiliary power transformers on the 22 kV bus; (2) the plant 480-volt load center bus "B3"; and (3) the plant 480-volt engineered safeguard bus "B6". Figure 8.2-3 show how these sources may be connected to the battery chargers.

The switchyard DC control bus is isolated from ground, and detectors are provided to alarm when a ground exists on either the positive or negative bus. All equipment will function properly when one side of the DC bus is grounded. If either battery charger fails, its associated battery is designed to carry its respective switchyard DC load without interruption for a minimum of eight hours.

8.2.1.4 Reliability

Reliability considerations to minimize the probability of power failure due to faults in the network interconnections and associated substations are as follows:

A. The 500 kV lines are designed to carry the full output of ANO-Units 1 and 2.

B. The 500 kV transmission lines are single circuit and the towers are designed as recommended by ASCE paper No. 3269.

C. System stability will be maintained on simultaneous tripping of the main generators of Units 1 and 2.

D. The high voltage systems are protected from lightning and switching surges by lightning protection equipment and by overhead electrostatic shield wires.

E. Primary and backup relaying are provided for each circuit along with local circuit breaker backup switching. These provisions permit the following:

   1. Any circuit can be switched under normal or fault switching without affecting another circuit.

   2. Any single circuit breaker can be isolated for maintenance without interrupting the power or protection to any circuit.

   3. Short circuits on a section of main bus will be isolated without interrupting service to any circuit, other than that connected to the faulty bus section.

   4. Circuit protection is insured by redundant relaying.

F. De-energizing of the 500-161 kV switchyard will be required at flood elevation of 356.5 feet. At this flood elevation, it will additionally be necessary to de-energize and bypass the 161 kV voltage regulator to Startup Transformer 2. In order to maintain a source of off-site power at flood elevations above 356.5 feet, it will be necessary to install temporary connections over the 161 kV switchyard to connect Startup Transformer 2 directly to the 161 kV Pleasant Hill transmission line. These temporary connections will be in the form of jumpers, which are sized and stored onsite. In the event of a flood, these jumpers would be installed by local office or plant personnel prior to flood waters reaching the site. This operation would take two men approximately three hours. All the equipment connections necessary to maintain off-site power are above the 361-foot design flood elevation or procedural controls have been established to ensure appropriate flood protection is verified prior to an external flood impacting site-specific SSCs. This off-site power source is provided with lightning arrester protection and shielding. This Pleasant Hill line has a minimum clearance of 17 feet above the 361-foot elevation.

In the event of loss of normal and preferred auxiliary power, the ESF loads will be supplied from the emergency power source. Unit 2 will have two separate and independent sources of off-site and onsite power capable of supplying the ESF loads.

8.2.2 ANALYSIS

System studies have been conducted to test the performance of the Arkansas Power & Light Company/Entergy System in both the steady-state mode and under transient conditions. The conditions studied included, but were not limited to: outages of multiple circuit lines using common towers; coincidental, but not simultaneous, loss of one transmission line and one generator, or of two generators; or of two transmission lines (for additional studies, see Section 8.3.1.6).

The results of these studies indicate that under steady state conditions no loss of power would occur, and adequate system voltage and acceptable loading of equipment would be maintained. Under the transient conditions, the studies indicate that the system is transiently stable and no loss of power or cascading type conditions would occur.

Historical data removed-To review the exact wording, please refer to Section 8.2.2 of the FSAR.

The availability of the three 500 kV lines at the ANO switchyard can be predicted by examining the history of the existing 500 kV transmission grid.

Using data from the 1966-1972 period on six 500 kV lines with a cumulative mileage of 740 miles, the frequency duration, and causes of outages on the three 500 kV lines to ANO should be as follows: the ANO-Ft. Smith Line will have an average of .98 outages per year; the ANO-Mabelvale will have an average of .93 outages per year; and the ANO-Pleasant Hill Line will have an average of 0.34 outages per year. The following table gives the causes and duration of outages.

Cause	Percent of Outages	Average Duration of Outages
Tornados or High winds	11	189 hours
Lightning	40	1 hour
Equipment Failure	35	5.79 hours
Unknown	13	1.14 hours
Operator Error	1	.13 hour

8.3 ONSITE POWER SYSTEMS

8.3.1 AC POWER SYSTEMS

8.3.1.1 Description

Figure 8.3-1 shows a single line diagram of the AC power system for Unit 2. With the Unit operating at power, the onsite AC power system consists of the Unit 2 Main Generator, the Unit Auxiliary Transformer, two diesel generators, one black-out diesel generator and the 6.9 kV, 4.16 kV, 480-volt and 120/208-volt AC distribution systems.

8.3.1.1.1 Main Generator and Main Transformer

The steam turbine driven main generator delivers AC power at 22 kV to the main transformer bank and the Unit Auxiliary Transformer (UAT). Power is stepped up to 500 kV for transmission to the switchyard and stepped down to 6.9 kV and 4.16 kV for the station auxiliaries during normal operating conditions.

The main generator is connected to the main transformers and the unit auxiliary with a forced air-cooled isolated phase bus system. The portion of the bus and its supporting structure which is located outdoors is designed to withstand maximum fault duty in a 70 mile per hour wind, combined with rain and/or snow.

A description and rating of the main generator and the isolated phase bus are as follows:

Main Generator	
Output, MVA	1133.3 @ 0.95PF
Voltage, kV	22
Speed, rpm	1800
Phases	3
Frequency, Hz	60
X"d	26.5% (sat)
SCR	0.58
Cooling	Hydrogen up to 60 psig for rotor Water up to 125 psig for stator
Excitation	Compact alterrex

Isolated Phase Bus	Rated Current @ 22kV
Main generator bus	29,000 A For Normal Loads 30,000 A For Peak Loads
Main transformer delta bus	17,320 A
Auxiliary transformer bus	1500 A

The main transformer bank consists of three single-phase 430 MVA transformers. The outdoor location of the transformer bank, east of the turbine building contains firewalls separating the transformers along with an automatic water deluge system which is discussed in Section 9.5.1.

Description and rating of the main transformer bank are as follows:

Main Transformers:	3 Single-Phase Units, rated
Output, MVA	430 (55 °C rise)
Frequency, Hz	60
Impedance, %	11.33 (average of three)
Low Voltage, kV	22.5
High Voltage, kV	512.5
Connection	Delta – Grd. Wye
Cooling Class	FOA

The main transformers are equipped with sampling valves for periodic testing of the transformer oil. Test switches are provided for testing sudden pressure relays on the transformer, and all protective relays and instruments have provision for inservice testing and calibration.

8.3.1.1.2 Unit Auxiliary Transformer, Startup Transformers and 6900-Volt Systems

The UAT and Startup Transformer 3 are physically and electrically identical and both are located east of the Unit 2 turbine building, in the transformer area. Firewalls separate the two transformer pads and an automatic water deluge fire protection system is provided (for discussion, see Section 9.5.1).

The three winding unit auxiliary transformer provides normal operating power to all of the station auxiliary loads. The high voltage winding is connected to the main generator isolated phase bus while the two low voltage windings supply the 6.9 kV buses 2H1 & 2H2 and the 4.16 kV buses 2A1 & 2A2.

The three winding Startup Transformer 3 provides startup, shutdown, and post-shutdown power to all of the auxiliary loads. The high voltage winding is connected to the 22 kV tertiary of the bus-tie autotransformer bank located in the switchyard. The two low voltage windings supply the 6.9 kV and 4.16 kV buses.

The three winding Startup Transformer 2 is common to Units 1 and 2 and is physically located east of the Unit 1 turbine building in the transformer area.

The high voltage winding is connected to the 161 kV ring bus located in the switchyard while the low voltage windings are connected to the Unit 1 and 2, 6.9 kV buses H1, H2 and 2H1, 2H2, respectively, and the 4.16 kV buses A1, A2 & 2A1, 2A2, respectively.

Each transformer is adequate for carrying all Engineered Safety Features (ESF) load groups under emergency conditions. Ratings of the transformers are as follows:

Unit Auxiliary Transformer & Startup Transformer 3

High Voltage winding H:	
Output, MVA	35.2/46.8/58.5
Voltage, kV	21.5
Low Voltage winding X:	
Output, MVA	19.7/26.2/32.8
Voltage, kV	6.9
Low Voltage winding Y:	
Output, MVA	15.5/20.6/25.7
Voltage, kV	4.16

Z IMPEDANCE		Z IMPEDANCE		
Unit Auxiliary Transf. %		Startup Transf. 3 %		
H-X	6.91	H-X	6.74	(19.7 MVA, 21.5 kV Base)
H-Y	9.11	H-Y	8.99	(15.5 MVA, 21.5 kV Base)
X-Y	17.32	X-Y	17.23	(15.5 MVA Base)

Cooling Class OA/FA/FOA
Taps Available Two-2 ½% above rated voltage
Two-2 ½% below rated voltage

Startup Transformer 2

High Voltage winding H:	
Output, MVA	27/36/45
Voltage, kV	157
Low Voltage winding X:	
Output, MVA	15/20/25
Voltage, kV	6.9
Low Voltage winding Y:	
Output, MVA	12.6/16.8/21
Voltage, kV	4.16

Z IMPEDANCE	%	
H-X	5.03	(15 MVA, 157 kV Base)
H-Y	4.84	(12.6 MVA, 157 kV Base)
X-Y	8.91	(12.6 MVA Base)

Cooling Class OA/FA/FOA
Taps Available Two-2 ½% above rated voltage
Two-2 ½% below rated voltage

Two 6,900-volt buses, designated as 2H1 and 2H2, have been provided. During normal operation, each bus will be fed from the 6.9 kV winding of the UAT. During plant startup and shutdown, the buses will be fed from the 6.9 kV secondary winding of Startup Transformer 3.

8.3.1.1.3 4,160-volt Auxiliary System

Four 4,160-volt buses have been provided. Each of the two main buses, designated as 2A1 and 2A2, provides power to non-ESF, 4 kV auxiliary motors, feeders to 480-volt non-ESF load centers, and a feeder to one of the two 4,160-volt ESF buses. Normally, these buses will be fed from the 4,160-volt winding of the UAT. During plant startup and shutdown, the buses will be fed from the 4,160-volt winding of Startup Transformer 3.

The two 4,160-volt ESF buses, 2A3 and 2A4, supply equipment essential for the safe shutdown of the plant. These buses are capable of being supplied from either the UAT, Startup Transformer 3 or Startup Transformer 2 via the 4,160-volt non-ESF buses 2A1 and 2A2.

Upon loss of normal and preferred power sources, each of the two 4,160-volt ESF buses is energized from its respective diesel generator. Bus load shedding, bus transfer to the diesel generator, and pickup of critical loads is automatic. The details are covered in Section 8.3.1.1.8.8. In accordance with 10CFR50.63, the Station Blackout Rule, an Alternate AC Power Source can be manually aligned to either safety bus 2A3 or 2A4. This system compensates for the simultaneous failure of the normal, preferred, and both emergency diesel power sources. See Section 8.3.3 for additional information.

The 4.16 kV and the 6.9 kV switchgear are comprised of 3-phase, indoor, metal-clad switchgear assemblies with drawout-type magnetic Air Circuit Breakers (ACB) except for the main supply breakers. The main supply breakers for the non-ESF buses are retrofitted vacuum circuit breakers. The ESF switchgear for 2A3 is equipped with retrofitted vacuum circuit breakers that have been upgraded from 250 to 350 MVA interrupting capacity. The Alternate AC Switchgear (Bus 2A9) is of similar construction; however, it utilizes drawout vacuum circuit breakers in a stacked configuration.

A 1200 A spare circuit breaker with a storage cubicle is provided for the ESF 4.16 kV switchgear 2A3 and 2A4. This spare circuit breaker is interchangeable with any of the circuit breakers in lineups 2A3 or 2A4.

The circuit breakers operate from 125-volt DC control power which is supplied from the DC power system as described in Section 8.3.2.1. These breakers are provided with "OPERATE", "TEST", and "WITHDRAWN" positions. Manual electrical and manual mechanical closing and tripping provisions with mechanical "CLOSE" and "TRIP" indicators are also provided. Each breaker can be controlled from either of two locations:

A. Control room (remote); or

B. Switchgear (local).

Power cables for the 4.16 kV system are shielded copper conductors rated 5 kV, 90 °C or greater with flame-resistant insulation and jacketing materials capable of withstanding the worst case environmental conditions to which the cable could be exposed. The conductors are sized to carry the maximum available short circuit current for the time required for the circuit breaker to clear the fault. They are also sized for continuous operation at 125 percent of nameplate full load current. All 4.16 kV system cables including those used in non-ESF circuits have been designed for operation under:

A. Ambient temperature of 40 °C with relative humidity of 50 percent increasing to temperature of 45 °C with 100 percent relative humidity for periods up to one week; and

B. Forty years integrated radiation dose at 1 x 10^7 rads at a radiation level of 100 rads/hr.

All of the safety-related distribution equipment, including raceway systems, was designed to meet the seismic requirements for Class 1E electric equipment as discussed in Section 3.10. The 4.16 kV switchgear is not seismically qualified in the racked-down configuration.

The 4,160-volt ESF switchgear is located within a Seismic Category 1 structure and is protected from potential missile hazards. Physical separation and isolation has been maintained in the location and installation of the ESF switchgear for the redundant systems. Switchgear 2A3 is separated from its counterpart 2A4 by a fire-rated door.

8.3.1.1.4 <u>480-Volt Auxiliary System</u>

The 480-volt system consists of a series of load centers that feed Motor Control Centers (MCCs), the loads fed from these load centers and MCCs, and interconnecting cables.

Each load center consists of a transformer and a 480-volt switchgear assembly. The load centers are arranged in pairs with one tie breaker between pairs for non-ESF buses and two tie breakers for ESF buses 2B5 and 2B6.

The load centers, designated 2B5 and 2B6, and eight of the MCCs, designated 2B51 thru 2B54 and 2B61 thru 2B64 supply all of the 480-volt Class 1E loads. During transfer to the emergency power supply, loss of voltage will trip all starter fed loads on these buses. Only the Class 1E loads will start automatically on the return of bus voltage. The non-ESF loads must be started manually.

The load centers switchgear assemblies include metal enclosed, drawout type ACB's. The circuit breakers are 3-pole, electrically operated, have mechanical "CLOSE" and "TRIP" indicators and have provision for manual operation. They are provided with "OPERATE", "TEST", and "WITHDRAWN" positions and have visual indication for each position. Electric operation is from 125-volt DC control power furnished from the DC power supply systems as described in Section 8.3.2.1.

The main incoming breakers, tie breakers and motor starter breakers of the load centers can be controlled from the control room (remote) and the switchgear. All other breakers can be controlled only at the switchgear. Mechanical and electrical interlocks have been provided as described in Section 8.3.1.1.9.4 to ensure safe and proper functioning of all Class 1E devices.

The 480-volt MCCs are comprised of magnetic feeder breakers, thermal-magnetic branch breakers, and combination motor starters consisting of 3-pole, molded case circuit breakers, magnetic NEMA Size 1 and larger, full voltage motor starters, 480/120-volt control transformers, and control devices. Some motor starters have control push buttons or one or more selector switches as required.

Combination starters for motor-operated valves, pump motors and fan motors are equipped with three single-pole ambient compensated thermal overload relays and heater elements.

Cables for the 480-volt power and control systems are rated 600-volt, 90 °C or greater with flame-resistant insulation and jacketing materials capable of withstanding the worst case environmental conditions to which the cable could be exposed. The copper conductors are sized to carry the maximum available short circuit current for the time required for the circuit breaker to clear a fault. They are also sized for continuous operation at 125 percent of nameplate full load current.

The ESF 480-volt distribution equipment is designed to meet the seismic requirements for Class 1E electric equipment as discussed in Section 3.10. Load center transformers, load center buses, and MCC buses have adequate capacity to supply the momentary and continuous loads connected to the 480-volt buses.

The ESF load centers and MCCs are located within Seismic Category 1 structures and are protected from potential missile hazards to minimize exposure to mechanical damage. Physical separation has been maintained in the location and arrangement of the redundant systems and components. Load center 2B5 is physically separated from its redundant counterpart, load center 2B6. Likewise, MCCs 2B51, 2B52, 2B53 and 2B54 are separated from their redundant counterparts, 2B61, 2B62, 2B63, and 2B64, by physical separation and fire barriers or fire walls.

Other non-ESF load centers and MCCs are located throughout the plant in areas of electrical load concentration.

8.3.1.1.5 120/208-Volt Instrument AC System

Four 120/280-volt distribution panels (2Y1, 2Y2, 2Y3 and 2Y4) have been provided for control and instrumentation and power supplies to non-ESF equipment.

Two buses (2Y1 and 2Y2) have alternate supplies from two ESF motor control centers via one of two 480-120/208-volt step-down transformers. Upon the loss of either source or transformer, the affected bus can be cross-tied to the other bus and its supply and transformer through tie breakers.

Each instrument AC supply includes the following:

A. One transformer:

Output, kVA	30 (For 2Y1, 2Y2) & 75 (For 2Y3 & 2Y4)
Type	Dry, indoor
Phases	3
Frequency, Hz	60
High Voltage, V	480
Low Voltage, V	208Y/120
Taps	Four 2.5% below normal Two 2.5% above normal

B. Distribution panel with:

1	-	Main breaker, 3-pole, 225A
1	-	tie breaker, 3-pole, 225A - (Applicable for 2Y1 & 2Y2 only).
42	-	distribution breakers, single pole, current rating as required
1	-	undervoltage relay to detect and annunciate the loss of voltage,
	-	(Applicable for 2Y1 & 2Y2 only).

8.3.1.1.6 120-Volt Uninterruptable AC Power System

A 120-volt uninterruptable AC power system has been provided to supply the reactor protection and ESF control and instrumentation channels. This power supply system consists of six inverters and four distribution panels which provide an independent power source to each redundant protective channel. Each inverter has two sources of power supply:

A. An ESF battery bank (2D11 or 2D12) as the normal source; and,

B. An ESF MCC (2B51, 2B53, 2B54, 2B61, or 2B64) as the emergency standby source.

Essential equipment such as nuclear instruments and nuclear auxiliary instruments have been connected to these four redundant panels. These four channels are commonly referred to as vital AC systems. The plant computer is connected to a seventh inverter unit. The system is arranged so that any type of single failure or fault will not prevent proper protective action of the Plant Protective System (PPS) at the system level.

Cables for the 120-volt AC power and control systems are rated 600-volt, 90 °C or greater with flame-resistant insulation and jacketing materials capable of withstanding the worst case environmental conditions to which the cable could be exposed, and copper conductors sized to carry the maximum available short circuit current for the time required by the circuit breaker or fuse to clear the fault. These cables are sized for continuous operation at 125 percent of nameplate full-load current.

8.3.1.1.7 Emergency Power Supply System

The entire emergency power supply system is designed to provide redundant emergency power sources capable of furnishing adequate power to safely shut down the reactor, remove reactor residual heat, and maintain the unit in a safe shutdown condition upon the loss of preferred power with or without a coincident design basis event. The emergency power supply system is a safety-related system.

Two emergency diesel generator units are designed to generate and supply the required emergency power to the redundant 4.16 kV ESF buses, 2A3 and 2A4. These buses supply all of the safety-related loads and those non-safety-related loads for which it is desirable to have manually switched access to the diesel generators.

The emergency power supply system consists of two identical diesel generator units, accessories, fuel storage and transfer systems, interconnecting cables and instrumentation. Each diesel generator set is a complete package unit with all auxiliaries (excluding a DC voltage supply) required to make it a self-sufficient power source capable of automatic starting and loading.

The diesel generator units are Model 38TD8-1/8 manufactured by the Fairbanks Morse Division of Colt Industries. They are rated at 3,250 kW (7-day rating). Reliability, quick response and load acceptance capability have been demonstrated by a series of tests performed on a similar unit. The test results are documented in IEEE Paper 69 CP 177-PWR, "Fast Starting Diesel Generators for Nuclear Plant Protection." Currently, nine units of the same model and rating are installed at the operating nuclear power stations listed below:

Station	Utility	Number of Units
Peach Bottom 2	Philadelphia Electric Co.	2
Hatch 1	Georgia Power Co.	3
Duane Arnold	Iowa Electric Light & Power Co.	2
Millstone 2	Northeast Utilities	2

Historical data removed - To review the exact wording, please refer to Section 8.3.1.7 of the FSAR.

The generators have open drip-proof frames, Class B insulation and are wye connected, synchronous type with static, solid-state excitation systems, capable of carrying full-rated load continuously without exceeding its rated temperature rise above 50 °C ambient. Each diesel generator is furnished with automatic field flashing equipment for quick voltage buildup during the startup sequence. The automatic voltage regulators provide steady state voltage regulation within ± 1.0 percent for any load from no load to full load.

A 24-volt DC backup field flashing system is provided for each diesel generator to assure voltage building for manual starting from the diesel generator rooms in the event of loss of the normal 125-volt DC flashing source. This backup system is non-class 1E.

The air starting system and the fuel oil storage and transfer systems are covered in detail in Sections 9.5.6 and 9.5.4, respectively. Flooding of the diesel fuel transfer pumps is precluded by operator action. Hydrologic studies, detailed in Section 2.4.4, predict that at least two days of warning will be available prior to the flood level reaching the watertight door to the underground storage vault. The watertight door, to the underground storage vault has an intrusion alarm that annunciates when it is open.

When a flood warning is received, all watertight doors will be shut and the alarm panel will be carefully monitored to ensure that watertight integrity is not endangered. Since all Class 1E electrical systems, which are below the potential maximum flood level of 361 feet, are located inside watertight buildings, closing of watertight doors will protect all Class 1E equipment.

Cooling water to the diesel generator heat exchangers is supplied from the Service Water System (SWS) as described in Section 9.5.5.

A separate air cooling system consisting of air inlet louvers and two exhaust fans has been provided for each diesel generator room as described in Section 9.4.2.4. Each diesel generator room has its own combustion air intake and exhaust system as described in Section 9.5.9.

Each diesel generator unit is designed to start automatically upon receipt of a start signal, attain rated speed and rated voltage within 15 seconds of receiving the start signal, and automatically accept ESF loads in sequence as shown in Table 8.3-1 or manually applied loads required for shutdown without off-site power. Each diesel generator is capable of sequentially starting all required motors and accelerating them to full load operation after receiving the start signal.

Diesel generator 2K4A supplies power to 4.16 kV bus 2A3, and diesel generator 2K4B supplies power to 4.16 kV bus 2A4.

The diesel generator controls are designed for automatic as well as manual operation. The manual control is from one of two locations: the control room (remote) or the diesel generator room (local). The choice of location is selected by a "LOCAL-REMOTE" hand switch on the diesel generator control panel (2E12 or 2E22). Placing the "LOCAL-REMOTE" switch in "LOCAL" position permits manual regulation and control of the generator from the diesel generator room only. This mode is indicated in the control room. Placing the "LOCAL-REMOTE" switch in the "REMOTE" position permits regulation and control of the generator from the control room only. This switch is for selection of generator control location only; it does not affect diesel engine starting either in manual or automatic.

A 3-position key-operated "AUTO-START-LOCKOUT" hand switch, with key removable in "AUTO" position only, is provided on the diesel generator control panel. This switch selects the starting mode for the diesel engine. Placing this switch in "LOCKOUT" will prevent automatic or manual starting of the diesel from any location. With the switch in the "LOCKOUT" position, an alarm will be initiated in the control room to indicate that the diesel generator is "NOT AVAILABLE". Placing this switch in the "START" position will initiate diesel starting.

With the "AUTO-START-LOCKOUT" switch in the "AUTO" position, the diesel engine can be started manually from the control room. The "LOCAL-REMOTE" switch should be in the "REMOTE" position to provide regulation and control of the generator in this situation.

Also, with the "AUTO-START-LOCKOUT" switch in the "AUTO" position, the diesel engine will start automatically on an undervoltage condition on the respective 4160 or 480-volt ESF buses, or upon receipt of a Safety Injection Actuation Signal (SIAS).

Voltage relays and speed-sensing devices are provided to prevent loading.

The diesel generators are wye-connected with the neutral of each grounded through its own continuously rated transformer-resistor combination. The grounding transformer-resistor combination is mounted in a well-ventilated metal-enclosed housing.

Provisions have been made for manually synchronizing the diesel generator with the incoming power source for test purposes. The sync-check relay is provided to prevent remote manual closing of the diesel generator breaker if: (1) there is no synchronism between the diesel generator and energized bus 2A3/2A4, or (2) the diesel is not running. The relay will permit manual closing of the diesel generator breaker if the bus 2A3/2A4 is dead and diesel generator voltage is established. The same type of interlock, i.e. sync-check, is provided in the bus 2A3/2A4 normal supply breakers. This relay will permit manual closing of the breakers 2A309/2A409 if: (1) there is synchronism between the bus 2A1/2A2 and bus 2A3/2A4, or (2) bus 2A3/2A4 is dead and 2A1/2A2 is live or (3) 2A1/2A2 is dead and 2A3/2A4 is live. Since the automatic transfer made is a dead bus transfer, automatic synchronization is not provided.

Each diesel engine has been provided with a preheat system which maintains adequate engine temperature to ensure fast starts. The preheat system includes a 15 kW jacket coolant heater and a 6 kW lubricating oil heater. Each heater is energized from a 480-volt ESF MCC. Interlocks have been provided to de-energize the lube oil and jacket coolant pre-heat systems upon starting of the respective diesel generators.

Control circuits for each diesel generator operate from separate 125-volt DC systems supplied from separate station batteries as described in Section 8.3.2.1.1. The ESF 125-volt DC systems are Class 1E electric systems.

Each diesel generator is capable of starting and carrying the maximum ESF loads required under postulated accident conditions. After the automatic starting and loading sequence is complete, (See Table 8.3-1.) each diesel generator will have a reserve capacity which is the difference between the diesel generator rating and the total load shown in Table 8.3-1. Additional loads may be manually started at the discretion of the operator, with such additional loading limited by the rated capacity of the diesel generators. A wattmeter, a varmeter, and an ammeter have been provided for continuous indication of diesel generator loading. Administrative control will be exercised to prevent loading the diesel generators over their rated capacities.

All of the emergency power supply system components are designed to meet the seismic requirements for Class 1E electric equipment as described in Section 3.10. Components of the emergency power supply system are located within Seismic Category 1 structures and are protected from potential missile hazards and fire. Physical separation and isolation have been maintained in the location and installation of equipment for redundant systems. Each diesel generator is housed in a separate concrete room in the auxiliary building at the 369-foot elevation. Normal access to one generator is through the room of the other. A watertight door separates these two rooms.

8.3.1.1.8 <u>Specific Details of Onsite AC Power System</u>

8.3.1.1.8.1 <u>Power Supply Feeders</u>

Figure 8.3-1 shows the network configuration. Power supply for the 6.9 kV and 4.16 kV bus sections can be obtained from either of the two startup transformers or from the UAT. The startup transformers are the offsite, or preferred, power sources. When in Modes 3 through 6, the Unit Auxiliary Transformer can be aligned as an offsite power source with the isophase bus disconnects removed and backfeeding through the main transformers. Flexibility of power supply is provided by connecting each of the four main bus sections to more than one source of power. Non-segregated, metal-enclosed, 6900- and 4,160-volt buses have been used for these feeders to improve reliability of supply.

ESF bus 2A4 is connected to non-ESF bus 2A2 through current limiting reactor 2X32. ESF bus 2A3 is connected to non-ESF bus 2A1. These two buses are also connected to the associated emergency diesel generator units. Power cables described in Section 8.3.1.4.2.2.3 have been used for these feeders.

Outgoing feeders from the two ESF buses are connected to the two 480-volt ESF load centers 2B5 and 2B6 through two 1,000 kVA step-down transformers. These two load centers in turn, feed all eight 480-volt ESF motor control centers. One feeder each from ESF MCCs 2B51 and 2B61 connect to 120/208-volt AC instrument buses 2Y1, 2Y2, 2Y3 and 2Y4 through four step-down transformers. One emergency standby feeder is provided from 480-volt ESF MCCs for each of the six 120-volt vital AC inverters as shown in Figure 8.3-6.

8.3.1.1.8.2 <u>Busing Arrangement</u>

Figure 8.3-1 shows the busing arrangement of the station for 6.9 kV, 4.16 kV and 480-volt load centers.

Two sections of 6900-volt switchgear, designated as 2H1 and 2H2 have been provided with no tie between the sections. Similarly, the main non-ESF 4,160-volt switchgear has been divided into two sections, designated as 2A1 and 2A2 with no tie.

Two completely redundant bus sections designated 2A3 and 2A4 have been provided for the 4,160-volt ESF system.

The two ESF 480-volt load centers have main breakers, tie breakers, MCC feeder breakers, and motor feeder breakers.

Single line diagrams of the 120-volt vital AC buses and 208/120-volt instrument AC buses are shown in Figure 8.3-6.

8.3.1.1.8.3 Loads Supplied From Each Bus

The design criterion governing the assignment of extra redundant loads (the third high pressure safety injection pump, the third service water pump, and the third charging pump and associated valves) is to maximize the availability of one of each type pump in each ESF channel under all conditions. Power supplies to the service water and high pressure injection pumps are electrically and mechanically interlocked so that no more than one pump of each type can be supplied from each ESF channel when normal power supply is not available (2A3 & 2A4 being supplied from the emergency diesel generators). The third pumps can be fed from either ESF channel through circuit breakers on the associated channel bus. Interlocks ensure that the third pump will not be connected to both ESF channel buses simultaneously, as described in Section 8.3.1.1.9.4.

8.3.1.1.8.4 Manual and Automatic Interconnections Between Buses, Buses and Loads, and Buses and Supplies

No automatic interconnections between buses or buses and loads have been provided for the two non-ESF 6.9 kV buses 2H1 and 2H2. Loads can be connected to the respective buses by manual control only.

Provisions have been made for manual and automatic transfer of buses between power supplies. Under normal operating conditions, supply to the two 6.9 kV bus sections is derived from the UAT. In the event of a loss of the UAT, transfer to either of the two startup transformers is capable of being accomplished automatically through protective relays as discussed below.

Normal bus transfers used on startup or shutdown of the main turbine generator unit are manual "live bus" transfers, i.e. the incoming source feeder circuit breaker is closed onto the energized bus section. After closing the circuit breaker of the incoming transformer, the supply breaker of the other transformer, is automatically tripped when the operator releases the control switch handle of the incoming breaker, resulting in transfers without power interruption. Synchroscope and synchronizing switches are employed to avoid paralleling sources which are out-of-phase.

Should the UAT become unavailable during normal power operation, manual transfer of full house loads to Startup Transformer 3 is acceptable without load shedding.

Emergency bus transfers, used on the loss of normal unit sources, are automatic fast bus transfers, i.e., the normal source feeder circuit breaker is tripped and, simultaneously, the emergency preferred source circuit breaker closes resulting in a transfer within a few cycles. The selection of one of the two startup transformers for emergency preferred duty is by means of duty selector switches in the control room. The duty selector switches determine which startup transformer is the first preferred backup.

Both Unit 1 and Unit 2 are prevented from automatic transfer to Startup Transformer 2 during normal power operations for all buses except Buses A1/A3 (Unit 1) and 2A1/2A3 (Unit 2). Procedures administratively control Unit 1 and Unit 2 access to Startup Transformer 2. Procedures may allow other fast transfer capabilities to Startup Transformer 2 for specifically analyzed conditions and restrictions defined in approved Engineering Calculations and Evaluations.

If full house load is automatically transferred to Startup Transformer 3 or 2 upon a unit trip, sufficient load is shed to insure no unnecessary Millstone degraded grid voltage isolations occur.

In the event that fast transfer is required with a safety signal, certain additional non-vital loads are shed. All ESF loads will be sequenced in accordance with Table 8.3-1. (For additional information, see Section 8.3.1.6, "Grid Undervoltage Protection.")

The non-ESF 4,160-volt system, 2A1 and 2A2, is identical to the 6900-volt system as regards the interconnections between buses, buses and loads, and buses and supplies.

Non-vital load centers on buses 2A1 and 2A2 will load shed anytime a SIAS actuation is present and feeder breakers from Startup Transformer 2 or 3 are closed.

The ESF buses 2A3 and 2A4 have been provided with a 4.16 kV cable interconnection with one breaker at each end of the tie. As described in Section 8.3.1.1.9.4, this interconnection is completely manual. Administrative control will be exercised so that this interconnection is used only during shutdown (Modes 5 and 6) or under post-accident emergency conditions. Automatic connection between the ESF buses and associated loads is covered in Section 8.3.1.1.8.8.

Automatic connection between the 4,160-volt ESF buses and the preferred source is achieved through the interconnection between the non-ESF 4,160-volt buses and the respective ESF 4,160-volt buses. Automatic connection between the ESF 4,160-volt buses and the associated diesel generator is discussed in Section 8.3.1.1.8.8.

As regards the 480-volt load centers and MCCs, there is no provision for automatic interconnection between buses. The ESF 480-volt loads identified in Table 8.3-1 are automatically connected to the respective buses on receipt of the appropriate ESFAS signal. Provision has been made to automatically close the main feeder breaker to the ESF load centers 2B5 and 2B6 upon receipt of an ESF signal unless these breakers have been locked out for maintenance. The tie breakers between the two ESF buses 2B5 and 2B6 are equipped with Kirk-key manual interlocks so as to prevent paralleling of the two redundant ESF sources.

No cross-channel electrical interlocking using breaker auxiliary contacts have been employed in the design. However, circuit breakers that can be racked out have been designed so that the auxiliary contacts used for interlocking will operate with the breaker in the operating position only. In the test/withdrawn positions, these contacts will remain in the position corresponding to the breaker "TRIP" position. Hence, disabling of one component by racking out the associated breaker will not render other components inoperable.

There is no arrangement of manual or automatic interconnection of the four 120-volt AC vital instrument buses. If the normal 125-volt DC sources fail, the inverters will be automatically switched to the emergency standby AC ESF source.

The two 120/208-volt AC instrument buses, 2Y1 and 2Y2, which are fed from redundant ESF motor control centers have provision for manual interconnection in the event of failure of one supply source. However, Kirk-key interlocks ensure that the two redundant supply sources are not paralleled.

8.3.1.1.8.5 Interconnections Between Safety- and Non-Safety-Related Buses

4.16 kV ESF bus 2A4 is connected to the 4.16 kV non-ESF bus 2A2 through a current limiting reactor. 4.16 ESF bus 2A3 is connected directly to 4.16 kV non-ESF bus 2A1. The implementation of the Station Blackout Rule (10CFR50.63) provided a connection between the non-safety related 4160 volt bus 2A9 and the safety related buses 2A3 and 2A4. No interconnection has been provided between the 480-volt ESF and non-ESF load centers.

8.3.1.1.8.6 Redundant Bus Separation

Separation of redundant buses has been accomplished through provision of fire-proof compartments or barriers. The two redundant diesel generators are housed in separate fire-resistant Seismic Category 1 structures, physically separated so that they are not vulnerable to a common hazard such as fire or flooding. The same is applicable in respect to the two 4,160 volt ESF switchgear lineups, 2A3 and 2A4; the two redundant load centers, 2B5 and 2B6; the two redundant groups of MCCs, 2B51, 2B52, 2B53, and 2B54 and 2B61, 2B62, 2B63 and 2B64; and the six redundant vital 120-volt AC inverters 2Y11, 2Y13, 2Y1113, 2Y22, 2Y24, and 2Y2224. Distribution panels 2RS1, 2RS2, 2RS3 and 2RS4 are likewise separated such that they are not vulnerable to a common fire or flood, or are otherwise evaluated for acceptable consequences.

8.3.1.1.8.7 Equipment Capacities

Ratings of all safety-related electrical equipment are shown in Table 8.3-2.

Equipment capacities have been conservatively selected keeping an adequate margin of safety. The two redundant diesel generators each have adequate capacity to supply all ESF and vital instrument loads required for safe shutdown of the reactor. Table 8.3-1 lists all of the ESF loads connected to each of the diesel generators under emergency conditions.

Historical data removed - To review the exact wording, refer to Section 8.3.1.1.8.7 of the FSAR.

8.3.1.1.8.8 Automatic Tripping and Loading of Buses

Each incoming supply breaker to the 6900-volt buses 2H1 and 2H2 and the non-ESF 4,160-volt buses 2A1 and 2A2 has been provided with an undervoltage relay to trip the incoming breaker if the voltage of the respective transformer source falls below a preset value. Failure of a fuse on the primary or secondary of a potential transformer will only initiate an alarm and not a false tripping. This has been achieved by monitoring the voltages on the 6900-volt and 4,160-volt windings of the transformers. Tripping of a supply breaker to these buses will initiate an automatic fast transfer of the buses to the preferred source (if available) as described in Section 8.3.1.1.8.4.

If the fast transfer fails, transfer to the preferred power source (if available) will be made by shedding all loads and then reconnecting and sequencing applicable loads on the ESF buses. Manual re-starting of other loads is permissible by the operator whenever bus voltages at load centers 2B5/2B6 can be maintained above the reset of the Millstone 92* percent undervoltage relays. In addition, for the above described fast transfer failure with preferred source available, all motor loads connected to the 6900 and 4160 volt non-ESF buses are shed automatically. No provision for automatic loading of these buses has been made.

The 4,160-volt ESF buses, 2A3 and 2A4, have been provided with undervoltage relays to monitor the voltage condition on these buses. If loss of voltage on these buses is sensed by the associated undervoltage relays, all loads except the ESF load centers 2B5 and 2B6 will be shed and the emergency diesel generators started automatically. When the diesel generator has attained rated speed and voltage (within 15 seconds after the start signal), the loads will be connected to the bus automatically per the loading sequence shown in Table 8.3-1. The undervoltage protection circuitry is blocked when ESF buses are powered by the diesel generators. This assures that load shedding of the ESF buses will not occur in the unlikely event of degraded voltage from the emergency diesel generator.

The emergency diesel generators will be started by an SIAS signal or an undervoltage condition on the respective 4160 or 480-volt ESF buses. If the preferred source is available and an SIAS signal is present, the ESF loads on buses 2A3 and 2A4 will be started in sequence. In the event the preferred source is not available and an SIAS signal is not present, permissible loads will be started in sequence on diesel power. If an SIAS signal is present, only the ESF loads will be started. The diesel generator or generators will attain rated speed and voltage in sequence but will not be connected to the ESF bus or buses if the preferred power source continues to be available.

The 480-volt ESF load centers 2B5 and 2B6 will not be shed by the load shedding undervoltage relays on buses 2A3 and 2A4. However, if the 4,160-volt primary or 480-volt secondary breaker of these load centers was open, but not locked out for maintenance, an SIAS will cause these breakers to be automatically closed.

Under normal operating conditions (absence of ESF signal) when the voltage at the ESF load centers 2B5/2B6 drops to the dropout of the Millstone 92* percent Undervoltage Relays and remains low for eight seconds, the associated diesel generator is started and the incoming breakers (preferred source breakers 152-309 and 152-409) to ESF buses 2A3 and 2A4 will be tripped, thus isolating the ESF buses from the degraded system. Loads on buses 2A3 and 2A4 will be restarted in sequence in accordance with applicable conditions in Table 8.3-1.

* NOTE: This is a nominal value. Refer to Unit 2 TS for allowable values.

All loads connected to the 480-volt ESF MCCs will be de-energized when voltage is lost on the 4,160-volt ESF buses. Loads shown in Table 8.3-1 will be automatically re-energized when voltage is restored to these buses by the diesel generator. (2CNA087704, 2CNA087708)

Loads connected to the ESF buses can be manually reconnected by the operator.

Automatic tripping by protective relays is discussed in Section 8.3.1.1.8.11. For additional information, see Section 8.3.1.6, "Grid Undervoltage Protection."

8.3.1.1.8.9 Safety-Related Equipment Identification

All safety-related equipment has been marked, tagged and identified in accordance with its respective train or channel marking. This is discussed under Section 8.3.1.5.

8.3.1.1.8.10 Instrumentation and Control Systems with Assigned Power Supply

Equipment has been provided in the control room for each diesel generator for manual starting, manual stopping, synchronization, frequency and voltage regulation. A "REMOTE-LOCAL" selector switch has been provided on the diesel generator control panel. Local manual starting during diesel generator testing, manual stopping, governor and voltage regulation and automatic or manual regulator selection have been provided on the diesel generator control panel. Operation of any of these local functions is made permissive only when the "REMOTE-LOCAL" selector switch is in the "LOCAL" position. The "LOCAL" position of this switch is indicated by an amber light in the control room. All safety operations of the diesel generator are independent of the "REMOTE-LOCAL" selector switch. The DC control power source for the diesel instrumentation and control system is of the same channel as the associated diesel generator.

Each diesel generator is equipped with the following alarms.

A. Local (Diesel Generator Room) Alarms

   Lubricating oil, low pressure
   Jacket water, low and high temperature
   Cooling water, expansion tank, low level
   Starting air, low pressure, compressor inoperable
   Lubricating oil low and high temperature
   Overspeed trip
   Service water, low pressure
   Crankcase pressure high
   Jacket water, low pressure
   Auxiliary switch not in AUTO
   Engine start failure
   Neutral overvoltage
   Differential trip
   Loss of excitation
   Automatic regulator trip
   Field ground
   Regulator shutdown Normal Flashing Disabled
   Control voltage failure
   EDG Not Available

B. Remote (Control Room) Alarms

Engine/Gen Trouble (operates on any jacket coolant level low, jacket water low temperature, jacket water pressure low, neutral overvoltage, auxiliary switches not in AUTO, lubrication oil low temperature, normal flashing disabled, automatic regulator trip, regulator shutdown, and start failure).

Potential Engine Failure (operates on lubrication oil pressure low, lubrication oil temperature high, crankcase pressure high, jacket water temperature high, service water low pressure trip, loss of excitation, differential trip, overspeed trip, and field ground).

Auto Start Command

Generator breaker not closed (operates when the breaker close signal is present without the breaker closing).

EDG not available (operates on generator breaker racked out, LSA (below 250 rpm) fail to reset, LSB (below 8 psi jacket water) fail to reset remote stop signal, shutdown relay not reset, generator breaker pull to lock, local DG start not in auto, CSI locked, DG breaker L.O.)

Diesel Generator Start Failure (operates on any starting malfunction).

Start Air Trouble (operates on compressor inoperable or low air pressure trouble alarmed on local annunciator).

Fuel System Trouble (operates for any fuel system related trouble alarmed on local annunciator).

Fuel Oil Day Tank Level High/Low

Electrical instruments have been provided in the control room and at the diesel generator for surveillance of generator voltage, current, frequency, power, and reactive volt amperes. The breaker status of each 4.16 kV breaker of the ESF system is displayed by red and green indicating lamps in the control room, and local indication at the switchgear has been provided for breaker status.

In addition to the specific local and remote alarms described above for the diesel generator, audible and visual alarms will be initiated in the control room to alert the operator to the following conditions of the safety-related electric equipment:

A. Lockout relays in operated position;

B. Operation of overload devices for 4160-V motor circuit breakers;

C. Auto-trip of circuit breakers;

D. Auto-close of circuit breakers of preferred and standby sources;

E. Control power not available and/or lockout relay coil failure; or,

F. "Pull-to-lock" position of control switches and/or breaker not in operating position.

Alarm circuitry and diesel generator control circuitry information with regard to Diesel Generator 1 is provided below. (Diesel Generator 2 is similar).

Conditions that render the diesel generator incapable of responding to an automatic emergency start signal include:

A. Local control switch RSI in lockout position;

B. SDR (shutdown relay) energized or not reset;

C. LSA (low speed switch) not reset (closed below 250 rpm);

D. LSB (low speed switch) not reset (closed below 250 rpm);

E. Lockout relay 186-2DG1 for 2DG1 energized or not reset;

F. CS1-2DG1 control switch for diesel in pull-to-lock;

G. ACB control switch in pull-to-lock position;

H. Loss of 125-volt DC control power; and,

I. Diesel generator breaker not available.

Insufficient starting air pressure also prevents diesels from starting, but low air pressure is alarmed at approximately 220 psi. However, the diesel can be started at a lower pressure.

The following wording on the annunicator window in the control room that is alarmed corresponds to the conditions listed above "A" through "I".

A. Alarmed locally and in the control room as "2DG1 NOT AVAIL".

B. Each of the conditions which pick up the SDR (shutdown relay) including start failure, engine overspeed, and low lubrication oil pressure is alarmed on the local panel. In addition, the start failure and low lubrication oil pressure are alarmed in the control room as follows:

   - Low oil pressure is alarmed as part of "ENGINE/GEN POTENTIAL FAILURE."

   - Start Failure is alarmed as "START FAILURE."

C. The low speed switch (LSA) is part of the control room alarm "ESF SYSTEM INOP ELECT SYSTEM," and "2DG1 NOT AVAILABLE."

D. The low speed switch (LSB) is part of the control room alarm "ESF SYSTEM CH1 INOP ELECT SYSTEM," and "2DG1 NOT AVAILABLE."

E. Alarmed in the control room as "GENERATOR L.O. RELAY TRIP."

F. Alarmed locally and in the control room as "2DG1 NOT AVAIL."

G. Alarmed in the control room as part of "MULTIPLE ESF SYS INOPERABLE," and "2DG1 NOT AVAILABLE."

H. Alarmed locally and in the control room as "2DG1 NOT AVAIL."

I. Alarmed locally and in the control room as "2DG1 NOT AVAIL."

When a diesel generator is manually stopped after a test, an interlock is provided which prevents automatic restart for 60 seconds following the shutdown.

Other alarm signals also causing the same annunciator to alarm include:

A. "ENGINE/GEN TROUBLE" - All alarms which are also found on the local annunciator (2K127/2K131):

1. Jacket water level low;
2. Jacket water pressure low;
3. Neutral overvoltage;
4. Auxiliary switch not in auto;
5. Jacket water temperature low;
6. Lube oil temperature low;
7. Normal flash disabled;
8. Regulator automatic trip;
9. Regulator Shutdown; and
10. Start Failure.

B. "POTENTIAL ENGINE FAILURE" - All alarms which are also found on the local annunciator (2K126/2K130):

1. Lube oil pressure low;
2. Lube oil temperature high;
3. Crankcase pressure high;
4. Jacket water temperature high;
5. Service water pressure low;
6. Loss of excitation;
7. Differential trip;
8. Overspeed; and,
9. Field ground.

C. "FUEL SYSTEM TROUBLE" - All alarms which are also found on the local annunciator (2K128/2K132):

1. Fuel storage tank level low;
2. Fuel transfer pump differential pressure high; and,
3. Fuel transfer pump inoperable.

D. "2DG1 NOT AVAIL" - All alarms which are also found on the local annunciator (2K134/2K135):

1. EDG1 (2) - Not Available
2. CF1 - control voltage failed;
3. CF2 - control voltage failed;
4. CF3 - control voltage failed; and,
5. CF4 - control voltage failed.

E. "GENERATOR L.O. RELAY TRIP" - Only alarm is from the lockout relay.

F. "START AIR TROUBLE" - All alarms which are also found on the local annunciator (2K129/2K133):

1. Compressor inoperable;
2. Starting air pressure low Tank A (C); and,
3. Starting air pressure low Tank B (D).

There are no conditions rendering the diesel generator incapable of responding to an automatic emergency signal which are not alarmed in the control room.

8.3.1.1.8.11 Electric Circuit Protection System

The entire electric circuit protection system has been designed for selective tripping of circuit breakers, thus limiting the loss of power to the affected circuit only. Fused switches of the type that would leave one or more phases energized following an overcurrent or short-circuit condition have not been used. One exception in this is the non-ESF 4,160-volt main chiller motors 2VCHIA and 2VCH1B. The starters for these two motors have been provided with fuses for protection. The following paragraphs describe the protection system in detail.

8.3.1.1.8.11.1 Main Generator Protection System (Normal Source)

This system comprises protections which lead to unit shutdown. These protections in turn are arranged in two functionally redundant groups as described below:

A. Protective Relays

	Group I	Group II
1.	Generator differential 287 (1)	Unit Differential 387 (2)
2.	Main Transformer, Sudden Pressure Relay 363 (1)	Generator Neutral Over-Voltage 259N (2)
3.	Unit Auxiliary Transformer Differential 187 at (3,4)	Unit Auxiliary Transformer Sudden Pressure Relay No. 1, 163 (3,4)
4.	Unit Auxiliary Transformer Sudden Pressure Relay No. 2 (3,4)	Unit Aux. Transformer, Neutral O/C, 6.9 and 4.16 kV, 151G-ATX & ATY (3,4)
5.	Antimotoring Relay 232-1(7) [Trips 286-G2-8 only]	Turbine Trip Contact 2 (5, 6)

A. Protective Relays (continued)

	Group I	Group II
6.	Turbine Trip Contact 1 (5,7)	EHC Master Trip Bus [Trips 286-G2-3 and -4 only] (8)
7.	Generator volts/hertz (259/281-1, -2)	Anti-Motoring Relay 232(5)
8.	EHC Master Trip Bus (6) [Trips 286-G2-1 and -2 only]	Output Breaker 5130/5134 Failure to Trip
9.	Loss of Field Relay 240	
10.	Overexcitation J4K	
11.	Negative Sequence 246	
12.	Backup Impedance 221	

B. Lockout Relays

Group I	Group II
286-G2-1	286-G2-3
286-G2-2	286-G2-4
286-G2-8	286-G2-9

C. Lockout Auxiliary Relays

Group I	Group II
286-G2-1/X1	286-G2-3/X1
286-G2-1/X2	286-G2-3/X2

Protective relays from one group are backed up by protective relays from the other group, thus making the protective system functionally redundant for most faults. The numbers in parentheses refer to the relays in one group which act as backup for relays in the other group. The DC supplies to the two groups are derived from different batteries.

The lockout relays in each group perform the following functions:

A. Trip the turbine;

B. Initiate transfer to the preferred source transformer;

C. Trip 500 kV, 4.16 kV and 6.9 kV (unit auxiliary) breakers and the field breaker;

D. Trip cooling equipment of main and unit auxiliary transformer; and,

E. Trip the diesel generator breaker to the ESF buses 2A3/2A4, if the diesel generator was in parallel with the system for test purposes and the UAT was in service.

8.3.1.1.8.11.2 Preferred Source Protection System

Startup Transformer 2 is common to both Units 1 and 2. The following protective relays have been provided as part of Unit 1: differential relay (instantaneous), 6.9 kV and 4.16 kV neutral overcurrent relays (inverse time), and sudden gas pressure relay.

The above relays or the switchyard ST #2 lockout relays will energize the Startup Transformer 2 lockout relay which will initiate the following:

A. Trip the associated incoming feeder breakers to buses 2H1, 2H2, 2A1, and 2A2;

B. Initiate transfer to Startup Transformer 3; and,

C. Trip the diesel generator breaker to the ESF buses 2A3/2A4, if the diesel generator was under test in parallel with Startup Transformer 2 supplying the auxiliary system.

Startup Transformer 3 has been provided with protective and lockout relays identical to those described for Startup Transformer 2. The operations initiated by the lockout relay are as follows:

A. Trip the associated incoming feeder breakers to buses 2H1, 2H2, 2A1, and 2A2;

B. Initiate transfer to Startup Transformer 2; and,

C. Trip the diesel generator breaker to the ESF buses 2A3/2A4, if the diesel generator was under test in parallel with Startup Transformer 3 supplying the auxiliary system.

Both Unit 1 and Unit 2 are prevented from automatic transfer to Startup Transformer 2 during normal power operations for all buses except Buses A1/A3 (Unit 1) and 2A1/2A3 (Unit 2). Procedures administratively control Unit 1 and Unit 2 access to Startup Transformer 2. Procedures may allow other fast transfer capabilities to Startup Transformer 2 for specifically analyzed conditions and restrictions defined in approved Engineering Calculations and Evaluations.

8.3.1.1.8.11.3 <u>6900 and 4,160-volt Non-ESF Buses 2H1, 2H2, 2A1 and 2A2</u>

Each of the buses has been provided with a lockout relay which can be operated by any one of the following relays provided on each incoming feeder breaker to the respective buses:

A. Phase overcurrent relays (3) (inverse time); or,

B. Ground overcurrent relay (inverse time).

The bus lockout relays have been arranged to:

A. Trip all the incoming supply breakers to the affected bus section; and,

B. Prevent closing the incoming supply breakers until the associated lockout relay is reset.

Shedding of all motor loads connected to these buses upon operation of the bus lockout relays is effected by undervoltage relays as described in Section 8.3.1.1.8.8.

The inverse time overcurrent relays on the incoming breakers have been set so that the bus lockout relays can operate only if a fault on an outgoing feeder is not cleared by the associated breaker or there is a fault on the bus itself.

8.3.1.1.8.11.4 <u>Protection of Non-ESF 6900-Volt and 4,160-volt Load Center and Motor Feeders</u>

The following protective relays have been provided for each of these feeders:

A. Phase overcurrent relays (3) (inverse time) with instantaneous elements for short-circuit protection;

B. Ground sensor (instantaneous); and,

C. Differential relays (3) (instantaneous), (for motors above 3,000 HP only).

In the case of load center feeders, the phase overcurrent relays have been arranged to trip the feeder circuit breaker. In the case of motor feeders, the middle-phase overcurrent relay has been set low for "overload alarm" and the two outer-phase overcurrent relays have been connected to trip the breaker on a stalled rotor condition and any overload above two times full load current with time delay.

The ground sensor relay has a very sensitive setting and can detect ground faults down to 15A, thus affording good protection to the associated motor and cables. The instantaneous protection has been set to ensure that:

A. The faulted section is isolated selectively;

B. The short-time current withstand capability of the cable is not exceeded; and,

C. Damage at the point of fault is minimized.

A short-circuit on any feeder will result in instantaneous tripping of the associated circuit breaker.

8.3.1.1.8.11.5 <u>ESF 4,160-volt Buses 2A3 and 2A4</u>

Each of these two buses has been provided with a lockout relay which can only be operated by the phase overcurrent relays (3) (inverse time) provided on the incoming feeder (from non-ESF bus 2A1/2A2) circuit.

The bus lockout relay has been arranged to:

A. Trip out the incoming supply breaker from the non-ESF bus, the bus-tie breaker and the diesel generator breaker; and,

B. Prevent closing the above-referenced breakers until the lockout relay is reset.

Shedding of motor loads connected to the buses will be effected by the bus undervoltage relays as described in Section 8.3.1.1.8.8. No automatic reloading of these buses can occur since the off-site supply feeder breaker and the diesel generator breaker will be locked out by the bus lockout relay.

The inverse time overcurrent relays on the incoming breaker have been set to ensure that the bus lockout relay can be operated only if a fault on an outgoing feeder is not cleared by the associated breaker or there is a fault on the bus itself. The ground overcurrent relay

151N-309/409 will only trip the incoming feeder breaker 2A309/2A409 since the ESF 4,160-volt system is designed to operate continuously with a single ground fault when the diesel generator is supplying the loads.

8.3.1.1.8.11.6 Protection of the Diesel Engine Generator System

Two relays, diesel engine shutdown and diesel generator lockout, are provided for each unit, located on the diesel generator local control panels and local generator switchgear, as follows:

A. Diesel Engine Shutdown Relay

   The following abnormal conditions will operate this relay and shut down the engine and trip the generator circuit breaker:

   1. Engine overspeed;

   2. Low lube oil pressure (time delayed) composed of three pressure switches, providing 2-out-of-3 coincident logic; or,

   3. Engine failure to start (see Section 9.5.6 for discussion).

B. Diesel Generator Lockout Relay

   The following abnormal conditions will operate this relay and trip the generator circuit breaker and generator excitation:

   1. Generator differential current relay;

   2. Generator phase overcurrent relay with voltage restraint;

   3. Generator loss of field relay;

   4. Generator anti-motoring relay; or,

   5. Diesel engine shutdown relay.

Operation of the generator differential current relay will also shut down the diesel engine, via the engine governor.

During the accident mode, on an SIAS, protective devices A.1, A.2, A.3, B.1 and B.5 are operational; all others are bypassed.

Protective trip bypass devices and circuitry are designed to comply with IEEE 279-1971, except bypass surveillance, which is not required to function during either accident or seismic mode periods and is classified non-Class 1E.

The occurrence of abnormal conditions, excessive values, or unit malfunctions is monitored on the local control panels and in the control room.

The diesel generator units are normally held in the standby status; however, a unit may be locked out of service by operating either lockout relay. Manual resetting of both lockout relays is required before the unit can be returned to the standby status. The out-of-service status of a unit is alarmed in the control room.

The trip settings of the unit protective devices are coordinated with those downstream on the main buses and feeder circuits to permit isolation of system faults and overloads without tripping the diesel generator circuit breaker.

8.3.1.1.8.11.7 Ground Fault in the4,160-volt ESF System

With the diesel generator operating and with the ESF bus disconnected from the preferred source, a single ground fault in the 4,160-volt system will not result in any tripping action. The diesel generator and the ESF loads will continue to function. However, an alarm will be initiated under this condition. The high impedance neutral grounding equipment of each diesel generator is continuously rated.

With the diesel generator in parallel with the system, a single ground fault in any of the outgoing feeder circuits will cause instantaneous tripping of the affected circuit due to the higher levels of ground fault current permitted by the UAT, Startup Transformer 2, or Startup Transformer 3 neutral resistors.

The diesel generator can be paralleled with the main non-ESF 4,160-volt system for testing purposes. To isolate the diesel generator in the event of a fault in the non-ESF 4,160-volt system, the following relays have been provided for the incoming breaker from the non-ESF bus 2A1/2A2:

A. Phase directional overcurrent relays (3); and,

B. A ground directional overcurrent relay.

These relays have been set to assure that selective tripping occurs with regard to the relays provided for the diesel generator.

8.3.1.1.8.11.8 ESF 4,160-volt Bus-Tie Breakers

The electrical interlock, maintenance and operational bypasses, and administrative control to allow the tie breakers to be used only during shutdown (Modes 5 and 6) or under post-accident emergency conditions are described in Section 8.3.1.1.9.4. However, in order to isolate the faulted bus section if the tie breakers were used under the described conditions, the following relays have been provided for each tie-breaker:

A. Phase overcurrent relays (3) (inverse time); and,

B. Ground overcurrent relay (inverse time).

8.3.1.1.8.11.9 <u>ESF 4,160-volt Motor and Load Center Feeders</u>

Following protective relays have been provided for each of these feeders:

A. Phase overcurrent relays (inverse time) with three instantaneous elements for short-circuit protection; and,

B. A ground sensor (instantaneous).

In the case of load center feeders, the phase overcurrent relays have been arranged to trip the respective breaker. In the case of motor feeders, the middle phase overcurrent relay has been set low for "overload alarm" and the two outer phase overcurrent relays have been connected to trip the breaker on a stalled rotor condition and any overload above two times the full load current with time delay.

The ground sensor relay cannot trip the diesel generator breaker on ground fault if the diesel generator is operating independently of the main system as described in Section 8.3.1.1.8.11.7. A short-circuit in any feeder will result in instantaneous tripping of the associated circuit breaker.

8.3.1.1.8.11.10 <u>Non-ESF 480-Volt System</u>

The incoming breakers to all non-ESF 480-volt load centers have been provided with the following relays:

A. Phase overcurrent relays (inverse time) (2); and,

B. A ground overcurrent relay (inverse time).

These relays have been coordinated with the overload and short-circuit relays provided on the ongoing feeder circuits and the rating of the load center transformer.

Feeders to 480-volt non-ESF MCCs have been protected by ACBs, each provided with a direct-acting, dual-magnetic trip element having short time and long time elements. These have been coordinated with the protections provided on the MCCs outgoing feeders.

The 480-volt MCC combination motor controllers have been provided with an instantaneous trip element (for short-circuit protection) and ambient compensated thermal overload relays for each phase. The overload elements have been set to protect the connected motor and the instantaneous element to protect the connected cable.

8.3.1.1.8.11.11 <u>ESF 480-Volt System</u>

The protective system for the ESF 480-volt system is identical to that described for the non-ESF 480-volt system in Section 8.3.1.1.8.11.10 with the following additional features:

A. When required to operate in the accident mode, thermal overloads for safety-related valves are bypassed by contacts of auxiliary relays. These relays are supplied from Class 1E 125-volt DC and are held energized during the non-accident mode. The torque limiting devices, however, are bypassed in all operating modes by valve position switches, adjusted to open at nearly 100 percent travel of the valve in the direction of the safety function. This ensures that motor operated valve movement in the direction of the safety function will be continued if the power supply failed and was restored during mid-travel.

B. Surveillance of the bypass status for overload and torque limiting devices is not provided because safety functions of the valves themselves have not been bypassed and because the valve motors have been sized for the duty under the accident mode.

8.3.1.1.8.11.12 <u>120/208-Volt Instrument AC System</u>

The outgoing feeders are each typically provided with a single-pole 20 A (There are some breakers larger than 20 amps.) thermo-magnetic trip element while the main and tie feeders are rated at 225 A and have an instantaneous trip and an adjustable short delay setting of 6-14 cycles. This ensures that a fault on any feeder circuit will result in the tripping of the associated breaker only.

8.3.1.1.8.11.13 <u>120-Volt Vital AC System</u>

The 120-volt vital AC system is ungrounded. The outgoing feeders are each provided with a 2-pole thermomagnetic trip element.

8.3.1.1.8.11.14 <u>The Scheme For Testing the Power Systems During Power Operation</u>

Operational and periodic tests, including inservice tests, have been performed after installation on the power and control circuits and components, including protective relays, meters, and instruments. All protective relays, meters, and instruments have provisions for inservice testing and calibration. Circuit breaker, control circuits and protective device design have features that allow periodic testing.

Each diesel generator is equipped with means for starting periodically to test for readiness, means for synchronizing the unit onto the bus without interrupting the service, and for loading.

Administrative control will ensure that both diesel generator units are not load tested simultaneously.

8.3.1.1.9 <u>Diesel Generators</u>

8.3.1.1.9.1 <u>Starting Initiating Circuits</u>

Each diesel generator can be started automatically either by an SIAS or by the undervoltage relays on the respective 4160- or 480-volt ESF buses. If both diesel generators are available, both will start automatically. If an ESF bus undervoltage relay senses a dead bus, the diesel generator will be automatically started and connected to its respective bus.

8.3.1.1.9.2 <u>Starting Mechanism and System</u>

Each diesel engine has been furnished with two completely independent air starting systems. Each air starting system has the capacity to crank the engine five times without the use of the air compressor. All operations necessary to maintain the starting system in a ready condition are entirely automatic and self-initiated. The compressors are driven by AC motors with automatic start-stop control.

The diesel engine starting system has been designed to start and operate automatically except when in lockout position. A local and remote manual starting and stopping arrangement has also been provided for emergency and testing purposes. Local operation can be done only by deliberate operator action since a key-locked three position "START-AUTO-LOCKOUT" selector switch, with key removable only in the "AUTO" position has been provided.

8.3.1.1.9.3 Tripping Devices

When the diesel generator has started on an SIAS, other engine protective devices except "low lube oil pressure," and "overspeed," the "generator differential current relay" and the "diesel engine shutdown relay," will not be able to trip the engine. Diesel generator protective relays have been arranged to trip the engine provided that the nature of the fault will prevent the generator from performing its function satisfactorily. Local manual engine tripping can be done only by the three position key-locked selector switch as mentioned in Section 8.3.1.1.9.2 or by the emergency manual stop button on the engine skid. Remote engine tripping is disabled when the unit is in SIAS operation. Tripping of the ACB when in SIAS operation can only be accomplished by pulling-to-lock the remote control switch in the control room.

8.3.1.1.9.4 Interlocks

Both 4.16 KV ESF bus tie breakers cannot be closed when one of the diesel generator breakers or one of the ESF bus feeder breakers are closed for both 2A3 and 2A4 and with the “Operational Bypass” key switch in either tie breaker cubicle in the “NORM” position. Electrical interlocks in both “Close” and “Trip” control circuits prevent the cross connection of the safety buses. The normal logic is such that closure of the tie breakers can only occur when at least one bus is disconnected from both its normal and emergency power sources. The “Trip” circuit contains an “Operational Bypass” key switch that is administratively controlled to allow cross connection during refueling operations or extreme emergencies. The “Close” circuit contains a “Maintenance Bypass” key switch to allow remote closing of the tie breakers when the control system for the Alternate AC Power Source (Section 8.3.3) is out of service. This “Maintenance Bypass” also allows for a local manual response to a station blackout with a concurrent failure of the computer based control system for the Alternate AC Generator.

The third High Pressure Safety Injection (HPSI) pump motor (4,160-volt), the third service water pump motor (4,160-volt), and the third charging pump motor (480-volt MCC) can be fed from either ESF bus. The third HPSI pump motor and the third service water pump motor each have two interlocked feeder breakers, one from each safety channel.

The DC control power for the 4,160-volt breakers are supplied from the independent ESF DC systems respectively, i.e. ESF Channel 1 breakers are supplied with control power from the ESF Channel 1 DC system and ESF Channel 2 breakers are supplied with control power from ESF Channel 2 DC system. (See Section 8.3.2.1.6 for further discussion on DC system independence.)

To prevent tying the two ESF systems together, the two breakers feeding the double-fed motor for the HPSI pump is mechanically interlocked by means of Kirk-Keys, so that only one of these two breakers can be closed at any time. The service water pumps are interlocked electrically using two control switches in the control room with a single interchangeable control handle to electrically operate non-fused disconnect switches. These hand switches also provide the electrical interlock with the 4160 volt switchgear such that only one of the two 4160 volt breakers can be electrically closed at a time, thus preventing the connection of pump 2P4B to both ESF channels simultaneously through their respective control circuits.

The third charging pump motor has two 480 volt starters, one from each safety channel, and two down stream contactors in 2C383. The hand switches for these starters are equipped with only one handle (removable only from the stop position) in 2C09. In addition, the two downstream contactors are electrically interlocked to prevent the simultaneous closure of both at the same time. Each of the two starters derives its control power from an individual 120-volt AC control power transformer located in the starter compartment. Independence is maintained due to the individual power source for each of the two interlocked contactors in 2C383, one from each safety channel. The use of key-locked switches and mechanically interlocked control switches in the case of all the three double-fed motors has resulted in a design totally free of any interconnecting wiring between the two safety channels.

Interlocks have been provided in the closing and tripping circuits of individual breakers to protect against the following conditions:

A. Automatic energizing of electric devices under maintenance. This has been achieved by means of a pull-to-lock feature in the individual control switches. In the case of ESF breakers, the pull-to-lock condition is alarmed audibly and visually to the operator.

B. Closing a breaker with the associated lockout relay in the operated position.

C. Connecting two sources out of synchronism. This has been achieved by inserting in the close circuit of each source breaker a contact of the applicable synchronizing switch. The fast autotransfer between normal and preferred sources uses a contact of a synchronizing check relay in the closing circuit.

D. Closing the diesel generator breaker by the local control switch (electrical) if the associated 4,160-volt ESF bus is energized.

E. Autoclosing the diesel generator breaker without first isolating the ESF bus. This has been prevented by the use of a normally closed auxiliary contact of the incoming feeder breaker in the closing circuit of the diesel generator circuit breaker.

F. Automatic connection of the ESF loads without voltage on the associated ESF bus. This has been ensured by a contact of the bus voltage sensing relays in the closing circuits of the individual breakers.

8.3.1.1.9.5 Permissives

A. To start the emergency diesel engine:

   1. Local selector switch in "AUTO" or "START" position;

   2. Diesel engine shutdown relay is reset.

   3. Diesel generator lockout relay in reset position; and,

   4. Neither the diesel generator ACB remote control switch or the diesel engine remote control switch is in the pull-to-lock position.

B. To trip the emergency diesel engine when the unit is on "AUTO" operation:

   This is covered in Section 8.3.1.1.9.3 above.

C. To close the diesel generator ACB:

   1. Manual - Remote:

      a. Diesel generator lockout relay in reset position;

      b. Associated 4.16 kV ESF lockout relay in reset position;

      c. Synch turned to "on" position.

D. To close 4.16 kV ESF bus tie breakers:

   1. Electrical interlocks in the “Close” and “Trip” circuits of each tie breaker as described in Section 8.3.1.1.9.4.

E. To close 480-volt ESF load centers bus tie breakers:

   1. Kirk-key transfer as described in Section 8.3.1.1.9.4.

F. To close 120-volt, instrument bus (2Y1-2Y2) tie breaker:

   1. Kirk-key transfer as described in Section 8.3.1.1.9.4.

G. To close ACBs to third pump (service water pump, HPSI and charging system):

   1. HPSI (Kirk-Key transfer as described in Section 8.3.1.1.9.4)

   2. Service Water Pump (Handswitch and disconnect switch line-up as described in Section 8.3.1.1.9.4)

   3. Charging Pump (as described in Section 8.3.1.1.9.4)

8.3.1.1.9.6 Load Shedding Circuits

Discussions of load shedding are included in Section 8.3.1.1.8.8, “Automatic Tripping and Loading of Buses” and Section 8.3.1.6, “Grid Undervoltage Protection.”

8.3.1.1.9.7 Testing

Each diesel generator is equipped with a means for starting periodically to test for readiness, a means for synchronizing the unit onto the bus without interrupting the service, and for loading.

The following types of tests will be performed periodically on each diesel generator:

A. Starting;
B. Load acceptance;
C. Design loading;
D. Load rejection; and,
E. Functional.

(For exact tests and their frequency, see the Technical Specifications)

8.3.1.1.9.8 Fuel Storage and Transfer System

The diesel fuel storage and transfer system is detailed in Section 9.5.4.

8.3.1.1.9.9 Basis For Diesel Generator Sizing

Table 8.3-1 lists all ESF loads and non-ESF loads which were used in sizing the diesel generator. This table shows the quantities of various loads, the number of each load that can be connected to the ESF bus, the rating of each load in HP, the actual loading in HP of each load, the loading sequence step number and other details.

The continuous rating of each diesel generator was based on the total calculated consumption of all loads, ESF and non-ESF, that have to be powered by the system under Design Basis Accident (DBA) or for safe shutdown conditions. The calculated consumption in HP of each motor or heater was based on conservative design calculations under the expected flow and pressure conditions, pump run-out condition or manufacturers' recommendations.

Each diesel generator has the following rating:

2850 Kw	-	8,760 hrs. (continuous)
3100 kW	-	2,000 hrs.
3135 kW	-	2-out-of-24 hours overload capability
3250 kW	-	7 days
3500 kW	-	30 minutes

Maximum continuous diesel loads are based upon nominal design service water flow of 800 gpm and a nominal service water temperature of 85 °F. The loading listed above may not be achievable at elevated service water temperatures. Operation of the EDGs, using service water at the anticipated worse case ECP temperature profile, has been evaluated against the EDG emergency load profile. The evaluation concludes that the load profile can be met with excess margin at design fouling conditions and with allowances for tube plugging. EDG capability under actual emergency conditions is procedurally assured by monitoring air scavenging and lube oil temperatures.

8.3.1.1.10 Cooling and Heating Systems

Cooling and heating systems provided for Class 1E equipment are described in Section 9.4.

Space heaters are provided for enclosed panels, switchgear cubicles, and all totally enclosed motors with the exception of explosion proof motors, which may not have space heaters. Open drip-proof and weather protected motors rated 250 HP and above also have space heaters.

A jacket coolant preheat system and a lubricating oil preheat system are provided for the emergency diesel generator engine to keep each in readiness to start.

8.3.1.1.11 Instrumentation and Control System With Assigned Power Supply

See Section 8.3.1.1.8.10 for a detailed discussion.

8.3.1.1.12 Diesel Loading

Table 8.3-1 shows the automatic and manual loading sequence of the emergency power supply system. All essential loads will be started automatically by their respective ESF actuation signals in a predetermined step-by-step loading sequence. Equipment which may require manual startup will only be started after the initial automatic sequential loading. As explained in Section 8.3.1.1.13, motor sizes for safety-related loads such as pumps, fans, etc. are based on vendor's recommendations and confirmed by prototype tests and preoperational trial runs. The horsepower ratings are conservative in relation to their functional performance requirements. The duration of time each safety-related load is required to be in operation is given in Table 8.3-1 along with the size of load, etc.

8.3.1.1.13 Design Criteria for Class 1E Equipment Parameters

Design criteria are discussed below for certain parameters of the Class 1E equipment.

A. Motor Size

Motor sizes have been selected based on calculations of load-torque requirements or on the basis of equipment (pump, fan, compressor, etc.) suppliers' recommendations.

In all cases motor rated horsepower will be greater than the connected pump or fan load and not less than the associated runout pump load.

Field tests have proved the capability of all motors to run design loads without exceeding design temperature limits.

B. Motor Starting Torque

Motors generally have been designed for normal starting torque and low starting current as per NEMA Class B. They are capable of delivering full load torque with 75 percent rated voltage available across the terminals and can accelerate with the load to rated speed with only 80 percent rated voltage. The ability of the motors to develop the required torque and perform the duty cycle has been demonstrated by actual load test at vendors' factories and during preoperational tests.

C. Motor Insulation

Insulation systems have been selected based on the particular ambient conditions to which the insulation will be exposed. For Class 1E motors located within the containment, the insulation system has been selected to withstand the postulated accident environment. In general, all Class 1E motors have Class B, or better, insulation and are suitable for high humidity operating conditions.

D. Interrupting Capacities

The interrupting capacities of the protective equipment have been determined as follows:

1. Switchgear

   In the calculation of medium voltage switchgear interrupting capacities, ANSI C37.010-1979 has been followed. The power system, alternate AC generator (large diesel), and connected motor contributions have been considered in determining the fault level.

2. Load Centers, Motor Control Centers and Distribution Panels

   Load centers, MCCs, and distribution panel circuit breakers have a symmetrical rated interrupting current as great as the calculated total available symmetrical current at the point of application. Determination of symmetrical currents has been calculated in accordance with procedures of ANSI C37.13-1981 for low voltage circuit breakers.

E. Electric Circuit Protection

Refer to Section 8.3.1.1.8.11 for criteria regarding the electric circuit protection.

F. Grounding Requirements

Equipment and system grounding is designed in accordance with IEEE 80, "Safety in AC Substation Grounding," and IEEE 142-1956, "Grounding of Industrial Power Systems." The system has been designed with neutral grounding for detection and clearance of ground faults. The neutral of the diesel generator is grounded through a combination grounding transformer and resistor. This will permit the diesel generator to function continuously under emergency conditions with a single ground fault in the 4,160-volt ESF system.

The neutrals of the 4160- and 6900-volt windings of the unit auxiliary transformer and Startup Transformers 2 and 3 have been grounded through low ohmic resistors.

Neutrals of all load center transformers are solidly grounded. All motor and equipment frames are also solidly connected to ground with conductors of adequate capacity to carry the maximum ground fault current.

Secondaries of current and potential transformers have been grounded in accordance with IEEE 52-1951, "Application Guide for Grounding of Instrument Transformer Secondary Circuits and Cases."

G. Electrical Penetrations

All electrical penetrations are of modular design with header plates of stainless steel (for high voltage) or carbon steel (for low voltage). The existing Amphenol-SAMS modules have dual pressure seals (while the Conax replacement modules have four O-rings) and a retaining ring arrangement with the header plates. All conductors are hermetically sealed to modules and terminate in pigtails or connectors. The header plate assembly bolts to a weld neck flange that is welded to the nozzle through the containment wall. Pressure seals between each header plate and its flange are provided by two O-rings. Dynamic module seals and/or O-rings, and header plate O-rings are continuously under positive nitrogen pressure of approximately 60 psig for

Amphenol - SAMS modules, to insure that moisture will not affect the electrical integrity of the Amphenol-SAMS Electrical Penetration Assemblies (EPAs). Nitrogen Pressure of 0-65 psig is available to the Conax-Buffalo EPAs, as required, for leakage monitoring only. The EPAs will be leak rate tested periodically in accordance with the Technical Specifications.

High voltage penetration conductors are equipped with bushing type terminations. The low voltage power and control modules are provided with pigtails. Instrumentation modules have multi-conductor shielded pigtails and coaxial modules have a flush connector outboard and pigtails with coaxial connectors, or coaxial pigtails with coaxial connectors.

In the event of an accident some systems are required to function under adverse environmental conditions to initiate or monitor engineered safety features. Typical components related to some of these systems are electrical penetration assemblies. During an accident event these assemblies are exposed to high levels of pressure and superheated containment conditions which they must be able to withstand without loss of function.

The following paragraphs describe historical analyses pertaining to the MSLB. The MSLB analyses completed for the new Westinghouse steam generators along with power uprated conditions produce lower temperatures than those presented below due to the flow limiting devices installed in the outlet of the new steam generator nozzles (refer to SAR section 6.2). As a result, the historical analyses that follow are considered bounding for the new Westinghouse steam generators and power uprated conditions.

In order to examine the influence of accident events on safety-related component temperatures an analysis was conducted with the Bechtel COPATTA computer code. For the analysis, a typical containment penetration was modeled as a slab, with a 1/16-inch steel cover, 2-inch air gap to a simulated cable consisting of 0.1-inch insulation and 0.2-inch thick copper core. The outside surface is covered with organic paint of 0.006-inch thickness.

For reasons of high containment superheated temperature conditions during a Main Steam Line Break (MSLB) event (exceeding 400 °F), a transient temperature analysis was performed to determine the effect of superheat on safety-related equipment. The calculations were carried out using assumptions for containment initial conditions, heat removal systems, blowdown data and condensing heat transfer coefficients that maximize heat transfer to exposed components. A 60 percent break area MSLB with a realistic spray initiation time of 56 seconds produced a temperature of 410 °F at 46 seconds. The surface temperature of the electrical penetration reached a peak value of 255 °F which is well below the design temperature of 300 °F. This substantial difference in containment vapor temperature and component temperature is due to the fact that the energy transferred into the heat sinks is a function of the heat transfer mechanism. Energy transfer into heat sinks is a maximum as long as the heat sink surface temperature is lower than T(SAT) since condensation occurs. When the heat sink temperature equals T(SAT), energy transfer is restricted to convective heat transfer which is significantly lower than heat transfer by condensation. Therefore, this change in heat transfer mechanism is responsible for heat sink surface temperatures following containment saturation temperature and exceeds it only if superheated

conditions prevail over a longer time period than those under consideration. This result implies that maximum heat sink temperatures are produced by an accident that furnished the highest saturation temperature and hence saturation pressure. This accident event is the DBA LOCA which is therefore the design basis for safety-related equipment qualification.

The double-ended pump suction break is the DBA producing a peak saturation temperature of 289 °F at 150 seconds. Therefore, the surface temperature of the electrical penetrations approach T(SAT) do not exceed 289 °F over the entire accident time period.

Since the equipment design temperature is 300 °F, well above DBA peak saturation temperature, the electrical penetration assemblies will function as designed during and after a DBA or MSLB. The EPAs were designed and engineered according to IEEE 317-1971 and meet the intent of IEEE 323-1971 (2CAN057804). The environmental qualification of the original penetrations was in accordance with Division of Operating Reactors (DOR) Guidelines contained in IE Bulletin 79-01B. Replacement penetrations are qualified in accordance with 10 CFR 50.49.

Similar analyses for other types of safety-related equipment, including cables, instruments, motors, motor controllers and motor operated valves, were performed for a spectrum of main steam line and Reactor Coolant System (RCS) pipe breaks. These analyses are conservative for Arkansas Nuclear One - Unit 2 and clearly demonstrate the relationship between surface temperature and saturation temperature described above for the EPAs. These analyses are discussed in Topical Report BN-TOP-3, Revision 3, and are described in detail in Reference 22 to that report.

The exception to the above temperature relationships occurs when high temperature water or steam impinges directly on a component. The high energy pipe break analyses described in Chapter 3 do not take credit for the functioning of any component which is subjected to direct impingement when evaluating the consequences of the pipe break. This includes the MSLB and LOCA analyses.

To assure that EPAs continue to maintain adequate integrity during their service life, they will be periodically leak tested in accordance with 10 CFR 50, Appendix J.

H. Cathodic Protection

Cathodic protection has been provided for all exterior surfaces of underground coated steel pipes and tanks. The cathodic protection system is of the impressed current type utilizing anodes in buried canisters. Permanent corrosion monitoring stations, including zinc reference electrodes, have been provided at significant locations for periodic testing of buried pipes, tanks, and the containment liner base plate.

8.3.1.2 Analysis

The Class 1E electric system is designed to ensure that any of the design basis events listed in IEEE 308 will not prevent operation of the minimum number of ESF loads and protective devices required to safely shut down the reactor and to maintain a safe post-shutdown condition. The system was designed to meet the requirements of IEEE 279-1971, IEEE 308-1971, IEEE 387-1972, 10CFR50 General Design Criteria 17 and 18, and Regulatory Guides 1.6 and 1.9.

General Design Criteria 17 and 18 are covered in detail in Section 3.1. The environmental qualification program is described in detail in Section 3.11.

The following design aspects illustrate the extent of conformance with Regulatory Guides 1.6, 1.9, 1.47, 1.63 and 1.75, IEEE 308-1971, IEEE 279-1971, IEEE 379-1972 and IEEE 387-1972.

8.3.1.2.1 Regulatory Guide 1.6

A. The electrically powered safety loads, AC and DC, have been separated into two redundant load groups such that loss of either group will not prevent the minimum safety functions from being performed.

B. Each AC load group has a connection to the preferred (off-site) power source and to an emergency (onsite) power source. The emergency power source has no automatic connection to the other redundant load group. Electrical Interlocks in both "Close" and "Trip" control circuits prevent the cross connection of the safety buses of Units 1 and 2.

C. Each DC load group has a separate battery and battery charger. No automatic connection has been provided between the battery charger combination of one group and the combination of the other redundant load group.

D. The two redundant emergency sources have no provision for automatic paralleling. Manual paralleling of the two diesel generators is possible only through the two non-ESF 4,160-volt buses 2A1 and 2A2. If the emergency sources are the only sources of power during an emergency, they will be automatically isolated from each other and the main system.

E. No provision exists for automatically connecting one load group to the other or transferring loads between redundant power sources.

F. The tie-breakers that connect the two 4.16 KV ESF buses are equipped with electrical interlocks in both the “Close” and “Trip” control circuits to prevent the cross connection of the two buses. Both 4.16 KV ESF bus tie breakers cannot be closed when one of the diesel generator breakers or one of the ESF bus feeder breakers are closed for both 2A3 and 2A4 and with the “Operational Bypass” key switch in either tie breaker cubicle in the “NORM” position. “Operational Bypass” key switches are provided in the tie-breaker cubicles to allow cross connection during refueling operations or extreme emergencies. The function of the tie-breakers and bypasses are further described in Section 8.3.1.1.9.4.

G. Each emergency power source consists of a single generator driven by a single prime mover.

8.3.1.2.2 Regulatory Guide 1.9

The emergency diesel generators are each rated as shown in Section 8.3.1.1.9.9. Table 8.3-1 provides the different loading combinations.

A. Preoperational tests are discussed in Chapter 14.

B. Preoperational tests have verified the capability of each diesel generator set to start and accelerate to rated speed all of the needed ESF and emergency shutdown loads in the required sequence.

During the period of load application or during the period of load removal, the generated voltage and frequency were maintained within limits which do not degrade the performance of the loads below their minimum requirements.

The overspeed device of the diesel generator has been designed to withstand without damage speeds up to 125 percent of normal rated speed. Also, the overspeed trip device is set sufficiently high to ensure that the unit will not trip on full short time load rejection.

C. Each diesel generator has adequate capacity to start and accelerate the largest single load out of sequence, with all other loads running.

8.3.1.2.3 Regulatory Guide 1.47

A. Protective Action System

The following features describe the "bypassed and inoperable" status indication for the protection action system, which includes the actuated equipment and the actuation devices.

1. One annunciator window has been provided for each of the seven redundant ESF systems to indicate the unavailability of a system. There are seven windows for the red channel system level indication on annunciator 2K07 on panel 2C17. Likewise, there are seven windows for the green channel system level indication on annunciator 2K04 on panel 2C16.

   In the event of inoperability of more than one system in either ESF channel, two windows have been provided for each channel to annunciate multiple system inoperability.

2. The windows for the red and green channel indications are demarcated and grouped by specific systems on their respective annunciators for easy operator identification.

3. Unavailability of a protection action system will be alarmed when any component in the respective system and channel has been deliberately rendered inoperable.

4. The group of devices that are connected to the common window is identified from the applicable P&IDs and electrical system drawings. This ensures that any auxiliary or supporting device that is necessary for the proper functioning of the system is included in the alarm.

5. All control switches and indicating lights have been grouped on the control panel on the basis of the ESF system with which they are associated.

6. Within each ESF system grouping, the switches and lights are further subgrouped (identified by background color or colored framework) according to the color the indicating lights will turn to after an automatic actuation signal operation. This will aid the operator to locate at a glance any failed component after an automatic actuation signal.

7. Under normal operating conditions, when a protection action system unavailability alarm is indicated on a window, the operator identifies the disabled component by looking at the concerned system area on the control panel. One or more of the following conditions will identify the disabled component:

   a. Control switch in pulled-to-lock position;
   b. Control switch in "OFF"/override position;
   c. Amber light "ON"; or,
   d. Both red and green lights "OFF".

B. Power System

The deliberately induced inoperability status of the power system (AC and DC) components is indicated by alarm windows on annunciator 2K01 on panel 2C10 for the red and green channels. Diesel generator "NOT AVAIL" alarm windows or annunciators 2K08 and 2K09 on panels 2C33-1 and 2C33-2 include the inoperable condition of the supporting systems required for satisfactory functioning of the unit. Power system components, the inoperability of which may render several ESF systems inoperable simultaneously, are connected to a master alarm window located under the seven windows described in "A" above.

8.3.1.2.4 Regulatory Guide 1.63

The electric penetrations were purchased in 1972 and meet the intent of the requirements of IEEE 317-1971. Regulatory Guide 1.63, dated October 1973, was not considered in the design of the electric penetrations. Therefore, the electric penetrations are not in full compliance with Regulatory Guide 1.63. Originally secondary (back-up) overcurrent and short circuit protection was provided for some circuits but not for others. FSAR Amendment No. 34, in response to NRC Question 222.93, revised the design basis and requires backup protection for all circuits. The backup protection is not in full compliance with Regulatory Guide 1.63 in regard to IEEE 279 requirements concerning electrical independence, online testability, bypassing, or manual initiation. The secondary protective device provides backup for the primary protective device in the same electrical circuit and therefore the above features of IEEE 279 cannot be met.

The electric penetration assemblies are not equipped with self-fusing characteristics. Penetration conductors which are not de-energized during reactor operation are protected by Technical Specification external circuit breakers and/or fuses that provide primary and secondary short circuit protection. The primary and backup protective devices protect the penetration conductors against maximum short circuit conditions as defined by IEEE 317 conductor damage curves. In addition, at least one of the series protective devices provides reasonable protection from overload conditions. The Technical Specifications require that the trip setpoints of the primary and backup breakers, described under items A, B, C, D, G, and I below, be checked periodically. The plant procedures will list all the applicable breakers and their setpoints.

There are nine basic types of circuits that penetrate the containment. A description of each type and its degree of compliance to Regulatory Guide 1.63 follows:

A. 6900-Volt AC

These electric penetrations provide power to the Reactor Coolant Pump (RCP) motors and are fed from non-Class 1E switchgear located in the non-Category 1 turbine building. Overcurrent and ground fault relays are provided for the primary circuit breaker as well as for the backup or 6900-volt bus feeder circuit breaker. Since the 6900-volt cables are all single conductor size 500 kcmil, shielded, and since the shield is grounded at each end of each run, only line-to-ground faults are considered to be credible. The bus feeder breaker provides complete backup protection for all line-to-ground faults. Also, limited backup protection against overloads, line-to-line and 3-phase faults is proved by the backup bus feeder breaker.

Diversity of DC control power has been provided for operation of the primary and the backup circuit breakers for the reactor coolant pump motors. Primary breakers (feeder breakers to RCP motors) on bus 2H1 are supplied from DC panel 2D21 (fed from DC control center 2D01 - red), and the primary breakers on bus 2H2 are supplied from DC panel 2D22 (fed from DC control center 2D02 - green). Backup breakers (bus feeder breakers) on 2H1 and 2H2 are supplied from DC panel 2D25 (fed from the DC control center 2D03 - black).

Two 500-kcmil cables per phase are used to supply each RCP motor through two 750-kcmil penetration conductors per phase. Maximum fault current available at the penetration is approximately 45,000 amps. At this fault current, the primary breaker will trip in approximately 0.09 second (5.6 cycles). If the primary breaker fails to operate, the backup breaker will trip in less than 1 second. Based on IEEE 317 conductor damage curve, the 750 kcmil penetration conductors can withstand 45,000 amps for approximately 1.4 seconds.

B. 480-Volt AC From Load Centers

These electric penetrations supply non-Class 1E loads in the containment. All load center circuit breakers are qualified for Class 1E service, but those supplying these loads within the containment are located in non-Category 1 structures. The electrical penetration conductors are the same size or one size larger than the cables supplying the power circuits. The load center main bus circuit breaker is equipped with current transformers, phase and ground fault relays. This provides complete protection against ground faults and limited protection for phase-to-phase and 3-phase faults.

Backup protection for circuits fed from 480-volt load centers is provided by a series breaker located in the respective load center. Diversity of DC control power has been provided by supplying the primary and the backup breakers from separate DC control centers.

Primary breakers on load centers 2B7 and 2B8 (for MCCs 2B71 and 2D81, respectively) are supplied from DC panel 2D25 (fed from DC control center 2D03 - black). The backup breaker on load center 2B7 is supplied from DC panel 2D21 (fed from DC control center 2D01 - red), and the backup breaker on load center 2B8 is supplied from DC panel 2D22 (fed from DC control center 2D02 - green). Both primary and backup breakers are located outside the containment.

Two 350-kcmil cables per phase are used to supply each MCC (inside containment) through two 350-kcmil penetration conductors fed from the load center breakers. Maximum available fault current at the penetration is less than 20,000 amps. At this fault current both the primary and backup load center breakers will trip in approximately 18 cycles. Based on prototype tests the 350 kcmil penetration conductors can withstand 35,613 amps for 30 cycles and 20,000 amps (interpolated by use of I^2t) for approximately 95 cycles.

C. 480-Volt AC From Motor Control Centers

Class 1E and non-class 1E motor control centers supply all circuits of this type that penetrate the containment.

In general, one of the two series breakers for these circuits is a thermal-magnetic breaker. Whether a thermal-magnetic or a magnetic-only breaker is utilized, at least one of the two series breakers provides reasonable overload protection, and both provide maximum short circuit protection. Both breakers are located within the source MCC (outside the containment.)

Maximum available fault current at the penetration is 5,000 amps RMS. At this fault current both the primary and the backup MCC breakers will trip in approximately one-half cycle. Based on prototype tests the penetration conductors can withstand 5,000 amps for 1-½ cycles.

D. 480-Volt AC From Lighting Panels

These electric penetrations supply non-class 1E loads in the containment. The electrical penetrations are the same size or one size larger than the cables supplying the power circuits. Primary protection is provided by thermal magnetic breakers located in lighting panel 21PA. Backup protection is provided by a breaker located in MCC 2B15. The primary and backup breakers are non-class 1E breakers which are located outside containment.

The primary breakers provide overload protection for the penetration conductors and both breakers provide maximum short circuit protection. At the maximum fault current of 5,000 amps RMS, both the primary and backup breakers will trip in approximately one-half cycle. Based on prototype test, the penetration conductors can withstand 5,000 amps for 1 ½ cycles.

E. 120-Volt AC Control Circuits From MCCs

All 120-volt AC control circuits are fed by Number 14 AWG conductors or larger.

Circuits of this type penetrating the containment are fed from control transformers located within individual MCC starter cubicles. There are six different sizes of transformers used: 50VA, 100 VA, 150 VA, 200 VA, 250 VA, and 300 VA. The maximum short circuit currents available to the circuits supplied by the transformers listed below are as follows:

Transformer	% Impedance	Max. S C Current
100 VA	8.02%	10.39A
150 VA	5.50%	22.73A
200 VA	5.17%	32.24A
250 VA	3.64%	57.23A
300 VA	3.61%	69.25A

The impedance values provided above are nominal and are provided to demonstrate adequate protection on typical circuits with fuses listed below. Short circuit currents listed above were conservatively calculated assuming an infinite bus.

Primary protection for these circuits is provided by a fuse in the hot leg secondary of the transformer. These fuses are sized as follows:

Transformer	Fuse Rating
100 VA	1 AMP
150 VA	2 AMPs
200 VA	3 AMPs
250 VA	3 AMPs
300 VA	3 or 4 AMPs

As the maximum available short circuit current from a 50 VA transformer is much less than the continuous current rating of the conductor, no backup protection is required for these circuits. Backup protection is provided for the 100 VA, 150 VA, 200 VA, 250 VA, and 300 VA transformer circuits in the form of an additional fuse identical to, and in series with, the primary fuse. These additional fuses are located within the MCC starter cubicles. The control circuit overcurrent protection provided will assure adequate protection for all current ranges, limiting the penetration conductor's temperature in short circuit conditions to below its 250 °C short circuit rating.

F. 120-Volt AC Circuits

These electric penetrations supply Class 1E and non-Class 1E loads in the containment. In all cases the primary protective device is a fuse located in control panels and terminal boxes. The fuses will blow in less than one-half cycle at the maximum available fault current of 5,000 amps at the penetration. The penetration conductors can withstand 5,000 amps for 1 ½ cycles.

The backup protective device is a molded case circuit breaker or fuse. Either the circuit breaker or fuse will interrupt the current in less than one-half cycle at the maximum available fault current of 5,000 amps at the penetration. Both provide maximum fault protection and at least one provides reasonable overload protection.

G. 125-Volt DC Circuits

In all cases the DC circuits are ungrounded. Each polarity of the DC circuit is fused. A DC short circuit would only have to blow one fuse to clear the fault. Either fuse could be considered the primary protective device and the other fuse could be considered

the backup protective device. The fuses will blow in less than one-half cycle at the maximum available fault current of 5,000 amps at the penetrations. The penetration conductors can withstand 5,000 amps for 1½ cycles.

Motors and lighting circuits are fed from two series connected 2-pole circuit breakers located at class 1E and non-class 1E DC control centers. At least one of the two series breakers provides overload protection and both provide maximum short circuit protection. These circuit breakers will trip in less than one-half cycle at a fault current of considerably less than the 5,000-amp short-circuit rating of the penetration conductors. Both provide maximum fault protection and at least one provides reasonable overload protection.

H. Instrumentation Circuits

The maximum short circuit currents available from the instrumentation circuits are well below the damage threshold of the penetration conductors for these circuits.

I. CEDM Power

Each Control Element Drive Mechanism's (CEDMs) set of coils is fed from a non-Class 1E 240-volt AC 4-pole circuit breaker rated at 10 amps for phases A, B, and C, and 30 amps for the neutral and located outside of containment. Backup protection is provided by 3-pole, non-Class 1E, 40-amp subgroup circuit breakers also located outside of containment. The maximum available short circuit current at the penetration is 1,732 amps. For this short circuit current the primary and backup breakers will trip in one-third cycle. The penetration conductors can withstand 5,000 amps for 1 ½ cycles and 1,732 amps for approximately 13 cycles (interpolated by use of I^2t).

8.3.1.2.5 <u>Regulatory Guide 1.75</u>

Regulatory Guide 1.75, dated February 1974, was not used in the design of the electrical system. Most of the electrical equipment such as emergency diesel generators, 4,160-volt switchgear, 480-volt load centers, MCCs, DC distribution equipment, batteries, battery chargers, electrical penetrations, DC inverters, and main control boards, were purchased prior to the issuance of this guide. Engineering and design of the NSSS-supplied cabinets were also essentially complete before the issue date of Regulatory Guide 1.75. Most of the raceways were designed and installation started before February 1974.

However, the design criteria used for separation of redundant devices and circuits meet the requirements of the guide except for minor deviations. An effort has been made to separate the non-Class 1E wiring from the Class 1E wiring within the main control boards, since the timing of their manufacture was not too late to consider this requirement of the guide. Additionally, fuses have been installed in certain non-Class 1E circuits in order to limit the available fault currents to a level below the thermal damage threshold of the wiring. The four PPS process measurement input channels and accompanying vital bus power distribution channels meet the physical independence criteria of Revision 2 of Regulatory Guide 1.75 with the exceptions justified in accordance with section 5.1.1.2 of the regulatory guide.

The following describes the extent of conformance to the various requirements of the guide, with the paragraph numbers corresponding to the paragraph numbers of Regulatory Guide 1.75, Appendix 1. An evaluation performed concluded that the omission of cable tray covers or barriers is not safety significant although their use as recommended in IEEE 384-1974 is a good engineering practice and should continue.

3 DEFINITIONS

3.2 ASSOCIATED CIRCUITS

Non-Class 1E circuits that share power supplies with Class 1E circuits have been isolated from the Class 1E circuits by the isolation devices described in Section 3.8 below. Non-Class 1E circuits that share the same main control panels and instrument cabinets as Class 1E circuits have been designed as described in Paragraphs 5.6.5 and 5.7 below.

3.8 ISOLATION DEVICE

The following devices have been used as isolation devices in the design of the system:

A. Between Redundant Channels

1. AC Power Circuits (4,160-volt and 480-Volt)

Two Class 1E metal-clad power circuit breakers that are normally locked open by key interlocks, as described in Section 8.3.1.1.9.4, located in separate rooms, have been used to separate 4,160-volt and 480-volt redundant power sources. It is not possible to tie any of the redundant system buses together unless one of the redundant sources has been rendered inoperable. Use of these ties will be permitted, by administrative control, only under a post-accident emergency condition or during shutdown.

The breakers for the "third pumps" at 4,160-volt and 480-volt levels are described in Section 8.3.1.1.9.4.

Two Class 1E manual transfer switches have been used to transfer the 480 VAC power supply to battery chargers 2D31B and 2D32B between the redundant 480 volt power sources. The transfer switches are break-before-make which prevents a possible tie between the redundant buses. The switches are locked in the normal position during power operations and use of the transfer switch will be permitted, by administrative controls, only during shutdown.

2. DC Power Circuits

These redundant systems are completely independent.

3. 120-Volt AC and 125-Volt DC Control Circuits, and 120-Volt AC Vital Power Circuits

These redundant systems are completely independent.

B. Between Class 1E and Non-Class 1E Circuits

1. 4,160-volt and 480-Volt Load Center Power Circuits

   One Class 1E breaker serves the non-Class 1E loads for these circuits. These are actuated by fault current and have provision for remote electrical trip as well as local manual trip.

2. DC Power Circuits

   One Class 1E breaker serves the non-Class 1E computer inverter and two Class 1E breakers are used in series for all other circuits.

3. 125-Volt DC 120-Volt AC Control Circuits

   Different contacts of a switch, or a relay, are used to provide isolation between Class 1E and non-Class 1E control circuits. Also, similar separation is accomplished by using a relay coil for one type of circuit and a contact of the relay for the other circuit.

4. 120-Volt Vital AC Circuits

   Individual loop power supplies provide isolation between 120-volt input circuits and low level output circuits. Buffers provide isolation between low level loops connected to the computer.

5. 480-Volt MCC Power Circuits

   Many of the non-Class 1E loads fed from Class 1E sources are automatically tripped by a Safety Injection Actuation Signal (SIAS). Exceptions include, but are not limited to, pressurizer heaters, RCP oil lift pumps, panels 43LA, 27LA and 21PC, instrument transformers 2X13 and 2X14, Control Room condenser 2VE6, cooling tower supply feeder, Control Room emergency cooling fan, 2X104 level transmitter, battery charger 2D33, inverters 2Y25 and 2Y26, pressurizer spray valves and elevators. In addition, the boric acid heat tracing transformers receive a SIAS trip signal via non-Q contactors.

6. SPDS Computer Inputs

   The qualified isolating devices separating electrically the non-class 1E SPDS computer input circuits from class 1E circuits, have been located within switchgear cubicles or control/distribution panel where each input originates. Maximum care was exercised to install these devices, providing required distance separation between these isolators and class 1E components. Also outgoing black cable wiring connected to an isolation device has been separated from class 1E wiring as stated in the response to Section 5.6.5B of Regulatory Guide 1.75.

4.6 Non-Class 1E Circuits

4.6.1 The extent of conformance of non-Class 1E circuits is discussed under Paragraphs 5.1.3, 5.1.4, 5.6.2 and 5.7 below.

4.6.2 There are no non-Class 1E circuits that are considered as associated circuits.

5 SPECIFIC SEPARATION CRITERIA

5.1 CABLES AND RACEWAYS

5.1.1 Whereas it is a general design practice not to use cable splices in raceways, an exception is taken in the area of electrical penetrations where cables are spliced to electrical penetration pigtail extensions and in specific cases of non-Class 1E power cables with long runs.

5.1.1.2 Based on guidance provided in Section 5.1.1.2 of Regulatory Guide 1.75 and analysis performed, separation distances less than those recommended in sections 5.1.3 and 5.1.4 have been justified for circuits operating below 600 volts.

5.1.2 IDENTIFICATION

Raceway markers are installed at each end of all tray sections and at each end of all runs of exposed conduit. Additional markers are installed where conduit or trays pass through walls or floors and where the length of Class 1E runs makes intermediate identification necessary. Within the containment, the raceway numbers are stenciled with ink.

5.1.3 CABLE SPREADING AREA AND MAIN CONTROL ROOM

A. Between Redundant Channels

The recommended separation distances are met by using open cable trays wherever practical. Separation distances less than those recommended in Section 5.1.3 were found to be acceptable based on the guidance provided in Section 5.1.1.2 of Regulatory Guide 1.75. A separation of metal enclosed raceways by a minimum of one inch was not a design requirement. However, a review of the general plant area and cable spreading room was made. All situations which are in the following categories were identified and documented.

1. Conduits of one channel, including pull cans, which did not meet minimum separation requirements with conduits of another channel.

2. Conduits of one channel which did not meet separation requirements with cable trays of another channel.

   All of the above cases were reviewed to determine if the cables in the raceways served redundant components. It was found that there was only a limited number of these situations, less than 10. All but one of these situations were justified either by cables being low energy (instrumentation), area of contact being minute, or by the cables not touching the sides of the pull cans, thus offering a sufficient air gap. For conduit EC2286 and tray EC123, the cables in the tray will be provided with an adequate thermal barrier for at least one foot on either side of the area where separation is less than one inch. Potential effects of fires on redundant equipment required for safe shutdown are discussed in detail in the fire hazards analysis as described in Section 9.5.1.

B. Between Class 1E and Non-Class 1E Raceways.

As described in Section 8.3.1.4.3, non-Class 1E cables are routed in separate raceways, but minimum separation distances, as specified in Regulatory Guide 1.75 were not a design requirement. However, a minimum vertical separation of seven inches is maintained for the majority of trays with a few exceptions as close as one inch. A minimum horizontal separation of three inches has been maintained with most trays being separated by distances greater than three inches. Separation distances less than those recommended in Section 5.1.3 were found to be acceptable based on the guidance provided in Section 5.1.1.2 of Regulatory Guide 1.75.

5.1.4 GENERAL PLANT AREAS

A. Between Redundant Channels. Conformance is identical to the description in 5.1.3(A) above.

B. Between Class 1E and Non-Class 1E Raceways.

Non-Class 1E cables are routed in separate raceways from Class 1E cables wherever practicable. However, in a limited number of locations where cable tray serves a Class 1E MCC, Class 1E and non-Class 1E cables share the same tray separated by a metal barrier. In no instance are they intermingled. Further, the non-Class 1E cables, after leaving the shared tray, continue to their destination in non-Class 1E raceway only. Separation provided between conduits and between cable tray and conduit was not a design requirement. The fire hazards analysis described in Section 9.5.1 evaluated the potential effects on safe shutdown capability for fires in non-Class 1E as well as Class 1E raceways that could expose safe shutdown related cabling.

The specific situations investigated and identified in 5.1.3(A) and (B) include situations in general plant areas as well.

The separation distances between non-Class 1E and Class 1E raceways, described in 5.1.3(B) and 5.1.4(B) above, are an improvement over the commitment in the Preliminary Safety Analysis Report, designed to increase the reliability of Class 1E circuits.

5.3 DC SYSTEM

5.3.1 Each battery room has its own independent ventilation system. Additionally, all exhaust fans are Class 1E. Failure of the fans is detected by low flow switches and alarmed in the control room.

The maximum safe period of operation with an inoperative ventilation system is calculated on the basis of the following worst case assumptions:

A. Batteries 2D11 & 2D13 are under float charge at 2.25 volts per cell. 2D11 has 58 LCR-31 cells and 2D13 has 60 LCR-31 cells.

B. The ambient temperature is 120 °F and the electrolyte temperature is 120 °F.

C. The maximum permissible hydrogen concentration is to be limited to four percent of the room volume.

From the hydrogen evolution calculations, the worst case hydrogen concentration is shown to be in the small battery room which houses 2D12. The hydrogen evolution for the worst case assumptions is calculated to be 1.26 cubic feet per hour for the 58 cell battery. At this evolution rate, the time required to reach a 4% level would be approximately 35 hours.

Within this time period, alternate means of ventilation, e.g. installation of portable exhaust fans, can be arranged by administrative control. The battery room door could also be opened periodically to improve hydrogen dispersion.

5.6 MAIN CONTROL BOARDS

The following consoles and vertical panels comprise the main control board located in the control room.

Consoles: 2C01, 2C02, 2C03, 2C04, 2C09, 2C69A, 2C69B, 2C100

Vertical Panels: 2C10, 2C11, 2C12, 2C14, 2C16, 2C17, 2C22, and 2C33

Of the above, consoles 2C01, 2C69A, 2C69B, and 2C100 and vertical panels 2C10, 2C11, 2C12 and 2C22 are non-Class 1E. The remaining vertical panels and consoles contain both Class 1E and non-Class 1E devices and circuits.

The fire hazards analysis described in Section 9.5.1 considered the potential effects on safe shutdown capability of a fire damaging all wiring within an individual console, panel, or subpanel and the risk of fire spread between them. This analysis concluded that such a fire would not cause loss of safe shutdown capability.

5.6.2 INTERNAL SEPARATION

Redundant devices and circuits are separated by a distance of six inches or by a barrier.

5.6.5 NON-CLASS 1E WIRING

The following design features have been incorporated to insure that a problem in any non-Class 1E wiring will not degrade the reliability of the Class 1E wiring:

A. A minimum of six inches separation has been maintained, wherever possible.

B. In a control console or panel where a majority of wires are Class 1E, the non- Class 1E wires have been installed in metallic wireways where practical.

   In a control console or panel where a majority of wires are non-Class 1E, the Class 1E wires have been installed in metallic wireways where practical.

C. Terminal blocks for Class 1E circuits are separated from the terminal blocks for non-Class 1E circuits by a distance of six inches or by a metal barrier.

D. Non-Class 1E circuits entering a control console or panel containing both Class 1E and non-Class 1E devices and circuits have been evaluated. In those circuits where the available fault currents exceed the thermal damage threshold of the wiring, and a minimum of six inch separation is not maintained, fuses have been installed. These fuses are sized to limit the conductor's temperature to below its thermal withstand ability thereby; insuring the reliability of the Class 1E wiring will not be degraded.

5.7 Instrument Cabinets

A. NSSS-Supplied Instrument Cabinets

The following panels are included in this category:

2C15	Process Protective Panel
2C23	Plant Protection System Panel
2C39, 2C40	Engineered Safety Features Auxiliary Relay Cabinets

2C70 thru 2C73	Control Element Drive Mechanism Control System Cabinets
2C29	Steam Dump and Bypass Cabinet
2C75	Reactor Trip Switchgear Cabinet

Of the above, cabinets 2C29 and 2C70 thru 2C73 are non-Class 1E. The remaining cabinets contain both Class 1E and non-Class 1E devices and circuits.

Though Regulatory Guide 1.75 was not used as a design basis for Arkansas Nuclear One - Unit 2, the Class 1E circuits and panels are designed in accordance with the majority of the requirements of Regulatory Guide 1.75.

Electrical independence of redundant safety-related systems is described in Section 7.1.2.2. This independence is amplified in Sections 7.2.2.3.2 and 7.3.2.2.2 and is in accordance with General Design Criterion 21 as indicated in Section 3.1.

Cables entering or leaving the Class 1E cabinets have been separated into Class 1E and non-Class 1E circuits. The Class 1E field cables are identified by color coding and are run in separate external cable trays or ducts separate from the non-Class 1E cables.

B. Radiation Monitoring Cabinet 2C25

Compliance is accomplished by separating redundant Class 1E channels from each other by locating each channel in a separate panel compartment. Isolation and separation of Class 1E from non-Class 1E circuitry is provided within each compartment. Class 1E circuitry is provided with a wire/cable covering that readily distinguishes it from non-Class 1E.

C. Local Instrument Racks/Cabinets

Separation criteria for redundant channel devices and wiring meet the requirements.

Non-Class 1E wiring is not separated from Class 1E wiring at the racks/cabinets but is separated in the external cable circuits. This is considered acceptable since the non-Class 1E wiring associated with such Class 1E wiring are low energy circuits such as annunciators or computer inputs.

D. Power Supply Cabinets (2C21A and 2C21B) and Remote Shutdown Panel (2C80)

The separation criteria followed are identical to that described in Sections 5.6.2 and 5.6.5 above. Safe shutdown related instrumentation was included in the fire hazards analysis described in Section 9.5.1 in evaluating the potential effects of fire on safe shutdown capability.

E. The following cabinets are non-Class 1E:

2C27A	Feedwater Control System A
2C27B	Feedwater Control System B/Reactor Regulating System
2C27C	Feedwater Control System Common/Reactor Regulating System

5.8 SENSORS AND SENSOR-TO-PROCESS CONNECTIONS

Redundant Class 1E sensors and their connections to the process system are located with sufficient physical separation to prevent a single design basis event from causing multiple channel malfunctions.

8.3.1.2.6 IEEE 308-1971: "Class 1E Electric Systems for Nuclear Power Generating Stations."

The Class 1E electric systems meet the intent of and are in conformance with, all of the criteria in IEEE 308-1971. The principal and supplementary design criteria were used in the development of the AC and DC power systems, vital instrumentation, and control power systems as demonstrated below.

A. Principal Design Criteria

1. Design basis events, both natural and postulated, have been defined; Class 1E electric systems design was developed and equipment purchased such that their safety-related functions can be performed, in the respective operating environment, under normal and DBE conditions.

2. The quality of the Class 1E electric system's output is such that all electrical loads are able to function in their intended manner, without damage or significant performance degradation.

3. Control and indicating devices, required to switch between the preferred and standby power supplies and to control the standby power supply system, are provided inside and outside the control room.

4. All Class 1E electric system components are identified, along with the proper channel assignment.

5. Class 1E electric equipment is physically located in Seismic Category 1 structures and separated from its redundant counterpart to prevent the occurrence of common mode failures.

6. Equipment qualification by analysis, tests, successful use under similar conditions, or a justifiable combination of the foregoing ensures that the performance of safety-related functions was demonstrated under normal and DBE conditions.

7. Tables 8.3-7 through 8.3-12 depict the single failure analysis and the failure mode analysis for the Class 1E electric systems.

B. Supplementary Design Criteria

1. The design features described in Section 8.3.1 demonstrate the following:

   a. AC power systems include power supplies, a distribution system and load groups arranged to provide AC electric power to the Class 1E loads. Sufficient physical separation, electrical isolation and redundancy have been provided to prevent the occurrence of common failure modes in the Class 1E systems.

      The electric loads have been separated into two redundant groups.

      The safety actions by each group of loads are redundant and independent of the safety actions provided by the redundant counterparts.

      Each of the load groups has access to both a preferred and a standby power supply.

   b. The preferred and the standby power supply do not have a common failure mode. Adequate protective relaying has been included to isolate the standby sources from the preferred power sources in order to preserve the availability of the standby sources.

2. Distribution System

   a. All distribution circuitry is capable of starting and sustaining required loads under normal and DBE conditions.

   b. Physical isolation between redundant counterparts ensures independence.

   c. Local and remote control and indicating components monitor distribution circuits at all times.

   d. Auxiliary devices that are required to operate dependent equipment are supplied from a related bus section to prevent loss of electric power in one load group from causing the loss of equipment in another load group.

   e. All Class 1E electrical circuits have the provision for isolation from non-Class 1E circuits through circuit breakers located in Class 1E structures.

3. The preferred power supply derives power from two alternative sources.

   a. Energy in sufficient quantities is available for normal, standby, and emergency shutdown conditions.

   b. Off-site power is available to start and sustain all required loads.

   c. As described in B.3.a. above, the alternate power source is available from the distribution network shown in Figure 8.3-1.

   d. Surveillance on the availability and status of the preferred power supply is maintained to ensure readiness when required.

4. The standby power supply consists of two diesel generators, connected to the ESF 4,160-volt AC buses. Each diesel generator represents a complete, independent source of standby power.

   a. The redundant standby power supplies provide energy for the emergency and ESF systems when the preferred power supply is not available.

   b. Independence of the two standby power systems ensures that a failure of either standby power source will not jeopardize the capability of the remaining standby power source to start and run the required Class 1E loads.

   c. Each diesel generator is available for service within the time specified upon loss of the preferred power supply.

   d. Status indicators in the control room and remotely located provide monitoring and alarm for the surveillance of all vital functions for each diesel generator with respect to standby and operating modes.

   e. Sufficient fuel is provided at the site to sustain the operation of one EDG continuously for at least seven days. Off-site supplies of fuel are available for transportation to the site within this time.

   f. Automatic and manual controls are provided for the selection, disconnection, distribution, and starting of all loads supplied by the standby power sources.

   g. Automatic devices disconnect and isolate failed equipment and indication to this effect is provided.

   h. Test starting and loading can be accomplished during normal station operation.

For the analysis of the DC system, see Section 8.3.2.2.1.

8.3.1.2.7 IEEE 379-1972: "Application of the Single-Failure Criterion to Nuclear Power Generating Station Protection Systems."

A. Para 5.2: Undetectable Failures

   In the single failure analysis presented in Tables 8.3-7 through 12, no undetectable failures have been identified. This is based on the fact that all components of the electrical power system have been fully checked for correctness of ratings, connections and installation during the preoperational tests. All failures in the electrical system are considered to be detectable single failures.

B. Para 5.3: Common Mode Failures

   Common mode failures due to system design were identified and eliminated during the design stage. However, common mode failures resulting from manufacturing and maintenance errors, certain unanticipated design shortcomings and factors not considered in the design basis are difficult to identify and eliminate. However, the following actions have been taken to minimize the effects of such common mode failures:

1. Administrative controls will ensure that after any maintenance operation, the availability and operability of each system will be checked.

2. Component/equipment design deficiencies and malfunctions observed and reported to date from various plants have been investigated and measures taken to correct such problems if applicable to the equipment used in this plant.

C. Para 6.5: Type 2 and Type 3 Single Failure Analysis:

Conformance with IEEE 279-1971 is discussed in Section 8.3.1.2. Independence of redundant systems is discussed in Section 8.3.1.4. Environmental qualification is discussed in Section 3.11.

D. Para 6.6: Overall System Failure Analysis

The descriptions in Sections 8.3.1.1.8.4 and 8.3.1.1.9.4 show that design features ensure that all interconnections between redundant channels meet the single failure criterion.

8.3.1.2.8 <u>IEEE 387-1972: "Trial Use Criteria for Diesel Generator Units Applied as Standby Power Supplies for Nuclear Power Generating Stations."</u>

A. The diesel generator units have been provided with surveillance systems to indicate occurrence of abnormal, pretrip or trip conditions. Periodic tests in accordance with the Technical Specifications are performed on the power and control circuits and components including protective relays, meters, and instruments to demonstrate that the emergency power supply equipment and other components that are not exercised during normal operation of the station are operable. The operational tests are performed at scheduled intervals to test the ability to start the system and run under load for a period of time long enough to establish that the system can meet its performance specifications.

Tests are performed on each diesel generator unit to check the following:

1. Engine cooling water and air starting systems;

2. Diesel generator starting, loading, and tripping; and,

3. Testing of protective relays, governor settings, and alarms.

8.3.1.2.9 <u>IEEE 279-1971: "Criteria for Protection Systems for Nuclear Power Generating System."</u>

A. Separation and independence has been maintained between all redundant systems including the raceways so that any component failure in one ESF channel will not disable any component in the other ESF channel.

B. A failure analysis of the Class 1E system demonstrates that a single component failure within the systems will not prevent satisfactory performance of the minimum ESF loads required for safe shutdown and maintenance of a safe post-shutdown condition.

Tables 8.3-7 through 8.3-12 provide analysis of failure of Class 1E electrical equipment at the system level as well as at the component level.

Interlocks (key operated switches) have been employed to allow cross connection of the redundant ESF power buses. Cross connection of the redundant buses is only allowed under strict administrative controls during refueling operations or extreme emergencies. The redundant power buses 2A3 and 2A4, 2B5 and 2B6, etc. are designed to prevent tying the two diesel generator systems together. Key switches and interlocks to allow cross connect are described in section 8.3.1.1.9.5.

The single failure analyses are based on physical independence between the redundant systems. This independence is shown by the physical separation of redundant equipment and electrical raceway on the layout design drawings.

C. Standard production tests were performed on all safety-related electric equipment in accordance with applicable standards.

D. Seismic test reports and analyses have been submitted by manufacturers that have qualified the safety-related electric equipment to meet seismic requirements in accordance with the individual specifications. Section 3.10 covers the details.

E. All safety-related electrical equipment that must operate in a hostile environment are described in Section 3.11. Conditions under which this equipment is required to operate include high radiation, pressure, humidity, and temperature. Furthermore, they are required to withstand earthquake loading conditions as stipulated in respective specifications. A detailed analysis of these conditions is given under Section 3.10. All Class 1E equipment has been designed to meet its functional requirements under conditions produced by the design basis events. Necessary certifications to this effect have been obtained from the manufacturers, as part of the quality assurance program. Qualification tests or analyses have been performed and the results documented. These documents confirm that the equipment will perform satisfactorily under the conditions stipulated for the duration of time and to the extent of loading that might be called for as a result of any design basis event. More detailed information regarding the environmental qualification program is described by Nuclear Program #71.

Manually Controlled Electrically Operated Valves

A review of safety-related equipment and their interfaces with nonsafety-related equipment was conducted to identify manually controlled electrically operated valves the failure of which could degrade an ESF system to unacceptable levels. None were identified.

8.3.1.3 Conformance With Appropriate Quality Assurance

All safety-related electrical equipment was designed, manufactured and installed under the approved quality assurance program. Conformance with the requirements of IEEE 336-1971 and NRC Quality Assurance Criteria enumerated in Appendix B to 10CFR50 was ensured through implementation of a field quality control program covering relevant aspects of installation, inspection and testing of such equipment and systems including documentation of the same as outlined below.

8.3.1.3.1 Procurement

Various measures were established to ensure control of purchased material, equipment, and services. These included Technical Specifications, selection of vendors, approval of vendor's quality assurance and quality control programs, and vendor's shop inspection prior to release of equipment for shipping.

The following general documentation was obtained from suppliers of Class 1E electric equipment:

A. Exceptions to material or fabrication specifications or codes, with explanations;

B. Design drawings;

C. Quality control inspection and test procedures;

D. Analysis or test reports certifying that the equipment meets the seismic requirements stated in the procurement document; and,

E. Schedule of quality control tests.

Also obtained from the equipment suppliers was confirmation and/or certified test reports that the equipment meets specified applicable NEMA, ANSI, and IEEE Standards.

8.3.1.3.2 Field Storage and Handling

Various types of storage areas were utilized for Class 1E electric equipment, during the construction phase.

A. Outdoor Storage - Outdoor storage consists of well-protected, well-drained areas separated from the actual construction area so that interference with traffic and work operation was avoided. The area was maintained free of weeds and debris.

B. Weatherproof Storage - Weatherproof storage consisted of outdoor storage utilizing weatherproof, flame-resistant covering. Materials and equipment were placed on pallets or cribbing and did not come in contact with the ground or water.

C. Indoor Storage - Indoor storage consisted of structurally sound metal buildings or equivalent frame structures which were weathertight, well ventilated and lighted.

D. Indoor Heated Storage - Indoor heated storage was similar to above except it was heated.

The type of field storage provided for Class 1E electric equipment and materials is identified in Table 8.3-3.

To preserve their integrity and prevent physical, mechanical and/or electrical damage while in storage, an inspection and maintenance program using written procedures was followed during handling, storage, and installation of all Class 1E equipment. The procedures included special handling equipment to be used, lift points, etc., and special receiving inspection requirements.

When controlled storage was required, a tag was provided on the equipment to indicate the type of storage.

8.3.1.3.3 Inspection and Installation

An inspection program was enforced to ensure the equipment was located, installed, assembled and/or connected in strict accordance with the latest approved-for-construction drawings, installation specifications and field quality control procedures. All inspections and tests were performed in accordance with these requirements and the results documented. Marking or other status indicators such as stamps, tags, labels, routing cards, and traceable records were used to ensure that the status of inspection and tests performed upon individual items was known or readily determinable.

This inspection program also included checking for the required separation of redundant ESF, reactor protection, and the balance of Class 1E electrical system cables and components, and for proper termination and marking of these cables.

8.3.1.3.4 Testing

Elaborate test procedures were planned and implemented as part of the quality assurance program to ensure that completed installation would conform to design requirements. Procedures and instructions were prepared and approved by qualified test personnel. Tests conducted on individual equipment include electrical continuity, insulation resistance, phase rotation, circuit functioning, high voltage tests and such tests as required to ensure that the installation has been made in accordance with design requirements. Accuracy of test instruments was ensured through periodic calibration. All test results were documented and evaluated. Non-conformance of equipment was identified and corrected. Final verification was conducted to ensure the elimination of all deficiencies, temporary connections and testing arrangements.

8.3.1.3.5 Records

The following quality assurance records were prepared and maintained for field work as required by the quality assurance program:

A. Quality assurance construction manuals and inspection procedures;

B. Material certifications;

C. Inspection and test reports;

D. Schematic, block, and connection diagrams used to indicate inspection acceptance and operating status;

E. Qualified special process procedures;

F. Personnel qualification records;

G. Nonconformance reports and corrective actions;

H. Nondestructive test reports and radiographs;

I. Records of weld repairs;

J. Raceway installed, cable pulled and connect cards;

K. Receiving inspection reports; and,

L. Audit reports

8.3.1.4 Independence of Redundant Systems

8.3.1.4.1 General

The redundant systems are designed to be physically independent of each other so that failure of one train or channel will not jeopardize safe shutdown of the reactor.

The Class 1E electric systems are designed to ensure that any of the design basis events listed in IEEE 308-1971 will not prevent operation of the minimum number of ESF equipment required to safely shutdown the reactor and to maintain a safe post-shutdown condition.

The Class 1E power system is designed to meet the requirements of IEEE 279-1971, IEEE 308-1971, 10 CFR 50, including Appendices A and B, and Regulatory Guide 1.6. ESF loads are separated into two completely redundant load groups. Each load group has adequate capacity to start and operate a sufficient number of ESF loads to safely shut down the reactor, without exceeding fuel design limits or reactor coolant pressure boundary limits, during normal operation or design basis event. As required by IEEE 308 and 10 CFR 50 General Design Criterion 17, each redundant ESF load can be powered by both onsite and off-site power supplies. Two diesel generators, one on each ESF bus, will furnish the required onsite emergency ESF power supply requirements. Consistent with Regulatory Guide 1.6, no provision exists for automatically transferring loads between the redundant power sources. Further, the redundant load groups cannot be automatically connected to each other, nor can the two emergency power sources be paralleled automatically. Separation and independence have been maintained between all redundant systems, including the raceways, so that any component failure in one ESF channel will not disable the other ESF channel.

8.3.1.4.2 Design Criteria and Bases

8.3.1.4.2.1 Cable Derating and Cable Tray Fill

Cable sizes for all ESF loads have been selected with an ampacity equal to or greater than that recommended in published IPCEA Standards. Motor feeder cable selection is based on 100 percent load factor and continuously rated for 125 percent of full load current for 6.9 kV, 4.16 kV and 480-volt switchgear-fed motors and for 460-volt motors fed from MCCs.

In general, cable trays are limited to a fill of 40 percent of their total cross-sectional areas. Tray fills greater than 40 percent by cross section have been evaluated to ensure that cable damage, either mechanical or thermal, will not take place.

8.3.1.4.2.2 Cable Routing In Congested Areas and/or Hostile Environment

8.3.1.4.2.2.1 Mechanical Damage (Missile) Zone

Cable trays and conduits of redundant systems have been routed or provided with protective barriers in such a way that no locally generated force or missile can disable both redundant systems. In the absence of confirming analysis to support less stringent requirements, in rooms containing high pressure piping or high pressure steam lines, a minimum separation of 20 feet or a 6-inch thick reinforced concrete wall has been provided between trays or exposed conduits containing cables of redundant systems.

8.3.1.4.2.2.2 Cable Routing Criteria

During plant construction, cable was routed in accordance with the criteria described below. Subsequently, a detailed fire hazards analysis has been performed, and additional protective features installed as described in Section 9.5.1 to assure that a fire will not cause loss of redundant safe shutdown systems.

A. Where there is potential for accumulation of large quantities of oil or other combustible fluids, through leakage or rupture, routing of ESF system cables has been avoided as far as practical. Where such routing has been unavoidable, only one of the redundant systems of cables has been allowed and these cables are routed in conduits or covered trays. Administrative controls and fire protection features have been established as described in Section 9.5.1 to prevent the accumulation of combustible materials.

B. In general, cable trays of redundant systems typically have a minimum horizontal separation of three feet. Deviations from this recommended separation distance have been evaluated and determined acceptable for non-safe shutdown cables. Separation of safe shutdown required cables was analyzed per requirements of NFPA 805 (10 CFR 50.48) which are more restrictive than Regulatory Guide 1.75, and modifications were made or determined to be acceptable.

C. Vertical stacking of redundant cable trays has been avoided whenever possible. Where trays of redundant systems are stacked one above the other, a 5-feet minimum vertical separation has typically been provided. Deviations from this recommended separation distance have been evaluated and determined acceptable for non-safe shutdown cables. Separation of safe shutdown required cables was analyzed per requirements of NFPA 805 (10 CFR50.48) which are more restrictive than Regulatory Guide 1.75, and modifications were made or determined to be acceptable.

D. Non-safety and safety features trays have not been considered redundant to each other. However, where a non-safety features tray has been interposed either horizontally or vertically between redundant safety features trays or conduits, it has been considered as a potential fire pathway or exposure source to safety features trays or conduits. Therefore, the fire hazards analysis described in Section 9.5.1 considered such non-safety trays as providing a fire exposure source or a pathway for fire propagation between redundant safety divisions; where these could lead to loss of safe shutdown functions, protective features were provided as described in Section 9.5.1.

E. The minimum horizontal and vertical separation and/or barrier requirements in the cable spreading room are generally as stated in the preceding paragraphs, except that the minimum horizontal and vertical separation between redundant system trays is typically one foot and three feet, respectively, in accordance with Regulatory Guide 1.75. Separation distances less than those recommended in Section 5.1.3 were found to be acceptable based on Section 5.1.1.2 of Regulatory Guide 1.75. Since this separation may not provide adequate protection for large exposure fires, additional protective features were provided for the cable spreading room as described in Section 9.5.1.

8.3.1.4.2.2.3 Cable Reliability

This section describes activities related to cable reliability for the cables originally procured for installation at ANO-2. Subsequent purchases are evaluated with respect to qualification tests per the requirements of the environmental qualification program described in Nuclear Program #71.

Qualification tests have been performed on the original critical types to demonstrate compliance with the following design requirements.

A. Radiation resistance with exposure of 3.3×10^7 rads of total radiation dose if located within the containment or 1×10^7 rads if located elsewhere.

B. Withstand the post-accident environment conditions after a radiation dosage described in "A." above with the conductor carrying full rated current for the circuit.

C. Prototype conductors were required to pass IPCEA Standard S-19-81 flame tests. Additionally, completed cables were given a 7-minute flame test as detailed below.

   Six samples of each cable (five in the case of 5 and 8 kV power cables) were mounted on a vertical steel type ladder tray, eight feet long and three inches deep with a 6-inch rung separation. The cables were placed with a half diameter separation between each cable and between cable and side wall. A ribbon type burner 10 inches wide, 7,000 Btu/hour/inch, with means for air and gas control was mounted horizontally in front of cables under test, 12 inches above the lower end of the tray. The burner was adjusted to provide a 14 to 16-inch flame with a flame temperature of 1,400 to 1,500 °F at the point of impingement on the cable for seven minutes.

   A 120/240-volt single phase test circuit with indicating lamps, relays, and timers were used to indicate insulation failure during the test.

   In the case of 5 kV and 8 kV power cables, three single conductor cables of same size were twisted with not less than one complete turn and placed in the center of the tray.

   Only those cables which did not propagate flame were considered acceptable.

D. Insulating and jacket material water absorption resistance characteristics in accordance with IPCEA Standard S-19-81, Section 3.13.3, in addition to the capability to withstand the containment spray.

8.3.1.4.3 Separate Cable Trays for Safety and Non-Safety Related Cables

Non-safety-related cables and safety-related cables do not share the same raceway. All ESF raceways have a channel number code and a color identification and all ESF cable jackets are color coded (4,160-volt cables have a colored marker) to ensure that one cable tray or conduit does not contain cables of more than one color coded channel.

This means that non-ESF cables are not routed with any red, green, yellow, orange, or blue jacketed cables. Additionally, a non-ESF cable is not routed in a raceway that is color coded. Color coded raceways contain only cables with jacket colors or color markers that correspond to the raceway color codes.

8.3.1.4.4 Cable and Cable Tray Markings

Cables installed in cable trays are grouped on the basis of their functions and/or voltages. In other words, the 6,900-volt power cables, 4,160-volt power cables, 480-volt power and control cables and instrumentation cables are grouped and physically separated from each other. Cables, conduits and trays have been identified by color and markers. Circuit schedules have been prepared to give a permanent record of the routing and terminations of all cables. The coding of circuits provide easy identification of the associated system. All cables have this code number permanently fixed with markers at both ends. These markers have a channel identification plus a color mark corresponding to the channel color. Further, non-critical cables are identified by black jackets and safety-related cables by color coded jackets. Exceptions to the preceding statement are 4,160-volt safety-related cables, some of which have black jackets. All the 4,160-volt safety-related, black jacketed cables (mostly installed during initial construction) are identified at both ends with a permanent channel number code and corresponding color dot. Typically, new 4,160-volt safety-related cables are color coded like all other safety-related cables.

In addition to visual inspection during and following installation, 4,160-volt safety-related, black jacketed cable routings have been electronically traced to ensure that these cables have been installed in the correct channelized raceway for their entire length. The results of this electronic signal tracing are documented. The electronic tracing was performed during initial construction but is not performed for post-commercial operation modifications due to energized circuit danger and routing verification.

There are three 4,160-volt safety-related trays in the plant design. The closest separation between any combination of trays 1, 2 and 3 occurs between trays 1 and 3 at a distance of approximately 12 feet in a non-missile area.

Raceways are identified by raceway markers installed at the ends of each tray section and at the ends of each run of embedded and exposed conduit. Additional markers are installed where conduit and trays pass through walls or floors and where the length of Class 1E runs make intermediate identification necessary. Approximately 20 percent of the safety-related tray sections are longer than 15 feet, and, except for a few cases, they are less than 25 feet.

Raceway markers inside the containment are stenciled on the raceway surface, using permanent marker ink of an appropriate color. All characters comprising a marker are stenciled in the respective channel color, eliminating any need for a separate color dot. Raceway markers for areas outside the containment are adhesive backed vinyl containing black characters on a yellow background, with an appropriate color spot added for safety-related raceway channel identification.

Raceway design was substantially complete and to a considerable degree installed before issuance of Regulatory Guide 1.75. Cable tray markers are installed in some cases at intervals exceeding 15 feet. Conduit markers have been installed with due consideration for verification of installation conformance with the separation criteria.

Referencing the channel number/color tabulation below, a typical installation would be a channel one tray having tray markers with a red color spot and a fill of red jacketed cables with red color coded markers.

The following table lists the tray marker code cable jacket color and cable marker code for the 480-volt power and control cables and instrumentation cables.

Channel Number	Channel Color Identification	Tray Marker Color Spot	600-Volt Cable Jacket color	Cable Marker Color Spot
1	Red	Red	Red	Red
2	Green	Green	Green	Green
3	Yellow	Silver on Yellow background	Yellow	Silver on Yellow background
4	Blue	Blue	Blue	Blue
5*	Orange	Orange	Orange	Orange

* Channel 5 is for power cables only, which are red/green. (See Section 8.3.1.1.9.4)

In a limited number of sizes of instrumentation/control/power cables where proper colored cables were not available, a different colored or black cable was used with appropriate color markers to identify the channel.

8.3.1.4.5 Spacing of Wiring and Components Associated with Class 1E Electric System in Control Boards, Etc.

Redundant Class 1E control and instrument wiring internal to the control board was provided with a minimum of 6-inch free air separation from that of a redundant counterpart. Where this was not possible, barriers or metal conduits have been installed to achieve the desired separation. The same practice has been followed in regard to cable entry to the control board or panel enclosures. Separate terminal blocks or sockets are used inside the control panel or relay rack for termination of redundant cables. All internal wiring associated with one redundant circuit has been bundled together, color coded and separated from its counterpart bundle with clearance as mentioned above. Since this separation and method of providing barriers may not provide adequate protection for a large fire in the cabinet, the fire hazards analysis described in Section 9.5.1 considered that a fire consumed all of the wiring within a panel or sub-panel, and evaluated the effect on safe shutdown capability. Protective features were provided as described in Section 9.5.1.

8.3.1.4.6 Additional Criteria

The following additional criteria have been applied in the design of the electric system.

A. Channel separation between the reactor protection channels and also between the ESF channels will be maintained through the electrical penetrations by using one of the four electrical penetration rooms for each channel.

B. The ESF 4,160-volt switchgear, 480-volt load centers and MCCs have been located within a Seismic Category 1 structure area to minimize exposure to mechanical, fire and water damage. This equipment has been properly coordinated electrically to permit safe operation of the equipment under normal and short circuit conditions.

C. The redundant emergency diesel generators are located within separate Seismic Category 1 rooms with flood and fire doors to minimize exposure to mechanical, fire and water damage. Likewise the redundant batteries and DC control centers are located in separate Seismic Category 1 rooms.

D. 480-volt MCCs have been located indoors in the areas of electrical load concentration. Those associated with the turbine generator auxiliary system have been located below the turbine generator operating floor level. Those associated with the Nuclear Steam Supply System (NSSS) have been located to minimize their exposure to mechanical, fire and water damage.

E. The cables installed in cables trays have been grouped on the basis of their functions and/or voltages.

   Separate cable tray, conduit and penetration systems have been furnished for the following classes of cable: 8 kV, 5 kV, and 600-volt power; and, control and instrumentation cables. Medium voltage power cables are run in the top trays, with 600-volt power and control, and instrumentation cables in the lower trays.

   All redundant buses and cables for essential systems, i.e., the ESF and the systems required for the safe shutdown of the plant, and for the balance of the plant have been run, as far as practical, by alternate routes.

F. Shielded instrumentation cables and thermocouple cables have been run in different trays than those used for power and control cables.

G. The UAT and Startup Transformer 3 are located out of doors and are separated by a fire wall. Lightning arresters have been used where applicable for lightning protection. All outdoor transformers are protected by automatic water spray systems to extinguish oil fires quickly and prevent the spread of fire.

H. Non-segregated, metal-enclosed 6900 and 4,160-volt buses have been used for all major bus runs where large blocks of power are to be carried.

I. All cable entries into a panel, excluding floor blockouts and sleeves, will be sealed with a nonflammable material to prevent moisture, dust, and dirt from entering the panel. Floor blockouts and sleeves beneath a panel in fire rated floors will be sealed to prevent fire from entering or leaving the panel through these openings for a fire duration that is adequate for the fire hazards involved. Refer to the Fire Hazards Analysis for a complete discussion of penetration seals.

8.3.1.4.7 Conformance to Separation Criteria

Historical data removed. To review the exact wording, please refer to Section 8.3.1.4.7 of the FSAR.

8.3.1.5 Physical Identification of Safety-Related Equipment

All Class 1E equipment such as 4,160-volt switchgear, 480-volt load centers, 480-volt MCCs, emergency diesel generators, batteries, battery chargers, DC control centers inverters, DC and AC distribution panels, and control panels have been identified with color coded markers matching the respective cable and raceway systems in accordance with Section 8.3.1.4.5.

The physical identification of all safety-related cables, trays and conduits insofar as the channel to which they belong has been covered in detail in Section 8.3.1.4.5.

In general, all terminal blocks within the main control boards and instrument cabinets are color coded with the assigned color for the respective redundant channels. All other control boards and switchgear, MCCs and relay racks contain circuits from only one channel; therefore, color coding of the terminal blocks is not necessary. Separation between Class 1E and non-Class 1E wiring within this equipment is maintained as described in Section 8.3.1.2.

8.3.1.6 Grid Undervoltage Protection (Millstone 2 and ANO Events)

On July 20, 1976, an event occurred at Millstone 2 which involved power system undervoltage problems.

Based upon the Millstone event, each licensee was requested to supply information regarding the design of the Class 1E electrical distribution system, including a description of the load shedding features, definition of the facility operating limits, and a description of any proposed actions or modifications.

AP&L responded to the request for information by providing analyses which demonstrated the adequacy of the ANO-2 design.

Subsequently, the NRC developed a number of positions with respect to this subject. During the time frame of the NRC questions/positions and the AP&L responses, a significant related undervoltage event occurred at ANO. This event, along with requirements from the Millstone event led to several modifications of the ANO-2 electrical design. The following lists the NRC positions along with the ANO-2 responses and subsequent design changes.

8.3.1.6.1 NRC Position/ANO Responses

Position 1: Second Level of Under- or Over-Voltage Protection With a Time Delay

NRC required that a second level of voltage protection for the onsite power system be provided and that this second level of voltage protection will satisfy the following criteria:

A. The selection of voltage and time setpoints will be determined from an analysis of the voltage requirements of the safety-related loads at all onsite system distribution levels;

B. The voltage protection will include coincidence logic to preclude spurious trips of the off-site power source;

C. The time delay selected will be based on the following conditions:

1. The allowable time delay, including margin, will not exceed the maximum time delay that is assumed in the FSAR accident analyses;

2. The time delay will minimize the effect of short duration disturbances from reducing the availability of the off-site power source(s); and,

3. The allowable time duration of a degraded voltage condition at all distribution system levels will not result in failure of safety systems of components.

D. The voltage monitors will automatically initiate the disconnection of off-site power sources whenever the voltage setpoint and time delay limits have been exceeded;

E. The voltage monitors will be designed to satisfy the requirements of IEEE 279-1971, "Criteria for Protection Systems for Nuclear Generating Stations"; and,

F. The Technical Specifications will include limiting conditions for operation, surveillance requirements, trip setpoints with minimum and maximum limits, and allowable values for the second level voltage protection monitors.

Position 1: Response

A. Two levels of voltage protections for the onsite power system have been provided as follows:

1. Two inverse-time undervoltage relays on each 4,160-volt safety bus with a nominal voltage setting of 78* percent (of motor base voltage) and time dial setting of 1.0.

   With the above voltage and time settings, the undervoltage relays will initiate load shedding and starting of the associated diesel generator in 1.0 second (approximately) upon total loss of power. The isolation of the safety-related buses will be delayed approximately 2.0 seconds to permit the off-site power to supply the safety-related loads in the event of failure of a fast transfer.

2. One instantaneous undervoltage relay on each safety-related 480-volt safety bus voltage to below its settings, will isolate the safety system at the 4,160-volt level subject to a delay of 8 seconds. The purpose of this relay is to isolate safety loads when the voltage degrades to a level unsatisfactory for their continuous operation. A second relay will be added to each bus 2B5/2B6 to provide the required coincidence logic.

B. The 78* percent undervoltage relays described in A.1 are connected in parallel. Operation of either relay will isolate the safety buses from the off-site source. This has been done to prevent the possibility of the failure of one of these relays (if the two relays were connected is series) to drop out resulting in a failure to isolate the safety buses upon loss of off-site source.

   After the addition of a second 92* percent (of 460 volts) undervoltage relay of each 480-volt bus 2B5/2B6, the contacts of the two 92* percent undervoltage relays on the respective buses will be connected in series to provide the required coincidence logic.

C. As stated in A.1, the maximum delay upon total loss of power is 3.0 seconds (approximately) to power the safety buses from off-site source with or without a safety signal. The diesel generator is started by a safety signal independently and would accept the safety loads in the predetermined sequence in a maximum of 15 seconds.

   The above timings are within the limits assumed in the FSAR accident analysis.

   1. The 92* percent undervoltage relay was delayed 10.0 seconds. This time setting was revised to 8.0 seconds with a new solid-state undervoltage relay. This delay is adequate to prevent spurious operation of the relay when motors start on the safety-related 4160 or 480-volt buses. However, a review of the 6.9 kV motor accelerating conditions revealed that this time delay was not adequate. Therefore, an interlock will be added to prevent operation of the timer when a reactor coolant pump is started. (2CAN037830)

   2. Under the conditions that were identified by the new system analyses the safety-related equipment will function satisfactorily.

D. The voltage monitors will automatically initiate the disconnection of the off-site power sources whenever the voltage and time setpoints have been exceeded.

E. The voltage monitors and the associated circuitry are designed as Class 1E circuits in accordance with IEEE 279-1971. (2CAN037830)

F. The Technical Specification will address these requirements.

* NOTE: These values are historical in nature. Refer to Unit 2 TS for allowable values.

Position 2: <u>Interaction of Onsite Power Sources With Load Shed Feature</u>

NRC requires that the current system designs automatically prevent load shedding of the emergency buses once the onsite sources are supplying power to all sequenced loads on the emergency buses. The design will also include the capability of the load shedding feature to be automatically reinstated if the onsite source supply breakers are tripped. The automatic bypass and reinstatement feature will be verified during the periodic testing identified in Position 3.

Position 2: <u>Response</u>

The design will be modified to prevent load shedding of the emergency buses when the diesel generators are supplying power, provided a safety signal is present.

Position 3: <u>Onsite Power Source Testing</u>

NRC requires that the Technical Specifications include a test requirement to demonstrate the full functional operability and independence of the onsite power sources at least once per 18 months during shutdown. The Technical Specifications will include a requirement for tests simulating loss of off-site power in conjunction with a Safety Injection Actuation Signal. Proper operation shall be determined by:

A. Verifying that on loss of off-site power the emergency buses have been de-energized and that the loads have been shed from the emergency buses in accordance with design requirements.

B. Verifying that on loss of off-site power the diesel generators start from ambient condition on the autostart signal, the emergency buses are energized with permanently connected loads, the autoconnected emergency loads are energized through the load sequencer, and the system operates for five minutes while the generators are loaded with the emergency loads.

Position 3: Response

The Technical Specifications include a requirement for tests at least once every 18 months during shutdown that verify items A and B of position 3.

8.3.1.6.2 Description of Changes

Circuit Changes

A. Fast transfer to off-site source with a safety signal: (2CAN017820)

  1. Shed two heater drain pumps and two main chillers only. See Section 8.3.1.6.5.
  2. Sequence idle ESF loads (per Table 8.3-1).
  3. Delay certain ESF 480-volt loads (per Table 8.3-1).
  4. Block load shedding feature on the 4,160-volt safety buses when the diesel generators are supplying these buses, provided a safety signal is present.

B. Off-site source available but fast transfer fails:

  1. Shed all non-ESF and ESF loads.
  2. Sequence ESF loads to off-site source (per Table 8.3-1).
  3. Delay certain ESF 480-volt loads (per revised Table 8.3-1).

C. Delete slow transfer.

D. Reduce the time setting of the 92* percent undervoltage relay to 8.0 seconds.

E. Trip 3 condensate pumps (one remains running) and additional load as described on fast transfer to Startup Transformer 2 (see Section 8.3.1.6.5).

F. Block the operation of the 92* percent undervoltage relay during start of reactor coolant pump.

<u>Hardware Changes</u>

A. Increase cable sizes for two 480-volt loads.

B. Increase size of control transformers in 89 Size 1 starters.

C. Add auxiliary relays in 11 starters.

D. Replace the existing 92 percent undervoltage relays with solid-state undervoltage relays.

<u>Administrative Procedures</u>

A. If system frequency falls to 59.5 Hz, manually isolate the safety buses (Synchronize the diesel generator and trip the off-site source breaker).**

B. During plant startup, auxiliary loads should be transferred to the unit auxiliary transformer prior to exceeding 13,400 KVA of the connected load.***

C. To prevent unwarranted plant trips, operator action should be initiated as follows:

   1. If ESF bus voltage degrades to a point which would challenge the millstone relays, monitor voltages. If voltage degrades to an unacceptable value, isolate the safety buses (one at a time) by synchronizing the diesel generator and tripping the incoming feeder breaker from 2A1 to 2A2.*

*NOTE: This is a nominal value. Refer to Unit 2 TS for allowable values.

**NOTE: During periods of grid disturbances (not gradual decreases) the diesel generators should be left in the E.S. standby condition.

***NOTE: This load limit no longer applies to operation on Startup Transformer 3 due to addition of the 22KV Voltage Regulator in the switchyard in 1994.

   2. If only one 500 KV or 161 KV transmission line is connected to the ring bus (indicative of degradation of available fault load to less than 2000 MVA or 610 MVA respectively) and a plant trip occurs, the 2B5/2B6 millstone relays will probably actuate.

8.3.1.6.3 <u>Conformance to IEEE 279</u>

The following briefly describes how the ANO-2 Millstone modifications conform to the requirements of each section of IEEE 279.

A. General Functional Requirements

The devices and equipment used are qualified for Class 1E application and the performance of the devices is highly reliable. The system is designed so that the protective action is automatically initiated as the system reaches preset levels.

B. Single Failure Criterion

The two load groups are provided with redundant protective actuation control systems. Also, wiring for each of the two control systems is routed in separate Class 1E raceways.

C. Quality of Components and Modules

The devices used for the two protection systems are qualified for Class 1E application.

D. Equipment Qualifications

The available type test data for Class 1E components qualifications confirms the required satisfactory performance of the protection equipment under the environmental conditions stated in Sections 3.7 and 3.9 of the IEEE 279-1971.

E. Channel Integrity

The protective systems proposed have been designed for fail-safe operation. The devices and circuitry used are Class 1E and therefore will remain operational under extreme environmental, energy supply and accident conditions.

F. Channel Independence

The equipment, devices, and raceways for one Class 1E system are independent and physically separated from the other system. The circuits for the two Class 1E protective systems are also routed in separate raceways.

G. Control and Protection System Interactions

All the equipment is considered part of the protection system which is designed to meet the requirements of IEEE 279 with the exception of the RCP starting bypass initiation signal, i.e. the contact from which the bypass signal is initiated. The signal, however, is isolated from the Class 1E portions of the system by a Class 1E buffer relay. For further details, refer to our response to Item 6.

H. Isolation Devices

Isolation devices are not used as the systems are completely Class 1E.

I. Single Random Failure and Multiple Failures Resulting From a Credible Single Event

There are no single failure points as the systems are completely Class 1E, separate, and redundant.

J. Derivation of System Inputs

The undervoltage relays proposed at the 480-volt ESF buses will measure the system degraded conditions directly and initiate the protective action at the system level within its respective load group.

K. Capability for Sensor Checks

The 92* percent undervoltage relays have been provided with functional test switches. Periodic testing will ensure the sensors' operational capability.

L. Capability for Test and Calibration

The system has the capability for testing. Calibration of devices is discussed elsewhere in the FSAR.

M. Channel Bypass or Removal From Operation

Systems have the capability to be tested inservice without initiating a protective action at the system level and also continue to meet the single failure criterion.

N. Operating Bypass

The protective action to the two systems is automatically bypassed during starting of the RCP motors. The operating bypasses are Class 1E.

O. Indication of Bypass

The bypasses will be alarmed in the control room to indicate that the bypass failed to reset. Bypasses using the test switches are not alarmed in the control room.

P. Access to Means for Bypassing

Manual bypass of protective action is provided through test switches. The access to the test switches will be under the administrative control of Operations.

Q. Multiple Setpoints

The protective devices are set at one setpoint only.

R. Completion of Protective Action Once It is Initiated

Once the protective action has been initiated the off-site source is automatically disconnected and the onsite source (diesel) is made available within a short time. The protective action will go to completion once initiated.

* NOTE: This is a nominal value. Refer to Unit 2 TS for allowable values.

S. Manual Initiation

Manual control is provided on each of the two breakers for connecting or disconnecting the off-site and onsite sources to the auxiliary power systems. Manual initiation requires operation of a minimum number of switches.

T. Access to Setpoints Adjustment Calibration and Test Points

Access to setpoint adjustment, calibration, and test points is controlled administratively by Operations and is limited to qualified personnel.

U. Identification of Protective Action

The breakers for the off-site and onsite sources have indications in the control room to identify the protective actions and that the breakers are closed.

V. Information Readout

Sufficient monitoring has been provided in the control room which will enable the operator to know the deteriorating conditions of the system.

W. System Repair

Periodic testing of the system will ensure the detection of the malfunction of components or modules. Plug in type of components are used where possible so that the faulty units can be replaced, repaired or adjusted expeditiously. Also, the system protective action is designed such that the failure of one undervoltage relay will not disable protective action.

X. Identification

The equipment and wiring of the two protective systems have been identified as red and green channels.

8.3.1.6.4 <u>Technical Specifications</u>

As part of the resolution of this issue, the Technical Specifications were revised to include the undervoltage relay settings and requirements for surveillance testing and limiting conditions for operation. See the Technical Specifications for further information.

8.3.1.6.5 <u>1983 Load Shedding Modifications</u>

The ANO-2 load shedding schemes have been modified to remove unnecessary shedding of loads in the non-IE areas of the ANO-2 electrical distribution system. Supporting analyses of computer load flow studies justify removal of SIAS actuated load shedding for all equipment with the exception of:

- 2P8A Feedwater Heater Drain Pump "A"
- 2P8B Feedwater Heater Drain Pump "B"
- 2VCH1A Main Chiller "A"
- 2VCH1B Main Chiller "B"

The load flow studies (Calculation 83-2058-01) show that full ANO-2 loads may be accommodated on Startup Transformer 3 as long as at least two 500 kV lines are in service. In the event of a unit trip, fast transfer to Startup Transformer 3 with all remaining loads is possible with at least one 500 kV line (2000 MVA) available. The unit will be able to function indefinitely in either of these two cases without the likelihood of Millstone degraded grid voltage actuations.

In the case of a fast transfer to Startup Transformer 3 with a concurrent Safety Injection Actuation Signal (SIAS), the transfer with unit trip would apply for initial conditions with immediate shedding of the loads listed above (T = 0). As the ESF loads sequence on

(T = 10…,90), starting voltages are maintained above minimum transient allowables. After each step and in steady state, the transient voltage recovers above the 92%* Millstone trip setpoint before the eight second time delay has expired. Thus, removal of SIAS load shedding from all non-ESF equipment, except the above listed loads, is justified. Removal of the SIAS load shedding will not cause unnecessary Millstone actuation and facilitates plant recovery from SIAS conditions by allowing retention of the unit condenser and turbine bypass valving as a shutdown heat sink.

Other load flow studies analyzed the load shedding scenarios of Startup Transformer 2 (see Calculation 83-2058-02). In this case, the existing shedding schemes are retained with the following exceptions: only one of two circulating water pumps will be tripped, the SIAS shedding override of the Startup Transformer 2 load shedding schemes (2H09 and 2A16) is removed, and a Startup Transformer 2 load shedding bypass means is installed in the 2H23 and 2A111 switchgear cubicles. A fast transfer to Startup Transformer 2 by ANO-2 after a trip will initiate shedding of:

- One out of two circulating water pumps
- Two out of four reactor coolant pumps
- Three out of four condensate pumps
- Two out of two heat drain pumps
- Two out of two main chillers

Analysis of this situation shows that steady state voltages are acceptable. The retaining of one of two circulating water pumps is necessary to provide a shutdown heat sink. Analysis of a fast transfer to Startup Transformer 2 with a concurrent SIAS signal requires initial conditions (T = 0) of loads remaining after unit trip, since the load shedding of two of four reactor coolant pumps is no longer blocked by SIAS. As the ESF loads sequence on (T = 10,...,90), starting voltages are maintained above minimum transient allowables. After each step and in steady state (T > 90), the transient voltage recovers above the 92%* Millstone trip setpoint before the eight second time delay has expired. Thus, removal of the SIAS load shedding override of the ST2 load shedding scheme and the retaining of one of two circulating water pumps running is justified. Again, no unnecessary Millstone actuations would likely occur under these conditions and the ability of the unit to achieve orderly shutdown is enhanced by the availability of the unit condenser as a shutdown heat sink.

* NOTE: These are historical values. Refer to Unit 2 TS for allowable values.

The bypass means provided to defeat Startup Transformer 2 load shedding is a key-operated switch and monitoring light combination provided on cubicles 2H23 and 2A111. During a shutdown of ANO-2, auxiliary electrical loads must be transferred to either Startup Transformer 3 or Startup Transformer 2. When Startup Transformer 3 is not available, Startup Transformer 2 load shedding is bypassed prior to transfer of auxiliary loads to avoid the reactor trip that would otherwise occur upon shedding of any of the reactor coolant pumps. The procedure for transferring electrical loads to Startup Transformer 2 includes steps to assure that voltage on the ESF buses does not drop below the Millstone trip setpoint. The bypass switches also provide a means to administratively control loading of Startup Transformer 2 when ANO-2 is in cold shutdown and degraded grid voltage conditions are not present.

8.3.2 DC POWER SYSTEMS

8.3.2.1 Description

The DC system has been designed to provide a source of reliable continuous power for control, instrumentation, RPS, ESFAS, and other loads for startup, operation, and shutdown under normal and emergency conditions.

The DC system consists of three 125-volt batteries, each with its own battery charger (plus a spare for each of the two ESF DC buses), DC control center, and distribution panels.

The Class 1E 125 VDC system consists of two independent, physically and electrically separated 125 volt batteries designated 2D11 and 2D12 which provide DC power to the 125 VDC control centers 2D01 and 2D02, respectively, along with associated distribution panels. Four 400 amp battery chargers (two associated with each DC electrical train) serve as normal supplies to the DC control centers with the associated battery floating on the bus. 2D31A and 2D31B are Red Train battery chargers. 2D32A and 2D32B are Green Train battery chargers. One battery charger per train is normally in service supplying its associated 125 VDC control center while the other charger in each train remains in standby, except when swapping battery chargers or during maintenance and/or testing activities Battery chargers 2D31A and 2D32A are supplied from the respective same-train 480-volt ESF MCCs. Battery chargers 2D31B and 2D32B are normally fed from the respective same-train 480-volt ESF MCCs, but can be fed from the opposite train 480-volt ESF MCC via manual transfer switches in order to support electrical maintenance activities during unit outage. The batteries supply important DC loads without interruption should the battery chargers fail.

The non-Class 1E 125 VDC system consists of a single (black) train 125 VDC battery designated 2D13 which provides power to control center 2D03. Battery charger 2D33 serves as the normal supply to 2D03 with battery 2D13 maintained in a float condition. Charger 2D33 is fed from Class 1E 480 VAC MCC 2B64. The battery supplies the load without interruption should the battery charger fail.

8.3.2.1.1 Batteries

Each of the batteries, designated 2D11, 2D12, and 2D13 consists of cells assembled in heat and shock resisting, polycarbonate, noncombustible jars. They are of the lead-acid type with lead-calcium grid construction. The batteries are mounted on racks made of structural steel members. All battery racks meet the Seismic Category I requirements stated in Section 3.10. Batteries 2D11 and 2D12 consist of 58 cells and are rated at 2064 A-hr for an 8-hour rate of discharge to 1.81 volts per cell at 77 °F. Battery ratings are given in Table 8.3-2. 2D11 and 2D12 have been designed to meet the duty cycle requirements shown in Tables 8.3-5 and 8.3-6, without use of the charger and without decreasing the voltage below 105 volts (1.81 volts per cell) at 60 °F ambient. The 125-volt DC loads supplied from batteries 2D11 and 2D12 are shown in Table 8.3-4A and 8.3-4B, respectively.

According to the battery manufacture, a float current of less than 2 amps indicates that the battery is at least 98% charged. Since only a 98% charge can be assumed, a 2% design margin factor is maintained in the battery sizing calculations to ensure 100% battery capacity is maintained.

The safety related batteries are sized per IEEE 485-1983. The minimum design limit for electrolyte temperature is 60 °F. The batteries are sized to include a temperature correction factor to compensate for the possibility of a 60 °F operating temperature. The batteries are also sized to include an aging factor to ensure adequate end of life battery capacity exists. In addition, the batteries are sized to include a design margin factor to account for factors other than aging and temperature. These margins are maintained under the Margin Management program.

Optimal long term battery performance is obtained by maintaining a float voltage greater than or equal to the minimum established design limits provided by the battery manufacturer, which corresponds to 127.6 V (calculated based on 2.20 V * 58 cells) at the battery terminals, or 2.20 Vpc. This is the minimum design limit for battery terminal float voltage established by the battery manufacturer and provides adequate over-potential, limiting the formation of lead sulfate and self discharge, which could eventually render the battery inoperable.

Batteries 2D11 and 2D12 are mounted on a 2-step rack with a single tier on the front step and two tiers on the rear step. Each battery is sized to provide the maximum simultaneous combination of steady state loads and peak loads for the periods as shown on the emergency duty cycle (Tables 8.3-5 and 8.3-6). Peak capacity of each battery will meet peak current demand for a minimum period of one minute. The total ampere hour capacity of the battery will also meet the 8-hour rate as shown in these tables. Voltage will not fall below 105 volts (1.81 volts per cell) during any peak or continuous load condition. The batteries are sized to comply with the IEEE standard shown in its respective table.

Battery 2D13 consists of 60 cells and is rated at 2175 A-hr for an 8-hour rate of discharge to 1.75 volts per cell at 77 °F. The battery is mounted on a 2-step rack with a single tier on the front step and two tiers on the rear step. The 125-volt DC battery 2D13 and associated control center are not required for the safe shutdown of the reactor, and as such, are not designed as a Class 1E system. Emergency oil pumps associated with the main turbine generator and other non class 1E loads are supplied from this DC system. Loss of this 125-volt DC supply is annunciated.

8.3.2.1.2 Battery Chargers

The 1E 125 VDC chargers, designated as 2D31A, 2D31B, 2D32A, and 2D32B (one standby backup per power train) and the non-1E 125 VDC charger, designated as 2D33, are of the thyristor full-wave rectifier constant average voltage type. The ratings of the chargers are given in Table 8.3-2. They are convection cooled, rated for continuous operation at 122 °F ambient. Each charger is rated at 400 A and suitable for float charging or equalizing the 125 volt DC battery. The chargers operate from 460-volt, 3-phase, 60 Hz supplies from 480-volt Class 1E MCCs. Each charger is designed to prevent the battery from discharging back into any internal charger load in case of AC power supply failure or charger malfunction. The chargers may be used as battery eliminators so that they can supply 125 volt DC power if the associated battery has to be taken out of service for testing or becomes unavailable for any reason. Load sharing and transfer controls are provided for load transfer between the two battery chargers on each of the class 1E power trains. Other than during load transfers or maintenance, only one battery charger per power train will be energized.

Each of the DC buses in the redundant DC control centers 2D01 and 2D02 is connected to a separate battery charger. The battery chargers are supplied from separate and redundant Class 1E MCCs which are designed to be energized automatically from their associated diesel

generator in the event of a coincident loss of normal and preferred power sources. The backup charger on each train can be switched in by operator action to replace the normal battery charger.

Each charger is capable of supplying the normal DC load while maintaining the battery in a charged condition. Tables 8.3-4A and 8.3-4B show the loads on the Class 1E batteries, 2D11 and 2D12, for an emergency duty cycle discharge without AC power available. Four separate DC power sources are provided for the reactor trip switchgear. Red and green power is supplied from separate batteries. Yellow and blue power is supplied from separate battery eliminators connected to the yellow and blue 120-volt AC distribution panels.

8.3.2.1.3 DC Control Centers

The 125-volt DC control centers 2D01, 2D02, and 2D03 are comprised of freestanding NEMA Type 1 enclosures with gasketed doors and cover plates. DC control centers 2D01 and 2D02 have been provided with drawout type circuit breakers with fuses to provide overcurrent protection. DC control center 2D03 includes molded case breakers with adjustable magnetic trip settings on each pole.

8.3.2.1.4 Distribution Panels

Four DC distribution panels, designated as 2D21, 2D22, 2D23, and 2D24 have been provided. Distribution panels 2D23 and 2D24 supply the DC requirements of all safety-related redundant loads. The other two panels 2D21 and 2D22 supply the requirements of all non-safety-related devices. In each channel, an autotransfer switch has been provided to ensure that DC supplies to all connected loads do not fail in the unlikely event of battery failure or if the battery has to be taken out for testing. There is a remote possibility of an inadvertent battery discharge in the event of a fault or overload condition on any of the non-class 1E circuits supplied by panels 2D21 or 2D22 coinciding with a failure of the primary class 1E breaker which protects that circuit. Such a discharge would be detected by bus undervoltage alarm and indication in the control room. Also provided are DC distribution panels 2RA1 and 2RA2, which supply 125-volt DC to Reactor Trip Switchgear trip circuits and 2B5/2B6 undervoltage relays.

8.3.2.1.5 System Operation

The 125-volt DC ESF systems are identified on the single-line meter and relay diagrams and the schematic diagrams in a manner similar to that described in Section 8.3.1.5. Each DC system operated ungrounded with a ground fault detector relay is set to annunciate the first ground on either the positive or the negative leg of the system. The annunciator provides an opportunity for corrective action before a second ground might occur. Single ground faults will not cause a DC circuit failure. With an arrangement of this type, two grounds are required before any of the circuit protective devices operate.

One undervoltage relay is provided on each bus section to initiate an alarm if voltage on the bus drops to a preset value. A charger failure relay provided on each charger detects and annunciates failures in AC power input and DC power output. Each safety bus has a "battery not available" alarm which annunciates blown battery fuses or an open battery disconnect switch.

Cables for the DC power and control systems are rated 600-volt, 90 C or greater with flame-resistant insulation and jacketing materials capable of withstanding the worst case environmental conditions to which the cable could be exposed, and copper conductors sized to carry the maximum available short circuit current for the time required by the primary circuit breaker to clear the fault. They are also sized for continuous operation at not less than 125 percent of nameplate full load currents. Additional information on cables and raceways for the DC power supply systems is provided in Section 8.3.1.4.5.

8.3.2.1.6 Equipment Separation and Redundancy

The 125-volt DC system is designed to meet the Seismic Category 1 requirement stated in Section 3.10. The two redundant batteries and their related accessories are located in separate rooms in the auxiliary building which is designed as a Seismic Category 1 structure, and they are protected from potential missile hazards. The third battery 2D13 has been installed in the same room as battery 2D11. The safety-related DC loads have been grouped into two redundant load groups such that the loss of either group will not prevent the minimum safety function from being performed.

Complete separation and independence have been maintained between components and circuits of the two 125-volt ESF DC systems, including the raceways. For the raceway separation criteria, see Sections 8.3.1.4.5 and 8.3.1.4.6. Because of the physical and electrical separation provided for the batteries, chargers, distribution equipment and wiring for the 125-volt DC ESF systems, a single failure at any point in either system will not disable both 125-volt DC systems. The single failure analysis for the 125-volt DC systems is given in Table 8.3-11.

8.3.2.1.7 Ventilation

Each class 1E 125-volt DC system battery and its related charger and the distribution equipment are located in a separate ventilated room. The ventilating fans for the battery rooms are powered from ESF MCCs of the respective channels.

8.3.2.1.8 Identification of Safety Loads and Time of Operation

Tables 8.3-4A and 8.3-4B identify the safety-related DC loads and the length of time they would be operable in the event of loss of all AC power.

8.3.2.1.9 Inspection, Servicing, Testing, Installation, and Qualification

The station batteries and their associated equipment are easily accessible for inspection, servicing and testing. Servicing and testing will be performed on a routine basis in accordance with the manufacturer's recommendations and the Technical Specifications. Typical inspection includes visual inspection for leaks, corrosion, or other deterioration, and checking all batteries for voltage, specific gravity, level of electrolyte, and temperature. At the time of installation, rated discharge acceptance tests were made to verify that the battery capacity meets the manufacturer's rating.

A Non-Class IE metering system is provided for batteries 2D11 and 2D12 for a means of accurately measuring the battery charging current when the battery is fully charged. The battery charging current can be used in lieu of the specific gravity parameter to declare the battery operable following a discharge test.

Each battery cell case is marked with a high and low electrolyte level line. The minimum electrolyte level is determined by the low electrolyte level line on the battery case.

The 125-volt DC system components were purchased and installed under a strict quality assurance program. Certified records of quality assurance inspection and tests performed during production were obtained from the equipment manufacturer. The equipment has been qualified by both tests and satisfactory operation at other operating stations.

The qualification of the 125-volt DC system equipment meets the requirements of IEEE 323-1971.

The battery test program was conducted in accordance with the ANO-2 Technical Specifications and the Combustion Engineering Standard Technical Specifications (March 15, 1975 version).

8.3.2.2 Analysis

The 125-volt DC Class 1E electrical systems are designed to meet the requirements of IEEE 279-1971, IEEE 308-1971, 10CFR50 General Design Criteria 17 and 18, and Regulatory Guides 1.6 and 1.32. They will also meet the requirements for the design basis events described and evaluated in Chapter 15.

8.3.2.2.1 Compliance with Design Criteria and Guides

The following analysis of the Class 1E DC system demonstrates compliance with General Design Criteria 17 and 18, Regulatory Guides 1.6 and 1.32, and IEEE 308-1971.

Criterion 17

The two systems which supply the 125-volt DC power to redundant Class 1E load groups from the two separate 125-volt DC buses are electrically independent and physically separated from each other. Each of the two systems has adequate capacity to supply the 125-volt DC power for the safety-related loads required to safely shut down the reactor.

Criterion 18

As described in Section 8.3.2.1.5, the Class 1E DC system is designed to permit appropriate periodic inspection and testing.

Regulatory Guide 1.6

As described in Section 8.3.1.2, the Class 1E DC system is designed with sufficient independence to perform its safety functions assuming a single failure.

Regulatory Guide 1.32

The battery chargers have been sized to furnish electric energy for the largest combined demands of the various steady state loads while restoring the battery from the minimum charged state to the fully charged state, irrespective of the status of the plant during which these demands occur.

IEEE Standard 308-1971

For the analysis per Principal Design Criteria of IEEE Standard 308-1971, see Section 8.3.1.2. The following presents an analysis per Supplementary Design Criteria as applicable to the Class 1E DC system.

The Class 1E DC system provides DC electric power to the Class 1E DC loads and for control and switching of the Class 1E systems. Physical separation, electrical isolation, and redundancy have been provided to prevent the occurrence of common failure modes. The design of the Class 1E DC system includes the following features.

A. The DC system is separated into two main redundant systems.

B. The safety actions by each group of loads are independent of the safety actions provided by its redundant counterpart.

C. Each DC redundant subsystem includes power supplies that consist of one battery and two battery chargers (one used as a standby backup).

D. Redundant batteries cannot be interconnected.

E. The batteries are arranged to prevent a common mode failure.

Each distribution circuit is capable of transmitting sufficient energy to start and operate all required loads in that circuit. Distribution circuits to redundant equipment are independent of each other. The distribution system is monitored to the extent that it is shown to be ready to perform its intended function. The DC auxiliary devices required to operate equipment of a specific AC load group have been supplied from the same load group.

Each battery supply is continuously available during normal operation and following a loss of power from the AC system, to start and operate all required loads.

Instrumentation is provided to monitor the status of the battery supply as follows:

A. DC bus undervoltage alarm (control room);

B. Battery current indication (battery room);

C. DC voltage indication (battery room);

D. DC ground indication (control room); and,

E. Battery not available (control room; safety buses only).

The batteries will be maintained in a fully charged condition and will have sufficient stored energy to operate all necessary circuit breakers and provide an adequate amount of energy for all required emergency loads.

The battery charger of one redundant subsystem is independent of the battery charger for the other redundant system. Instrumentation has been provided to monitor the status of the battery charger as follows:

A. Output voltage at charger;

B. Output current at charger;

C. Breaker position indication at charger; and,

D. Charger malfunction alarm in control room, including input AC undervoltage, DC undervoltage, DC overvoltage, and output breaker open.

Each battery charger has an input AC and output DC circuit breaker for isolation of the charger. Each battery charger power supply has been designed to prevent the AC supply from becoming a load on the battery due to a power feedback as the result of the loss of AC power to the chargers.

Equipment of the Class 1E DC system are protected and isolated by fuses or circuit breakers in case of short circuit or overload conditions. Indications have been provided to identify equipment that is made unavailable per the following:

	Event	Available Indication
A.	Battery charger AC input breaker trip	Charger malfunction alarm
B.	Battery charger DC output breaker trip	Charger malfunction alarm
C.	DC control center feeder trip	DC panel undervoltage alarm
D.	Distribution circuit breaker trip	Individual equipment alarm
E.	Inverter DC feeder breaker trip	Inverter malfunction alarm
F.	Inverter output AC breaker trip	Inverter trouble alarm
G.	Blown battery fuses or open battery disconnect	Battery not available (safety buses only)

Periodically the battery charger AC supply breaker is opened to verify the load carrying ability of the battery.

Dependable power supplies have been provided for the RPS and ESFAS. Two independent DC and four independent AC power supplies have been provided for control and instrumentation of these systems. The independent DC supplies have been provided by distribution circuits from each of two redundant DC distribution panels. Independent AC supplies have been provided by the six inverters and four associated 120-volt AC vital buses. Refer to Section 8.3.1.1.6 for further description of these vital instrument AC power supplies.

IEEE Standard 450-1980

Operational procedures for normal maintenance, testing and replacement comply with IEEE Standard 450-1980 to the extent practical. The acceptability of any deviations from the recommendations of the standard will be evaluated by Engineering. Acceptance tests were made in accordance with the standard. The batteries will be tested, serviced, and inspected at regular intervals, as outlined in Section 8.3.2.1.9, to ensure that batteries and associated equipment are maintained in a satisfactory condition.

Batteries will be replaced when their capacity, as determined in Section 6.5 of the standard, drops to 80 percent of the manufacturer's rating. Records are maintained in accordance with the recommendations in the standard.

8.3.3 ALTERNATE AC POWER SOURCE

8.3.3.1 System Description

The Alternate AC (AAC) power source consists of a 4160 volt generator which utilizes a diesel engine as its prime mover, electrical power distribution, control, and instrumentation as well as necessary support systems. With the exception of the Bulk Fuel Oil Storage System, the AAC system is independent of plant systems. The basic configuration and function of the AAC power source is to provide sufficient AC power to safely shut down either unit at ANO following a station blackout. A station blackout is defined as a total loss of all AC power on either unit. This includes the simultaneous loss of the normal, preferred, and emergency AC power sources. The generator set can also be used to supply certain non-safety related, but operationally important, loads during other plant events.

8.3.3.2 Alternate AC Generator

8.3.3.2.1 Building

With the exception of the power distribution switchgear, all of the major components are located in the AAC Generator Building. The building is a steel frame, pre-cast concrete panel structure designed and built to the Uniform Building Code. The building is divided into an electrical equipment area, which also serves as the local operations station, and an engine room. This building houses the engine generator set, fuel oil transfer pump, fuel oil day tank, air start system, engine generator control cabinets, HVAC, and fire protection systems.

8.3.3.2.2 Engine Generator Set

The engine generator set consists of a diesel engine and matching generator mounted on a rigid steel frame. The package has a continuous rating of 4400 kW at 4160 volts, 60 hertz, 0.8 PF. The machines prime rating, which equates to a 2 hour rating, is 4840 kW (110% of the continuous rating). The engine generator set is a Caterpillar Model 3616 TA.

The prime mover is a 16 cylinder 'V' configuration, 4 cycle, fuel injected, turbocharged diesel engine that operates at 900 RPM. The generator is a Kato Engineering Company Model 8P11-4000, 4 pole synchronous, air cooled generator rated at 4400 kW continuously with class F insulation. This generator utilizes a permanent Magnet Generator (PMG) pilot excitor, a Kato voltage regulator, and is configured for a 4160 volt, 3 Phase, resistance grounded neutral power distribution system.

8.3.3.2.3 SUPPORT SYSTEMS

8.3.3.2.3.1 Cooling System

The cooling system is made up of two separate cooling circuits, each with its own gear driven pump, and air cooled radiator. One circuit is for the jacket water, cylinder heads and turbocharger. The other is for the aftercooler and oil coolers. Both cooling circuits utilize a 50% mixture of glycol and demineralized water with rust inhibitors and other chemical additives. Both cooling circuits maintain a constant flow through the engine and contain temperature control valves which partially bypass the radiator to maintain a constant temperature into the engine. The air cooled radiators are mounted in the same housing and are of a forced air design. The radiator is located immediately to the west of the building. Integral to the cooling system are the "keep warm" system, a glycol drain/fill pump and tank, and the expansion tank.

8.3.3.2.3.2 Air Start System

The air start system is made up of two 100% capacity air compressors, air dryer system, and two air receiver/storage tanks along with the piping to the engine generator package skid. The air receivers are internally coated and the piping is stainless steel to avoid corrosion and the introduction of corrosion products into the air stream. The two air receiver tanks independently contain sufficient energy, when fully charged, to attempt 5 engine starts. A start attempt refers to the normal cranking duration of approximately 3 to 4 seconds as documented in Engineering Change 20107. The system down stream of the air receivers is configured such that no single active failure will prevent starting attempts. The air receivers may be isolated from each other when necessary for maintenance. The remaining "in-service" receiver will be available for starting the generator.

8.3.3.2.3.3 Fuel Oil System

The fuel oil system consists of a gear driven pump, an AC motor driven pump, a DC motor driven pump, a fuel oil transfer pump, a day tank, a fuel oil cooler, valves, and piping. The gear driven fuel oil pump draws fuel from the approximately 600 gal. day tank and supplies the fuel injection header. The fuel injectors draw from this header to fuel the engine and cool themselves then return the excess fuel to the day tank. The excess fuel is cooled by an air cooler located within the engine room. The AC driven fuel pump serves to provide fuel during and immediately after engine starting and as a back up for failure of the gear driven pump. The DC driven pump serves as a backup for the AC pump. The minimum level in the bulk fuel oil storage tank includes a sufficient quantity of fuel to operate the AAC machine at full rated load for a minimum of 4½ days.

Fuel oil is transferred from the bulk fuel oil storage tank via a fuel transfer pump located in the AAC Generator Building. This transfer pump can simultaneously fill the day tank and supply the engine at full load. Additionally, a bypass valve on the bulk storage tank can be opened that will gravity feed the engine mounted fuel oil pumps.. In this mode the excess fuel is returned to the day tank and any overflow is returned to the bulk storage tank.

8.3.3.2.3.4 HVAC, Combustion Air, Exhaust

The building design includes the necessary heating, ventilation, air conditioning, exhaust, and combustion air systems for the proper operation of the generator set. The Engine Room Ventilation System is comprised of three separate exhaust fans. One exhaust fan is a small fan for basic ventilation and fuel oil fume control. The other two are thermostatically controlled and provide adequate ventilation during the operation of the engine generator set. Outside air, drawn through motor operated louvers, flows across the generator and the engine and is exhausted by these fans. Under design outside air conditions, the temperature within the room will remain within the engine generator ratings. Heating, provided by unit heaters and the engine keep warm system, will maintain the temperature above a value where engine starting could be jeopardized.

Filtered air drawn from outside by the turbocharger is utilized for engine combustion. The engine exhaust is also discharged from the building after passing through a silencer. The combustion air intake and exhaust are located on the roof of the building to avoid drawing the exhaust into the intake filters.

8.3.3.2.3.5 125 Volt DC System/120 VAC UPS System

A 125 Volt DC power system for the AAC Building made up of a battery, battery charger, and distribution equipment has been provided. The battery bank is comprised of valve-regulated (sealed) lead-acid batteries mounted in a rack located in the electrical equipment room. The battery is sized to operate the Programmable Logic Controller (PLC), control and instrumentation system, the DC fuel oil pump, essential circuit breakers, and equipment protective devices. The duty cycle assumes a 30 minute period prior to the starting of the machine after the loss of building power as part of a station blackout. During this period the computer based control system will remain functional. Critical control equipment located in Unit 2 is powered by a source independent of either units preferred, normal, or safety related power sources.

A separate 120 VAC Uninterruptible Power Supply for the AAC Building (made up of battery, battery charger, and inverter) has also been provided. This package unit provides power for the PC and Monitor which interface with the PLC at the building and also provides uninterruptible control power to the AAC Building 480 VAC Switchgear that transfers the building from preferred offsite power to generator power.

8.3.3.2.3.6 480 Volt Auxiliary Power

The 480 volt power distribution system for the AAC Building is normally aligned to an offsite 13.8kV source. Upon loss of this normal source, the building will automatically transfer to the AAC generator once it is started manually. The loss of power in the building is indicated in the Control Room. The instrumentation and control systems remain operable for several hours on the building batteries without building power. The engine generator set can be started remotely without AC power, requiring only DC power. The local manual start does not require any power. The 480 volt system is sized to carry the expected loads during engine generator operations at rated load.

8.3.3.3 Instrumentation & Control System

The instrumentation and control system for the AAC power source is an integrated Programmable Logic Controller and personal computer based control system. This system uses a fiber optic data and command transmissions network and is tied into the plant computer as well as the site Local Area Network. This system provides the operations staff the ability to control, monitor, collect data, and trend the performance of the machine from the Control Room as well as locally in the AAC building. This AAC machine can be started and aligned to either of the safety buses by local manual action in the event of failure of the PLC-PC control system. The primary man-machine interface will be through touch screens and computers located in the Unit 2 Control Room and the AAC Building.

8.3.3.4 Power Distribution

The 4160 volt power is distributed to either safety related bus and/or to one non-safety related bus in either unit through bus 2A9 located in Unit 2. Bus 2A9 is located on elevation 372’ of the Turbine Building adjacent to the 6900 and 4160 volt offsite power buses. Through remote manual operation of the circuit breakers in 2A9, the power can be aligned to 1A1, 1A3/1A4, 2A1, or 2A3/2A4. Final re-energization of safety bus 1A3, 1A4, 2A3, or 2A4 is accomplished by operator action within the respective unit’s Control Room. The AAC Generator is sized to carry the largest load from any of the four safety buses plus its support and auxiliary system loads with considerable margin.

8.3.3.5 Testing & Peaking Operations

The AAC Generator can be synchronized with the offsite power source for the purpose of testing and peaking operations. This provides the ability to conduct surveillance, post maintenance, and performance testing. The use of the AAC machine for system peaking is acceptable under controlled conditions that limit its vulnerability to failures on the transmission system.

Table 8.3-1

DIESEL LOAD TABLE

The below load profile represents an approximation of the actual worst case loads and their duration on the diesel generators during each emergency condition. For actual load configuration control, see Calculation No. 85-S-00002-01.

Equipment	KV	No. Of Component Per Diesel	Component H.P. Rating (KW/KVA)	Actuation Signal	Component Start Times (Sec.) (1)	DIESEL GENERATOR LOADING CONDITIONS: Condition I Loss of Coolant With Loss of Offsite Power		Condition II Main Steam Line Ruptures With Loss Of Offsite Power		Condition III Loss of Offsite Power

	Diesel Generator 1										
	Diesel Generator 2					2495		2560		2041	

NOTES:

(1) Sequencing of the diesel generator loads is accomplished by time delay relays on the individual components. This column gives the delay setpoints of the individual relays. The time delays start after:

a) The diesel generator supply breaker to the ESF bus closes to re-energize the bus (15 sec. maximum).

b) The particular EFAS signal is received.

Table 8.3-1 (continued)

(2) In determining diesel loading conditions, manufacturer's test data and system operating conditions were utilized. On components for which manufacturer's test data was not yet available, the motor horsepower ratings were used to ensure conservativeness of design. Table 8.3-1 does not list all loads connected to the ANO-2 Emergency Diesel Generator. However, the total expected maximum load (KW) values were derived from the total load, for all EDG loads, indicated in EDG calc. #85S-00002-01.

(3) The reactor coolant system pressure will be increased above the shutoff head of the safety injection pumps shortly after the main steam line rupture. These loads can be secured by the operator after the low system pressure signal has cleared. For the LOOP condition, no load should be present due to the LPSI pumps until shutdown cooling is established some time after 2 hours.

(4) Due to the short duration of these loads, their loading values were not considered for Diesel Continuous Rating.

(5) Switchgear Room Unit Coolers will auto re-start following LOOP if running pervious to loss of power.

(6) Capability to re-energize heaters (when the diesel generators are supplying power) is included.

(7) Battery charger rating for worst case charger, 2D31B, 400A current limit at 125 VDC (Non-1E charger, 2D33, rated 400A current limit at 125 VDC). Load assumes diesel generator is started after an 8-hour emergency duty cycle discharge of battery. Assume 1HP = 1KVA.

(8) Condition 1, Loss of Coolant Accident (LOCA) with loss of offsite power, actually includes the Small Break Loss of Coolant Accident (SBLOCA) condition. Both conditions are addressed in Calculation No. 85S-00002-01, and the equipment HP values shown in the table reflect the worst case loading of the two conditions.

(9) Full EFW flow is assumed during the first 2 hours of either accident condition. Operator action is generally credited with controlling flow beyond the 2 hour time frame.

(10) The 1E inverter loads are assumed to be zero for all periods because the battery charger loading is assumed to be at maximum output and this conservatively accounts for all DC loads, including inverters, throughout all load periods.

(11) The load shown for load center transformers 2X25 & 2X26 represent transformer losses only. The actual connected load on these transformers is represented by the loads on specific components downstream.

(12) There are 3 EDG backed Battery Room Exhaust Fans. Fan 2VEF61 is connected to EDG #1, and Fans 2VEF65 and 2VEF49 are connected to EDG #2. 2VEF61 and 2VEF65 have 2.5 HP motors, but the motor for 2VEF49 is 3 HP. Fans 2VEF49 and 2VEF61 will auto re-start following LOOP if running pervious to loss of power

NOTES

1. Battery sizing includes factors for 80% end of life and 60°F minimum operating temperature per IEEE 485-1983. These factors are in addition to the actual loads indicated above.

2. This emergency duty cycle curve represents an approximation of the actual loads on station battery 2D12. For the most current emergency duty cycle curve, review the controlled engineering calculations.

Table 8.3-7

4.16 kV ENGINEERED SAFETY FEATURES SYSTEM SINGLE FAILURE ANALYSIS

FAILURE	CAUSE	CONSEQUENCES AND COMMENTS
1. 4.16kV Power to bus 2A3 or 2A4	a. Failure of the associated DG (diesel generator) to start.	a. Failure of the DG to start will result in the loss of one complete ESF actuation channel. The redundant DG will start and supply the redundant ESF loads. The reliability of the DG to start has been enhanced considerably by the following design features: Starting Signal: SIAS backed-up by under voltage relays on 4.16 kV Bus. Starting System: Two air starting systems for each DG
	b. Failure of the DG to develop rated speed and voltage	b. The consequences will be identical to item a. A static excitation system has been used to improve reliability and to ensure fast voltage build-up.
	c. Failure of DG ACB 2A308/2A408 to autoclose	c. Consequences will be identical to item a. Electrical circuits have been designed so that failure of a single relay does not prevent autoclosing of the DG ACB.
	d. Bus fault on bus 2A3/2A4	d. A bus fault will lead to the operation of the bus lock-out relay. The redundant bus will provide the power to the redundant ESF loads.
	e. Loss of associated dc control power source.	e. DC control power to the two redundant 4.16 kV ESF systems supplied from the two redundant batteries. Loss of control power to any one system will not prevent the redundant system from performing the safety function.

Table 8.3-7 (continued)

FAILURE	CAUSE	CONSEQUENCES AND COMMENTS
	f. Failure of a tie/feeder breaker	f. The two tie breakers between the two busses 2A3 and 2A4 are mechanically locked out during plant operation. These can be used only during post-accident emergency situations when the preferred source is not available and one of the two diesels cannot be started. A failure of one of the two tie breakers cannot affect both redundant systems. One system can, however, be lost if a tie breaker develops a fault, or a fault on a feeder cable is not cleared by the association feeder breaker. This will lead to the operation of the bus lockout relay. Under this condition, the redundant 4.16 kV bus will supply the redundant ESF loads. The Alternate AC Power Source is electrically connected between the two tie breakers. Therefore, the tie breaker on the selected bus must be closed in response to a station blackout (Item 3 below). The ESF System is designed to operate without isolating any component on a single ground fault. As multi-phase faults are relatively few in number, reliability to complete safety functions is greatly increased. The tie/feeder breaker can also be used during shutdown (Modes 5 and 6).
2. 4.16 kV Load (Load Center, Service Water Pump,etc.)	a. Failure of Associated ACB to autoclose b. Stalled Motor c. Feeder Cable Fault	a,b,c. The redundant load on the redundant bus will perform the safety function. The load center feeder breakers are not tripped by load shedding relays. They remain connected to the bus so that they are instantly energized when the DG ACB auto closes. In order to guard against an accidental tripping, however, these breakers have an auto-close signal from the SIAS.

Table 8.3-7 (continued)

FAILURE	CAUSE	CONSEQUENCES AND COMMENTS
3. 4.16 kV Power to bus 2A3 and 2A4	a. Non-mechanistic failures as defined in the Station Blackout Rule (10CFR50.63) Loss of all AC Power, Station Blackout b. Loss of Offsite Power and simultaneous failures of both Emergency Diesel Generators due to any combination of items 1.a.-e. above.	This is recognized as a beyond design basis event, is outside of the accident analysis, and beyond the single failure criteria. However, due to the installation of the Alternate AC Power Source per 10CFR50.63, manual operator actions are available to respond to a total loss of AC Power. Within 10 minutes of procedurally declaring a Station Blackout, the operators will start and align the Alternate AC Power Source to either of the safety related 4160 volt buses 2A3 or 2A4. This will energize the selected bus and convert the consequences and operator responses to this scenario to ones similar to item 1.a. above.

Table 8.3-8

480-VOLT ENGINEERED SAFETY FEATURES SYSTEM SINGLE FAILURE ANALYSIS

FAILURE	CAUSE	CONSEQUENCES AND COMMENTS
1. 480 Power to bus 2B5 to 2B6	a. Failure of associated load center transformers b. 4.16 kV Cable Fault c. Bus Fault d. Failure of any Load Breaker to clear a fault.	Any of the four events a,b,c or d will cause the loss of 480 Volt ESF loads on one channel. The redundant 480 Volt load center bus will supply the redundant ESF loads.
	e. Loss of dc control power source.	The redundant 480V ESF load centers are supplied from the redundant batteries. A single failure will not result in the loss of control power to both redundant systems.
2. 480V MCC Feeders	a. Feeder Cable Fault b. MCC Bus Fault c. Failure of any MCC load feeder breaker to clear a fault.	Any of the events a, b, or c will result in the loss of 480V power to the ESF loads connected to the affected MCC. The redundant loads connected to the redundant MCC will perform the safety function.
3. 480 Volt Loads	a. Feeder cables Fault b. Stalled Motor	The result will be the loss of the affected actuated component. The redundant component on the other channel will perform the safety function.

Table 8.3-9

120/208-VOLT INSTRUMENT AC SYSTEM SINGLE FAILURE ANALYSIS

FAILURE	CAUSE	CONSEQUENCES AND COMMENTS
1. Power to bus 2Y1/2Y2	a. Failure of associated transformer 2X11/2X12 b. Cable fault c. Failure of any load breaker to clear fault d. Bus Fault e. Fault on the tie breaker	Any of these five events will result in the loss of power to the 120/208V loads on one channel. The unaffected bus will supply the redundant ESF The tie breakers between buses 2Y1 and 2Y2 are mechanically interlocked with the incoming feeder breakers (See Figure 8.3-6) to prevent tying the two diesel generator systems together. Since the two tie breakers are locked out during plant operation, a fault on one cannot affect both redundant systems
2. Any distribution feeder	Cable fault	This will result in loss of power to the connected loads. The redundant loads on the unaffected channel are adequate to insure safety.

Table 8.3-10

120-VOLT VITAL AC SYSTEM SINGLE FAILURE ANALYSIS

FAILURE	CAUSE	CONSEQUENCES AND COMMENTS
1. 120 VAC Power to buses 2RS1, 2RS2, 2RS3, 2RS4	a. Bus Fault b. Cable Fault c. Failure of a distribution breaker to clear a fault	The result will be the loss of 120 volt vital ac power supply to one of the four channels of the protection system. As a 2 out of 3 with the fourth channel bypassed criteria is used in all the logic circuits, the remaining channels ensure safe shutdown. The 120 volt vital AC system has been designed as an ungrounded system. The reliability of any channels is consequently greatly enhanced.
2. Any distribution feeder	Cable Fault	This will result in the loss of power to the connected loads. The redundant loads in the remaining three channels are adequate to ensure safety.
3. De-energization of (2RS1 and 2RS3) or (2RS2 and 2RS4)	2D01 or 2D02 bus fault	Loss of vital instrument power to two channels of vital AC results in the RPS failing safe (reactor trips). ESFAS functions with increasing signal setpoint remain operable with one channel tripped and one channel unable to function. ESFAS functions with decreasing signal setpoints fail to their actuated position. Loss of power to the instrumentation for one load group results.

Table 8.3-11

125-VOLT DC ENGINEERED SAFETY FEATURE SYSTEM SINGLE FAILURE ANALYSIS

FAILURE	CAUSE	CONSEQUENCES AND COMMENTS
1. 125V DC power to bus 2D01 or 2D02	a. Bus Fault b. Failure of Load Breaker to clear fault	The bus fault is **assumed** to cause a secondary plant trip that results in loss of 480 VAC to the faulted train due to loss of control voltage to the secondary plant, offsite switchgear, on-site switchgear, and EDG. Thus, both vital AC inverters on the faulted train de-energize. In the event of the loss of one DC bus, the redundant bus will supply control power to the ESF loads of the non-faulted train/load group including two vital AC inverters.
2. Battery Charger	a. 480V Power Supply Failure b. Charger Fault	The battery charger is the normal source of DC power. If there is a charger failure, the battery will provide the DC power without interruption. The batteries are sized to meet all ESF load requirements to ensure safe shutdown.
3. Loss of any Control Center breaker	a. Cable Fault b. Bus Fault in the Distribution Panel Distribution Feeder fault not cleared by associated breaker in the distribution panel.	Loss of power to one of the redundant 125V DC distribution panels will result in loss of control power to the connected ESF loads. The redundant loads connected to the redundant DC system will ensure safe shutdown.
4. Loss of any Distribution Feeder	a. Cable Fault	The fault will be isolated by the associated breaker in the distribution panel. Connected loads on that feeder circuit will lose 125V DC control power. The redundant loads supplied by DC control power from the redundant DC system will provide the ESF function for the disabled circuits.

Table 8.3-12

SINGLE FAILURE ANALYSIS OF TRANSFER TO PREFERRED POWER SOURCE UPON UNIT TRIP

FAILURE	CAUSE	CONSEQUENCES AND COMMENTS
1. DC power supply lockout relays 286-G2-1&2 or DC power supply to lockout relays 286-G2-3&4	a. Loss of DC associated distribution panel b. Control DC fuse failure	No effect. The duplicate set of lockout relays powered from its associated DC distribution panel will perform all emergency functions and ensure transfer to the preferred power source. Fast transfer will take place if offsite power is available. If the preferred power source is not available, the undervoltage relays on the 4.16 KV ESF buses will start the diesel generators (DG) automatically and meet the load requirements.
2. Damage raceways to panel 2C20 or 2C10	Earthquake or foreign objects falling on the non-class IE raceways	This is the worst case failure. Complete destruction of all non-class 1E cables will disable control circuits of unit auxiliary and preferred source switchgear. Hence, tripping of unit auxiliary transformer No. 2 breaker or transfer to the preferred source cannot occur. Undervoltage relays 127-2A3/2A4-1 on 4.16 KV. ESF busses 2A3/2A4 isolate the DG busses by tripping the incoming feeder breakers 2A309/2A409. Consequently, the functioning of the safety related loads will not be affected.
3. Unit auxiliary transformer No.2 breaker 2A112/2A212	Mechanical failure to trip on trip signal	This will lead to the lockout of one of the bus sections 2A1/2A2. The remaining bus section will be transferred to the preferred source.
4. De-energization of switchgear control power	a. Loss of DC associated distribution panel b. Control DC fuse/circuit breaker	Loss of single power train. The second power train applies control DC independent of the faulted train.

9 AUXILIARY SYSTEMS

The auxiliary systems discussed in this chapter are those supporting systems which are required to ensure the safe operation, protection or servicing of the major unit systems and, principally, the Reactor Coolant System. In some cases the dependable operation of several systems is required to fulfill the above requirements and, additionally, certain systems are required to operate under emergency conditions. The extent of the information provided for each system is commensurate with the relative contribution of, or reliance placed upon the system in relation to the overall plant safety.

The majority of the active components within these systems are located outside of the containment. Those systems with connecting piping or duct work between the containment and the reactor auxiliary building are equipped with containment isolation valves as described in Section 6.2.4.

9.1 FUEL STORAGE AND HANDLING

Design criteria for the fuel storage and handling equipment in the spent fuel pool storage facility are specified to meet the intent of Regulatory Guides 1.13 and 1.29.

Under conditions of the normal loads augmented by the Design Basis Earthquake (DBE), no equipment failure will result in the breaching of the cladding of more than one spent fuel bundle, or result in a condition of criticality due to destruction of the geometry of the fuel storage arrays. Assurance is provided by designs which prevent components, under seismic conditions, from falling into the stored fuel. More than one load cannot be moved over the spent fuel at the same time if the combined weight is greater than 2000 pounds.

9.1.1 NEW FUEL STORAGE

9.1.1.1 Design Bases

The new fuel storage rack is designed to:

A. Store 63 fuel assemblies;

B. Provide sufficient spacing between the fuel assemblies to maintain a subcritical array during flooding with non-borated water;

C. Maintain a subcritical array under all design loadings, including the DBE;

D. Preclude the possibility of a fuel assembly being placed between the new fuel cavities;

E. Maintain a subcriticality of at least five percent for the simultaneous occurrence of Design Bases "B" and "C";

F. Maintain a subcriticality of at least two percent in the event of optimum moderation due to envelopment in a uniformly dense aqueous foam.

9.1.1.2 Facility Description

The method of transferring new fuel into the fuel handling building and placing it into the new fuel storage racks is discussed in Section 9.1.4.

Security-Related Information
Text Withheld Under 10 CFR 2.390

The new fuel storage racks consist of 63 square cavities fixed together in a large array. The internal dimensions of the cavities (8.56 inches x 8.56 inches) are sufficient to hold one fuel assembly in a vertical position.

The supporting structure is designed to limit deflections so that subcriticality is maintained under all anticipated loadings. The clearance between structural framing members is small enough to prevent the wedging of a fuel assembly between adjacent cavities.

The new fuel is subjected to a maximum ambient temperature of 120 °F.

There is not sufficient room in the new fuel racks to store all the fuel assemblies for a full core load. New fuel assemblies may also be stored in the spent fuel racks which are described in Section 9.1.2.

9.1.1.3 Safety Evaluation

The new fuel in the storage racks is subcritical by at least five percent under the assumption of flooding with non-borated water.

The new fuel storage racks are designed in accordance with the American Institute of Steel Construction (AISC) Specification for the Design, Fabrication and Erection of Structural Steel for Building and meets ANSI Standard N18.2, Paragraph 5.7.4.1.

Lateral loads exerted on the rack support structure are resisted by a vertical bracing system which transmits these forces to the concrete floor or through horizontal members into the concrete walls via anchor bolts. Lateral movement of the rack with any number of fuel assemblies is prevented by these supports for all anticipated loadings.

Structural deformation of the racks is limited to ensure that adequate edge to edge spacing between assemblies is maintained to prevent inadvertent criticality.

The new fuel storage racks are Seismic Class 1, i.e., designed to withstand loads that may be induced by earthquake and tornados.

The storage facility design precludes inadvertent placement of fuel assemblies in any location except specified storage locations.

The principal method for the criticality analysis of the new fuel vault is the three-dimensional Monte Carlo code MCNP4a. MCNP4a is a continuous energy three-dimensional Monte Carlo code developed at the Los Alamos National Laboratory. MCNP4a was selected because it has been used previously and verified for criticality analyses and has all of the necessary features for this analysis. MCNP4a calculations used continuous energy cross-section data based on ENDF/B-V.

The following conservative modeling assumptions were used in the analyses:

- All structural materials of the new fuel storage racks, refuel canal racks, and the fuel handling equipment are conservatively neglected and replaced with water.

- The distance between the new storage racks and the surrounding concrete walls, measured from the center of the outer storage locations range between about 44 inches to 100 inches. In the analysis, a distance of 40 inches was used on all sides. This is conservative since it places the concrete walls closer to the fuel, resulting in increased neutron reflection from these walls.

- For all full density water calculations, the models use the bounding assumption regarding manufacturing tolerances, i.e. maximum fuel enrichment, maximum fuel density, and minimum assembly pitch (if applicable).

- A bounding nominal fuel density of 10.522 g/cm^3 and a bounding active length of 150 inches are used for the fuel types analyzed.

- Tolerances for fuel enrichment and fuel density are assumed values based on industry standards.

- The fuel pellet density is conservatively used for the stack density.

Considering new fuel assemblies described by the parameters shown in Table 9.1-7 with enrichments of up to 4.95 weight percent U-235, K_{eff} is calculated to be 0.9765, which is less than 0.98, for postulated conditions of envelopment of the entire array with a uniform low density aqueous foam, and, 0.9215, which is less than 0.95, under conditions of flooding by unborated room temperature water. The calculated K_{eff} includes a conservative allowance for uncertainties.

Regulatory Position 3 of Regulatory Guide 1.13 requires that "Interlocks should be provided to prevent cranes from passing over stored fuel...when fuel handling is not in progress." The only device capable of placing loads over the new fuel racks is the 4-ton capacity fuel transfer hoist. This hoist is used for fuel handling and may be used to move other loads over the SFP if under proper supervision, administrative controls, and in compliance with Technical Specifications. The hoist may also be used to lift loads in excess of 2000 pounds, but they cannot be moved over the SFP. The hoist disconnect switch is open under administrative control is open under administrative control to control operation of the hoist.

9.1.2 SPENT FUEL STORAGE

9.1.2.1 <u>Design Bases</u>

The spent fuel pool design satisfies the following criteria:

A. Safe storage is provided for approximately one core and eleven reload batches of spent fuel assemblies (including Control Element Assemblies (CEAs)), new fuel stored under water during core reloading and the spent fuel shipping cask.

B. Handling equipment includes protection devices such as travel limits and interlocks to minimize the probability of damage to fuel assemblies or handling equipment.

C. Spacing of fuel in the storage rack ensures a subcriticality of at least five percent assuming: (1) the storage configurations described in Technical Specification Table 3.9-1 are maintained and fuel assemblies contain enrichments no greater than 4.95 weight percent U-235 described by the parameters shown in Table 9.1-7; (2) the consideration of structural, fuel assembly position, and fuel parameter tolerances; (3) an allowance for calculational and manufacturing uncertainties; and (4) no credit for fixed integral poisons within the fuel assemblies. In addition, credit was taken for soluble boron in the pool water to offset the effects of postulated accidents and to maintain $K_{eff} < 0.95$.

D. Sufficient pool water level is maintained at all times to ensure that the pool surface dose rate does not exceed 5 mrem/hr. Shielding is further discussed in Chapter 12.

E. The spent fuel rack is designed such that its natural frequency is above the normal range of earthquake critical frequencies and the structure will withstand design basis earthquake loadings.

9.1.2.2 Facilities Description

The spent fuel storage racks provide 988 storage locations in a rectangular array for spent fuel assemblies or other items (e.g. incore detectors) which require long term submerged storage. The racks are comprised of four modules, containing 81 fuel storage locations each, in a 9 x 9 array; four modules, containing 90 fuel storage locations each, in a 9 x 10 array; two modules containing 80 fuel storage locations, in an 8 x 10 array; and, two modules containing 72 fuel storage locations, in an 8 x 9 array. Region 1 and Region 2 storage rack cell layouts are shown in Figures 9.1-18 and 9.1-12, respectively. All twelve modules are free standing structures and are arranged as shown in Figure 9.1-13. The spent fuel pool is lined with type 304L stainless steel.

Non-fuel irradiated components are stored in the Spent Fuel Pool for radioactive decay until such time as they can be shipped offsite. An inventory of these items is maintained.

Each fuel storage module is made up of rectangular storage cells which are capable of accepting one fuel assembly. The cells are open at the top and bottom to provide a flow path for convective cooling of spent fuel assemblies through natural circulation. The fuel storage cells are structurally connected to form storage modules which provide the assurance that the required minimum fuel assembly spacing is maintained for all design conditions including the DBE.

All welded construction is used in fabrication of the fuel storage cells and in the interconnection of cells to form each module. The fuel storage modules are constructed of type 304 stainless steel. The all welded construction ensures the structural integrity of the storage modules and provides assurance of smooth snag free paths in the storage cells so that it is highly improbable that a fuel assembly could become stuck in the racks.

Structural and Seismic Considerations

The purpose of the seismic and stress analysis is to analyze the spent fuel racks under various loading conditions. The racks are evaluated for both operating basis earthquake (OBE) and safe shutdown earthquake (SSE) conditions and meet Seismic Category I requirements. A detailed stress analysis is performed to verify the acceptability of the critical load components

and paths under normal and faulted conditions. The racks rest freely on the pool floor and are evaluated to ensure that under various loading conditions they do not impact each other, nor do they impact the pool walls.

Seismic Analysis

The dynamic response of the fuel rack assemblies during a seismic event is the condition which produces the governing loads and stresses on the structure. The dynamic response, internal stresses, and loads are obtained from a seismic analysis which is performed in two phases. The first phase is a time history analysis on a simplified nonlinear finite element model. The second phase is an analysis of a detailed rack assembly finite element model. The damping values used in the seismic analysis are two percent damping for OBE and four percent damping for SSE as specified in NRC Regulatory Guide 1.61.

The simplified nonlinear finite element model is used to determine the fuel rack response for the structural characteristics of a submerged rack assembly. The nonlinearities of the fuel rack assembly, which are accounted for in the model, are in the gaps between the fuel cell and the fuel assembly, the boundary conditions of the fuel rack support locations, and the energy losses at the support locations. Additionally, gaps between the rack and pool walls were included in the single rack models, and gaps between the racks were included in full pool models which included representation for all twelve racks simultaneously.

For the Region 2 racks, the WECAN computer program was used to determine the nonlinear time history response of the fuel assembly/fuel rack system. The fuel assembly to cell impact loads, and overall rack response were obtained from the nonlinear time history results.

The detail model for the Region 2 racks is a three-dimensional finite element representation of a rack assembly consisting of discrete three-dimensional beams interconnected at a finite number of model points. The results of the nonlinear time history model are incorporated in the detail model. Since the detail model does not account for the nonlinear effect of a fuel rack assembly, the internal loads and stresses for the rack assembly obtained from this model are corrected by load correction factors. The load correction factor is derived from the nonlinear model results and is applied to the components in the stress analysis. The responses of the model from accelerations in three directions are combined by the Square Root Sum of the Squares method in the stress analysis. The loads in two major components (support pad assembly and fuel cell) are examined, and the maximum loaded section of each of these components is found. These maximum loads from the detail model are corrected by the nonlinear load correction factors and used in the stress analysis to obtain the stresses within the rack assembly.

The Region 1 racks were evaluated to determine the nonlinear time history response of the assembly/fuel rack system, and also for the whole pool multi rack configuration. Similar to the analysis of the Region 2 racks, the fuel assembly to cell impact loads and overall rack responses were obtained from the nonlinear time history results.

The detailed models for the Region 1 racks consist of three-dimensional finite element representations of the rack assemblies using shell and beam elements. The detailed models were used to determine equivalent structural properties for the simplified nonlinear models, and also to determine stresses and displacements using results from the nonlinear analyses as input. A thermal analysis of the Region 1 rack was also performed using the detailed model.

Fuel Rack Structural Analysis

The stress analysis for the racks is performed using the load combinations specified in the "NRC Position for Review and Acceptance of Spent Fuel Storage and Handling Application."

The thermal loads due to rack expansion relative to the pool floor are negligible since the support pads are not structurally restrained in the lateral direction. The major seismic loads are produced by the operational basis earthquake (OBE) and safe shutdown earthquake (SSE) events.

It is noted from the seismic analysis that the magnitude of stresses vary considerably from one geometrical location to the other in the model. Consequently, the maximum loaded cell assembly, grid assembly, and the leveling pad assembly are analyzed. Such an analysis envelopes the other areas of the rack assembly.

For the Region 2 racks, the detailed models considered a single cell. Because of structural symmetry of the cell assembly about the x and y axes, the x and y direction horizontal seismic events produce identical loads. Consequently, the margins of safety for the multi-direction (x and y directions simultaneously) seismic event is computed by multiplying the unidirectional loads by $\sqrt{2}$. The loads described in the seismic analysis section are adjusted by load modification factors obtained from the nonlinear analysis.

For the Region 1 racks, the detailed models were for the full racks, and the maximum x and y directions horizontal seismic load effects from the nonlinear models were applied and combined by SRSS.

The computed stresses from all the rack analyses are below the allowable stresses as required by the NRC Position Paper.

Fuel Handling Crane Uplift Analysis

A fuel handling crane uplift analysis demonstrates that the racks can withstand the maximum 3000 pound uplift load of the fuel handling crane without violating the criticality acceptance criteria. In this analysis the uplift load is assumed to be applied to a fuel cell. Resulting stresses are within acceptable limits, and there is no change in rack geometry of a magnitude which causes the criticality acceptance criteria to be violated.

Fuel Bundle/Module Impact Evaluation

An analysis is performed to evaluate the effect of an impact load due to fuel assembly and fuel storage cell interaction during a seismic event. The fuel rack system consists of an array of cells which form the fuel rack structure and fuel assemblies. The fuel rack system is located in the spent fuel pool and is submerged in water.

Since the fuel assembly is stored within the cell, the gap between the fuel assembly grid and cell changes (i.e., opens and closes) during a seismic event. From the equation of motion for such a system it is evident that the fuel rack system is nonlinear. This condition necessitates the performance of a transient dynamic analysis.

The mathematical features of the nonlinear fuel rack model facilitate the determination of the fuel assembly/cell interaction and hydrodynamic mass (fluid mass) effects on the fuel rack response during seismic excitation.

The effect of fuel assembly and fuel storage cell impact force on the rigid body displacements is obtained from the nonlinear analysis. The analysis is conducted with a minimum coefficient of friction of 0.2, and it is shown that the rigid body displacement is minimal. Thus, impact between adjacent rack modules or between a rack module and the pool wall is precluded.

The fuel assembly and fuel storage cell impact forces obtained from the nonlinear analysis are used to evaluate the effects on the fuel rack structure and fuel assembly structure. These loads are within the allowable limits of the fuel rack module material and fuel assembly materials. Therefore, there is no damage to the fuel assembly or fuel rack module due to impact loads.

The fuel racks are analyzed for the normal and faulted load combinations in accordance with the "NRC Position for Review and Acceptance of Spent Fuel Storage and Handling Applications."

The major normal and upset condition loads are produced by the operational basis earthquakes (OBE). The thermal stresses due to rack expansion relative to the pool floor are negligible since the support pads are not structurally restrained in the lateral direction.

The faulted condition loads are produced by the safe shutdown earthquakes (SSE) and a postulated fuel assembly drop accident.

The stresses for the SSE load combinations are below the allowable stresses as required by the ASME B&PV Code, Section III, Subsection NF.

For the postulated fuel assembly drop accident, the acceptance criteria is that the impact resulting from the drop of the fuel assembly will either not cause permanent damage in the active fuel region, or that the consequences of damage in the active fuel region are shown by a criticality analysis that the neutron multiplication factor does not exceed 0.95. For the Region 1 racks, such damage from the fuel assembly drop accident was shown to extend slightly into the active fuel region; however, a subsequent criticality analysis demonstrated acceptability.

In summary, the results of the seismic and structural analyses show that the ANO spent fuel storage racks meet all the structural acceptance criteria adequately.

Pool Structural Analysis

The existing structures were analyzed for the modified fuel rack loads using the STARDYNE finite element computer program. The finite element models consisted of the pool walls and floor, foundation walls, cask laydown area, and fuel transfer canal area with the lowest elevation of 335'-0" assumed as a fixed boundary. The pool walls and floor slabs are modeled utilizing two layers of three dimensional solid "brick" elements with three degrees of freedom per node. In order to permit recovery of cube surface stresses, extremely thin quadrilateral membrane elements coincident with the nodes forming the surface of the solid elements were utilized. Recovery of these stresses along with cube centroidal stresses permitted the calculation of the required resultant forces and moments for an American Concrete Institute Code evaluation. The foundation walls were modeled using only one layer of brick elements through the thickness.

The pool liner was not modeled since it is not acceptable to count on its stiffness contribution to the overall pool capacity. However, stress evaluation of this component was conducted using results obtained from the computer analysis.

In order to correctly represent boundary conditions, modeling of the floor diaphragms and shear walls attached to the spent fuel pool was accomplished utilizing STARDYNE matrix elements.

Section 9.1.4.2.10 discusses design features which prevent movement of the spent fuel cask over the spent fuel racks. The postulated cask drop incident on the racks is therefore not addressed.

During loading of spent fuel assemblies for shipment, the spent fuel shipping cask is located in the cask loading pit to allow the required minimum water level covering over spent fuel being transferred. After placing the cask cover on the cask, the unit is transferred to the cask work platform or washdown area by the fuel handling crane.

Interlocks on the spent fuel handling machine prevent movement of a fuel assembly into the pool walls. Limit switches prevent raising fuel where less than 9.5 feet separate the top of the active fuel and the surface of the pool water. The maximum dose rate at the water surface will be less than 5 mrem/hr and is calculated using the most active fuel assembly 100 hours after shutdown. The concrete walls of the fuel transfer canal and spent fuel pool and the structure of the spent fuel handling machine will supplement the water shielding and limit the maximum continuous radiation dose level in working areas to less than 2.5 mrem/hr. The machine cannot physically raise fuel more than one foot above the interlock setpoint if the interlock should fail and there is no operator action. Design of the spent fuel grapple prohibits accidental release of fuel. A wall separates the fuel pool from the cask loading pit.

9.1.2.3 <u>Nuclear Considerations</u>

The spent fuel rack design described herein employs two separate and different arrays. The smaller array, referred to as Region 1, uses Metamic®, a fixed poison absorber, in a "flux trap" design. The larger array, Region 2, utilizes a "spacer pocket" design.

<u>Criticality Analytical Methodology</u>

The principal method for the criticality analysis of the storage racks is the three-dimensional Monte Carlo code MCNP4a. MCNP4a is a continuous energy three-dimensional Monte Carlo code developed at the Los Alamos National Laboratory. MCNP4a was selected because it has been used previously and verified for criticality analyses and has all of the necessary features for this analysis. MCNP4a calculations used continuous energy cross-section data based on ENDF/B-V and ENDF/B-VI libraries.

Fuel depletion analyses during core operation were performed with CASMO-4 (using the 70-group cross-section library), a two-dimensional multi-group transport theory code based on capture probabilities. CASMO-4 is also used to determine the isotopic composition of the spent fuel. In addition, the CASMO-4 calculations are restarted in the storage rack geometry yielding the two-dimensional infinite multiplication factor (k_{inf}) for the storage rack to determine the reactivity effect of fuel and rack tolerances, temperature variation, depletion uncertainty, and to perform various studies. For all calculations in the spent fuel pool racks, the Xe-135 concentration in the fuel is conservatively set to zero.

Fuel assembly and rack geometry mechanical tolerances are evaluated through a statistical combination of the reactivity associated with each tolerance. The maximum k_{eff} is determined from the MCNP4a calculated k_{eff}, the calculational bias, the temperature bias, and the applicable

uncertainties and tolerances (bias uncertainty, calculational uncertainty, rack tolerances, fuel tolerances, depletion uncertainty). In the geometric models used for the calculations, each fuel rod and its cladding were described explicitly and reflecting or periodic boundary conditions were used in the radial direction which has the effect of creating an infinite radial array of storage cells.

Criticality Analysis

The objective of this analysis is to ensure that the effective neutron multiplication factor (k_{eff}) is less than or equal to 0.95 with the storage racks fully loaded with fuel of the highest permissible reactivity and the pool flooded with borated water at a temperature corresponding to the highest reactivity. In addition, it is demonstrated that the k_{eff} is less than 1.0 under the assumed accident of the loss of soluble boron in the pool water, i.e. assuming unborated water in the spent fuel pool. The maximum calculated reactivities include a margin for uncertainty in reactivity calculations, including manufacturing tolerances, and are calculated with a 95% probability at a 95% confidence level.

- USNRC Regulatory Guide 1.13, Spent Fuel Storage Facility Design Basis, Rev. 2 (proposed), December 1981.
- ANSI ANS-8.17-1984, Criticality Safety Criteria for the Handling, Storage and Transportation of LWR Fuel Outside Reactors.
- Code of Federal Regulation 10 CFR 50.68, Criticality Accident Requirements (for soluble boron).

ANO Unit 2 currently complies in whole with 10 CFR 50.68(b).

Criticality of fuel assemblies in the spent fuel storage racks is prevented by the design of the rack which limits fuel assembly interaction, and by establishing loading restrictions for Region 1 and Region 2 storage racks. Technical Specification Table 3.9-1 shows the loading restrictions for the Region 1 and Region 2 racks, the peripheral cells for Region 2, and rack interface allowances.

To assure the true reactivity will always be less than the calculated reactivity, the following conservative design criteria and assumptions were employed:

1. Moderator is borated or unborated water at a temperature in the operating range that results in the highest reactivity, as determined by the analysis.

2. Neutron absorption in minor structural members is neglected, i.e., spacer grids are replaced by water.

3. The effective multiplication factor of an infinite radial array of fuel assemblies was used in the analyses, except for the assessment of certain abnormal/accident conditions or where neutron leakage is inherent, such as for the analysis of the peripheral rack cells.

4. The B_4C loading in the neutron absorber panels is nominally 30.5 wt%, with an uncertainty of +0.5/-1.0 wt%.

5. The presence of burnable absorbers (B_4C, Gadolinium, Erbium, IFBA) in fresh fuel is neglected. This is conservative as burnable absorbers would reduce the reactivity of the fresh fuel assembly.

6. When multiple enrichments are used within an assembly, the average enrichment is used for all fuel pins, i.e. distributed enrichments are neglected.

Calculations have been performed to qualify the Region 1 racks for storage of fuel assemblies with a maximum nominal initial enrichment of 4.95 wt% $_{235}U$. The criticality analyses for Region 1 of the spent fuel storage pool demonstrate that for the defined acceptance criteria, the maximum k_{eff} is less than 1.0 without credit for soluble boron and less than 0.95 with credit taken for soluble boron.

Calculations have been performed to qualify the Region 2 racks for storage of fuel assemblies with a maximum nominal initial enrichment of 4.95 wt% $_{235}U$ which have accumulated a minimum burnup of 46.8 GWD/MTU or fuel of initial enrichment, burnup and cooling time combinations depicted in Tech Spec Table 3.9-1. Additionally, the spent fuel configuration is qualified to store lower burned fuel on the rack periphery, which have accumulated a minimum burnup of 33.3 GWD/MTU or fuel of initial enrichment and burnup combinations depicted in Tech Spec Table 3.9-1. It is also demonstrated that a checkerboard of empty storage locations and fresh fuel assemblies with a maximum nominal enrichment of 4.95 wt% 235U is acceptable. The criticality analyses for Region 2 of the spent fuel storage pool demonstrate that for the defined acceptance criteria, the maximum k_{eff} is less than 1.0 without credit for soluble boron and less than 0.95 with credit taken for soluble boron.

Rack interface calculations have been performed to include spent and fresh fuel loading patterns within the same rack and between interfacing racks (Region 2-Region 2 and Region 1-Region 2) to determine acceptability. Results of these interface calculations and a description of acceptable loading patterns are depicted in Tech Spec Table 3.9-1.

Credit for soluble boron is required to ensure k_{eff} is maintained less than 0.95 and the required soluble boron concentrations are less than the Technical Specifications requirement of > 2000 ppm.

Postulated Spent Fuel Storage Criticality Accidents

Most accident conditions will not result in an increase in K_{eff} of the rack. However, there are accidents that can be postulated to increase reactivity. For these accident conditions, the double contingency principle of ANS N16.1-1975 is applied. This states that it is unnecessary to assume two unlikely, independent, concurrent events to ensure protection against a criticality accident. Thus, for accident conditions, the presence of soluble boron in the storage pool water can be assumed as a realistic initial condition since its absence would be a second unlikely event.

A fuel assembly dropped on top of the rack will not deform the rack structure pertinent for criticality. The rack structure is such that an assembly positioned horizontally on top of the rack is more than twelve inches away from the upper end of the active fuel region of the stored assemblies. This distance precludes interaction between the dropped assembly and the stored fuel.

A vertical drop of a fuel assembly onto the top of a Region 1 rack may damage the neutron absorbers around the cells. For conservatism, the top 20 inches of the Metamic® material covering the active fuel length were assumed to be replaced with water in all fuel cells. Results show that the maximum k_{eff} including bias and uncertainties remains below regulatory limits. It is also possible to vertically drop a fuel assembly into a location that might be occupied by another assembly or that might be empty. Such a vertical impact would at most cause a small compression of the stored assembly, if present, or result in a small deformation of the baseplate for an empty cell. These deformations could potentially increase reactivity. However, the reactivity increase would be small compared to the reactivity increase created by the misloading of a fresh assembly and is therefore bounded by the misloading accident.

An inadvertent drop of an assembly between the outside periphery of the rack and the pool wall cannot occur. The distance between all the rack modules and to the pool walls is less than the width of a fuel assembly.

The fuel assembly misplacement accident was considered for all storage configurations. The misplacement of a fresh unburned fuel assembly of the highest permissible reactivity could, in the absence of soluble poison result in exceeding the regulatory limit (k_{eff} < .95). This could occur if a fresh fuel assembly of the highest permissible initial enrichment (4.95 wt% U-235) were to be inadvertently loaded into a storage cell which is intended to store spent fuel assemblies or remain empty. Soluble boron in the spent fuel pool water, for which credit is permitted under these accident conditions, would assure that the reactivity is maintained substantially less than the design limitation. Calculations confirm that the required boron concentration to maintain k_{eff} less than 0.95 is less than the Technical Specification requirement of > 2000 ppm.

For fuel storage applications, water is usually present. An "optimum moderation" accident is not a problem in spent fuel pool storage racks because the rack design prevents the preferential reduction of water density between the cells of a rack (e.g., boiling between cells).

Acceptance Criterion for Criticality and Other Considerations

Fuel pool piping is designed with siphon breakers to ensure that no postulated failure would result in uncovering the fuel. Appropriate pool cooling temperature and level alarms are provided. Backup cooling or makeup water may be provided from the Refueling Water Tank (RWT), boric acid makeup tanks, or Service Water System (SWS).

The spent fuel storage facility is located in the containment auxiliary building adjacent to the east side of the containment. The pool is a Seismic Class 1 structure. Controlled ventilation exhausting through carbon and HEPA filters is provided in this area.

Series isolation dampers are not provided for the fuel storage area ventilation system because the system must remain in operation following the fuel handling accident (see Section 15.1.23). Since the fuel handling area is not tornado missile protected, fuel handling during tornado watch periods is administratively prohibited. In addition, the system is not Seismic Category 1 based on the fact that a seismic event and a fuel handling accident were not postulated to occur simultaneously. Furthermore, the building siding is not Seismic Category 1.

Shielding and radiological controls are discussed in Chapter 12. Location of the spent fuel pool is such that, of the spent fuel and new fuel, only new fuel is transported across the pool. Spent fuel casks are not carried over any area of the pool. No other fuel handling activities have to be carried out above the pool. Loads may be transported over the SFP if under the proper supervision, administrative controls, and in compliance with Technical Specifications.

In accordance with Position 5.b of Regulatory Guide 1.13, the fuel pool is designed to withstand, without leakage which would uncover the fuel, the impact of the heaviest load to be carried by the overhead fuel handling crane, L-3, from the maximum height to which it can be lifted. Using the missile penetration techniques described in Section 3.5.4.1, an analysis was performed to determine the penetration of a fuel element and grapple dropped from the maximum hoisting height of the fuel handling crane to the fuel pool floor. A maximum 4-inch penetration in the 5-foot, 9-inch thick floor slab was calculated using the following extremely conservative assumptions:

A. No credit was taken for kinetic energy lost due to splashdown wave formation;

B. No credit was taken for deceleration due to viscous drag in the water;

C. No credit was taken for obstruction in the fuel pool such as the fuel rack structure;

D. A perpendicular impact was assumed with no credit taken for impingement at some obtuse angle due to the lateral motion of the traversing crane at the time of drop;

E. No credit was taken for kinetic energy lost due to liner plate perforation; and,

F. No credit was taken for deformation or plastic strain energy absorption by the fuel element upon impact.

More than 90 percent of the fuel pool floor area is protected by the fuel storage racks and cooling piping. In the unlikely event that a fuel element was dropped from the maximum height possible and it did strike the fuel pool floor, the damage to the floor would not be significant or result in leakage in excess of the normal pool makeup capacity.

9.1.2.4 Testing and Inspection

The spent fuel racks are a Seismic Class 1, Quality Class 2 structure and are manufactured in accordance with the requirements of an approved Appendix B Quality Assurance Program. Alignment of the racks and spent fuel handling equipment is periodically checked prior to handling fuel assemblies by operation of the systems with the use of a dummy fuel assembly which has the same weight, center of gravity, exterior size and end geometry as a fuel assembly.

9.1.2.5 Instrumentation Applications

Temperature, water level, and radiation monitoring and alarm instrumentation are provided in the control room and/or locally to verify that the decay heat from the spent fuel assemblies is being removed. The location of the area radiation monitoring in the fuel handling area is discussed in Chapter 12. An indication of the radiation in the area is given by the high radiation alarms.

9.1.2.A VSC-24 Dry Spent Fuel Storage

The Independent Spent Fuel Storage Installation (ISFSI) is a passive, dry cask storage system consisting of a concrete cask storage pad located within a separate fence inside the site controlled area, portions of the site rail system for movement of components between the pad and the plant train bay, and the support equipment to lift and transport the cask from the spent fuel pool to its assigned storage location. The ISFSI is expandable to meet future site storage requirements. One dry cask storage system utilized is Sierra Nuclear Corporation's Ventilated Storage Cask (VSC) system. The VSC is comprised of a metal basket, the Multi-assembly Sealed Basket (MSB) that contains the fuel, a transfer cask, the MSB Transfer Cask (MTC), and a concrete outer shell, the Ventilated Concrete Cask (VCC). These components are Safety Related as described in the NRC approved SAR and Certificate of Compliance (C of C) for Dry Spent Fuel Storage Casks under 10 CFR 72.214. Since the dry fuel storage cask system has been independently reviewed and approved for use by the NRC, apart from the reactor licenses, the full description of the system is in other documents. These include the VSC SAR, the VSC C of C, the ANO site specific VSC Specifications and Drawings, the NRC Safety Evaluation Report (SER), and ANO Engineering Report 95-R-0015-01. Equipment used with the VSC system include non safety related impact limiters that are positioned at the bottom of the Cask Loading Pit (CLP), safety related impact limiters that attach to the bottom of the MTC, a work platform that holds the MTC over the CLP for welding of the MSB following fuel loading, a MTC dolly, a VCC rail car, and an air pallet system that is used to move the VCC from the storage pad to the VCC rail car and back with a loaded MSB. The MTC dolly is used to transport the MTC to and from the Auxiliary Building to the Turbine Building in the train bay.

The ANO ISFSI cask storage pad for the VSC-24 system is not seismically qualified, but has been analyzed and designed to support the postulated worst case static cask loading conditions. The storage pad is a 2′ thick reinforced concrete slab with reinforced 8″ deep by 2′0″ wide haunches around the perimeter of the pad. The pad is 45′0″ wide by 135′0″ long. The pad is located within the ANO security fence approximately 500 feet east of the Auxiliary Building. The pad area was undercut four (4) feet and filled with compacted low plasticity fill material to significantly reduce any potential differential movement of the pad due to plasticity characteristics of the soil. The design basis earthquake for the site is specified at ground level (elevation 354′), and the top of the pad is at 356′-8″, therefore, amplification of the seismic loading on the cask by the pad is not significant.

9.1.2.B Holtec Dry Spent Fuel Storage

The other dry fuel storage system utilized is Holtec International's HI-STORM system. The HI-STORM system is comprised of a metal basket, the Multi-Purpose Canister (MPC) that contains the fuel, an on-site transfer cask (HI-TRAC 125D), and a concrete and steel storage container (HI-STORM 100S). These components are classified as important to safety (ITS) as described in the NRC approved SAR and Certificate of Compliance (CoC) for the Holtec dry fuel storage cask system licensed under 10 CFR 72.214. These components are treated as safety related (Q) at ANO. Since the dry fuel storage cask system has been independently reviewed and approved for use by the NRC apart from the site reactor licenses, the full description of the system is in other documents. These documents include the Holtec CoC, Holtec Safety Analysis Report (SAR), NRC Safety Evaluation Report (SER) and ANO Engineering Request 2000-3333-010.

Ancillary equipment used with the Holtec system include: 1) a work platform that holds the HI-TRAC over the spent fuel pool cask loading pit for welding of the MPC closure lids following fuel loading, 2) a HI-TRAC Yoke for lifting and moving the HI-TRAC, 3) MPC lifting cleats for lowering the MPC into the HI-STORM, and 4) an on-site cask transporter (split railcar), an air pallet system that is used to move the HI-STORM assembly on the cask storage pad and the ISFSI cask storage pad.

The ANO ISFSI cask storage pad for the Holtec system, which is classified as not important to safety (non-Q), was seismically designed and qualified to support the worst case casks loading conditions. The storage pad is an approximately 3 feet thick reinforced concrete slab. One section is 55 feet wide by 190 feet long and a second section is 41 feet wide by 95 feet long. The pad is located north of the VSC-24 ISFSI pad and west of the eastern most security fence and bounded by railroad tracks on the west.

Prior to loading or unloading a cask in the SFP, a SFP criticality analysis has to be performed to ensure the SFP criticality requirements are satisfied.

Holtec HI-STORM 100 MPC-32 Criticality Controls

The MPC-32 complies with 10 CFR 50.68 criticality requirements when the cask loading pit gate is open to the spent fuel pool.

The methods used in the analysis of the MPC-32 include MCNP4a and CASMO-4. The base assembly analyzed was CE 16 x 16 fuel assemblies.

The analyses assumes the most reactive fuel and moderator temperature, no credit for the presence of control rod assemblies, and no credit was taken for soluble boron present in the water for normal operations. The analysis also conservatively assumed the ANO-2 spent fuel with initial enrichments up to 5.0 wt%. The neutron absorption of fuel length material in the active fuel region was taken where both Metamic and Boral poison material were evaluated. Credit was taken for 3 years of decay time and for fuel assembly burnup. Credit was taken for soluble boron only under accident conditions.

The result of these analyses is a 95 percent probability/95 percent confidence level of k_{eff} less than 0.95 for storage of spent fuel in the MPC-32 while it is in the SFP cask loading pit with the cask loading pit gate open. This is assured through the spacing of fuel assemblies per the

storage requirements described in Technical Specification Figure 3.9-1, where the loading equation for the graph is the minimum required burnup (GWd/MTU) and is equal to 9 times the fuel assembly average enrichment minus 16.

When evaluating postulated accidents associated with loading/unloading any design of dry casks, the double contingency principle of ANS N16.1-1975 is applied, which specifies that at least two unlikely independent and concurrent events are required to produce a criticality accident. Therefore, for accident conditions, the presence of soluble boron up to 2000 ppm in the SFP water can be assumed as a realistic initial condition since its absence would be a second unlikely event. The MPC-32 is analyzed such that $k_{eff} \leq 0.95$ can be easily met for postulated accidents, since any reactivity increase will be much less than the negative worth of the dissolved boron.

The effects of credible abnormal and accident reactivity conditions previously analyzed for pool racks were evaluated for the HI-STORM 100 MPC-32. None of the abnormal or accident conditions identified cause the reactivity of the MPC-32 to exceed the limiting reactivity value ($k_{eff} \leq 0.95$) considering the presence of the Unit 2 Technical Specification minimum soluble boron.

9.1.2.C Cask Transfer Facility

The ANO Cask Transfer Facility (CTF) Component Number DFS-CTF-1 is a passive reinforced concrete structure, which will support the stack-up configuration of a fully-loaded HI-TRAC, mating device, and HI-STORM during MPC transfer operations from the HI-TRAC into the HI-STORM. In addition, the CTF may be used to load an empty MPC into an empty HI-TRAC. The CTF is basically a 12’-8” x 12’-8” by approximately 14 feet deep cavity in the ground. The cavity is constructed from 4,500 psi at 28 days concrete. Lateral seismic restraints are installed in the cavity to assist in energy absorption and transferring loads to the surrounding soil. The CTF also has a concrete apron around the CTF cavity structure.

A Vertical Cask Transporter (VCT) is used to carry the HI-STORM overpack and straddle the CTF while lowering the overpack into the CTF cavity as well as carry the HI-STORM overpack to the new or existing ISFSI Pads. The Low Profile Transporter (LPT) is used to carry the loaded HI-TRAC from Auxiliary Train Bay to the loading dock, or the turning pads (DFS-PAD-1/2) from where the VCT will carry the HI-TRAC to the CTF and position it for stack-up. When transitioning the VCT across the approach slab to the top slab of the CTF, the site may choose to place down a 3/4” thick plate. The VCT is capable of traversing over this plate.

The ANO CTF (DFS-CTF-1) supports the stack-up configuration of a fully-loaded HI-TRAC, mating device, and HI-STORM during MPC transfer operations. The CTF consists of a below grade passive reinforced concrete structure, (4) removable upper lateral restraints, and (4) removable lower lateral restraints. The lateral restraints (wedges) are used to secure the HI-STORM in position and transfer lateral loads, which may result from a seismic event into the surrounding soil.

The CTF also includes a removable handrail system, which was installed around the perimeter of the CTF Cavity for personnel protection. The CTF includes a removable work platform, which provides access for personnel to facilitate the stack-up configuration of a fully-loaded HI-TRAC, mating device, and HI-STORM during MPC transfer operations. In addition, the CTF includes a personnel access ladder, which facilitates installation of the lower lateral restraints. The CTF is protected from inclement weather by the Non-Safety Related CTF Building which consists of a

metal building and concrete shallow foundation. The CTF Building envelopes and encloses the stack-up configuration of a fully-loaded HI-TRAC, mating device, and HI-STORM during MPC transfer operations.

The CTF has been designed to accommodate both the HI-STORM 100S, Version C, and HI-STORM 100S (232), which are currently in use at ANO. The CTF will accommodate the combined loads of a fully-loaded HI-STORM 100S, Version C with high density concrete shielding during both placement and retrieval.

9.1.3 FUEL POOL SYSTEM (SPENT FUEL POOL COOLING AND CLEANUP SYSTEM)

9.1.3.1 Design Basis

The fuel pool system is designed to:

A. maintain the pool temperature less than or equal to approximately 150 °F during full core offload conditions, while removing a heat load of less than or equal to 38.10 MBTU/hr. The cooling system's heat removal capacity as a function of service water temperature is depicted in Figures 9.1-19 and 9.1-20. Refueling operations are administratively controlled in order to minimize the potential of exceeding a pool temperature of 150 °F during a full core discharge whenever service water system temperature is elevated.

B. maintain purity and optical clarity of the fuel pool water;

C. maintain purity of the water in the refueling cavity and in the refueling water tank; and,

D. maintain the water level a minimum of 9.5 feet above the top of the active fuel of a full fuel assembly (9.0 feet above the top of the active fuel of an individual fuel pin) during fuel handling and storage operations.

9.1.3.2 System Description

The simplified diagram of the fuel pool system is shown in Figure 9.1-1. The system process flow data is shown in Table 9.1-1. The cooling portion of the fuel pool system is a closed loop system consisting of two half capacity pumps for normal duty and one full capacity heat exchanger. The fuel pool water is drawn from the fuel pool near the surface and is circulated by the fuel pool pumps through the fuel pool heat exchanger where heat is rejected to the service water system.

From outlet of the fuel pool heat exchanger, the cooled fuel pool water is returned to the top of the fuel pool via distribution header at the opposite end of the pool from the intake. It has been demonstrated by CE that return of the cooled fuel pool water to the top, as opposed to the bottom, of the pool does not increase the probability of an accident.

The heat removal capacity of the ANO-2 fuel pool cooling system as a function of service water temperature is depicted in Figures 9.1-19 and 9.1-20. During the cooler months of the year when refueling is typically scheduled, the system's heat removal capacity at a pool temperature of 150 °F exceeds the maximum theoretical heat load associated with a full core discharge. Refueling operations are administratively controlled in order to minimize the potential of exceeding a pool temperature of 150 °F during a full core discharge whenever service system temperature is elevated. The administrative controls include evaluation of decay heat loads

using the guidelines of ASB 9-2, Residual Decay Energy for Light Water Reactors for Long Term Cooling. Station administrative controls ensure that the heat removal capacity of the pool is sufficient for future core offloads given the type and enrichment of fuel, and the number of assemblies to be offloaded.

The clarity and purity of the water in the fuel pool, refueling cavity, and refueling water tank are maintained by the purification portion of the fuel pool system. The purification loop consists of the fuel pool purification pump, ion exchanger, filters, strainers, and an installed connection for a floating skimmer. The purification flow is drawn from the suction piping and can be aligned to three different levels within the fuel pool. A basket strainer is provided in the purification line to the pump suction to remove any relatively large particulate matter. The fuel pool water is circulated by the pump through a filter, which removes particulates larger than 5 micron size, and through an ion exchanger to remove ionic material. Connections to the refueling water tank and refueling water cavity are provided for purification and makeup. Fuel pool water chemistry is given in Table 9.1-2.

Makeup to the fuel pool is provided from the CVCS via the blending tee, the refueling water tank via the purification pumps, or the BMS holdup tanks if chemistry specifications are met. In an emergency, Seismic Category I makeup is available from either service water system loop. The boric acid makeup tanks are also available for boration of the spent fuel pool. Overflow protection is provided by transferring the fuel pool water on high level alarm to the refueling water tank or one of the BMS holdup tanks via the purification pump.

The fuel pool system is manually controlled from a local control panel. High fuel pool temperature and high and low fuel pool water level alarms are annunciated in the control room. Spent resins from the fuel pool ion exchanger are sluiced to the solid waste management system as described in Section 11.5.2. Local sample connections are provided on the influent and effluent of the fuel pool purification filters and the fuel pool ion exchanger effluent for verifying purification performance.

<u>Local Fuel Bundle Thermal-Hydraulic Assumptions and Considerations</u>

A local fuel bundle thermal-hydraulic analysis was performed to determine the maximum fuel clad temperatures which may occur as a result of using the spent fuel racks in the Arkansas spent fuel pool. Conservative assumptions were incorporated into the bounding local thermal hydraulic analysis, such that actual decay heat loads are lower than calculated. The local thermal hydraulic analysis predicated decay heat loads using ORIGEN2 based methodology.

Included among the key assumptions used in the analysis are:

- All passive losses (i.e., conduction through walls and slab or losses from the surface) are completely neglected. This conservatively maximizes the net heat load, thereby maximizing both global and local temperatures.

- All calculations are performed with the hydraulic resistance of the most resistive fuel assembly type assigned to every rack storage location. This conservatively maximizes the overall hydraulic resistance of the rack.

- The calculated fuel assembly hydraulic resistance parameters are worsened to ensure an analysis that bounds any small deviations in fuel assembly and rack geometry. The two calculated parameters, permeability and inertial resistance factor, are conservatively worsened by 10%.

- The bottom plenum gap (i.e., between the floor and the rack base plate) is conservatively modeled as less than the actual value. This ensures that the effects of additional flow restrictions around rack pedestals and bearing pads are bounded in the model.

- No downcomer flow is assumed to exist between the rack modules.

- Flow through the flux trap gaps are conservatively neglected in the analysis.

- The model credits conservatively lower rack-to-wall gaps instead of the actual values. This conservatively maximizes the downcomer flow resistance and ensures that the calculations will encompass slight positional deviations in the as-installed rack configuration.

- The large flow holes in the rack base plate at the non-pedestal rack cell locations are not credited. This conservatively reduces the water flow area into the storage cells, thereby increasing the hydraulic resistance. This increased flow resistance is applied to all the cells in the SFP racks.

- The hydraulic resistance of every rack cell in the spent fuel storage rack includes the inertial resistance that would result from a dropped fuel assembly lying across the top of the rack. This conservatively increases the total rack cell hydraulic resistance and bounds the thermal-hydraulic effects of a fuel assembly dropped anywhere in the spent fuel storage area.

- All the freshly discharged fuel assemblies are assumed to be located together at the center of the spent fuel pool, conservatively maximizing the local decay heat generation rates.

- For the bounding peak fuel cladding computations, the maximum local water temperature (at the fuel rack cell exit) and peak heat flux (typically near the mid-height of the active fuel region) are considered to occur co-incidentally. The superposition of these two maximum values ensures that the calculated peak fuel cladding temperature bounds the fuel cladding temperature anywhere along the length of the fuel assembly.

- Bounding maximum allowable SFP bulk water temperature of 150 °F is used in the analysis.

- For calculating the peak cladding temperature, the cladding superheat is based on the design basis hydraulic diameter and the fuel rod outside diameter used for the calculation of the resistance to water flow in the storage cell.

<u>Description of Analytical Method and Types of Calculations Performed</u>

The spent fuel pool storage racks are loaded with spent fuel assemblies. There are water gaps, also called downcomers, between the racks and the walls of the SFP. The rack pedestals maintain a water gap, also called the bottom plenum, between the floor of the spent fuel pool and the rack base plates. These gaps allow water flow from the area above the rack through the downcomers, into the bottom plenum and into the bottom of the rack cells. An elevation

view of a typical model is sketched in Figure 9.1-15 where the flow paths are indicated by arrows. Each cell shown actually corresponds to a row of cells that are located at the same distance from the pool walls. This is more clearly shown in a plan view, Figure 9.1-15A.

The decay heat generated by the fuel assemblies stored in the racks induces a buoyancy-driven water flow upward through the fuel rack cells. Cooler water is supplied to the bottom of the rack cells through the downcomers and the bottom plenum. Quantification of the coupled flow and temperature fields in the spent fuel storage racks is accomplished through the use of a Computational Fluid Dynamics (CFD) analysis. The CFD analysis is performed utilizing the FLUENT fluid flow and heat transfer modeling program.

A three-dimensional model of the spent fuel pool area is made using FLUENT. The regions in the SFP occupied by the fuel racks loaded with heat generating fuel assemblies are modeled as a porous media region. Flow through the narrow fuel assembly passages is laminar and governed by Darcy's Law.

Navier-Stokes equations of fluid motion along with the energy conservation equation are solved to obtain the local flow field and the steady-state temperature distribution in the SFP. Buoyancy effects and turbulence effects are included in the CFD analysis. Turbulence effects are modeled by relating time-varying "Reynolds Stresses" to the mean bulk flow quantities using the standard k-ϵ model. As stated in the previous paragraph, the flow through the fuel rack will be laminar and turbulence effects are "turned off" in the porous media region.

The decay heat generated by the spent fuel assemblies stored in the fuel racks is included in the model as a volumetric decay heat generation in the porous media region.

Once the spatial temperature distribution in the spent fuel storage area is obtained from the CFD solution, the difference between the cladding surface temperature and the local water temperature (also called the cladding superheat) is conservatively calculated from the principles of laminar flow heat transfer. The cladding superheat is added to the CFD computed peak local water temperature to obtain a bounding cladding surface temperature.

Acceptance Criteria

The criteria used to determine the acceptability of the design from a thermal-hydraulic viewpoint are summarized as follows:

- The bounding peak local water temperature in the spent fuel pool storage cell must be less than the local saturation temperature of water when normal forced cooling is available.

- The bounding peak fuel cladding temperature for the hottest spent fuel assembly, determined by adding the bounding temperature difference between cladding material and water in the rack to the maximum local water temperature, should be less than the local saturation temperature of water. If the fuel cladding temperature exceeds the local saturation temperature of water, it must be shown that departure from nucleate boiling (DNB) will not occur.

Rack/Pool Thermal Hydraulics – Design Bases

The Spent Fuel Pool and Pool Cooling Systems are designed to keep the pool water temperature below 120 °F for normal operations and below 150 °F for the maximum normal condition, which is a full core discharge during refueling operations. During the cooler months of the year when refueling is typically scheduled, the system's heat removal capacity at a pool temperature of 150 °F exceeds the maximum theoretical heat load associated with a full core discharge. Refueling operations are administratively controlled in order to minimize the potential of exceeding a pool temperature of 150 °F during a full core discharge whenever service system temperature is elevated. The administrative controls include evaluation of decay heat loads using the guidelines of ASB 9-2, Residual Decay Energy for Light Water Reactors for Long Term Cooling. Station administrative controls ensure that the heat removal capacity of the pool is sufficient for future core offloads given the type and enrichment of fuel, and the number of assemblies to be offloaded.

Since bounding calculations have been performed for the local thermal hydraulic analysis and bulk temperature limits are satisfied through a combination of administrative controls and cooling system performance curves, a maximum theoretical heat load of up to 38.10 MBTU/hr can now be accommodated.

Design Evaluation

During normal operation, the Spent Fuel Pool Cooling System can typically maintain the pool water at temperatures below 120 °F by recirculating spent fuel cooling water from the spent fuel pool through pumps and a cooler and back into the pool. However, operation at fuel pool temperatures above 120 °F that could result from elevated service water temperatures or equipment outages is acceptable. For the maximum theoretical heat load, the system can maintain pool temperature at or below 150 °F assuming a service water inlet temperature that is representative of the cooler months of the year when refueling is typically scheduled. Refueling operations are administratively controlled in order to minimize the potential of exceeding a pool temperature of 150 °F during a full core discharge whenever service water system temperature is elevated.

The clarity and purity of the water in the fuel pool, refueling cavity, and refueling water tank are maintained by the purification portion of the fuel pool system.

Maximum dose rates from a spent fuel assembly as a function of the water height above the top of the active fuel are shown in Figure 9.1-3 and for horizontal water distances in Figure 9.1-4 for various decay times based on core power level of 2,815 MWt. Long-term operation and infinite irradiation are assumed for the dose rate calculation. An axial power distribution with maximum power at the top and bottom of the fuel was used for the axial dose rate calculations while an axial peak of 1.47 was used for the radial (side) dose rate calculations for shielding requirements as described in Section 12.1. Additionally, both cases assumed a maximum radial fuel assembly peaking factor of 1.40. The decay times are not representative of any particular point in the refueling cycle and are only given to show the dose rate variation with time. Other decay times between two days and 60 days can be obtained by interpolation between the existing points. The existing points can also be adjusted proportionately for other power levels and final assembly peaking factors.

9.1.3.2.1 Component Description

All piping, valves, instruments, and components are located in the auxiliary building. Design data for the major components are listed in Table 9.1-3.

A. Fuel Pool Heat Exchanger

The fuel pool heat exchanger is a horizontal shell and tube design with a two pass tube side. A slight pitch, three degrees above the horizontal, is provided for complete draining of the heat exchanger. The service water circulates through the shell side, and pool water circulates through the tube side.

B. Fuel Pool Purification Filters

The fuel pool purification filters are located upstream of the fuel pool ion exchanger to remove any particulates in the pool water. Due to the possible buildup of high activity in the filter, the unit has been designed and installed to provide for removal of the contaminated element assembly with remotely operated handling equipment. The filter drains to the drain collection header in the waste management system.

C. Fuel Pool Ion Exchanger

Fuel pool ion exchanger removes ionic matter from the water. Mixed bed resin is used with the anion resin converted to the borate form and the cation resin in the hydrogen form. The units are provided with all connections required to replace resins by sluicing. The ion exchanger contains a flow distributor on the inlet to prevent channeling of the resin bed and a resin retention element on the discharge to preclude discharge of resin with the effluent.

D. Fuel Pool Purification Pump Suction Strainer

The fuel pool purification pump suction strainer prevents any relatively large particulates from entering the purification pump. The strainer has a drain connection allowing local draining.

E. Fuel Pool Ion Exchanger Strainer

The wye strainer removes particles larger than 149 microns from the purification flow. Blowdown is directed to the spent resin tank in the solid waste system.

F. Fuel Pool Pumps

There are two fuel pool pumps installed for parallel operation. Under normal operating conditions, one pump is operating and one pump is in standby. The pumps are provided with mechanical seals. To increase seal life and reduce maintenance, the seals are cooled by circulating a portion of the pump discharge flow to the seals which returns to the pump suction. The seals are provided with leakoff vent and drain connections.

G. Fuel Pool Purification Pump

The fuel pool purification pump is used for purification and skimming operations. Mechanical seals minimize shaft leakage. To increase seal life and reduce maintenance, the seals are cooled by circulating a portion of the pump discharge flow to the seals which returns to the pump suction. The seals are provided with leakoff vent and drain connections. The internal wetted surfaces of the pump are stainless steel.

H. Piping and Valves

All the piping used in the fuel pool system is stainless steel with welded connections throughout, except for flanged connections at the suction and discharge of the pumps.

All the valves in the fuel pool system are stainless steel, 150-pound class.

9.1.3.3 Safety Evaluation

9.1.3.3.1 Cooling System

Depending upon actual fuel pool heat load and service water inlet temperature, either one or two fuel pool pumps and the fuel pool heat exchanger are in service. The system is manually controlled and the operation monitored locally. The fuel pool temperature high alarm and the fuel pool water level switch high and low level alarms are annunciated in the control room.

In addition to the normal makeup available from the CVCS, the refueling water tank, and the BMS holdup tanks, Seismic Class 1 makeup to the spent fuel pool is available from the service water system. Two redundant paths are provided, one from each of the service water headers, to ensure that makeup is available to the spent fuel pool under all operating or accident conditions. The service water makeup piping is piped to the pool and the valves are located such that minimal operator action is required to initiate makeup from either or both service water headers. This design satisfies the requirement of Regulatory Guide 1.13 for a Seismic Class 1 makeup system and backup source of makeup water.

The spent fuel pool system cooling piping and the service water lines to and from the fuel pool heat exchanger were analyzed and designed to withstand the forces associated with the DBE through the addition of Category 1 supports where required. This design meets the requirement of Regulatory Guide 1.29. The purification piping is not designed to Seismic Class 1 requirements. Additionally, Seismic Class 1 cooling is provided to the spent fuel pool by allowing the pool to boil and supplying adequate makeup to maintain spent fuel pool level.

In accordance with Regulatory Guide 1.13, the fuel pool piping is arranged so that the pool cannot be inadvertently drained to uncover the fuel. All fuel pool piping is arranged to prevent gravity draining the fuel pool. To prevent siphoning of the fuel pool, the fuel pool cooling intake, discharges and purification suction lines have ½-inch holes, respectively, six inches below the normal water level. The purification suction line from the refueling canal also has a siphon breaker.

9.1.3.3.2 Purification System

The purification loop is normally run on an intermittent basis when required by the fuel pool water conditions. It is possible to operate with either the ion exchanger or filter bypassed. Local samples permit analysis of ion exchanger and filter efficiencies.

Spent filters and ion exchanger resins are removed to the solid waste system described in Section 11.5 for eventual disposal.

9.1.3.4 Testing and Inspection

Historical data removed; see Section 9.1.3.4 of the FSAR.

Prior to transferring spent fuel to the pool, the system was tested to verify satisfactory flow characteristics through the equipment, to demonstrate satisfactory performance of pumps and instruments, to check for leak tightness of piping and equipment, and to verify proper operation of controls. Also, the overall cooling capability is checked during initial refueling by analyzing pool temperature versus quantity of fuel transferred into the pool and comparing with expected performance.

Since the active components of the system are in either continuous or intermittent use during normal plant operation, no periodic tests are required. Data is taken and periodic visual inspections and preventive maintenance are conducted, as necessary. This periodic inspection will also verify adequate heat transfer, purification efficiency and component differential pressures.

9.1.3.5 Instrumentation Application

Instrumentation is provided to monitor fuel pool temperature and water level together with significant temperatures and pressures around the cooling and purification loops. Alarms annunciated in the control room are provided for fuel pool water level and fuel pool temperature.

A tabulation of originally installed instrument channels is included in Table 9.1-4.

NRC Order EA-12-051, “Issuance of Order to Modify Licenses with regard to Reliable Spent Fuel Pool Instrumentation,” required plants to provide reliable SFP instrumentation in partial response to the March 2011 Fukushima accident. NRC interim staff guidance JLD-ISG-2012-03 endorsed NEI 12-02, “Industry Guidance for Compliance with NRC Order EA-12-051,” as an acceptable approach for satisfying the requirements of Order EA-12-051. Primary and backup SFP level instruments have been installed which output in the Control Room. The level instruments aid in the monitoring and maintenance of SFP level to support operation of the SFP cooling system, provide radiation shielding for personnel on the SFP operating deck, and to ensure the fuel remains covered. The instruments are powered from battery-backed vital 120 VAC power and each have a backup battery source installed.

9.1.4 FUEL HANDLING SYSTEM

9.1.4.1 Design Bases

9.1.4.1.1 System

The fuel handling system is used for the handling and storage of fuel assemblies and Control Element Assemblies (CEAs), and for the required assembly, disassembly, and storage of reactor internals. As appropriate, the fuel handling equipment includes interlocks, travel limiting features, and other protective devices to minimize the possibility of mishandling or equipment malfunction that could result in inadvertent damage to a fuel assembly and potential fission product release.

The refueling water is the coolant during spent fuel transfer. The spent fuel storage pool is provided with a spent fuel pool cooling and purification system discussed in Section 9.1.3.

Conducting all spent fuel transfer and storage operations underwater, except with dry fuel storage system casks, ensures adequate shielding during refueling and permits visual control of the operation at all times. The fuel handling system also provides for the disassembly, handling, and reassembly of the reactor vessel closure head, and incore instrumentation.

9.1.4.1.2 Fuel Handling Equipment

The principal design criteria for the fuel handling equipment (refueling machine, fuel transfer equipment, spent fuel handling, and new fuel elevator) are as follows:

A. The stresses under the combined deadweight, live and DBE loads shall not exceed the allowable stress of the material per AISC requirements.

B. The load bearing members of the equipment shall withstand the loading induced by the design bases earthquake vertical and horizontal seismic loadings which are considered as acting simultaneously on this equipment in conjunction with the combined deadweight and live loads without exceeding minimum material yield stresses as specified by AISC. Where required, keepers shall be provided to preclude derailment of equipment under seismic loading.

C. Grapples and mechanical latches which carry fuel assemblies or CEAs shall be mechanically interlocked against accidental opening.

D. Equipment shall be provided with locking devices or restraints to prevent parts, fasteners, or limit switch actuators from becoming loose. In those cases where a loosened part or fastener can drop into, or is not separated by a barrier from, or whose rotary motion will propel it into the water of the refueling cavity or spent fuel pool, these parts and fasteners shall be lockwired or otherwise positively captured.

E. The refueling machine shall be capable of removing and installing a fuel assembly at each operating location at the most adverse combined tolerance condition for the equipment, core internals and fuel assemblies.

F. A positive mechanical stop shall prevent the fuel from being lifted above the minimum safe water cover depth and shall not cause damage or distortion to the fuel or the refueling machine when engaged at full operating hoist speed.

G. The refueling machine hoist shall be provided with a load measuring device with a visual display of the load. If an overload occurs, hoisting is interrupted by an overload cutoff limit set less than or equal to 100 pounds more than the expected nominal weight of the load being lifted (i.e., the fuel assembly, one CEA, the grapple, and, in the “fuel plus hoist box” region, the hoist box). If an underload occurs during lowering, motion is interrupted by an interlock set sufficiently below the nominal fuel assembly weight to protect the fuel assembly from grid-to-grid interactions (plus allowances for the grapple and the fuel hoist, where applicable).

H. In the event of loss of power, the equipment and its load shall remain in a safe condition.

I. Equipment remaining within the containment is capable of withstanding, without damage, the internal building test pressure.

9.1.4.2 System Description

The fuel handling system is an integrated system of equipment, tools and procedures for refueling the reactor. The system is designed for safe handling and storage of fuel assemblies from receipt of new fuel to shipping of spent fuel.

The equipment is normally used at approximately 18-month intervals for a period of approximately three weeks; the system is designed to operate continuously without maintenance or service during this time. The fuel handling crane and the spent fuel handling machine may be used on a monthly basis.

The major components of the system are the refueling machine, the fuel transfer equipment, the spent fuel handling machine, the new fuel elevator, and the containment temporary storage rack. The refueling machine moves fuel assemblies into and out of the core and between the core and the transfer equipment. The fuel transfer equipment tilts fuel assemblies from the vertical position to the horizontal, shuttles them from the refueling pool in the containment through the containment wall into the spent fuel pool and returns them to the vertical position. The spent fuel handling machine handles fuel between the transfer equipment and the fuel storage racks in the spent fuel pool. The new fuel elevator lowers the new fuel assemblies down into the spent fuel pool where they are accessible to the spent fuel handling machine. Fuel assemblies may be stored in the containment temporary storage rack during fuel shuffling before being transferred to the core or the spent fuel pool.

Special tools and lifting rigs are also used for disassembly of reactor components and are included in the refueling system.

NUREG-0612, Control of Heavy Loads at Nuclear Power Plants, contains the NRC guidance to ensure that load handling systems are designed and operated such that their probability of failure is low and appropriate for the critical tasks in which they are employed. ANO has implemented the NUREG-0612 Phase I guidance for these load handling systems. In a Safety Evaluation issued in October 1984 (0CNA108406), the NRC concluded that the Phase I requirements of NUREG-0612 had been satisfied for ANO. In a June 26, 1985 generic letter (Generic Letter 85-11) (0CNA068520), the NRC further concluded that the NUREG-0612 Phase II effort was considered complete. Further evaluation was performed pursuant to NEI 08-05, Industry Initiative on Control of Heavy Loads, which verified that the Unit 2 Reactor Vessel Closure Head Load Drop Analysis demonstrates allowable stress limits per ASME Section III, Appendix F, with acceptable piping deformation.

9.1.4.2.1 Refueling Machine

The refueling machine is shown in Figure 9.1-6. The refueling machine is a traveling bridge and trolley which is located above the refueling canal and rides on rails set in the concrete on each side of the refueling canal. Motors on the bridge and trolley position the machine over each fuel assembly location within the reactor core or fuel transfer carrier. The hoist assembly contains a grappling device which, when rotated by the actuator mechanism, engages the fuel assembly to be removed. The hoist assembly and grappling device are raised and lowered by a cable attached to the hoist winch. After the fuel assembly has been raised into the refueling machine, the refueling machine transports the fuel assembly to its designated location.

The controls for the refueling machine are mounted on a console which is located on the refueling machine trolley. Coordinate location of the bridge and trolley is indicated at the console by digital readout devices which are driven by encoders coupled to the guide rails through rack and pinion gears. The hoist vertical location is provided by a tag-line actuated encoder to the machine control console for control functions and digital readout.

During withdrawal or insertion of either a fuel assembly, or a fuel assembly with a control element inserted, the load on the hoist cable is monitored at the console to ensure that movement is not being restricted. Limits are such that damage to the assembly is prevented.

Locking between the grapple and the elements is provided by the engagement of the grapple actuator arm in axial channels running the length of the fuel hoist assembly. Therefore, it is not possible to uncouple even with inadvertent initiation of an uncoupling signal to the actuator assembly. The drives for both the bridge and the trolley provide close control for accurate positioning, and brakes are provided to maintain the position once achieved. In addition, interlocks are installed so that movement of the refueling machine is not possible when the hoist is withdrawing or inserting an assembly. After operation of the hoist a console mounted bypass button must be pressed to allow movement of the bridge or trolley.

For operations at the core, the bottom of the hoist assembly is equipped with a spreading device to move the surrounding fuel assemblies to their normal core spacing to ensure clearance for fuel assemblies being installed or removed. An anti-collision device at the bottom of the mast assembly prevents damage should the mast be inadvertently driven into an obstruction, and a positive mechanical up stop is provided to prevent the fuel from being lifted above the minimum safe water cover depth. A system of points and scales serves as a backup for the remote repositioning readout equipment. Manually operated handwheels are provided for bridge, trolley and winch motions in the event of power loss. Manually operated handwheels for the bridge, trolley, and winch may also be used for equipment checkouts, accessing areas that otherwise are electrically interlocked out, making minor adjustments in position and various other evolutions, when necessary. Such evolutions, if performed with or in close proximity to active fuel, are performed in an administratively controlled manner as dictated by procedures. Outward motion of hoist in core region by using winch handwheel is prohibited administratively because overload protection is defeated. Manual operation of the grappling device is also possible in the event that air pressure is lost.

9.1.4.2.2 Transfer Carriage

A transfer carriage conveys the fuel assemblies between the refueling canal and the spent fuel pool. Fuel assemblies are placed in the transfer carriage in a vertical position, lowered to the horizontal position, moved through the fuel transfer tube on the transfer carriage, and restored to the vertical position in the spent fuel pool.

Wheels support the carriage and allow it to roll on tracks within the transfer tube. The track sections at both ends of the transfer tube are supported from the pool floor and permit the carriage to be properly positioned in the upending mechanism. The carriage is driven by steel cables connected to the carriage, and through sheaves to its driving winch mounted in the fuel handling area. A 2-pocket fuel carrier is mounted on the carriage and is pivoted for tilting by the upending machines. The load in the transfer cables is displayed at the master control console. An overload will interrupt the transfer operation. Manual override of the overload cutout allows completion of the transfer. The supports for the replaceable rails on which the transfer carriage rides are welded to the 36-inch diameter transfer tube. The rail assemblies are fabricated to a length which will allow them to be lowered for installation in the transfer tube. No rails are installed in the valve on the spent fuel pool side of the transfer tube.

9.1.4.2.3 Upending Machine

Two upending machines are provided: one in the refueling canal and the other in the spent fuel pool. Each consists of a structural support base from which is pivoted an upending straddle frame which engages the 2-pocket fuel carrier. When the carriage with its fuel carrier is in position within the upending frame, the pivots for the fuel carrier and the upending frame are coincident. Hydraulic cylinders, attached to both the upending frame and the support base, rotate the fuel carrier between the vertical and horizontal position as required by the fuel transfer procedure. Either hydraulic cylinder acting alone can perform the upending operation; either can be isolated in the event of its failure. A long tool is also provided to allow manual rotation of the fuel carrier in the event that both cylinders fail or hydraulic power is lost.

9.1.4.2.4 Fuel Transfer Tube and Valve

A fuel transfer tube extending through the containment wall connects the refueling canal with the spent fuel pool as shown in Figure 9.1-1. During reactor operation, the transfer tube is closed by means of a manually operated valve located in the spent fuel pool side of the transfer tube and a blind flange located inside the containment. Prior to filling the refueling canal, the blind flange is removed. After a common water level is reached between the refueling canal and the spent fuel pool, the valve is opened. The procedure is reversed after refueling is completed.

The 36-inch diameter transfer tube is contained in a 42-inch diameter penetration which is sealed to the containment. The transfer tube and penetration sleeves are sealed to each other by welding rings and bellows type expansion joints.

The transfer tube valve is attached to the spent fuel pool end of the transfer tube. The valve is supported in such a manner to allow for horizontal movement along the centerline of the transfer tube. The manual operator for the valve is designed to allow for movement of the valve due to thermal expansions and still permit operation. The valve stem extends above the spent fuel pool water level and is designed for manipulation from within the auxiliary building.

9.1.4.2.5 CEA Change Mechanism

This section has been intentionally deleted due to the removal of the CEA change mechanism.

9.1.4.2.6 Fuel Handling Tools

Two fuel handling tools are used to move fuel assemblies in the spent fuel pool area. A short tool is provided for dry transfer of new fuel, and a long tool is provided for underwater handling of both spent and new fuel in the spent fuel pool. The short tool is used with the new fuel hoist (2L-35) and the long tool is operated manually from the walkway on the spent fuel handling machine.

9.1.4.2.7 Reactor Vessel Head Lifting Rig

The reactor vessel head lifting rig is shown in Figure 9.1-8. This lifting rig is composed of a removable three part lifting frame and a column and skirt assembly which is attached to the reactor vessel closure head. The skirt assembly supports the three hoists for handling the hydraulic tensioners, the studs, washers and nuts, and links the lifting frame with the reactor vessel head. There is also a support frame with a circular monorail and trolleys installed to support a Reactor Vessel Head Shielding System.

9.1.4.2.8 Reactor Internals Handling Equipment

Two lifting rigs are used to remove either the upper guide structure or the core support barrel from the reactor vessel and to raise and lower the incore instrumentation support plate assembly.

The upper guide structure lifting rig is shown in Figure 9.1-9.

This lifting rig consists of a delta spreader beam which supports three columns providing attachment points to the upper guide structure. Attachment to the upper guide structure is accomplished manually from the working platform. The integral in-core instrumentation hoist connects to an adaptor which is manually attached to the in-core instrumentation structure. The in-core instrumentation is then lifted by the crane hook. The upper clevis assembly, which is common to this and the core support barrel lifting rig, is installed prior to lifting of the structure by the crane hook. Correct positioning is ensured by attached bushings which mate to the reactor vessel guide pins.

The core support barrel lifting rig, shown in Figure 9.1-10 is provided to withdraw the core barrel from the vessel for inspection purposes. The upper clevis assembly is a tripod shaped structure connecting the lifting rig to the containment crane lifting hook. The lifting rig includes a spreader beam providing three attachment points which are threaded to the core support barrel flange. This is accomplished manually from the refueling machine bridge or the auxiliary gantry crane bridge. Correct positioning of the lifting rig is ensured by attached guide bushings which mate to the reactor vessel guide pins.

9.1.4.2.9 Spent Fuel Handling Machine

The spent fuel handling machine is a traveling bridge and trolley, located over the spent fuel pool, which rides on rails set in the concrete sides of the spent fuel pool. Motors on the bridge and trolley position the machine over the spent fuel assembly storage racks, the new fuel elevator, the cask loading pit, and the upending machine in the spent fuel pool.

An auxiliary crane, 2L35, is used to transfer new fuel from the new fuel storage pit to the new fuel elevator. The spent fuel handling machine hoist assembly contains a grappling device which, when rotated by the actuator mechanism, engages the fuel assembly to be moved. Once the fuel assembly is grappled, a cable and hoist winch raises the fuel assembly. The machine then transports the fuel assembly from the upending machine to the spent fuel storage racks (spent fuel) or from the new fuel elevator to the upending machine (new fuel).

The controls for the spent fuel handling machine are mounted on a console which is located on the spent fuel handling machine trolley. Coordinate locations of the bridge and the trolly are indicated by the pointer and target systems.

During withdrawal or insertion of either a fuel assembly or a fuel assembly with a control element inserted, the load on the hoist cable is monitored to ensure that movement is not being restricted. Limits are such that damage to the assembly is prevented.

Positive locking is provided between the handling tool and the assembly to prevent inadvertent uncoupling. The drives for both the bridge and the trolley provide close control for accurate positioning. In addition, interlocks are installed so that movement of the spent fuel handling machine is not possible when the hoist is withdrawing or inserting an assembly.

Manually operated handwheels are provided for bridge, trolley and winch motions in the event of a power loss. Manually operated handwheels for the bridge, trolley, and winch may also be used for equipment checkouts, accessing areas that otherwise are electrically interlocked out, making minor adjustments in position and various other evolutions, when necessary. Such evolutions, if performed with or in close proximity to active fuel, are performed in an administratively controlled manner as dictated by procedures. Outward motion of hoist by using winch handwheel is not recommended because overload protection is defeated.

9.1.4.2.10 Auxiliary Building Crane

A 130-ton capacity single failure proof bridge crane, designated L3, is provided to handle the spent fuel shipping cask in the Unit 1 and 2 auxiliary buildings. The L3 crane transports the spent fuel cask to and from the rail car located in the train bay at Elevation 354'and to the Unit 1 and Unit 2 cask loading pits. Auxiliary 15-ton capacity and 4-ton capacity hoists are also provided on the L3 crane. Unit 1 and Unit 2 new fuel may be handled by the L3 crane or the separate 4-ton capacity monorail bridge crane, 2L35, at the north end of the Unit 2 auxiliary building. The 130 ton main hoist is designed to NUREG-0554 criteria and Table 9.1-10 provides site specific information regarding Unit 2 compliance with Ederer's Generic Topical Report for single-failure-proof cranes.

Figure 9.1-14 shows the Unit 2 fuel handling area. The cask is hoisted in the railroad bay through a hatch at Elevation 404 feet. It is carried north from the hatch to the cask loading pit where it is lowered into the pit for loading by the spent fuel handling machine. After loading the cask with spent fuel, the cask is lifted from the cask loading pit, transported to the hatch, and lowered to the railroad bay. This arrangement is such that the cask is never carried over the spent fuel pool. Because the crane is single failure proof, a postulated cask drop is not a credible event; therefore, any affect on plant operation as described in SAR section 15.1.23 is not anticipated to occur and the structural integrity of the spent fuel cask will not be impaired. The only safety-related equipment over which the cask must be carried is the relay room between column lines A2 and C2 and 4 and 5 shown in Figure 9.1-14. The floor slab at Elevation 404 feet is the relay room ceiling.

Safety features, inherent with single failure proof crane design, are provided to ensure that the cask can be moved above the relay room ceiling. Additional features as described below are provided to ensure that the cask will never be carried over the spent fuel pool to satisfy the requirements of Regulatory Guide 1.13.

Regulatory Position 5.b of Regulatory Guide 1.13 states that "provisions should be made to prevent this crane (the fuel handling bridge), when carrying heavy loads (the spent fuel cask), from moving in the vicinity of stored fuel." Based on this, the fuel handling floor was arranged as shown in Figure 9.1-14 and the crane was provided with a control system interlock and a crane power limit as shown in Figure 9.1-14 and described below.

The combination of layout and safety controls limits the incidents involving heavy loads in the vicinity of stored fuel to five concurrent failures:

A. Failure of the operator to stop the crane;

B. Failure of the limit switch control interlock to stop the crane;

C. Failure of the bridge braking system to de-energize on loss of power;

D. Failure of the crane hoist, and,

E. All administrative controls must fail.

Because the spent fuel crane is designed as single failure proof, item D above is not considered a credible failure. Also, a concurrent occurrence of these five failures is not considered credible, the design meets the requirements of Regulatory Guide 1.13.

An analysis was performed on the 3-foot, 6-inch thick reinforced concrete relay room ceiling slab, located below the cask travel path between column lines A2 and C2 as shown on Figure 9.1-14. The analysis was performed to demonstrate that a postulated cask drop would not damage any safety- related equipment located in the relay room. The analysis followed an energy absorption method which is identical to that described in Reference 1. The energy input to the relay room ceiling slab was based on a 260 kip cask weight, 92-inch cask diameter and a drop height of one inch. This considers that the main hoist is designed such that the maximum load motion following a single wire rope failure is less than 1.5 feet and the maximum kinetic energy of the load will be less than that resulting from one inch free fall of the maximum critical load.

The analysis indicated that the one way slab would respond in an elastoplastic region with a ductility ratio of approximately nine, which is less than the maximum of 30 indicated in Table 4-4 of Reference 1.

A typical section of the relay room ceiling slab is shown in Section A Figure 3.8-17 at Elevation 404 feet between column lines 4 and 5.

Trolley track limit switches are provided to confine the east-west travel of the trolley to that required for cask loading during cask handling.

Layout of the fuel handling area in the auxiliary building is such that the spent fuel cask are never required to transverse the spent fuel pool during removal of spent fuel elements. Diverse electrical interlocks (a limit switch and a power disconnect from the main contact rails) are provided to the fuel handling crane to prevent an inadvertent transverse of the pool with a cask.

The electrical interlocks, crane, and crane rails are designed to stop the fuel handling crane from full speed, assuming that one electrical interlock fails and that no operator action is taken. At full speed the crane travels a maximum of 25 fpm resulting in a minimal pendulum-like swing of the cask. The runway interlocks (limit switch and power disconnect from the main contact rails) are positioned to interrupt the power and/or apply the brake to bring the crane to a stop with sufficient margin to ensure that the cask will not encroach on the spent fuel pool.

In addition, the crane control system is such that the operator can operate the bridge, trolley, and hoist at any speed up to rated speed from the crane pendant control station or remote control unit.

Redundant crane controls and safety features are not generally provided. However, diverse safety features do provide redundant protection against postulated accidents. The crane control system is a fail safe design and safety features are common mode and single failure proof in mitigating postulated accidents.

To drop the cask in the spent fuel pool, the following must occur:

- The operator must fail to stop the crane;
- The runway travel interlock must fail to stop the crane;
- The bridge must fail to brake on loss of power; and,
- The crane hoisting system must fail completely.
- All administrative controls must fail.

Crane interlock preoperational testing is described in the Technical Specifications.

In order to transverse the floor area on Elevation 404' just north of the Railcar Loading Hatch (Figure 9.1-14); the VSC-24 transfer cask with a loaded canister will utilize four slings. While not located over a safety related system, component, or structure, that section of spent fuel floor is 1 foot, 9 inches thick and not designed to withstand the static weight or drop of the cask. Instead of using a yoke to lift the loaded cask, the redundant slings are attached from the four trunnions of the transfer cask to the L-3 main hook. This dual path sling arrangement provides compliance with NUREG-0612 Section 5.1 regarding alternative measures to increase crane reliability by providing increased safety factor, redundant load paths, etc.

Section 15.1.23 presents the results of an analysis of off-site doses for a fuel cask drop of 50 feet into the railroad bay.

9.1.4.2.11 <u>Stud Tensioners</u>

Three hydraulically operated stud tensioners are used to apply and remove the preload on the reactor vessel head closure studs. These tensioners are suspended from pneumatic hoists which are attached to the head lift rig. The tensioner assemblies, when placed over the studs, rest upon the reactor vessel head flange. An internal socket is attached to the studs by engagement with the stud upper threads and when hydraulic pressure is applied to the stud tensioner pistons, the studs are elongated a predetermined amount. After the closure nuts are seated, the hydraulic pressure is released which results in the preload necessary to maintain the seal between the reactor vessel and reactor vessel head.

A portable pumping unit mounted on a 2-wheel truck is the source of hydraulic power. Two air operated pumps connected in parallel produce the hydraulic pressure which is routed by hose to the tensioner pistons. The control panel contains an air gauge indicating the regulating air pressure and an air valve for operating the pump. A hydraulic gauge showing the pump pressure is also provided as is the hydraulic release valve.

9.1.4.2.12 Surveillance Capsule Retrieval Tool

A retrieval tool is used during the refueling shutdown for manual removal of the irradiated capsule assemblies of the reactor vessel materials surveillance program described in Section 5.2.4.4. The surveillance capsule retrieval tool is shown in Figure 9.1-11. The tool is operated from a position on the carriage walkway of the refueling machine. Access to the capsule assembly is achieved by inserting the tool through 3-inch diameter retrieval holes in the core support barrel flange provided at each capsule assembly radial location. A female acme thread at the end of the retrieval tool is mated to the surveillance capsule lock assembly by turning the retrieval tool handle. A compressed spring in the lock assembly exerts a high frictional force at the retrieval tool lock assembly interface to prevent disengagement during retrieval.

The overall length of the tool is 549 inches. The tool consists of two parts to facilitate storage. The upper portion is a 2-inch diameter tube and handle. The lower portion of the tool is also a 2-inch tube with a 1-inch outer diameter at the connector end. A 3/4-inch diameter hole in the upper end of the tool permits the polar crane to assist with the retrieval procedure and prevents inadvertent dropping of the tool. The tool is made of aluminum and has a dry weight of 40 pounds.

9.1.4.2.13 CEA Uncoupling Tool

This tool consists basically of two concentric tubes with a conical lead in at the end to facilitate engagement with the CEDM extension shafts. When installed, pins attached to the outer tube are engaged with the extension shaft outside diameter and the pins carried by the inner tube are inserted in the inner operating rod of the extension shaft. The inner tube of the tool is then lifted and rotated relative to the outer tube which compresses a spring allowing the gripper to release, thus separating the extension shaft from the CEA. The extension shaft is then handled by the tool.

9.1.4.2.14 Underwater Television

A high resolution closed circuit television system is provided to monitor the fuel handling operations inside the containment. The camera is mounted on the refueling machine mast so that the fuel assembly can be sighted prior to and during grappling and removal from the core. The system may be used for core alignment verification. A TV monitor is provided at the refueling machine control console. If required for remote surveillance or inspection, the camera could be unbolted from its mount on the mast and handled separately.

9.1.4.2.15 Failed Fuel Detection

9.1.4.2.15.1 In-Mast Sipping

The In-Mast Sipping Skid, installed by DCP 96-3254-D201, is connected to the hoist box, and monitors the water surrounding the test assembly. As the hoist box is raised (containing the suspect fuel assembly), water is drawn off from the surrounding area. This water is then passed through a water-gas separator, where the water is directed back into the Refueling Canal. The gasses that have been stripped from the coolant are directed through a scintillation detector. There, the gasses are analyzed for activity which corresponds to energy levels associated with Krypton and Iodine. Local indication is provided to personnel should these fission product gasses be detected. After the gasses have been analyzed, they are routed to the Refueling Canal.

9.1.4.2.16 Hydraulic Power Package

The hydraulic power package provides the motive force for raising and lowering the upender with the fuel carrier. It consists of a stand containing a motor coupled to a hydraulic pump, a sump reservoir, valves and the necessary hoses to connect the power package to the hydraulic cylinders on the upender. The valves can be aligned to actuate either or both upenders. The hydraulic fluid may be either borated or non-borated water.

9.1.4.2.17 Refueling Pool Seal

The annular space between the reactor vessel flange and the bottom of the fuel transfer canal is sealed off prior to removal of the reactor closure head by placement of eight gasketed seal plate access covers. These covers are bolted to the permanent seal plate which is welded to the shield ring embedded in the annulus shield wall and to the reactor vessel flange seal ledge. Leak rate is monitored during refueling to ensure that no sudden change in water level will occur.

9.1.4.2.18 Containment Temporary Storage Rack

The containment temporary storage rack consists of a stainless steel rack designed to store up to four (4) new or spent fuel assemblies in containment during refueling. The nominal center-to-center assembly spacing is 17.812 inches.

9.1.4.3 System Evaluation

9.1.4.3.1 SystemOperation

A. New Fuel Transfer

After arrival in the auxiliary building, new fuel assemblies are removed from their shipping containers and placed in the new fuel storage racks or into the new fuel elevator and then into the spent fuel storage pool. Transfer to the new fuel storage racks or to the new fuel elevator is accomplished by using the short fuel handling tool attached to the 4-ton hoist of the new fuel crane, 2L35.

During reactor refueling operations, the new fuel is removed from the new fuel storage racks and transferred to the new fuel elevator in the spent fuel pool, if necessary. This operation is accomplished using the new fuel crane and the short fuel handling tool.

The new fuel elevator lowers the fuel assembly down into the spent fuel pool where the spent fuel handling machine transfers the fuel assembly to the spent fuel pool storage racks or upending mechanism. Interlocks are provided to prevent the spent fuel handling machine from lowering the fuel assembly unless the upender is in the vertical position. During an in-core fuel shuffle, a new fuel assembly has been placed in the upending mechanism and then a spent fuel assembly is removed from the other position of the fuel carrier and transferred to a designated position in the spent fuel storage racks using the spent fuel handling machine.

B. Spent Fuel Transfer

After a period of time in which the spent fuel decay heat and radioactivity level have decreased, the spent fuel handling machine transfers the assemblies from the storage racks to the spent fuel cask. The cask loading area is connected to the pool by a gate sized to allow passage of the tool with fuel element attached. The spent fuel assemblies are then transferred underwater and loaded into the cask using the spent fuel handling machine. Once loading is complete, the loaded cask is cleaned to remove any radioactive material and residual coolant. After the washdown is complete, the spent fuel cask is loaded into a transporter for shipment or storage.

9.1.4.3.2 Refueling Procedure

Prior to refueling, the plant is shutdown and cooled to refueling temperature. During the cooldown, preparations are begun for the refueling operation.

Refueling operations are initiated by disconnecting the CEDM cooling shroud two upper ductwork expansion joints (2M-249A and 2M-249B), piping, and electrical connections. The missile shield is then moved to allow access to the reactor vessel head area. CEDM, RVLMS, and incore detector cabling is disconnected and the reactor vessel head maintenance structure removed with duct work attached and stored. Insulation from the vessel head flange is then removed and the vessel vent line spool disconnected. The eight (8) hatch covers and gaskets are installed on the seal plate and are leak tested to prevent water from entering the lower portion of the reactor vessel cavity when the refueling canal is flooded. The stud tensioners are employed to remove the preload on the vessel head studs. The nuts and some of the studs are removed.

Two alignment pins are inserted in the north and south stud hole locations to assist in subsequent operations. Plugs are installed in any remaining stud hole locations to protect the empty stud holes.

Lead shielding blankets may be installed, if necessary, at designated locations around the vessel head in order to minimize radiation exposure. The number of studs removed from the head and the number of lead shielding blankets used will be such that the total rated capacity of the reactor building polar crane (150 tons) is not exceeded. A lifting frame is then installed on the head assembly and, by means of the polar crane, the head is removed to its storage location.

The fuel transfer tube connects the refueling canal with the spent fuel pool. During reactor operation, the transfer tube is closed by a manually operated valve in the fuel pool and a double gasketed blind flange inside the containment. The flange is removed and, after a common water level is reached, the valve is opened preparatory to the refueling.

The upper guide structure lift rig is installed on and locked to the upper guide structure. The CEDM drive shaft extensions are disconnected from their CEAs and are then removed with the vessel upper guide structure. The instrumentation support plate is then raised and secured. The upper guide structure is removed from the vessel and installed on its storage pads.

Provision is made in the refueling canal for the temporary storage of the upper guide structure. After this is removed from the vessel, the refueling machine hoist mechanism is positioned at the desired location over the core. Alignment of the hoist to the top of the fuel assembly is accomplished through the use of a digital readout system. After the fuel hoist is lowered, minor manual adjustments can be made to properly position the hoist if misalignment is indicated. The operator then energizes the actuator assembly which rotates the grapple at the bottom of the hoist and locks the fuel assembly to the hoist. The hoist motor is started and the fuel assembly withdrawn into the fuel hoist box assembly so that the fuel is protected during transportation to the fuel upender. The grapple is designed to preclude inadvertent disengagement as the fuel assembly is lifted vertically from the core. When the fuel has been withdrawn out of the grapple zone, positive locking between the grapple and the fuel assembly is established so that uncoupling is prevented even in the event of inadvertent initiation of an uncoupling signal to the assembly. After removal from the core, the spent fuel assembly is moved underwater to the transfer area of the pool. The spent fuel assembly is lowered into the transfer carriage in the refueling canal.

The upending machine lowers the spent fuel assembly to the horizontal position after which a cable drive transports the carriage on tracks through the transfer tube into the spent fuel pool.

Once received in the spent fuel pool, another upending mechanism returns the transfer carrier to the vertical position. The spent fuel handling machine then removes the spent fuel assembly from the transfer carriage and transports it to the spent fuel rack.

After a new fuel assembly has been moved from the new fuel storage racks or the spent fuel pool storage racks and placed in the upending mechanism by the spent fuel handling machine, the new fuel assembly is carried through the transfer tube to the refueling canal where the refueling machine picks it up and places it in its proper position in the core. A spent fuel assembly being reloaded would be handled in the same manner.

Refueling can be performed by a core shuffle or core offload/reload. In the case of the shuffle, the refueling machine is used to shuffle fuel within the core in accordance with the fuel management scheme. In the core offload/reload, all fuel assemblies are removed from the core to the spent fuel storage racks, then those scheduled for operation in the next cycle are transferred back to the reactor vessel. CEAs can be shuffled in either the refueling canal or the spent fuel pool.

See section 9.1.4.2.15 for failed fuel monitoring during fuel handling operations.

At the completion of the refueling operation, the transfer valve is manually closed. The upper guide structure is reinserted in the vessel and the in-core instrumentation support plate is lowered into position. The CEA drive shaft extensions are reconnected to their respective

CEAs. The upper guide structure lift rig is removed from the upper guide structure. The water in the refueling pool is lowered, utilizing at least one of the shutdown cooling pumps. The head is then lowered until the drive shaft extensions are engaged by the CEDMs. Lowering of the head is continued until it is seated. Then the studs are installed in the lower vessel flange, the two alignment pins are removed with studs installed in the vessel flange holes, and the head is bolted down, and the transfer tube blind flange installed. The eight (8) hatch covers and gaskets are unbolted and removed from the seal plate and stored. The missile shield is then moved to its furthest west position. The vessel maintenance structure is placed on the vessel head with the polar crane. CEDM power, CEDM, RVLMS, and incore instrumentation cabling is reconnected and the missile shield returned to its normal position directly over the reactor vessel. The CEDM cooling duct expansion joints (2M-249A and 2M-249B) are connected to the CEDM shroud ducts. Piping for the vessel head vent and CEDM cooling chill water is reinstalled.

9.1.4.3.3 Safety Evaluation

A. Cask Handling

See Section 9.1.4.2.10.

B. Fuel Handling

Direct communication between the control room and the refueling machine console is available whenever changes in core geometry are taking place. This provision allows the control room operator to inform the refueling machine operator of any impending unsafe condition detected from the main control board indicators during fuel movement.

Operability of the fuel handling equipment including the bridge and trolley, the lifting mechanisms, the upending machines, the transfer carriage, and the associated instrumentation and controls is ensured through the implementation of preoperational tests and routines. Prior to the first actual fuel loading, the equipment is cycled through its operations using dummy fuel. In addition, the equipment has the following special features:

1. Provision for seismic loading is made by structural design and arrangement of the equipment. Where required, mechanical means (clips, guide rolls, etc.) are utilized to prevent overturning or derailing of the equipment during an earthquake.

2. The bumper ring mounted on the refueling machine mast interrupts the bridge and trolley should the mast be driven into an obstruction. This feature prevents damage to either the refueling machine or to members or components into which it may be driven.

3. The two major systems of the overall fuel handling system (refueling machine and fuel transfer system) are electrically interlocked with each other to assist the operator in properly conducting the fuel handling operation. Failure of any of these interlocks in the event of operator error will not result in damage to more than one fuel assembly. The radiological consequences associated with the activity release from an entire assembly is discussed in Section 15.1.

4. Mechanical interlocks are provided for operation when handling fuel assemblies. They include positive mechanical locking of the refueling machine grapple to the fuel assembly and a positive mechanical stop to prevent raising a fuel assembly above the minimum depth of water.

5. Miscellaneous special design features which facilitate handling operations include: a dual wound transfer system motor to permit applying an increased pull on the transfer carriage in the event it becomes stuck; a viewing port in the refueling machine trolley deck to provide visual access to the reactor for the operator; electronic and visual indication of the refueling machine position over the core; a protective shroud into which the fuel assembly is drawn by the refueling machine; transfer system upenders manual operation by a special tool in the event that the hydraulic system becomes inoperative; removal of the transfer system components from the refueling pool for servicing without draining the water from the pool. Manual operated handwheels for the bridge, trolley, and winch are provided in the event of a loss of power and may also be used for equipment checkouts, accessing areas that otherwise are electrically interlocked out, making minor adjustments in position and various other evolutions. Such evolutions are performed in an administratively controlled manner when performed in close proximity to active fuel.

6. The fuel transfer tube is sufficiently large to provide natural circulation cooling of a fuel assembly in the unlikely event that the transfer carriage should be stopped in the tube. The manual operator for the fuel transfer tube isolation valve extends from the valve to the operating deck. Also, the valve operator has enough flexibility to allow for operation of the valve even with thermal expansion of the fuel transfer tube.

7. Travel stops in both the refueling and spent fuel handling machines restrict withdrawal of the spent fuel assemblies. This results in the maintenance of a minimum water cover of 9.5 feet over the active portion of the fuel assembly resulting in a radiation level of 5 mrem/hr or less at the surface of the water. The depth of water surrounding the fuel transfer canal, transfer tube and spent fuel storage pool will be sufficient to limit the maximum continuous radiation levels in working areas to 2.5 mrem/hr.

8. A closed circuit television system is provided on the refueling machine to allow visual observation.

9. The spent fuel handling machine is designed to Seismic Class 1 requirements to preclude structural failure of this machine in the area of the spent fuel pool. This design ensures compliance with the positions set forth in Regulatory Guide 1.13.

10. Fuel reconstitution equipment will contain hard stops to restrict withdrawal of individual fuel pins from fuel assemblies and maintain a minimum water cover of 9.0 feet over the active fuel portion of the individual fuel pin. The net affect of handling a single fuel pin with reduced water cover relative to a complete fuel assembly is a dose rate at the surface of the water that still remains well below 5 mrem/hr.

As discussed above and in Section 9.1.4.2.10, handling in the area of the spent fuel pool is minimized as much as possible in accordance with Regulatory Guide 1.13.

Additionally, criticality safety evaluations show that two fuel assemblies with enrichments up to 5.0 weight percent U-235 described by the parameters shown in Table 9.1-7 can be transported in the fuel carrier while maintaining the required criteria, i.e., the 95 percent probability / 95 percent confidence level reactivity is less than 0.95. This analysis assumes a credit for 400 ppm soluble boron. In the evaluation of a dropped assembly next to the carrier containing two fuel assemblies, credit is assumed for 1000 ppm soluble boron, as allowed by the double contingency principle which states it shall require two unlikely, independent, concurrent events to produce a criticality accident. By crediting soluble boron, the criteria of K_{eff} less than 0.95 is maintained for this postulated accident.

Criticality evaluations of the containment temporary storage rack show that new fuel assemblies with enrichments up to 5.0 weight percent U-235 described by the parameters shown in Table 9.1-7 can be safely stored while maintaining K_{eff} less than 0.95 for both normal and accident conditions. In the evaluation of a dropped assembly next to the containment temporary storage rack, credit is assumed for 1000 ppm soluble boron, as allowed by the double contingency principle which states it shall require two unlikely, independent, concurrent events to produce a criticality accident.

9.1.4.3.4 Single Failure Mode Analysis

A single failure mode analysis of the fuel handling equipment is provided in Table 9.1-5.

9.1.4.4 Testing and Inspection

During manufacture at the vendor's plant, various in-process inspections and checks are required including certification of materials and heat treating, and liquid penetrant or magnetic particle inspection of critical welds. Following completion of manufacture, compliance with design and specification requirements is determined by assembling and testing the equipment in the vendor's shop. Utilizing a dummy fuel assembly and a dummy CEA, each having the same weight, center of gravity, exterior size and end geometry as an actual assembly, all equipment is run through several complete operational cycles. In addition, the equipment is checked for its ability to perform under the maximum limits of loads, fuel mis-location and misalignment. All traversing mechanisms are tested for speed and positioning accuracy. All hoisting equipment is tested for vertical functions and controls, rotation, and load misalignment. Hoisting equipment is also tested to 125 percent of maximum working load. Setpoints are determined and adjusted and the adjustment limits are verified. Equipment interlock function, and backup systems operations are checked. Those functions having manual operation capability are exercised manually. During these tests, the various operating parameters such as motor speed, voltage, and current, hydraulic system pressures, and load measuring accuracy and setpoints are recorded. At the completion of these tests, the equipment is checked for cleanliness and the locking of fasteners by lockwire or other means is verified.

The equipment is again tested after final installation and the results compared to the results of tests performed at the vendor's plants.

This allows determination of any changes in adjustment and condition which may have occurred in transit to the site. In addition, this post-installation testing permits determination of characteristics which are unique to the actual installation and therefore cannot be duplicated in

the vendor's shop test. Each component is inspected and cleaned prior to installation. Recommended maintenance, including any necessary adjustments and calibrations, is performed prior to equipment operation. Preoperational tests also include checks of all control circuits including interlocks and alarm functions.

9.1.4.5 Refueling Interlocks

Mechanical stops and positive locks have been provided to prevent damage to or dropping of the fuel assemblies. In the design of the refueling machine, positive locking between the grapple and the elements is provided by the engagement of the actuator arm in vertical channels in the hoist assembly so that relative rotational movement and uncoupling is not possible, even with inadvertent initiation of an uncoupling signal to the actuator assembly. Therefore, failure of an electrical interlock will not result in the dropping of a fuel assembly.

The following list identifies and defines the function of the interlocks contained in the fuel handling equipment. In no case has a method been provided to directly inform the operator that an interlock is inoperative. However, in most cases a redundant device has been provided to perform the same function as the interlock or to present information to the operator allowing him to deduce that an interlock has malfunctioned.

9.1.4.5.1 Refueling Machine

A. Refueling Machine Hoist Interlock

   Interrupts hoisting of a fuel assembly if the load increases above the overload setpoint. The hoisting load is visually displayed so that the operator can manually terminate the withdrawal operation if an overload occurs and the hoist continues to operate.

B. Refueling Machine Hoist Interlock

   Interrupts hoisting of a fuel assembly when the correct vertical position is reached.

   A mechanical up-stop has been provided to physically restrain the hoisting of a fuel assembly above the elevation which would result in less than the minimum shielding water coverage.

C. Refueling Machine Hoist Interlock

   Interrupts insertion of a fuel assembly if the load decreases below the underload setpoint.

   The load is visually displayed so that the operator can manually terminate the insertion operation if an underload occurs and the hoist continues to operate.

D. Refueling Machine Hoist Interlock

   Interrupts lowering of the hoist under a no load condition when installing a fuel bundle.

   The weighing system interlock is backed up by an independent slack cable switch which terminates lowering under a no-load condition.

E. Refueling Machine Movement Interlock

Denies movement of the bridge and trolley while the fuel hoist is operating.

An additional circuit is provided which, after initiation of a hoisting operation, requires that a separate switch be actuated before normal operation of the movement drives is possible.

F. Refueling Machine Hoist Interlock

Hoisting is denied during movement of the bridge and/or trolley. No backup or additional circuitry is provided for this interlock.

G. Refueling Machine Movement Interlock

Denies motion of the bridge and/or trolley with the spreader extended.

The underwater TV system can be used by the operator to determine whether the spreader has been raised, and lights on the control console indicate whether the spreader is withdrawn or extended.

H. Refueling Machine Mast Anti-Collision Interlock

Stops movement of the bridge and/or trolley when the collision ring on the mast is contacted and deflected.

Redundant switches are provided to minimize the possibility of this interlock becoming inoperative and slow bridge and trolley speeds are mandatory for movement of the refueling machine in areas other than its normal travel route which might contain obstructions. Travel limits also restrict running the mast into the pool wall.

I. Refueling Machine Hoist Speed Interlock

Mandatory slow hoisting speed while fuel assembly is within the core and not in a clear water position. The fuel assembly is considered in clear water position when it is within the core but is positioned such that spacer grid interaction is not possible.

During insertion and withdrawal, the change in hoist speed can be monitored by observation of the hoist vertical position indicator. A change in the sound of the hoist will accompany the change in hoist speed.

J. Refueling Machine Hoist Interlock

Interrupts hoisting of a fuel assembly if the load increases above the drag overload during engagement of the hoist box. The hoisting load is visually displayed so that the operator can manually terminate the withdrawal operation if an overload occurs and the hoist continues to operate.

9.1.4.5.2 Transfer System

A. Transfer System Winch Interlock

Terminates winching of the fuel carriage through the transfer tube if the load increases above the overload setpoint.

The winching load is visually displayed so that the operator can manually terminate the transfer operation if an overload occurs and the interlock fails. An overload is indicated by a light on the control panel and by an audible alarm.

B. Transfer System Winch Interlock

Prevents the winch from attempting to pull the fuel carriage through the transfer tube with an upender in a vertical position. If this interlock fails and a transfer signal is initiated, winching will be terminated when the load increases above the overload setpoint.

C. Transfer System Upender Interlock

Rotation of the upender is denied while the refueling machine is at the upender station.

Failure of this interlock while the refueling machine is at the upending station will allow an upending signal by the transfer equipment operator at the station only to initiate rotation of the fuel carrier by the upender. In the event that this signal is erroneously initiated while the fuel assembly is being lowered from or raised into the refueling machine, a bending load will be applied to the fuel bundle.

D. Transfer System Upender Interlock

Rotation of the upender is denied unless the fuel carrier is correctly located for upending.

Failure of this interlock will

1. with the fuel carrier in the transfer tube allow the upender to rotate with no effect on the carrier or fuel bundle, and

2. with the fuel carrier partially in the upender, attempt to but not be successful in rotating the carrier since a mechanical lock prevents premature carrier rotation.

E. Isolation Valve Interlock

Contacts are provided in the control system of the transfer system which, when connected to a limit switch on the isolation valve, will prevent movement of the fuel carrier unless the valve is fully opened.

If this switch is not provided, or if provided this interlock fails with the valve partially closed, the fuel carrier will contact the valve and winching will be terminated by an overload signal. No damage to the fuel assembly will result since the fuel assembly is enclosed in the carrier.

9.1.4.5.3 CEA Change Machine

This section has been intentionally deleted due to the removal of the CEA change mechanism.

9.1.4.5.4 Spent Fuel Handling Machine

A. Spent Fuel Handling Machine Hoist Interlock

Interrupts hoisting if the load increases above the overload setpoint.

Since the tool is manually controlled by the operator, failure of the tool to move or reduction in tool speed as a result of an overload can be sensed by the operator if the interlock becomes inoperative.

B. Spent Fuel Handling Machine Hoist Interlock

Interrupts lowering if the load decreases to below the underload setpoint.

Since the tool is manually controlled, a slack cable condition can be visually determined by the operator and hoisting terminated.

C. Spent Fuel Handling Machine Translation Interlock

Speed is restricted to low speed unless the load is in the full up position, at which time fast speed is allowed.

If this interlock fails, the mandatory slow speed restriction is removed. However, since the translation speed controls are infinitely variable, the operator can run at slow speed when the interlock malfunction is recognized.

D. Spent Fuel Handling Machine Translation Interlock

Zone switches protect against running the load into walls or the gate of the storage area.

No backup or additional circuitry is provided for this interlock. However, the operator has direct vision of the tool and the attached load so that translation can be terminated if an interlock fails to operate.

9.1.4.5.5 New Fuel Elevator

A. New Fuel Elevator Hoist Interlock

Interrupts lowering if the load decreases below the underload setpoint.

9.2 WATER SYSTEMS

9.2.1 SERVICE WATER SYSTEM

The Service Water System (SWS), shown in Figure 9.2-1, provides water for the following equipment:

A. Cooling water for the following Engineered Safety Features (ESF) equipment:

1. Emergency Diesel Generator Heat Exchangers 2E20A and B, 2E63 A and B, 2E64 A and B;
2. Switchgear Rooms Unit Coolers 2VUC2A, B, C, and D;
3. Control Room Emergency Condensing Units 2VE1A & 1B;
4. Auxiliary Building Shutdown Heat Exchanger Room Unit Coolers 2VUC1A, B, C, D, E, F;
5. Auxiliary Building High Pressure Safety Injection (HPSI) Pump Room Unit Coolers 2VUC11A, B;
6. Containment Spray Pump Coolers 2E47A, B;
7. Low Pressure Safety Injection (LPSI) Pump Coolers 2E52A, B;
8. HPSI Pumps Inboard and Outboard Bearing Jacket Coolers and Seal Coolers 2E53A and D (2P89A), 2E53B and E (2P89B), and 2E53C and F (2P89C);
9. Shutdown Cooling Heat Exchangers 2E35A, B;
10. Auxiliary Building Charging Pump Room Coolers 2VUC7A, B, C;
11. Containment Cooling Unit Service Water Coils 2VCC2A, B, C, D;
12. Auxiliary Building Emergency Feedwater Pump Room Unit Coolers 2VUC6A, B;
13. Auxiliary Building Electrical Equipment Unit Coolers 2VUC19A, B & 2VUC20A, B;
14. Post-Accident Hydrogen Analysis Panels 2C128A, B.

B. Alternate water supply for the Emergency Feedwater Pumps 2P7A, B.

C. Cooling water for the following plant auxiliary equipment:

1. Fuel Pool Heat Exchanger 2E27;
2. Component Cooling Water Heat Exchangers 2E28A, B, C;
3. Condenser Vacuum Pump Coolers 2E46A, B;
4. Control Room Chillers 2VCH2A, B;

5. Turbine-Generator Lube Oil Coolers 2E15A, B;

6. Turbine-Generator Electro-Hydraulic Fluid Coolers 2E16A, B;

7. Turbine-Generator Stator Liquid Coolers 2E50A, B;

8. Main Generator Hydrogen Coolers 2E13A, B;

9. Exciter Air Cooler 2E14;

10. Steam Packing Exhauster Condenser 2E10;

11. Main Chiller Condensers 2E-112A,B with or without Service Water System Booster Pumps 2P147A, B;

12. Auxiliary Building Cable Spreading Room Unit Cooler 2VUC3A (Abandoned in place);

13. Heater Drain Pump Area Cooler 2VUC3B;

14. Auxiliary Building Electrical Equipment Room Unit Cooler 2VUC21;

15. Steam Generator Blowdown Heat Exchangers 2E68A, B;

16. Auxiliary Building Extension Chillers 2VCH3A, B; and,

17. Regenerative Waste Evaporator Packages 2M89A, B.

D. Makeup water to cooling tower basin.

E. Emergency makeup to spent fuel pool.

F. Makeup to the Emergency Cooling Pond.

9.2.1.1 Design Bases

Continuation of the minimum required cooling water flows to the ESF equipment served by the system and continuation of the availability of water supplies to the emergency feedwater pumps is essential to assure safe operation and shutdown of the plant. Accordingly, the portions of the system required to deliver these flows are designed to meet Seismic Category 1 requirements.

The portions of the SWS essential to a safe shutdown of the plant, including pumps, strainers, piping and valves were designed to meet the requirements of Section III Class 3 of ASME Boiler and Pressure Vessel Code. The containment penetrations are ASME Code Section III Class 2. The remaining portions of the system were designed to ANSI B31.1.0, Power Piping Code.

The system is designed to use the Dardanelle Reservoir as the water supply during normal operation. An alternate water supply for the system is available from the Emergency Cooling Pond (ECP), which can be used during normal plant shutdown operation and postulated Design Basis Accident (DBA) recovery. The system design includes allowance for corrosion and provides for inhibition of organic fouling of the system water passages sufficient to prevent long-term degradation of system design capability.

The original design of the SWS during normal operating conditions with the water source being the Dardanelle Reservoir was based on the following expected temperature ranges.

Period	Average Temperature °F
December through March	48
April, May, October, November	64
June through September	80
Design water temperature	85

Operating experience has resulted in Dardanelle Reservoir exceeding the original design water temperature during summer months; however, safety-related equipment cooled by the SWS has been determined to be capable of fulfilling required functions up to the maximum potential temperature (see Section 9.2.5.3).

The maximum temperature of service water supplied from the ECP is 116 °F. This maximum temperature is a result of Unit 2 DBA and a concurrent safe shutdown of Unit 1, the temperature bounds a Unit 1 DBA and concurrent safe shutdown of Unit 2 or a concurrent shutdown of both units.

9.2.1.2 System Description

9.2.1.2.1 General Description

A diagram of the SWS is shown in Figure 9.2-1. The components comprising the system are two traveling water screens preceded by bar grates, three pumps, three basket strainers, and the required interconnecting piping, heat exchangers, valves, and instrumentation. During normal plant operation, water is supplied from the Dardanelle Reservoir through the bar grates and traveling water screens. Prescreens are installed downstream of the traveling water screens in the existing stop log slots located in the SW fore bay area. The water entering the system has biocide added by the Unit 1 Sodium Bromide/Sodium Hypochlorite System. Biocide may also be added to the Service Water System using metered pumps for injection.

The system consists of two independent Seismic Category 1 flow paths (designated Loop I and Loop II) and two non-Seismic Category 1 flow paths. The Seismic Category I flow paths supply two independent trains of 100 percent capacity ESF equipment as well as providing an alternate water supply for the emergency feedwater pumps and an emergency source of makeup for the spent fuel pool. The two non-Seismic Category 1 flow paths are the auxiliary cooling system which supplies cooling water to various non-safety-related portions of the plant, and the path supplying component cooling water heat exchangers and main chiller condensers. The portion of the service water piping supplying water to the spent fuel cooling heat exchangers was analyzed for SSE loading.

The Seismic Category 1 flow paths are normally isolated from each other, and are isolated from the Seismic Category 2 portions of the system by automatic closure of isolation valves upon the initiation of a Safety Injection Actuation Signal (SIAS) or Main Steam Isolation Signal (MSIS). The Seismic Category 2 systems can be supplied with water from either Seismic Category 1 train during normal operation.

An alternate source of water, the ECP, is provided for the system, and can be utilized in the event that the normal supply from the Dardanelle Reservoir is unavailable. Water is supplied to the system from the pond by gravity flow through a single 42-inch diameter line to the service water pump compartments in the intake structure. After having circulated through the SWS, the emergency cooling pond water is directed back to the pond via a 30-inch diameter return line.

The Dardanelle Reservoir is the source of water for the system during normal cold shutdown operations and will also be used as the preferred system source of supply during accident conditions as described in Section 9.2.1.2.3.7.

The SWS components inside the intake structure include the service water pump columns and motors, block walls between the pump motors, basket strainers, service water pump discharge piping and associated valve operators, intake sluice gates and the gate operators, and SWS sodium bromide/sodium hypochlorite piping. The intake structure also contains the bar gates, traveling water screens, prescreens, and screen wash water piping at the intake structure. Units 1 and 2 screen wash systems are tied together as described in Section 9.2.1.2.2.1.

9.2.1.2.2 Component Descriptions

9.2.1.2.2.1 Traveling Water Screens, Screen Wash, Corrosion Inhibitor Injection System, and Biocide Addition System

One traveling water screen is installed in each of two independent flow paths to the service water pumps. Data for these screens is shown in Table 9.2-2. The screens are cleaned periodically using the Unit 1 screen wash pumps discharging into high velocity spray nozzles which clean the debris from the screens as they travel past the nozzles. The debris can be sluiced to trash collection baskets outside the intake structure.

The Unit 1 Sodium Bromide/Sodium Hypochlorite System injects a biocide into the Unit 2 intake structure in the forebay or through three separate spargers located downstream of each of the three intake structure sluice gates on the Service Water bay side. Biocide may also be added to the Service Water System using metered pumps for injection.

To help limit biological fouling such as flow blockage from bivalve mollusks, Corbicula (Asiatic clams), a biocide is added at the intake structure in sufficient concentration to kill the mollusks. The service water intake bays are inspected and cleaned at least once every refueling outage to prevent clam buildup and fouling. In addition, flow measurement orifices and instrumentation have been added to several of the auxiliary building coolers. Where permitted by cooler fitting design, most of the 1/2-inch and 3/4-inch cooler piping have been replaced with 316L stainless steel 1-inch lines. Much of the service water supply and return carbon steel piping has been replaced with 316L stainless steel piping. Flow measurements are periodically taken and trended to detect any possible developing flow blockage from biological fouling.

The traveling water screen systems are classified Seismic Category 2, and in case of failure service water supply will be manually transferred to the ECP.

The Corrosion Inhibitor Injection System injects corrosion inhibitor and dispersant for control of suspended solids into each service water bay using metered pumps for injection. Corrosion rates are monitored by using test coupons.

9.2.1.2.2.2 Service Water Pumps

Nominal design data for each of the three interchangeable service water pumps are listed in Table 9.2-3 and performance curves are shown in Figure 9.2-2.

The power supplies to the pump motors are electrically interlocked so that when the emergency diesel generators are in operation and supplying power to the pumps, no more than one pump will operate from each ESF channel (red or green).

Unfused disconnect switches are utilized for service Water Pump 2P4B. One of the disconnects is fed from red 4160V Switchgear 2A303 and the other from green 4160V Switchgear 2A403. The disconnects are operated from the control room using two control switches that have one removable and interchangeable handle. This allows the closure of only one disconnect switch at any time. These switches also provide an electrical interlock with the 4160V switchgear such that only one of the two 4160V breakers can be electrically closed at a time. Thus, the connection of pump 2P4B to both ESF channels simultaneously through their respective control circuits is prevented. The pumps were designed in accordance with the standards of the Hydraulic Institute and Section III Class 3 of ASME Boiler and Pressure Vessel requirements.

The following elevations provide descriptive information of the pump suction conditions:

Dardanelle Reservoir	normal water level	- Elev. 338'-0"
Dardanelle Reservoir	low water level	- Elev. 336'-0"
Service Water Pump Compartment	bottom	- Elev. 322'-6"
Service Water Pump Suction Impeller Eye	inlet	- Elev. 324'-9"
Service Water Pump Inlet Bell	inlet	- Elev. 323’-6.5”
Service Water Pump	required submergence	- 8'-0"
Available submergence at	low water level	- 12'-5.5"
Minimum Water Level to Satisfy Submergence	Elevation	- Elev. 331’-6.5”
Emergency Cooling Pond	normal water level	- Elev. 347'-0"
Emergency Cooling Pond	minimum water level	- Elev. 346'-7.2" (346.6’)
Emergency Cooling Pond	bottom	- Elev. 341'-4.8" (341.4’)
Top of water supply pipe from the ECP		- Elev. 341'-6"

The service water pump motors are located at Elevation 366 feet which is five feet above the probable maximum flood level. Each service water pump and associated motor is located inside a Seismic Category 1 structure and is protected from the others by a concrete wall.

Each pump is sized to deliver 100 percent of water requirements during accident shutdown conditions. During normal operation, two pumps are in service, one supplying water to each ESF loop. Pump 2P4A is connected directly to SWS Loop I, and pump 2P4C is connected directly to SWS Loop II, pump 2P4B can be connected to either SWS loop by opening motor operated valves. The third pump is normally aligned to one of the two operating loops and serves as a standby.

9.2.1.2.2.3 Service Water Basket Strainers

Data for the three identical service water basket strainers are shown in Table 9.2-4. One strainer is installed in the discharge line of each service water pump. Differential pressure across the strainers can be monitored in the control room. A high differential pressure alarm in the control room indicates when a strainer is clogged. The associated pump must then be shut down after the standby pump is brought into operation so that the clogged strainer may be cleaned.

9.2.1.2.2.4 Piping

Seismic Category 1 piping 6 through 24 inches in diameter is seamless carbon steel. Essentially all piping four inches and smaller is 316L stainless steel, except the Loop II emergency spent fuel pool makeup line. Piping 26 inches in diameter and larger is seam welded carbon steel. The exterior surfaces of all buried pipe are covered with a double wrapping consisting of fibrous-glass mat and bonded coal tar saturated asbestos felt.

9.2.1.2.2.5 Valves and Sluice Gates

All valves that open or close automatically upon emergency diesel generator start, Safety Injection Actuation Signal (SIAS), Main Steam Isolation Signal (MSIS), Recirculation Actuation Signal (RAS) or Containment Cooling Actuation Signal (CCAS) are motor operated valves. Motor operated gate valves with the exception of the inlet valves to the Shutdown Heat Exchanger Room Unit Coolers 2VUC-1A, 1B, 1C, 1D, 1E and 1F, are provided at the inlet to each room unit cooler served by the system, and either open automatically upon the starting of their associated fans or remain locked open. The inlet valves to the Shutdown Heat Exchanger Room Unit Coolers are manually operated.

Motor operated gate valves are provided at the inlet to the low pressure safety injection and spray pump coolers. The isolating valves in the discharge lines from the heat exchangers are manually operated except for those on the discharge lines from the containment cooling coils, and the emergency diesel generator heat exchangers, which are motor operated.

Valves necessary for isolating system loops during SWS pump switching operations are motor operated butterfly valves. All power operated valves have control switches and associated position indicating lights located in the control room. Selector switches are provided in Motor Control Centers (MCCs). Local mechanical position indicators are also provided.

Check valves are provided at the discharge of each service water pump to prevent back flow through an idle pump. Globe valves have been provided at the outlet of all room and pump coolers, except for the HPSI pump coolers, to allow the establishment of proper flows through these parts of the system.

Water flow from the Dardanelle Reservoir or the ECP is controlled by sluice gates in the intake structure openings at opposite ends of each compartment. The three sluice gates in the intake structure from the ECP are normally closed. The three Dardanelle Reservoir supply sluice gates are normally open.

The sluice gates are provided with cast iron guides on each side and are designed to withstand the total thrust due to water pressure and wedging action. The guides are machined on all contact surfaces with a groove machined the entire length of the guide. The disc has a machined tongue to mate with the guides. The guides are of sufficient length to retain and

support at least one-half the disc in the full open position. The sluice gates are motor operated, powered from the ESF electrical system, and the entire assembly is designed to meet Seismic Category 1 requirements.

Maintenance of sluice gate stems and operators can be performed above normal water level. Maintenance of the guides and wedge portion of the gate located below the normal water level will be carried out by a diver or, if necessary, after dewatering the pump compartment. Major work will be done during plant shutdown. At this time, the service water forebay can be isolated from the Dardanelle Reservoir with stop logs and dewatered. The ECP can be isolated from the service water pump compartments by a sluice gate located at the ECP.

9.2.1.2.2.6 <u>Venturies and Associated Equipment</u>

Two 20 inch venturies constructed of 316L stainless steel are installed in the service water system. A venturi is installed in each loop header of the service water system to provide an accurate hydraulic measurement of the service water pumps. This measurement will assist in determining pump degradation. Hydraulic analysis of the service water pumps is part of ANO Unit 2 Inservice Testing Program required by ASME OM Code. An additional venturi is installed in the Auxiliary Cooling Water System to assist in this measurement. Measurement of flow in gallons per minute through these venturies is accomplished by local flow instrumentation utilizing differential pressure.

MHI flow straighteners were installed upstream of the venturies to improve the accuracy of the flow measurement.

9.2.1.2.3 <u>System Operation</u>

The following modes of operation have been considered:

A. normal power operation;
B. startup;
C. cold shutdown with outside power;
D. cold shutdown without outside power;
E. hot shutdown with outside power;
F. hot shutdown without outside power; and,
G. ESF actuation.

9.2.1.2.3.1 <u>Normal Operation</u>

During normal plant operating conditions, water flow is through both Seismic Category 1 loops and the Seismic Category 2 portions of the system. Two pumps are required to deliver the flow for this mode. Water supply for the system during normal operation is from the Dardanelle Reservoir. The third pump will act as a standby for the two in operation, and will be periodically put in service to equalize wear between all three pumps.

Differential pressure indicating switches mounted across each service water basket strainer can be monitored from the control room and the strainers are cleaned as necessary. The differential pressure switches will also sound an alarm on high ΔP, indicating a clogged strainer. The standby pump and its associated clean strainer will then be brought into service, and the clogged strainer basket will be removed and cleaned manually.

Upon loss of pressure in either loop, a low pressure alarm will sound in the control room. Switchover to the standby pump is done manually.

Discharge from the system is channeled to the cooling tower basin as makeup, to the Dardanelle Reservoir via the Unit 1 outfall, or the ECP.

The amount of cooling tower basin makeup is controlled by a level indicating controller, 2LIC-1207 mounted in the cooling tower basin which controls an air operated modulating control valve, 2CV-1460, located in the 30-inch service water discharge line to the Unit 1 outfall. All water not required as makeup to the cooling tower basin is either returned to the Dardanelle Reservoir or the ECP.

9.2.1.2.3.2 Startup

During startup, two pumps are in operation with both loops supplying water. The water source is the Dardanelle Reservoir.

9.2.1.2.3.3 Cold Shutdown With Off-Site Power

In this mode, two pumps are in operation with both loops supplying flows. The water source is the Dardanelle Reservoir.

9.2.1.2.3.4 Cold Shutdown Without Off-Site Power

In this mode, power for the system is supplied from the emergency diesel generators. Each Seismic Category 1 loop and associated pump and essential power operated valves will be powered by one diesel generator unit. Two pumps will be in operation with both loops supplying flows. The water source is the Dardanelle Reservoir.

9.2.1.2.3.5 Hot Shutdown With Off-Site Power

In this mode, two pumps will be in operation with both loops supplying water. The water source is normally the Dardanelle Reservoir.

9.2.1.2.3.6 Hot Shutdown Without Off-Site Power

In this mode, power for the pumps and essential power operated valves will be provided by the emergency diesel generators. Two pumps will be in operation supplying water. The water source is the Dardanelle Reservoir.

9.2.1.2.3.7 ESF Actuation

A SIAS causes actuation of ESF equipment as a result of postulated accident conditions and causes automatic startup of both emergency diesel generators. The SIAS causes the following to occur:

A. automatic starting of two of the three SWS pumps;

B. isolation of all Seismic Category 2 portions from the system; and,

C. initiation of water flow to the ESF equipment.

During this mode, two pumps are in operation, one supplying each loop of ESF equipment.

A CCAS or MSIS causes automatic opening of valves 2CV-1511-1, 2CV-1510-2, 2CV-1513-2 and 2CV-1519-1, allowing service water to flow through the four containment service water cooling coils.

To eliminate the possibility of severe water hammer in voided containment service water cooling coils piping, containment service water cooling coil inlet valves 2CV-1511-1 and 2CV-1510-2 are controlled by a logic that includes a time delay to keep the valves closed immediately after the CCAS or MSIS and undervoltage is detected at bus MCC2B54 or MCC2B63, respectively.

The undervoltage at MCC2B54 or MCC2B63 would indicate a loss of service water pump flow to the respective service water loop.

A time delay of 17.11 seconds before the valves begin to open allows emergency diesel generators to start, the service water pumps to sequence on, and the voided containment coolers piping to slowly refill through 1" diameter normally open bypasses around 2CV-1511-1 and 2CV-1510-2.

The outlet valves, 2CV-1519-1 and 2CV-1513-2, are interlocked with their respective inlet valves and begin to open when the inlet valves are greater than zero but less than 10% open. This keeps the containment service cooling coil piping filled and prevents water hammer during valve actuation.

There is no time delay if undervoltage is not detected.

The Emergency Feedwater Actuation Signal (EFAS) causes automatic starting of two of the three SWS pumps to supply service water to the emergency feedwater pump room coolers and to provide an assured source of emergency feedwater if needed.

The RAS causes automatic opening of valves 2CV-1453-1 and 2CV-1456-2 thus allowing service water flow through the two shutdown cooling heat exchangers.

During normal operation, the source of water for the system is the Dardanelle Reservoir. Under accident conditions the SWS discharge is automatically changed to the ECP upon the initiation of an SIAS or MSIS. The SWS discharge can be switched back to the Dardanelle Reservoir by remote manual operation of the control switches by overriding the SIAS or MSIS. Dardanelle Reservoir water is circulated through the system for the time period required to shift the source from the Reservoir to the ECP, which also serves to maximize pond inventory. Switchover of service water suction to the ECP is a manual action. The sluice gate motor operators have been sized to open or close within a maximum of five minutes.

9.2.1.3 <u>Safety Evaluation</u>

The SWS serves two identical (full capacity) loops of ESF equipment, each consisting of one shutdown cooling heat exchanger, one emergency diesel generator, one emergency feedwater pump, one train of room and pump coolers for ESF equipment, and two containment service water cooling coils. Only one loop of these components is required for shutdown of the plant after any postulated accident condition. A failure analysis for the system is given in Table 9.2-5.

Each loop supplying water to ESF equipment has been designed to Seismic Category 1 requirements. Both loops are isolated from each other and from Seismic Category 2 parts of the system by automatic closure of the system isolation valves upon the initiation of a SIAS or MSIS or by normally closed manually operated valves (with the exception of the spent fuel pool heat exchanger return line, which is isolated by check valves). This prevents a failure in one Seismic Category 1 loop from affecting the other loop, and any failures in the Seismic Category 2 parts will not affect either Seismic Category 1 loop.

System capability under power failure conditions is assured by automatic switching of the system to operation from preferred power upon failure of the normal power source and automatic switching of the system to the emergency diesel generators upon failure of both normal and preferred power sources. Channel separation is provided for the control systems and power supplies to each train as further described in Chapter 8.

The sluice gate at the ECP is normally locked open. It is not required to perform any active function during and/or following postulated accident conditions.

Each SWS loop is capable of supplying 100 percent of the required cooling water flows thus meeting the single-failure criterion. This provides the basis for the Technical Specifications with regard to limiting conditions for operation and surveillance.

The effect of long-term corrosion of the system water passages is minimized sufficiently through the use of materials compatible with the river water, adequate material thickness corrosion allowances and external wrapping of buried piping to prevent failure of any component due to the effects of corrosion for the duration of the life of the plant. Fouling of components is prevented by the traveling water screens, prescreens, service water strainers, and biocide addition to the water.

Security-Related Information
Text Withheld Under 10 CFR 2.390

Since the sluice gates can be opened or closed in approximately five minutes, sufficient time is available to operate all six Unit 2 sluice gates before the water level falls below the minimum submergence required by the service water pumps.

Three full capacity service water pumps are provided. In the event any one pump is out of service, the remaining two pumps will provide cooling water for the two redundant essential loops. An active failure of one of the two remaining pumps or a piping failure in the SWS will not prevent the safe shutdown of the plant.

In the event of a passive failure in an essential loop header, any associated branch supply or return line or a heat exchanger connected to an essential loop, the subject loop is isolated and secured. The other essential loop with redundant heat exchangers is fully capable of effecting a safe plant shutdown. No single failure of an active or passive component can lead to a Loss of Coolant Accident (LOCA).

A leak in the SWS will be found in several ways. If a break occurs in a main supply header, a decrease in service water pressure in the header will be detected and alarmed. If a break occurs in a line serving an individual component, high cooled fluid outlet temperatures or low service water flow will be detected and alarmed. In addition, a high level alarm in the auxiliary building sump will initiate a search for the source of water causing this condition. The design of the plant and of the SWS incorporates protection from degradation of the ESF equipment due to passive failures in the system.

All components of ESF equipment located in the intake structure whose operation could be degraded by flooding have been located in the 366-foot level of the intake structure so that a service water pipe or strainer rupture in the 354-foot level room will not affect these components. The 354-foot level room in the intake structure is provided with three openings in the floor to provide access to the service water bays. Two of the openings are provided with deck grating. The third opening (center) is provided with solid checker plate. The deck grating provides sufficient open area to pass the maximum flow of water that could occur from a single failure of any SWS pipe or component in the room.

All components of ESF equipment at Elevation 317 feet in the auxiliary building are located in three separate watertight rooms, so that any postulated piping failure in a service water loop will not render components of the second SWS loop inoperable, or damage other ESF equipment not related to the SWS.

For a safety evaluation of the system water supplies, see Section 9.2.5.

9.2.1.4 <u>Tests and Inspections</u>

Historical data removed - To review the exact wording, please refer to Section 9.2.1.4 of the FSAR.

The hydraulic performance of each service water pump is verified at intervals required by ASME OM Code utilizing the service water and auxiliary cooling water venturis to determine flow rates or degradation of service water pump capacities.

The integrity and capability of all components in the system are monitored by alternating the operation of the components within the system during normal plant operating conditions. Periodic testing of the emergency control functions of the system is conducted as described in the Technical Specifications 3/4.7.3. All equipment, piping, valves and instruments are arranged so that they can be visually inspected, except for the buried pipeline which can be pressure tested.

9.2.1.5 Instrument Applications

The traveling screens are provided with a differential pressure indication to ensure the screen wash system is manually activated when necessary. The differential pressure can be measured across the traveling screen or across the traveling screen and prescreen in combination. A level indicating controller in the cooling tower basin controls modulating control valve 2CV-1460 which controls makeup water flow to the cooling tower basin.

Alarms actuated by flow indicating switches in the shutdown cooling heat exchanger outlet lines will indicate the loss of adequate service water flows through this equipment. Service water inlet and outlet temperatures to each emergency diesel generator can be monitored for periodic heat exchanger testing using installed thermowells.

The discharge header from each pair of containment service water cooling coils is fitted with a flow detector. Each detector actuates a low flow alarm in the control room if a CCAS or MSIS signal is present,resulting in an alarm annunciation in the event of a loss of cooling water flow through either pair of containment cooling coils.

The instrumentation provided for indication and alarm functions is listed in Table 9.2-6. In addition to the instrumentation listed in this table, pressure indicator test connections are provided where required for testing and balancing the system.

Ultrasonic flowmeter spool pieces and instrumentation were added to the service water portion of the following equipment:

A. Emergency Switchgear Room Coolers - 2VUC 2A-2D

B. EFW Pump Room Coolers - 2VUC 6A & B

C. Charging Pump Room Coolers - 2VUC 7A, B & C

D. HPSI Pump Room Coolers - 2VUC 11A & B

E. Shutdown Cooling Heat Exchanger Room Coolers 2VUC-1A, 2VUC-1B, 2VUC-1C, 2VUC-1D, 2VUC-1E, and 2VUC-1F

Flow instrumentation consisting of venturis and local flow indicators were added to the main headers of Loop 1 and 2 of the service water system and to the auxiliary cooling water system as part of the Inservice Testing Program required by ASME OM Code.

Provisions for temperature measurement instrumentation were installed to meet the requirements of Generic Letter 89-13.

An annubar flow instrument tap location was added to the service water portion of Control Room Emergency Air Conditioning Condensing Unit 2VE1A.

A flow element is located in the Service Water supply to the main chiller condensers, 2E-112A and B. A local flow readout is provided as well as a low flow signal to isolate the SW to the main chiller condensers.

9.2.2 COMPONENT COOLING WATER SYSTEM

The Component Cooling Water (CCW) System shown in Figure 9.2-6 is a closed cycle system that provides cooling water to the following components.

Reactor Coolant Pump (RCP) Motor Coolers
RCP Lube Oil Coolers
RCP Seal Cooling
Secondary Sampling System Panels
Service Air Compressor Aftercooler
Service Air Compressor
Condensate Pump Motor Bearings
Heater Drain Pump Motor Bearings
Heater Drain Pump Seal Coolers
Reactor Coolant Sample Cooler
Steam Generator Sample Coolers
Safety Injection and Shutdown Cooling Sample Cooler
Waste Gas Compressor Units
Isophase Bus Coolers
Letdown Heat Exchanger
Main Feedwater Pump Lube Oil Coolers
Primary Sample Panel Chiller
Feedwater Sample Coolers
Condenser Hotwell Sample Panel
Primary Sample Panel Chiller
Radiation Chemistry Sample Room Cooler
Startup and Blowdown Demineralizer Sample Panel Coolers
Steam Generator Blowdown Corrosion Product Sample Coolers
Boric Acid Concentrator (BAC) Condenser*
BAC Distillate Cooler*
BAC Gas Condensate Cooler*
Waste Concentrator Condenser*
Waste Concentrator Gas Condensate Cooler*
Waste Concentrator Distillate Cooler*
BAC Steam Condensate Pump Jacket Cooling*
Waste Concentrator Steam Condensate Pump Jacket Cooling*

*Currently not in use.

The original design of the system was a two loop operation with a swing pump and a swing heat exchanger to support the two loops. An evaluation has been performed to justify also operating the system with the two loops cross-connected as an alternate, preferable configuration.

9.2.2.1 Design Bases

The CCW System is designed to remove heat from components in various reactor auxiliary systems which carry radioactive or potentially radioactive fluids and require higher water quality conditions than offered by the SWS. It provides a monitored intermediate barrier between reactor auxiliary system fluids and the SWS, and reduces the probability of leakage of reactor coolant into the service water.

The system was originally designed to remove the maximum heat loads developed by the components served while maintaining the temperature of the water leaving the CCW heat exchangers at 95 °F maximum, during normal operation. The design calculations assumed a maximum service water temperature of 85°F and service water flow of 4,600 gpm through each CCW heat exchanger.

The system is designed to permit the use of corrosion inhibitors for the prevention of long-term corrosion and organic fouling of the water passages in the system.

The pumps were designed and fabricated in accordance with the Standards of the Hydraulic Institute, ANSI and ASTM. The CCW heat exchangers were designed and fabricated in accordance with ASME Boiler and Pressure Vessel Code, Section VIII. CCW heat exchangers A and B were designed and fabricated in accordance with TEMA standards for Class R heat exchangers, and CCW C heat exchanger was fabricated in accordance with TEMA standards for Class C heat exchangers. The CCW surge tanks were designed and fabricated in accordance with API-620.

The entire system except for containment penetrations and associated isolation valves is designed to meet Seismic Category 2 requirements. Containment penetration piping and associated isolation valves are designed to meet Seismic Category 1 requirements.

The containment penetration piping was designed, fabricated and installed in accordance with Section III, Class 2 of ASME Boiler and Pressure Vessel Code. All other system piping was fabricated and installed in accordance with ANSI B31.1.0 Code for Power Piping.

9.2.2.2 System Description

The CCWS consists of two interconnected loops (Loops I and II). Each loop is equipped with a pump, a heat exchanger, a surge tank, piping, instrumentation and controls. Loops I and II are interconnected at the entrance and outlet of the heat exchangers with a third parallel heat exchanger which serves as a standby for either loop. Similarly, a third pump is connected in parallel with the pumps in each loop, also serving as a standby. For the majority of plant life, the system has been operated as two independent loops. An evaluation has been made to allow the loops to be operated as a single loop with the two loops cross-tied. This was desirable to reduce operation and maintenance costs to operate Loop I which has very few active loads.

The system is of the closed cycle type with the same fluid being continuously recirculated through both loops by one of the three CCWS pumps. A positive pressure is maintained at all points in the system by the elevated CCWS surge tanks. The tanks also provide for the expansion and contraction of water inventory of each loop during plant startup, shutdown and changes in load during operation.

Each loop is provided with a bypass pressure control valve which maintains a constant differential pressure across all system components, thus assuring constant flow to each component under various conditions and system modes of operation. With the loops cross-connected, only one of the bypass pressure control valves is needed to maintain the differential pressure.

Makeup water is supplied to the system from the condensate storage tank through the condensate transfer pump, and enters the system via the surge tanks. Makeup flow is controlled by level switches mounted on each surge tank which open or close air operated valves depending upon water level in the tank.

As originally designed, the loads on Loop II were required to be in continuous service during all periods of normal plant operation and Loop I was needed for intermittent use. With the system cross-connected, the system will function with either the Loop II pump or the swing pump in operation or standby. Either the Loop II or swing pump will automatically start upon loss of pressure in the discharge line of the operating pump. With the loops cross-connected, the Loop I pump and heat exchanger cannot be used due to the potential for the automatic actuation of the cross-connected valves isolating Loop II.

Data for the CCW pumps and heat exchangers are listed in Tables 9.2-7 and 9.2-8, respectively. Data for the CCW surge tanks are listed in Table 9.2-9.

9.2.2.3 Safety Evaluation

None of the components served by the CCW System are required for a safe shutdown following a postulated DBA.

Preceding the original issuance of Safety Guide 29 in June, 1972 NRC published in April, 1972 its safety evaluation of Unit 2. The review concluded that the auxiliary systems design basis, functions and preliminary design were acceptable. Evaluated were the design, fabrication, construction, and testing criteria, and expected performance characteristics of the plant structures, systems and components important to safety to determine that they were in accord with the Commission's General Design Criteria, Quality Assurance Criteria, Safety Guides and other appropriate rules, codes, standards, and the departures from these criteria, codes and standards were identified and justified. The design of the CCW System proceeded on the basis that none of the components served by it would be required following a postulated DBA. The CCW System was not required, at the time of the Construction Permit, to be designed to Seismic Category 1 requirements and was not built as a Seismic Category 1 system. Further discussion of the CCW cooling water supply to the letdown heat exchanger and the reactor coolant pumps can be found in Sections 9.3.4.4.1 and 5.5.1.3, respectively. As indicated in these sections, a Seismic Category 1 cooling water supply is not required for these components.

The only portions of the CCW System which are related to shutdown of the plant under any of the postulated accident conditions are the two containment penetrations including the associated isolation valves. These assemblies form part of primary containment, and therefore are designed to meet Seismic Category 1 requirements and single failure criteria.

The standby CCW heat exchanger and CCW pump(s) increase system availability and permit repair and maintenance of one heat exchanger and/or one pump while the system is in operation.

Radiation monitoring provided in the inlet line to the heat exchanger in each loop will alarm in the control room, should the radioactivity level in the loop rise above a preset limit. In this event, the atmospheric 3-way vent valve on the surge tank will be manually operated to switch the vent from atmosphere to the auxiliary building radwaste area ventilation system.

As the operating pressure of the SWS at the CCW heat exchangers is higher than that of the CCW System at the same point, any leakage is therefore from the SWS into the CCW System.

In the event the system does become contaminated, provisions have been made to drain the system to the Waste Management System (WMS).

9.2.2.4 Tests and Inspections

Each component was inspected and cleaned prior to installation into the system. Major components of the system such as pumps, tanks and heat exchangers are accessible for periodic inspection during plant operation.

Instruments were calibrated during pre-operational testing. Automatic controls were tested for actuation at the proper setpoints. Alarm functions were checked for operability and limits during preoperational testing. The relief valves were set and checked.

The system was operated and tested initially with regard to flow paths, flow capacity and mechanical operability.

9.2.2.5 Instrumentation Applications

Level switches are provided on each surge tank to permit automatic makeup to the system by operation of valves 2CV-5210 and 2CV-5214. The standby pumps will automatically start to supply the system when a low pressure condition is detected. Flow indicating switches are provided in the outlet from the reactor coolant pump motor and lube oil coolers, and seal cooling lines to prevent starting of these pumps in the event of insufficient CCW flow. To prevent a low flow alarm condition when the CCW System is intentionally not in service, an interlock has been added to the system which defeats the low flow alarm when the respective reactor coolant pump is in the "pull-to-lock" position. An additional interlock is provided in Loop I to prevent a high/low temperature alarm when the loop is intentionally not in service. During cross-connect operation, the low flow alarm for Loop I will be disabled. Table 9.2-10 lists the CCW instrument indicating and alarm functions.

In addition to the applications noted above, pressure test connections have been located at various points in the system to facilitate initial system balance and periodic inspection during operation.

9.2.3 DEMINERALIZED WATER SYSTEM

The Plant Makeup and Domestic Water System (PMU) is shown in Figure 9.2-7. Most of the original Plant Makeup Demineralizer Water System has been removed from service. Due to changes in demineralized water technology, it has become more economical to use an outside vendor to supply the plant with demineralized water. The vendor is under contract to supply makeup water of the required quality and flowrate. The water contract quality specifications are upgraded as improvements in technology occur. Water of the required quality is provided for the following purposes:

A. reactor coolant makeup;

B. steam generator feedwater makeup;

C. CST makeup;

D. CCW makeup;

E. sampling system; and,

F. resin sluicing in the radwaste system.

The PMU has no safety function.

9.2.3.1 Design Bases

Plant Makeup water is currently supplied by an outside Vendor using state of the art equipment.

9.2.3.2 System Description

9.2.3.2.1 General Description and System Operation

Most of the original demineralization equipment has been removed from service due to the cost of upgrading this system to meet the current water quality requirements of the plant. The major components still in use are the acid tank, caustic tank, the neutralization tank and the associated piping, valves and controls for these systems. Normally, demineralized water from the vendor's Mobile Water Treatment Facility is routed to the Makeup Water Degasification system for oxygen removal before being transferred to the Condensate storage tanks. See Figure 9.2-7A.

9.2.3.2.2 Component Description

The descriptions of the original PMU Water Treatment Filters, Demineralizer Trains, and Demineralizer Regeneration Equipment components that have been removed from service have been deleted.

Waste collected in the Unit 2 neutralizing tank, 2T-87, which normally consists of sample drains from panel 2C377, is discharged to the Regenerative Waste Tanks. The neutralizing tank, a 10,000 gallon fiberglass vessel, was sized for two successive regenerations of the entire makeup demineralizer train.

9.2.3.3 Safety Evaluation

The PMU is designed to produce demineralized water at a rate corresponding to the maximum continuous requirements of the plant.

Loss of the PMU is not critical until the volume in the condensate storage tank reaches that required for reactor decay heat removal per Section 9.2.6.1. An alarm will alert the operator prior to this condition being reached.

9.2.4 POTABLE AND SANITARY WATER SYSTEM

Potable and sanitary water is supplied by the PMU as shown in Figure 9.2-7B. Water of quality acceptable for human consumption is supplied to plumbing fixtures, and makeup water is supplied to the plant heating system and chilled water systems. The system has no safety function.

9.2.4.1 Design Bases

The domestic water portion of the PMU is designed to supply 80 gpm of treated water with one pump in operation. This capacity is sufficient to meet anticipated demands from domestic water service and makeup supplies for the plant heating system and chilled water system. All components of the system are designed to meet Seismic Category 2 requirements.

The system is also designed in accordance with all requirements of the National Plumbing Code regarding water supplies for human consumption. All pressurized tanks were designed and fabricated in accordance with the ASME Code, Section VIII.

9.2.4.2 System Description

The domestic water portion of the PMU, shown in Figure 9.2-7B, consists of the following:

A. an 8-inch supply line from the Russellville City Water System;

B. raw water holdup tank (T61);

C. domestic water pumps (2P10A, B);

D. domestic water pressure tank (2T44);

E. domestic water storage heater (2E43);

F. domestic hot water circulating pump (2P30); and,

G. interconnecting piping and controls.

All components of the system with the exception of the raw water holdup tank are located at Elevation 370 feet of the auxiliary building. The raw water holdup tank is located outdoors.

Water is supplied to the raw water holdup tank from the Russellville City Water System via an 8-inch line. Flow to the tank is controlled by a tank mounted level switch which operates a control valve in the supply line. Water from the tank then flows by gravity to the domestic water pumps which operate periodically to maintain the level in the domestic water pressure tank. The instrument air system and tank mounted pressure controller maintain an air pressure in the domestic water pressure tank of 60 psig. A 3-inch line from this tank provides cold water supply for all plant domestic water services. The domestic hot water supply is provided by the domestic water storage heater and the domestic hot water circulating pump, which continuously circulates water in the loop through the water heater.

Drains for sanitary service are directed to the ANO sewage treatment plant.

Data for the individual components of the system is shown in tables as follows:

Raw Water Hold-up Tank (T-61)	Table 9.2-11
Domestic Water Pumps (2P10A, B)	Table 9.2-12
Domestic Water Pressure Tank (2T44)	Table 9.2-13
Domestic Water Storage Heater (2E43)	Table 9.2-14
Domestic Hot Water Circulating Pump (2P30)	Table 9.2-15

9.2.4.3 System Evaluation

The domestic water portion of the PMU does not serve any safety-related function and is not required for safe shutdown of the plant.

The design of the piping system ensure that impurities cannot enter the system by backflow and furthermore, that backflow into the Russellville City Water System is not possible. Location of major system components in areas far removed from possible sources of radiological contamination and maintenance of a 40 to 60 psig internal pressure throughout the system precludes the possibility of radiological contamination within the plant.

The system is conservatively designed to provide quantities of water adequate to enable proper functioning of the plumbing fixtures in all parts of the plant, and to meet the maximum requirements of makeup to the plant heating system and chilled water systems.

9.2.4.4 Tests And Inspections

Historical data removed - To review the exact wording, please refer to Section 9.2.4.4 of the FSAR.

9.2.4.5 Instrumentation Applications

Instrumentation for automatic and manual control of the system is provided as described in Section 9.2.4.2 and as shown in Figure 9.2-7A and 9.2-7B.

9.2.5 ULTIMATE HEAT SINK

The plant ultimate heat sink consists of two water sources:

A. The Emergency Cooling Pond (ECP) with the following associated Seismic Category 1 reinforced concrete structures:

    1. Pipe inlet structure (see Section 9.2.5.2.1.2)

    2. Pipe outlet structure (see Section 9.2.5.2.1.2); and,

B. The Dardanelle Reservoir with the associated Seismic Category 1 reinforced concrete service water intake structure (see Section 9.2.5.2.2).

The service water intake structure serves both the ECP and the Dardanelle Reservoir.

9.2.5.1 Design Bases

The design basis of the ultimate heat sink is to provide sufficient heat removal capability and reliability for a minimum of 30 days to permit and maintain individual or simultaneous shutdown of Unit 1 and Unit 2.

The shutdown modes considered for ECP sizing purposes were as follows:

A. normal shutdown of Unit 1 only;

B. normal shutdown of Unit 2 only;

C. simultaneous normal shutdown of Unit 1 and Unit 2;

D. simultaneous normal shutdown of Unit 1 and emergency shutdown of Unit 2 following a LOCA in Unit 2; or,

E. simultaneous normal shutdown of Unit 2 and emergency shutdown of Unit 1 following a LOCA in Unit 1

The greatest heat load occurs during mode (D) above which was used for sizing the ECP.

The design basis safety functions of the ultimate heat sink are assured following:

A. the most severe natural phenomena associated with the site location, including earthquake, tornado, flood or drought, taken individually;

B. site-related events, such as canal blockage, ice formation, transportation accidents, oil spills, or fires that historically have occurred or that may occur during the plant lifetime; and,

C. any single failure of a man-made structure, including failure of the Dardanelle Dam, or any upstream dam or dams.

The ultimate heat sink must meet the design requirements noted above while limiting plant returning cooling water temperature to less than 116 °F, the maximum allowable inlet water temperature taking into account the rate at which the heat energy must be removed, the cooling water flow rate, and the capabilities of the respective heat exchangers.

9.2.5.2 System Description

The ultimate heat sink consists of two independent water sources, the ECP and the Dardanelle Reservoir. The following sections provide descriptive information for each source.

9.2.5.2.1 Emergency Cooling Pond

The ECP portion of the ultimate heat sink consists of the pond, the pond inlet and pond outlet structures, associated piping to and from tie points to the SWS, pond spillway to the Dardanelle Reservoir, and the 225-acre[Note 1] watershed area necessary to maintain the minimum required water level in the pond. A topographic map of the pond area is provided in Figure 9.2-9. Details of the design and construction of the above noted parts of the ECP are provided in the following sections.

Provisions have been made to manually make up for evaporative water loss in the pond by supplying Russellville City water or Lake Dardanelle Water via service water pumps to maintain the minimum required pond water level as set forth in the Technical Specifications.

Note 1: The natural surface drainage area during site construction was approximately 225 acres. No credit is taken for drainage area in the ECP inventory analyses; therefore, it is not required to maintain a minimum 225 acre drainage area (Reference CR-ANO-C-2008-1728).

9.2.5.2.1.1 Pond Construction

The ECP is located entirely within the site boundary, and comprises an area of approximately 14 acres. The minimum average pond level is maintained at a depth of 5.2 feet for a total water volume of approximately 70 acre-feet. The ECP, in general, is excavated in impervious clay strata with the bottom of the pond about 4 to 16 feet above rock. Weathered shale which extends to or above the pond bottom is excavated to a depth of two feet below the pond bottom and replaced with well compacted impervious clay material. The pond sides are handled in a similar manner as required. Stability analyses as described in Section 9.2.5.3 were performed to verify the integrity of the pond during both normal conditions and DBE conditions. The side slopes of the dike and pond are 2.5 horizontal to 1.0 vertical.

A typical section of the pond is shown in Figure 9.2-10.

The minimum spillway crest elevation is 347 feet, which is below the existing ground. The spillway is a reinforced concrete ogee shaped structure located approximately 60 feet downstream of the original spillway. The original spillway was constructed within the pond embankments at the west end of the north bank and was replaced with the concrete spillway due to erosion concerns. Earth dikes are constructed on either side of the location of the original spillway, and along a portion of the southeast pond perimeter. Additionally, similarly constructed embankments were added to form a channel to the reinforced concrete spillway. The inside face and the top of the dikes are lined with rip-rap. The top of the dikes are at Elevation 353 feet providing a nominal freeboard of 2 feet 6¾ inches during flood conditions as discussed in Section 9.2.5.2.1.3. The added embankments have a crest at Elevation 354 feet.

Placement of the rip-rap adjacent to the spillway was accomplished using clam shell bucket type equipment. First, a 6-inch layer of bedding material was placed. Then a 1½-foot thick rip-rap layer was placed on top of the bedding material. Both the rip-rap and the bedding material have a resistance to abrasion of 26 percent loss of material as measured by the Los Angeles Abrasion Test. Gradation of the rip-rap is as follows: Maximum 1,000 pounds; 25 percent greater than 300 pounds; 45 percent to 75 percent from 10 to 300 pounds; 25 percent less than 10 pounds; sand and rock dust less than five percent; specific gravity 2.5 or greater. Gradation of bedding material is from 3/16 to 3½ inches. These gradations are based on the requirements of the Department of the Interior, Bureau of Reclamation's Book "Design of Small Dams," First Edition, Page 207.

Additional rip-rap was placed all around the pond to prevent wave action from causing erosion of the banks of the pond.

Earth fill for embankments and backfill consists of red silty or sandy clay from required excavation, free of gravel, cobbles, boulders, or pockets of silt, sand or other non-plastic material. Embankment material was placed in 8-inch loose layers, moisture conditioned and compacted to 95 percent of maximum dry density as determined by the Modified Compaction Procedure ASTM Test Designation D-1557. Per EC-443, for the embankments added with the reinforced concrete ogee spillway, it was demonstrated that the embankment material placed in 8-inch loose lifts, compacted to 90 percent of maximum dry density, provided adequate stability and met permeability requirements.

Natural surface drainage (drainage area, 225 acres[Note 1]) is used for initial fill as well as makeup for evaporation losses. In the event of a prolonged drought period, the pond minimum water volume of 70 acre-feet can be maintained by supplying makeup water from the Russellville water supply line to the plant site. A spillway is provided for the overflow of excess water, and is further described in Section 9.2.5.2.1.3.

Note 1: The natural surface drainage area during site construction was approximately 225 acres. No credit is taken for drainage area in the ECP inventory analyses; therefore, it is not required to maintain a minimum 225 acre drainage area (Reference CR-ANO-C-2008-1728).

9.2.5.2.1.2 Intake and Discharge Pipes and Related Pond Structures

Separate intake and discharge water lines are used for supplying pond water to the Unit 1 and Unit 2 SWSs. The 42-inch diameter line to the Unit 2 SWS inlet structure is a gravity flow line running approximately 2,200 feet underground and is covered on exterior surfaces with a double wrapping of fibrous-glass mat and bonded coal tar-saturated asbestos felt to prevent corrosion.

The 30-inch diameter return line to the pond from Unit 2 SWS valves 2CV-1541-1 and 2CV-1560-2 also runs underground and is coated in the same manner. It is a pressure line utilizing the service water pump discharge pressure. Both intake and discharge pipes are welded carbon steel, SA-155 Grade KC-60, or equivalent substitution, Class 2, with a 0.375-inch nominal wall thickness.

The separate intake lines for Units 1 and 2 originate from adjacent Seismic Category 1 inlet structures located on the pond perimeter. Discharge lines from each unit terminate in adjacent Seismic Category 1 outlet structures located on the pond perimeter at the opposite end of the kidney shaped pond from the inlet structures.

Design methods and design criteria for the pipe inlet and outlet structures are described in Sections 3.8.4 and 3.8.5, and details are shown in Figure 3.8-25.

Screens are provided in the inlet structure to prevent inclusion of soil or foreign objects in the water delivered from the pond. The inlet screens consist of two screens in series each of 12 gauge stainless steel wire with 3/8-inch openings. Provisions have been made for access to clean these screens periodically.

A distribution weir as shown in Figure 2.5-21 is provided near the pond outlet structures to distribute the discharge evenly across the surface.

9.2.5.2.1.3 Spillway

The spillway is provided for the overflow of excess water in the pond. The spillway is a reinforced concrete ogee shaped design, located at the east end of the pond, approximately 60 feet downstream of the location of the original spillway. The original spillway is left in place.

The pond spillway is designed to accommodate one-half the maximum probable rainfall, based on a total rainfall of 19.5 inches in two hours. A histogram of the spillway design basis rainfall is given in Figure 9.2-12.

The spillway rating curve is shown in Figure 9.2-13, and was developed following the methodology of the Bureau of Reclamations publication “Design of Small Dams,” Third Edition.

The maximum water surface, for the design flow rate of 1,063 cfs, has been determined by a hydraulic analysis to be approximately Elevation 350 feet, 5¼ inches. The indicated maximum water surface relative to the original spillway was estimated to be at Elevation 350 feet, to which a freeboard of three feet was added to arrive at a crest elevation of 353 feet for the dikes. The increased maximum height of the pond during the design storm results from abandoning the original spillway in place, with no modifications. The new spillway was designed with the consideration that the top layers of articulated blocks would be removed from the original spillway. The blocks were left intact to alleviate future potential erosion concerns, with the result of a reduction in the efficiency of the new spillway. The three foot freeboard originally provided was based on standard practice at the time of original construction with no consideration for

actual wave-height and wind setup calculations for the ECP. From EC-443, a maximum rise in the water surface from the design wind of 90 mph was conservatively estimated to be 0.13 feet and the significant wave height was conservatively estimated to be 1.88 feet. Combined, this gives an estimated maximum wave height to be considered of 2.01 feet. This is less than the nominal 2 feet 6¾ inch freeboard provided with the pond level at 350 feet 5¼ inch.

9.2.5.2.2 Dardanelle Reservoir

Section 2.4 provides a detailed description of the characteristics of the Dardanelle Reservoir portion of the plant ultimate heat sink while Section 3.8.4 covers the design criteria and design methods for the Seismic Category 1 service water intake structure.

The Dardanelle Reservoir is the source of cooling water for the SWS's of both Unit 1 and Unit 2 during normal operating conditions. Switchover from the reservoir to the pond may be accomplished by actuation of the motor operated sluice gates in the SWS intake structure, and either remote manual actuation of the SWS discharge valves if the ECP is used for normal shutdown or automatic actuation of the SWS discharge valves during accident conditions.

9.2.5.3 Safety Evaluation

During any normal or abnormal plant shutdown operation, the design objectives of the plant ultimate heat sink are assured through the availability of the ECP, together with the associated intake and discharge piping. The Dardanelle Reservoir provides the primary heat sink during normal plant operation, while the emergency cooling pond may provide the seismic Category I backup source for plant safe shutdown if necessary under normal or accident conditions.

The design basis for heat rejection to the ECP is a LOCA in Unit 2 and a concurrent normal shutdown of Unit 1.

ECP performance has been analyzed in accordance with Regulatory Guide 1.27, Revision 1. ECP performance was simulated using a numerical cooling pond model with the following main characteristics:

A. Two layers, with horizontal temperature gradients.

B. Initial mixing and mixing between layers is simulated by a single entrainment coefficient.

C. Horizontal dispersion is neglected.

Pond temperatures were originally analyzed using the worst 1-day average meteorology followed by the worst 30-day average meteorology for Little Rock for the period of record (1930-1973). Worst meteorology is defined as those conditions resulting in maximum pond outlet temperature. To determine whether the Little Rock long-term meteorological data is representative of conditions at the plant site, a comparison was made of simultaneous data taken by the onsite instrumentation and the Little Rock data. Since maximum pond temperatures are expected only during summer months, the period April 1 through September 30, 1972 was used for this study. A digital computer program was used to compute the daily and 30-day running average equilibrium temperatures and evaporation rates for each location.

Because only temperature and wind speed data were taken at the site, the Little Rock relative humidity, solar radiation, and cloud cover were also used in the site calculations. Pond performance was simulated using the worst case meteorology for both the site and Little Rock. It was found that the peak pond outlet temperature, based on site data, was 6.5 °F higher than the peak pond outlet temperature based on Little Rock data. Brady's wind speed function (Reference 9) was used for this temperature analysis.

The maximum pond outlet temperature, based on worst case Little Rock meteorology for the period 1930-1973 and Brady's wind speed function, was computed to be 123 °F, including the effects of diurnal fluctuations. The worst case 1-day and 30-day meteorology conditions are summarized in Table 9.2-17. Adjustment for the difference between site and Little Rock data results in an estimated peak pond outlet temperature of 129.5 °F.

The 129.5 °F peak pond temperature, which was determined in a revised analysis performed in accordance with Revision 1 of Regulatory Guide 1.27, is 9.5 degrees higher than the temperature determined in the previous analysis. As a result of this temperature increase, a study was conducted to determine the impact of these higher temperatures on the safety-related equipment which is cooled by the SWS and required to function throughout the post-LOCA recovery period. Both Unit 1 and Unit 2 equipment were included in this study. The pond temperature versus time curve shown in Figure 9.2-19 was sent to the suppliers of each of the equipment involved.

As a result of this study, some of the equipment was re-rated for the higher temperatures based on existing test data. For the remainder of the equipment, additional testing was performed and/or equipment modifications were made to ensure that this equipment will function properly throughout the period of elevated pond temperatures.

Required modifications to the control room emergency air conditioning system which were made to meet operating requirements with the above maximum pond temperature are described in Section 9.4.1.

Further analysis of ECP response, consistent with Regulatory Guide 1.27, Revision 1, with a computer model which has been benchmarked against an operating cooling pond and more accurately reflects pond behavior has yielded a much lower peak temperature of 120.8 °F or 121 °F (Ref.18). This computer model maintains the assumptions utilized in the previous model except the discharge water is assumed to be pulled from all layers of the pond not just the top layer. The meteorology was reviewed to ensure compliance with the Regulatory Guide was maintained. Changes to the meteorological data used related to the inclusion of diurnal fluctuations for the first five days of the event to verify the peak pond temperature had been attained.

The most recent analysis was performed in accordance with Regulatory Guide 1.27, Revision 2, accepted methodology using a meteorological data record that also includes local and site observed data. This analysis has yielded a lower peak temperature of approximately 116 °F (115.8 °F) (Reference 20). This analysis uses the record of observed ECP temperatures (approximately 33 years) to identify the period of highest ECP temperature (July, 1980). Regional meteorological data supplemented by local data was then used to demonstrate that the surface heat exchange model reproduces the ECP temperature observations. Wind speed reduction calibration methods of local (met tower) and regional (Little Rock) wind speed data were used to reproduce local temperature observations to eliminate the need for a temperature correction of 6.5 °F between the site and Little Rock data.

The heat loads used in this analysis are shown in Figures 9.2-14 through 9.2-16, with the resulting most recent temperature profile shown in Figure 9.2-21.

Pond evaporation losses were analyzed using the worst 30-day meteorology with respect to natural evaporation rate and dew point depression. Total pond evaporative water loss during the 30 days of operation after the postulated LOCA was computed to be 24 inches, or 28.2 acre-feet. The emergency cooling pond inventory loss analysis includes the effect of evaporative losses, safe shutdown unit condensate requirements, spent fuel pool makeup requirements, sluice gate leakage, system boundary valve leakage, two hours fire pump usage, the impact on pond inventory due to transferring service water system discharge and suction from the lake to the pond, piping leakage, and seepage (Ref. 20). Margins are maintained such that the minimum pond depth for proper hydraulic performance (cooling capability) is computed at 18 inches. Operator action is credited, as allowed by Regulatory Guide 1.27, to increase pond inventory analysis during the transfer of the Service Water System to the pond. Specifically, pump returns are transferred to the pond shortly after a loss of lake event and pump suctions are transferred later in the event depending on pump bay level. In the time frame between the transfer of the returns and suctions to the pond, lake water is pumped into the pond increasing level. This additional water is required, along with that maintained by technical specifications to ensure a 66.9 inch pond depth which corresponds to a 30 day supply of cooling water (Ref. 20).

The required Net Positive Suction Head (NPSH) for each service water pump at 9,500 gpm is 33 feet. The available NPSH at 9,500 gpm, 130 °F and an initial ECP level of Elevation 346 feet is 51.4 feet. At Elevation 342 feet, 6 inches, which is the minimum level expected under worst case meteorological conditions at the end of 30 days, the NPSH available is 50.8 feet at a temperature of 111 °F.

The stability of the pond side slopes was investigated under normal operating conditions and under a seismic loading of 0.2 g ground acceleration.

For normal operating conditions a factor of safety of 1.5 was required, and for the above-mentioned seismic condition a factor of safety of 1.1 was considered acceptable. The varying depth to bedrock below the bottom of the pond was taken into consideration in the analyses.

Stability analysis design strength parameters for the pond slopes were based on residual shear strengths obtained from drained direct shear tests on undisturbed samples of overburden soils.

These are as follows:

Unit weight of soil above ground water table	124 lb./cu.ft.
Submerged unit weight of soil	62 lb./cu.ft
Consolidated drained direct shear strength	$s = 200 + p \tan(23°)$

(s is the shear strength in pounds per square foot and p is the normal pressure in pounds per square foot on the plane on which the shear strength is measured).

The analyses were made in accordance with the Modified Swedish Slip Circle method, known as the "Method of Slices." It was assumed that the water and earth pressures on the sides of each slice are in balance. The earthquake load used in the analysis was the DBE with 0.2 g ground acceleration acting on the mass of soil and water in the slope. The added embankment slopes for the reinforced concrete spillway were analyzed using the Simplified Bishop Method,

the Simplified Janbu Method, and Spencer's Method. These methods are also part of the family of the "Method of Slices," and together produce equivalent or more conservative results compared with the Modified Swedish Slip Circle Method. For the added embankments, an effective DBE acceleration of 0.355g was used, which was determined from an updated seismic soil-structure interaction analysis relative to the 0.2g ground acceleration.

The results of the above analyses indicate that soil slopes of 2.5 horizontal to 1.0 vertical will be adequately stable under the conditions stated above. Combinations with other natural phenomena and/or site related events are considered less critical and, therefore, are not considered in the analyses.

Section 2.2 discusses Industrial, Transportation and Military Facilities. Based on flight routes and airport locations, the likelihood of an aircraft crash at the site is remote. The operation of the existing rail spur is not considered a credible origin for an ECP incapacitating accident as it is used only infrequently and it is removed from the vicinity of the ECP. As discussed in Section 2.2.2.4, it is not possible for large floating objects in the Dardanelle Reservoir to enter the plant site area. Therefore, it is not credible for the ECP to be damaged by large floating objects such as a ship or barge. The physical remoteness of the ECP to the avenues of bulk petroleum transportation makes massive fouling of the heat sink surface by an oil spill incredible. Vehicles delivering diesel fuel oil to the site will not enter the area of the ECP and, therefore, are not a source of an oil spill from an undefined accident involving the delivery vehicle. In as much as the ECP and related equipment are largely heat resistant or noncombustible, a fire would have minimal impact upon safe shutdown cooling. A gas line rupture event is discussed in Section 2.2.2.1 and was found to have no adverse consequences.

Should it become necessary to use fire fighting equipment while the pond is being used concurrently for plant shutdown, a 2,500 gpm fire pump may be operated for two hours without reducing the normal pond water inventory by more than 1.1 percent (a decrease in pond level of approximately 0.79 inch) assuming an initial depth of 6 feet.

The results of permeability tests made in the field as well as tests made in the laboratory indicate that little or no water losses due to seepage are to be expected.

If a leak in the underground piping to or from the pond were to occur, it would be indicated by the appearance of water on the surface of the ground and/or by a collapse and erosion of the soil long before the water level in the pond is reduced significantly. A leak equivalent to a 2-inch diameter unrestricted hole in a pipe buried 13 feet underground will cause a ground collapse or water appearance at the surface in one hour or less. In the event this occurs at night and goes unnoticed for six hours, about 9,000 cubic feet of water will be lost. This will reduce the pond level by 0.18 inch. SW piping leakage is not accounted for in the design basis ECP inventory analysis.

Makeup from normal rainfall is expected to be well in excess of that required to offset losses due to normal evaporation and leakage from all sources. It is considered that possible layers of ice on the pond surface would not cause flow blockage of the cooling water system. Since the use of oil-base insect sprays in the area surrounding the pond will be minimal, small amounts of this spray which might settle on the surface of the cooling pond will have a negligible effect on its performance.

Due to the very shallow depth of the pond and the six feet of normal freeboard, no wave action will top the pond banks with the exception of the spillway, and the minor losses at this point will be more than offset by normal makeup due to rainfall.

9.2.5.4 Tests and Inspections

Prior to startup of Unit 2, pond performance was verified during shutdown operations of Unit 1. Periodic inspections of the pond area will be made during the life of the plant to detect leakage or erosion which may endanger the safety function of the pond.

9.2.5.5 Instrument Application

The water level in the pond will be monitored daily to ensure that it is above the minimum level specified in the Technical Specifications. The level will be read from a permanently installed device in the pond and recorded by plant personnel. Since changes in water level will be small from day to day, more than sufficient time will be available to observe dangerous trends, e.g. decreasing water level, and take appropriate action.

To ensure that water level measurements are accurate, soundings will be made annually to determine if the pond bottom elevation has changed.

9.2.6 CONDENSATE STORAGE AND TRANSFER SYSTEM

The condensate storage and transfer system, shown in Figure 9.2-7A and 9.2-7B, stores and supplies water for the following services:

A. condenser hotwell makeup;

B. emergency feedwater suction supply;

C. CCW makeup;

D. sample panel and sink;

E. hydrazine and ammonium hydroxide tanks;

F. generator stator cooling water system;

G. emergency diesel generator expansion tanks; and

H. zinc injection skid.

9.2.6.1 Design Bases

The condensate storage and transfer system is designed to have sufficient capacity to supply all anticipated normal condensate makeup requirements for the plant while retaining a volume of at least 160,000 gallons. This water volume is adequate to bring the reactor to a hot shutdown condition at a cooldown rate of 75 °F per hour with 1-hour hot standby time allowed.

Condensate storage tank water is maintained above a nominal temperature of 80 °F to minimize the thermal shock to the steam generators during emergency feedwater injection.

All components of the system are designed to meet Seismic Category 2 requirements. The condensate storage tanks are stainless steel and were designed and constructed in accordance with the American Petroleum Institute, API-650, "Standard for Welded Steel Tanks for Oil Storage."

9.2.6.2 System Description

The condensate storage and transfer system consists of two condensate storage tanks (2T41A, B), two condensate transfer pumps (2P9A, B), and associated piping, controls, and instrumentation.

A Makeup Water Degasification System that is normally in use has been added to remove oxygen from the makeup water prior to being transferred to the Condensate Storage Tanks. In addition to removing oxygen from the makeup water, demineralized water is recycled through the degasifier in order to maintain a low level of oxygen in the condensate storage system. The Degasification system is located in a building just west of the Unit-1 condensate storage tank (T-41).

The condensate storage tanks are located outdoors in the area adjacent to the northwest side of the containment. The condensate transfer pumps are located in the turbine building at Elevation 335 feet.

The EFW pumps are normally aligned to the safety-grade storage tank T-41B (QCST). One Unit 2 condensate storage tank is normally on-line and directly connected to the condenser. With the EFW pumps aligned to the QCST, the Unit 2 condensate storage tanks can be cross-connected to provide the largest possible volume of water for condensate supply.

The hotwell level was designed to be automatically controlled by the makeup and reject valves. The hotwell level is now manually controlled by Operations and the automatic system is not used due to the potential of increasing condensate oxygen levels and contaminating the Condensate Storage Tanks. The condensate tank levels are also manually controlled by Operations. The controls for automatically maintaining CST levels have been either defeated or not used. These controls did not function adequately to meet the needs of the plant.

Each condensate storage tank is provided with an internal steam heating coil which is used in periods of cold weather, maintaining the tank water temperature above a nominal 80 °F. Data for the condensate storage tanks are listed in Table 9.2-16. The condensate transfer pumps are horizontal centrifugal type, each rated to discharge 50 gpm at 80 feet total head.

All piping connected to the tanks is enclosed in heated pipe trenches to prevent freezing during subfreezing outdoor temperature conditions. All piping connected to the tanks is stainless steel to minimize corrosion problems.

Tank level indication is displayed in the control room on a level recorder.

A low level switch annunciates an alarm in the control room which is selectable to either CST. The level switch setpoint is set at greater than 80 percent indicated level.

9.2.6.3 Safety Evaluation

As discussed in Section 9.2.3, the PMU is designed to produce demineralized water at a rate in excess of the anticipated normal condensate makeup consumption. Therefore, the condensate storage tank volume is maintained above an indicated level of 80 percent by manual control. The minimum volume setpoint of 160,000 gallons ensures that sufficient water is available to maintain the RCS at hot standby conditions for one hour with steam discharge to atmosphere concurrent with total loss of off-site power.

With the tank at its 160,000 gallon setpoint (80 percent), there is sufficient volume for about four hours of decay heat removal or one hour of hot standby operation before a 99,000 gallon volume is reached, at which point cooldown toward cold shutdown would begin.

Freezing of the tank water is prevented by the installed steam heating coil, fed from either the Unit 1 startup boiler or Unit 2 turbine extraction steam. Freezing at tank nozzles and piping is prevented by location of all nozzles and piping in heated trenches. The reactor makeup water tank is heated in exactly the same manner. Both tanks have low temperature alarms which annunciate in the control room.

The condensate storage and transfer system is a Seismic Category 2 system. The QCST is the preferred source of water for the EFW system. The QCST has a 30 minute (minimum) supply of EFW protected by a tornado missile shield wall, giving operators amply time to align the EFW pump suction to the Service Water System. The Unit 2 Condensate Storage Tanks 2T-41A and B (CSTs) can be connected to the Unit 2 EFW system or isolated from the system by closed double isolation valves.

The water in the condensate storage tank is not normally radioactive. However, in the event of primary-to-secondary leakage due to a steam generator tube leak it is possible for the CFS to become radioactively contaminated. A full discussion of the radiological aspects of primary-to-secondary leakage, including anticipated operating concentrations of radioactive contaminants, means of detection of radioactive contamination, and anticipated releases to the environment is presented in Section 10.4.8.

In the event of a tank rupture, some water would be drained to the turbine building drainage system, and the balance would flow toward the Dardanelle Reservoir.

Long-term system degradation due to corrosion is prevented by the use of stainless steel components in the system. The condensate storage tank, and piping to the PMU, condenser hotwell and emergency feedwater pump is type 304 stainless steel.

9.2.6.4 Tests and Inspections

Tank contents are sampled to ensure maintenance of water quality required by the steam generators.

9.2.6.5 Instrument Application

A level switch and alarm is provided to alert the operators whenever the tank level falls below setpoint as described in Section 9.2.6.2.

9.3 PROCESS AUXILIARIES

9.3.1 COMPRESSED AIR SYSTEM

Compressed air is supplied by the Instrument and Service Air Systems as shown in Figure 9.3-1. The Instrument and Service Air Systems provide all plant compressed air for pneumatic instruments and valves and for service air outlets located throughout the plant which will be used for operation of pneumatic tools and other requirements. The Instrument and Service Air System are not required for the safe shutdown of the plant.

The Breathing Air System is designed to provide compressed air for use in air-fed respirators in Controlled Access areas. The Breathing Air System is not required for the safe shutdown of the plant.

9.3.1.1 Design Bases

The air compressors are designed to supply air at a nominal pressure of 100 psig, with pressure reduced, as necessary, at the point of use for various service requirements. The rated capacity of each of the two instrument air compressors is 456 scfm at 100 psig discharge pressure. This rating is based on the total instrument air demand for the Nuclear Steam Supply System (NSSS) and the balance of the plant. Both the service air compressor and the backup service air compressor have the capacity to deliver 100 scfm at 100 psig discharge pressure to supply average service air requirements for reactor refueling operation and miscellaneous uses in the plant.

Each of the two instrument air filters and instrument air dryers are sized to treat the total instrument air quantity required (456 scfm) for the Instrument Air System and delivers dry air having a dew point of at least 18 °F below the minimum local ambient temperature onsite (Ref. ISA Quality Standard for Instrument Air S7.3-1975).

All parts of the system, with the exception of the containment penetrations, are designed to meet Seismic Category 2 requirements, and were fabricated and installed in accordance with ANSI B31.1.0, Code for Power Piping. The containment isolation valves and piping between these valves are designed to meet Seismic Category 1 requirements and were fabricated and installed in accordance with ASME Code, Section III, Class 2. The air receivers and instrument air dryer towers were designed and fabricated in accordance with ASME Code, Section VIII.

The Breathing Air compressor is designed to supply air at a nominal pressure of 100 psig, with pressure reduced, as necessary, at the point of use for respirator requirements. A connection to the Instrument Air cross-connect between Units 1 and 2 is provided to enable Breathing Air to backup Instrument Air.

9.3.1.2 System Description

The Instrument Air System consists of two oil-free air compressors (2C27A, B), two air receivers (2T88A, B), two dual tower air dryers (2M70 and 2M76), two air filters (2F173A, B), instruments, piping, and valves. One of the two 100 percent capacity compressors is required to be in operation for normal operation and normal startup or shutdown of the plant, while the other one serves as a standby. The Unit 1 and Unit 2 Instrument Air Systems have interconnection capabilities; these interconnections are operated as desired for split or common system operation.

The Service Air System consists of a rotary screw air compressor (2C-43) and an air receiver (2T-148), instruments, piping, and valves. Standby capacity is provided by a lubricated air compressor (2C3) with its associated aftercooler (2E19) and air receiver (2T63). The cooling water for the standby service air compressor and aftercooler is supplied from the Component Cooling Water (CCW) System. Compressor 2C-43 serves as the primary service air compressor for both Unit 1 and Unit 2. During periods of high usage additional capacity can be installed at temporary compressor connection points.

Compressed air for instrument air use passes through a drying unit and an air filter before being distributed to the instrument air piping system. The arrangement of the filters allows cleaning or changing of filters while the unit is in operation by diverting the air flow through the other parallel filter. The air dryer in use automatically alternates flow of air through each of the chambers to permit automatic drying of the desiccant in one chamber while the other chamber is in service.

The Breathing Air System consists of one compressor (C-30) that is designed to supply compressed air to be used in Breathing Air respirators in ANO-1 & 2 Controlled Access Areas. The Breathing Air System is shown schematically on Figure 9.3-1.

9.3.1.3 Safety Evaluation

The Instrument and Service Air Systems are required for normal operation and startup of the plant. However, all pneumatically operated devices in the plant which are essential for safe shutdown are designed to assume a fail-safe position upon loss of air supply. Therefore, the Instrument and Service Air Systems are not required to effect a safe shutdown of the plant or for an ESF component to perform its intended function and the systems are, accordingly, designed to meet seismic Category 2 requirements. A discussion of loss of the Instrument and Service Air Systems is presented in Section 15.1.34, including a list of safety-related pneumatic valves and their failure modes. Containment penetration piping is provided with double isolation valves to prevent radioactive releases from the containment following a postulated LOCA. Pressure points are provided to check the integrity of the penetration piping.

Required instrument air dewpoint is monitored by periodic system testing. Additionally, the following system features contribute to maintaining the required instrument air quality:

A. air compressor inlet filters;

B. oil-free compressors;

C. air dryers with high humidity alarm; and,

D. filters installed after the air dryers

The compressors are designed for full capacity operation with a maximum inlet air temperature of 40 °C (104 °F).

The Breathing Air System is not required for the safe shutdown of the plant. In the event of a Breathing Air compressor failure, the air receiver tanks (T-120 and T-118) are designed to contain enough air to allow the worker on breathing air to get to a non-respirator environment.

9.3.1.4 Tests and Inspections

Historical data removed; see Section 9.3.1.4 of the FSAR.

The “lag” and “lead” instrument air compressors are periodically rotated by increasing the setpoint of the “lag” compressor to the “lead” setting and verifying that it starts automatically. The existing “lead” compressor is then placed in standby by decreasing its setpoint to the “lag” setting.

9.3.1.5 <u>Instrument Applications</u>

Pressure switches sensing the air pressure in the air receiver are provided for automatic control of the compressors. The instrumentation for monitoring the Instrument and Service Air Systems includes:

A. high air temperature alarms;

B. high cooling water temperature alarm (2C-3 only);

C. low oil pressure alarms;

D. motor over current alarms;

E. header low pressure alarms;

F. instrument air high moisture alarm;

G. air dryer high temperature and valve failure alarms; and,

H. local pressure and temperature indication.

9.3.2 PROCESS SAMPLING SYSTEM

Process sampling is accomplished by a Primary Sampling System (PSS), a Secondary Sampling System (SSS), and a Waste Gas Analyzer System (WGAS). A description of the equipment comprising these systems is presented in this section.

9.3.2.1 <u>Design Bases</u>

The PSS is designed to collect samples of fluids contained in the Reactor Coolant System (RCS) and associated auxiliary system process streams, as listed in Table 9.3-1, for analysis by the plant operating staff. Chemical and radiochemical analyses are performed on the samples as appropriate to determine boron concentration, fission and corrosion product activity levels, residual hydrazine, phosphate, sulphite, and radiation levels in the steam generators, crud concentration, dissolved gas concentration, chloride concentration, pH, lithium and conductivity levels, and gas compositions in various vessels. The results of the analyses are used to regulate boron concentration, monitor fuel rod and steam generator tube integrity, evaluate ion exchanger and filter performance, specify chemical additions to the various systems, and maintain the proper hydrogen and nitrogen overpressure in the volume control tank. The PSS is designed to permit sample collection during all modes of operation from full power to cold shutdown without requiring access to the containment. Water chemistry requirements for the PSS are given in Section 9.3.4 for reactor coolant and Section 10.3.5 for steam generator water.

The Secondary Sampling System (SSS) is designed to collect samples from the Makeup Water System, the turbine cycle, and the Circulating Water System (CWS) as listed in Table 9.3-2. Water quality analyses are performed on these samples as appropriate to determine pH and conductivity levels, silica, dissolved oxygen, sodium, and residual hydrazine concentrations. The hydrazine and pH analyzers are used to monitor the hydrazine concentration and pH level in the main feedwater lines with alarm initiation upon the occurrence of abnormal conditions.

Ammonium hydroxide, an amine, and/or hydrazine is added to establish the desired pH range (see Table 10.3-2). Output signals from other analyzers are used to initiate alarms in the event of abnormal conditions. The Waste Gas Analyzer System (WGAS) provides the capability to monitor the gas space of the tanks and equipment listed in Table 9.3-3. A hydrogen oxygen analyzer panel is provided to monitor free oxygen and free hydrogen during degassing operations. Manual grab sampling is the backup method of monitoring.

The Post Accident Sampling System (PASS) is designed to determine the types and quantities of fission products released to the containment in the liquid and gas phase, and provide information on coolant chemistry and containment hydrogen while minimizing personnel exposure to increased radiation levels which could exist during and subsequent to a nuclear accident. The PASS consists of piping, tubing, valves, components and instrumentation mounted in a sample station with an accompanying control panel. The equipment enables remote analysis of the reactor coolant and containment air and remote collection of the reactor coolant and containment air samples for subsequent analysis. Liquid samples for the PASS may be obtained from the reactor coolant hot leg and containment sump. Pressurizer gas and liquid samples can be aligned to the post accident sampling system. However, the samples are not aligned due to code compliance issues regarding associated PASS sample valves. The containment atmosphere is monitored for radionuclide isotopic and hydrogen analyses. For more detailed information on containment hydrogen analysis, see Section 6.2.5.

Note: NRC letter (0CNA080005) dated 8/17/2000, eliminated the requirement for PASS from the ANO Units 1 and 2 Technical Specifications (TSs). ER-ANO-2003-0221-000 isolated PASS components by maintaining closed PASS boundary valves and de-energizing Unit 1 liquid solenoid valves SV-1440 and SV-1443. The PASS is no longer used and will be isolated from the plant, but remains part of the plant configuration management process. Therefore, PASS components still appear in LBDs. The design bases of PASS have not changed. Should the PASS be put back into service, the PASS would perform its design function. Note: PASS sample lines for Containment Spray and containment air (Hydrogen Purge) have been permanently capped. PASS nitrogen supply line connected to the liquid nitrogen bulk storage tank (2T-138) has also been permanently capped.

9.3.2.2 System Descriptions

9.3.2.2.1 Primary Sampling System

The PSS collects samples from the RCS and auxiliary systems as listed in Table 9.3-1, and brings them to a common location in the sample room in the auxiliary building. Figure 9.3-2 shows a schematic diagram of the PSS.

The high pressure, high temperature samples from the RCS pass through a run of piping long enough to ensure a minimum 90-second decay of short-lived radioactivity, including N-16, before the fluid leaves the containment. The samples are then cooled to a nominal temperature of 105 °F in the reactor coolant sample cooler and then reduced in pressure by means of manually set throttling valves.

The reactor coolant samples may be collected in a detachable sample container for gas analysis.

Samples taken from the Safety Injection System (SIS) and Shutdown Cooling (SDC) System are at intermediate temperatures and pressures and are cooled in the safety injection and shutdown cooling sample cooler, reduced in pressure by means of manually set throttling valves in the sampling room.

Low temperature, low pressure liquid samples from the Chemical and Volume Control System (CVCS) are routed directly to the sampling room.

All of the PSS liquid sampling lines except the steam generator water sample are connected to a common header and discharged to the Waste Management System (WMS). RCS and CVCS sample streams may be returned to the Volume Control Tank. Temperature, pressure, and flowrate indication of all of the above samples is provided in the sampling room.

To obtain a representative sample, the lines are purged for an appropriate amount of time prior to diverting the flow to the sample sink, where the sample is drawn off at a flow rate of 0.6 gpm. System pressure provides the motive force for the purging flow. The sample sink is of stainless steel construction with a raised edge to retain any splashed fluid. The sink area is provided with a hood equipped with an exhaust ventilator exhausting to the plant vent system. Demineralized water is provided at the sample sink to flush and clean the sink. The sink drains by gravity through a water trap to the WMS. In addition to the above, in-line sensors and display units are available to monitor the RCS sample water for hydrogen, oxygen, pH, and conductivity concentrations.

Steam generator water samples are monitored on a continual basis from each steam generator. The system draws samples from the blowdown line for use in chemistry control. The samples are first cooled in the steam generator sample coolers and then reduced in pressure by means of manually set throttling valves. The pressure, temperature, and flow rate of each of the steam generator water samples is indicated in steam generator blowdown sample panel 2C377. In addition, each sample is continually monitored for specific conductivity, cation conductivity, pH, sodium concentration, and radiation. Should any of these parameters rise above operating limits, an alarm is activated at the sample panel and in the control room. Demineralized water is provided to allow cleansing of the measuring cells and cation exchange columns. Sample effluent flow from the steam generators can be routed to either the turbine building sump or the neutralizer tank 2T-87 depending on secondary activity levels. The only exceptions are the flows to the hot lab sample sink and the radiation monitors, which return to the MFP seal tank. The sample sink flows may also return to the WMS. The alignment of the sample panel 2C377 drain path is controlled by the use of spectacle flanges. This arrangement prevents cross-connection between contaminated and non-contaminated systems from being established only by changes in valve positions. Capability to obtain a grab sample from either steam generator is also provided.

9.3.2.2.2 Secondary Sampling System

The SSS, shown on Figure 9.3-2, consists of primary coolers, secondary coolers, sample panels, automatic analyzers, multi-point recorders, interconnecting tubing, and controls as required for continual monitoring of the turbine cycle and makeup water system. In addition, an Ion Chromatograph Analyzer is used to analyze feedwater, main steam, condensate, steam generators, heater drains, and SU/BD demineralizer inlet and outlet. Sample points and inlet conditions of these sampling systems are listed in Table 9.3-2. The temperature control of the high temperature samples is accomplished by two stages of cooling. The first stage of cooling is through roughing coolers (or primary coolers) to bring the temperature of sample to 140 °F, followed by second stage coolers (or secondary coolers) to cool samples to 77 °F or appropriate level as required for the analyzers.

The temperature control of the low temperature samples of 140 °F or below is accomplished through the secondary coolers only. The CCWS removes the heat from the primary and secondary coolers. Pressure control valves are provided to reduce pressure and also to maintain a constant pressure to the analyzers. Relief valves are provided to protect the equipment.

The automatic analyzers of sodium and hydrazine are provided with 3-way solenoid valves which may be used to supply demineralized water to the analyzers to keep them wet whenever the systems fail to operate or are taken out of service. Pre-collection purging is provided for high pressure sample lines to purge the system whenever necessary to obtain representative samples. Capability to obtain a grab sample for all sample points is provided. Uncontaminated drains from the sample lines are collected and returned to the condenser.

The sodium analyzer added to the secondary sample system provides the capability of detecting contaminants entering the feed stream via condenser tube inleakage, secondary demineralizer exhaustion, or heat exchanger inleakage from heating systems charged with sodium nitrite.

9.3.2.2.3 Waste Gas Analyzer System (WGAS)

The WGAS, which consists of one instrument panel, provides the capability to monitor the tanks and equipment listed in Table 9.3-3 for free oxygen and hydrogen. This monitoring capability is backed-up by the capability for analysis of manual grab samples.

The WGAS displays the free oxygen and hydrogen concentrations and alarms at or below the lower flammable gas concentration range.

The WGAS will also alarm on high sample temperature and low sample flow.

The WGAS has been designed so that the panel can monitor the discharge flow, and therefore the suction source, from either waste gas compressor during degassing operations. The operating range of the panel is 20-300 psig. A back pressure regulator on the compressor discharge allows near instantaneous sampling of the waste gas. The panel can also sample each of the waste gas decay tanks as long as tank pressure exceeds 20 psig. Grab samples are the back-up method for obtaining hydrogen and oxygen concentrations when the analyzer is not operable. Grab samples are the primary method used for analyzing the spent resin tank and the liquid holdup tanks and the waste gas decay tanks when decay tank pressure is less than 20 psig.

9.3.2.2.4 Post-Accident Sampling System (PASS)(0CAN038013)

The PASS building and equipment was constructed to permit prompt, safe, remote sampling of primary systems and containment air during accident (and in some cases normal) conditions. Shielded sample lines and remotely controlled analyzers, MOVs, and solenoid valves are provided to minimize dose and reduce the time required for sampling. Samples are available from the following locations: hotleg, containment sump, and containment air. Pressurizer gas and liquid samples can be aligned to the post accident sampling system. However, the samples are not aligned due to code compliance issues regarding associated PASS sample valves. Note: PASS sample lines for Containment Spray and containment air (Hydrogen Purge) have been permanently capped. PASS nitrogen supply line connected to the liquid nitrogen bulk storage tank (2T-138) has also been permanently capped.

Sample lines leading to (and in some cases from) PASS analyzers and equipment have been insulated and in the case of containment air, heat traced, in an effort to reduce temperature depression. Liquid samples remain at or near system pressure and temperature until exiting the area of the radionuclide detector. These liquid samples are then cooled (not depressurized) and pass through an inline hydrogen detector. After exiting the hydrogen detector, the samples are depressurized and flow is then diverted to the desired destination (i.e. containment building during accident conditions).

During design and construction, special consideration was given to radii and bends in sample lines to reduce the potential for crud traps and line losses.

Several shielded, portable grab sample vessels have also been provided in the event that it becomes necessary for analytical test to be performed offsite. The capability exists to obtain grab samples of either containment air or reactor coolant liquid samples.

Flushing water is provided for liquid sample lines to reduce radiation levels in the analyzer rooms. Purge air is available to reducing radiation levels in containment air sample lines. Therefore, should it become necessary to perform maintenance, the radiation levels can be reduced significantly.

The PASS facility is equipped with a separate, packaged, air conditioning system which includes a dedicated exhaust system. Air exiting the building passes through filters to remove particulates and radioactive iodines. Radioactive material that may penetrate these filters is monitored prior to exiting the PASS building stack.

9.3.2.3 Design Evaluation

The sampling systems are not essential for safe plant shutdown and serve no emergency function during operation. The PSS (other than the steam generator water sample) is operated intermittently; sample lines are therefore normally closed with no flow. The isolation valves both inside and outside containment (except the steam generator water sample lines) are solenoid operated valves with position indicating lights in the sampling and control rooms which fail closed on loss of operating power. The outside isolation for the safety injection tanks sampling and all RCS sampling isolation valves inside and outside containment receive a Containment Isolation Actuation Signal (CIAS) and a Safety Injection Actuation Signal (SIAS) to close. A CIAS override capability is provided to permit RCS sampling capability at all times during an accident sequence. The overridden condition is annunciated on main control board 2C16 in the control room.

The steam generator water samples are monitored continuously from each steam generator. The steam generator sample line isolation valves inside and outside of the containment are motor operated, fail-as-is valves with indicating lights located in the control room. The outside isolation valves receive a CIAS to assure closure in the event of a Loss of Coolant Accident (LOCA) or Main Steam Line Break (MSLB) inside containment.

All sample piping and valves, except RCS sample piping and valves, are designed and fabricated in accordance with the same piping and valve codes as the systems to which they are connected, up to and including the first isolation valve.

The sampling nozzles on the RCS contain integral 3/16-inch diameter orifices. As such, in the event of a severance of one of the RCS sample lines during normal reactor operation, the reactor can be shut down and cooled down in an orderly manner using normal makeup from the CVCS.

RCS sample lines and sample lines which penetrate the containment (up to and including the outside isolation valve) are designed in accordance with ASME Code, Section III Class 2. The balance of the system is tubing designed to ANSI B31.1.0. All sample coolers are designed and fabricated in accordance with the ASME Code, Section VIII.

The sample coolers are located in a shielded area outside of the containment. The sample coolers for both PSS and SSS receive their cooling water from the CCW System.

The sampling systems are designed to minimize any hazard to operating personnel or public safety. Thermal insulation is provided to protect personnel from contact with high temperature parts. All sample coolers are designed to limit the temperature of the fluid samples to a maximum of 115 °F for safe handling. The pressure of each sample is reduced to approximately one atmosphere. Pressure relief protection is provided to avoid damage to components.

The PSS sample room is shielded as described in Section 12.1. It is an enclosed room with controlled ventilation and drainage to confine any leakage or spillage of radioactivity. All PSS grab samples are collected within a vented sample hood to exhaust any gaseous leakage to the gas collection header. Any liquid leakage is collected in the sink and drained to the WMS for processing. Any leakage from the system inside containment is collected in the containment sump.

The SSS contains no radioactive streams and thus presents no hazard to public safety. Design conditions for the various sample points are listed in Tables 9.3-1, 9.3-2, and 9.3-3. Local indicators are provided to permit manual control of sampling operations to ensure that samples are at suitable pressures and temperatures before flow is diverted to the sample sink.

9.3.2.4 Inspection and Tests

The materials and nondestructive examinations used in the process sampling system are in accordance with the applicable design codes as delineated in Section 9.3.2.3 above.

Proper operation of the process sampling system was demonstrated during preoperational testing by establishing the appropriate sample flow for each sample point. All automatic analyzers were calibrated and their output results were verified.

The sampling systems are inspected during normal operation by observing proper operation of the components while samples are being drawn. The malfunction of analyzers will be observed by inappropriate readouts on the recorders or by alarms.

9.3.2.5 Instrument Application

The PSS and SSS use local pressure, temperature, and flow indicators to facilitate manual operation and to determine sample conditions before samples are drawn. Radiation elements continuously monitor each steam generator sample for primary-to-secondary tube leaks. The output is available on a trend recorder in the control room and the plant computer. A high radiation alarm in the main control room warns of radioactivity in excess of limits given in Section 11.4.2.1.4 in the steam generator sample.

Every sample point in SSS for continual monitoring is provided with an individual alarm at each sample panel.

Alarms for the WGAS are displayed locally and in the control room to indicate the presence of high oxygen and/or hydrogen concentration.

9.3.3 EQUIPMENT AND FLOOR DRAINAGE SYSTEMS

9.3.3.1 <u>Design Bases</u>

A. The design bases are as follows. The design and arrangement of the non-radioactive drainage systems assure that no infiltration of potentially radioactively contaminated materials will occur.

B. The WMS collects liquid wastes, at atmospheric pressure, from equipment and floor drainage of the containment, the auxiliary building and from decontamination, laboratory, and waste treatment areas. All such drainage is conveyed by gravity to sealed sumps and pumped from there to the waste tanks, or is conveyed directly to the waste tanks.

C. Sump pumps are designed to discharge at a flow rate adequate for preventing sump overflow during normal anticipated drainage periods.

D. Where deemed necessary to provide venting for any liquid radwaste collection system drainage line, the highest portion of the horizontal run of pipe is continued to an elevation and location where connection can be made to the gaseous radwaste system.

E. Systems which are not potentially radioactive are provided for the collection and disposal of roof drainage, storm drainage, sanitary drainage, oily waste, acid waste, and clean drainage.

9.3.3.1.1 <u>Codes and Standards</u>

Equipment and floor drainage collection piping from the areas of potential radioactivity and the gravity collection system piping are constructed in accordance with ANSI B31.1.0 (1967), Power Piping. All other drainage systems comply with the requirements of the National Plumbing Code as regards permits, materials of construction, installation, tests, inspections, and approval. All drainage systems comply with the intent of the following sections of Title 29, Chapter XVII, Part 1910 (Occupational Safety and Health Standards) of the Code of Federal Regulations, as set forth in the Federal Register, Volume 37, Number 202, and dated October 18, 1972: Sections 1910.96, 1910.106, 1910.141, 1910.151, 1910.156, and 1910.159 (c)(3).

9.3.3.2 <u>System Description</u>

The equipment floor drainage systems consist of collection piping, equipment drains, floor drains, vents, traps, cleanouts, and collection sumps. The arrangement is such that the non-radioactive drain systems serve only non-restricted areas where no radioactivity is present, exclusive of the water closet and urinal wastes in the access control area which are collected by the sanitary system. The nature of the sanitary system makes it unlikely that radioactive wastes would enter the sanitary system through this path.

9.3.3.2.1 Component Description

COLLECTION PIPING - In areas of potential radioactivity, the collection system piping for the liquid waste system is stainless steel. Where deemed necessary to maintain atmospheric pressure in the radwaste drainage collection system, relief valves are provided to the Gaseous Radwaste System (GRW). Offsets in the piping are provided where necessary for radiation shielding. The fabrication of the piping provides for a uniform slope which induces waste to flow in the piping at a velocity of not less than two feet per second. Long horizontal drainage piping runs are kept to a minimum in order to minimize problems of elevation, slope, and interference with the layout of other equipment and to provide efficient removal of large volume waste discharges such as those resulting from activation of the Fire Protection System (FPS). Equipment drainage piping is terminated a few inches above the finished floor. The final connections are made after the equipment is installed in its proper location.

AUXILIARY BUILDING DRAINS - The auxiliary building drains are run so that leakage in one Engineered Safety Features (ESF) drain does not flow into the rooms of the other train through the drains. Components and floor drains drain into a separate sump which is fitted with a sump pump.

EQUIPMENT DRAINS - Equipment which discharges waste at a pressure in excess of atmospheric is separated from the drain by an air gap. Connection to other equipment discharge piping varies as required, from solid to open (air gap) types.

FLOOR DRAINS - All floor drains are installed with grates (except the HPSI pump room "C" floor drain). The tops of the grates are flush with the low point elevation of the finished floor. Floor drains in areas of potential radioactivity are welded directly to the collection piping and are provided with threaded, T-handle plugs of the same material, to facilitate selective liquid waste collection and maintenance of system integrity. Floor drains in areas not restricted due to potential radioactivity are provided with caulked or threaded connections.

TRAPS - Inlets to all drainage systems, except those in areas of potential radioactivity and those in rainwater and gravity collection service, are provided a water seal, in the form of a vented P-trap to minimize entry into the building of vermin, foul odors, and toxic, corrosive, or flammable vapors. Air pressure vent lines to the outside atmosphere are provided downstream of the P-traps to prevent excessive backpressures which could cause blowout or siphonage of the water seal. No traps are installed at inlets in areas of potential radioactivity for two reasons. The first is the tendency for radioactive particulates to accumulate in the traps. The second is the difficulty of maintenance, cleaning, and retention of the water seal.

Loop seals are also provided in the equipment drains from the Control Room Emergency Air Handling Units to provide an air seal to prevent unfiltered air inleakge.

CLEANOUTS - Cleanouts are provided in all collection system piping, when practicable, where the change of direction in horizontal runs is 90 degrees, at offsets where the aggregate change is 135 degrees or greater, and at maximum intervals of 50 feet. Cleanouts are welded, threaded, and caulked directly to the piping and located with their covers flush with the finished floor or wall.

9.3.3.2.2 System Operation

GENERAL - The various subsystems drain directly to the appropriate collection point by gravity. Sump pumps are started automatically when a predetermined high level in the sump is reached.

POTENTIALLY RADIOACTIVE DRAINAGE - Fluids conveyed by potentially radioactive drainage systems either flow by gravity to sealed sumps in the respective building and are pumped thence to waste tanks, or flow by gravity directly to waste tanks.

ROOF DRAINAGE - The roof drainage system collects water resulting from precipitation on all building roofs and open area ways within the buildings, and conveys it to the storm drainage system.

STORM DRAINAGE - The storm drainage system collects rainwater from the roof drainage system, rainwater and irrigation run-off from surfaces outside the buildings, and subsoil drainage water.

SANITARY DRAINAGE - The sanitary drainage system collects liquid wastes and some entrained solids discharged by plumbing fixtures located in areas not restricted due to radiation hazard and conveys them to a sewage treatment facility located on the plant site.

OILY WASTE - The oily waste system collects liquid waste which enters floor drains located in areas which are not restricted due to a radiation hazard and where capability for oil spillage exists, and conveys it to a sealed interceptor of approved design. The clarified effluent from the interceptor is conveyed to a suitable point of connection to the gravity collection system piping.

ACID WASTE - The acid waste system collects liquid waste containing chemicals and corrosive substances discharged by laboratory fixtures or equipment, or which enter floor drains located in areas not restricted due to radiation hazard, and conveys it to a dilution/neutralization tank of approved design. The effluent from the tank is conveyed to a suitable point of connection to the gravity collection system piping.

GRAVITY COLLECTION - The gravity collection system collects liquid waste that is discharged by equipment, or which enters floor drains located in areas not normally restricted due to radiation hazard, and which contains no oil, detergent, acid, or other objectionable contaminants, and conveys it to a grease traps that are sealed of approved design. The clarified effluent from the interceptor is conveyed to the intake canal.

9.3.3.3 Safety Evaluation

Since this system has no safety design bases, no safety evaluation is provided. Section 9.3.3.2 provides an assessment of system design and operation.

9.3.3.4 Tests and Inspections

Historical data removed - To review the exact wording, please refer to Section 9.3.3.4 of the FSAR.

OPERATION TESTING CAPABILITY - The operability of equipment and floor drainage systems dependent on gravity flow can be checked by normal usage. Portions of these systems dependent upon pumps to raise liquid waste to gravity drains may be checked through instrumentation and alarms registry in the control room.

9.3.3.5 Instrumentation Applications

Level indication and alarms in the control room are provided for those sumps in the auxiliary building which serve safety features pumps rooms. Level indication, in addition to the level-operated switch used for pump control, is provided for all sumps in the containment and the auxiliary building to provide backup indication of the presence of large leaks and to provide information as to the source of leakage.

9.3.4 CHEMICAL AND VOLUME CONTROL SYSTEM

9.3.4.1 Design Bases

9.3.4.1.1 Functional Requirements

The CVCS is designed to perform the following functions:

A. maintain the chemistry and purity of the reactor coolant during normal operation and during shutdowns, including crud burst cleanup;

B. maintain the required volume of water in the RCS by compensating for coolant contraction or expansion resulting from changes in reactor coolant temperature and for other coolant losses or additions;

C. provide a controlled path for discharging fluid to the BMS;

D. control the boron concentration in the RCS in order to maintain acceptable CEA configuration, compensate for reactivity changes associated with burnup and major changes in coolant temperature and xenon concentration, and provide the required shutdown margin to maintain the reactor subcritical;

E. provide auxiliary pressurizer spray for operator control of pressure during the final stages of shutdown and to allow pressurizer cooling;

F. provide a means for functionally testing the check valves which isolate the SIS from the RCS;

G. provide continuous measurement of reactor coolant fission product activity;

H. collect reactor coolant pump seal controlled bleedoff;

I. leak test the RCS;

J. inject concentrated boric acid into the RCS upon a Safety Injection Actuation Signal (SIAS);

K. automatically divert the letdown flow to the BMS when the volume control tank is at the highest permissible level; and,

L. provide an alternate means for filling the RCS.

M. A soluble zinc compound may be added to the reactor coolant as a means to inhibit corrosion of primary system materials and components, and to control radiation fields. The compound used may be either natural zinc or zinc depleted of ^{64}Zn. When used, the target system zinc concentration is normally maintained to a concentration no greater than 40 ppb.

9.3.4.1.2 Design Criteria

The CVCS is designed in accordance with the following criteria.

A. Accept the letdown when the reactor coolant is heated at the administrative rate of 75 °F/hr and to provide the required makeup using two of three charging pumps when the reactor coolant is cooled at the rate of 75 °F/hr.

B. Supply reactor makeup water or accept excess coolant as power decreases or increases.

C. Allow design transients of ± 10 percent of full power step changes and ramp changes of ± 5 percent of full power per minute between 15 and 100 percent power.

D. Provide sufficient capacity to accommodate the inventory change resulting from a full to zero power decrease with no makeup system operation, assuming that the volume control tank level is initially in the normal operating level band.

E. Provide a means for maintaining activity in the RCS within the appropriate limits, assuming one percent failed fuel condition and continuous full power operation.

F. Maintain the reactor coolant chemistry within the limits specified in Table 9.3-4.

G. Provide boron addition to the reactor coolant by using one charging pump at a rate sufficient to counteract the maximum reactivity increase due to cooldown at 75 °F/hr and maximum xenon decay.

H. The regenerative heat exchanger and the letdown heat exchanger are designed to withstand the design transients discussed in Section 9.3.4.3.

I. To accommodate the environmental design conditions of the CVCS given in Section 3.11.

J. Bring the reactor coolant to refueling boron concentration.

Components of the CVCS are designed in accordance with applicable codes discussed in Section 9.3.4.3.

9.3.4.2 System Functional Description

9.3.4.2.1 Normal Operation

The CVCS is shown on Figure 9.3-4. The system parameters are given in Table 9.3-5.

Normal operation includes hot standby operation and power generation when the RCS is at normal operating pressure and temperature.

Coolant flow from the cold leg in loop 2P32A of the RCS passes through the tube side of the regenerative heat exchangers for an initial temperature reduction. The cooled fluid is reduced to the operating pressure of the letdown heat exchanger by one or both letdown control valves, 2CV-4816 or 2CV-4817. The final reduction to the operating temperature and pressure of the purification system is made by the letdown heat exchanger and one or both letdown backpressure valves 2CV-4810 or 2CV-4811. The flow then passes through a filter, one or more letdown ion exchangers and a strainer and is sprayed into the volume control tank (VCT).

The charging pumps take suction from the volume control tank and pump the coolant into the RCS. One charging pump is normally in operation and one letdown control valve is controlled to maintain pressurizer level at the desired value. Normally this maintains an exact balance between letdown flow rate plus reactor coolant pump bleedoff flow rate and charging flow rate. The charging flow passes through the shell side of the regenerative heat exchanger for recovery of heat from the letdown flow before being returned to the RCS.

Typically, a letdown flow of 40 gpm is normal purification operation, a letdown flow of 84 gpm is intermediate purification operation and a letdown flow of 128 gpm is maximum purification operation.

A makeup system provides for changes in reactor coolant boron concentration and for reactor coolant chemistry control. Concentrated boric acid solution, prepared in an electrically heated batching tank, is stored in one of the two boric acid makeup tanks. Two boric acid makeup pumps are available to transfer the concentrated boric acid either to the VCT or to the suction of the charging pumps. RCS boron concentration is increased by adding a predetermined amount of boric acid. Reducing the RCS boron concentration is accomplished by adding reactor makeup water. To add to the VCT with no concentration change, concentrated boric acid solution is transferred for mixing with reactor makeup water in a predetermined ratio to produce the desired boron concentration. The controlled boric acid solution is then directed to the charging pump suction header or into the VCT. A chemical addition tank is used to transfer chemical additives to the suction of the charging pumps.

The volume of water in the RCS is automatically controlled by water level instrumentation mounted on the pressurizer. The pressurizer level setpoint is programmed to vary as a function of reactor power in order to minimize the transfer of fluid between the RCS and the CVCS during power changes. This linear relationship is shown in Figure 5.5-9. Reactor power is determined by the reactor coolant average temperature across a steam generator. A level error signal is obtained by comparing the programmed level setpoint with the measured pressurizer water level.

Water level control is achieved by automatic control of the constant speed charging pumps and the letdown control valves in accordance with the pressurizer level control program. On-off control of pumps and high and low level alarms are functions of the error signal and the indicated mode of pump operation as shown in Table 5.5-13. (This signal also controls pressurizer heaters as discussed in Section 5.5.10.) The letdown control valves are controlled by an integrating controller to maintain pressurizer level. Normally one valve is used but both may be in service. Letdown flow normally equals total charging pump flow minus the total reactor coolant pump controlled bleedoff flow. Only one charging pump is usually operated, but 2 or 3 pump operation can be selected for higher purification flow, if desired. Proper level can normally be maintained by valve positioning; large changes in pressurizer water level due to power changes or abnormal operations result in changes of charging pump operation as well.

The volume in the VCT is normally controlled manually. Makeup to the VCT is provided by the chemical addition subsystem as described above. Letdown flow is diverted to the BMS as needed to maintain VCT level. Letdown flow is automatically diverted to the BMS when the highest permissible VCT water level is reached. An automatic VCT level control system also exists. If the makeup system is set to the automatic mode of operation, a volume control tank low level signal will cause a preset solution of concentrated boric acid and reactor makeup water to be introduced into the volume control tank.

A low-low level signal automatically closes the outlet valve on the volume control tank and switches the charging pump suction to the Refueling Water Tank (RWT).

The chemistry and purity of the reactor coolant are controlled to ensure the following.

- The plant is accessible for maintenance and operation without excessive radiation exposure to the operating personnel.
- Long-term operation of the plant is achieved without excessive fouling of heat transfer surfaces.
- The corrosion rate of the materials in contact with the reactor coolant is kept at a minimum.

9.3.4.2.2 Plant Startup

Plant startup is the series of operations which bring the plant from a cold shutdown condition to a hot standby condition at normal operating pressure and zero power temperature with the reactor critical at a low power level.

The charging pumps and letdown backpressure valves are used during initial phases of RCS heatup to maintain the RCS pressure until the pressurizer steam bubble is established. One charging pump will normally operate during plant startup to cool the letdown fluid to maintain design pressure and temperature limits in the letdown portion of the system.

During the heatup, the pressurizer water level is controlled using the backpressure control valves and the letdown control valves. The letdown flow is diverted to the BMS as necessary to accommodate RCS volume expansion during heatup. The volume control tank is initially purged with nitrogen or hydrogen and a hydrogen overpressure is established.

Within the limitations placed on the shutdown margin, the boric acid concentration may be reduced during heatup.

Compliance with the shutdown margin limitations is verified by sample analysis.

9.3.4.2.3 Plant Shutdown

Plant shutdown is accomplished by a series of operations which bring the reactor plant from a hot standby condition at normal operating pressure and zero power temperature to a cold shutdown for maintenance and/or refueling.

Prior to plant cooldown, letdown is diverted to the vacuum degasifier and the degasified reactor coolant is returned to the Volume Control Tank (VCT) or the gas space of the VCT is vented to the GWS to reduce dissolved hydrogen concentration and fission gas activity. The letdown flow rate may be increased to accelerate the degasification, ion exchange and filtration processes. Control of system chemistry via ion exchange or chemical addition is used to control corrosion product transport and contaminants.

The RCS boron concentration needed to maintain the required shutdown margin is determined prior to cooldown of the plant. The volumes of concentrated boric acid and demineralized water needed to obtain this RCS boron concentration are also determined. As the cooldown is begun, the volume shrinkage is compensated by addition of concentrated boric acid and demineralized water to ensure the required boron concentration is maintained. This is done to assure that sufficient shutdown margin exists throughout the cooldown period.

During the cooldown, the charging pumps, letdown control valves, and letdown backpressure valves are used to adjust and maintain the pressurizer water level. All or a portion of the charging flow may be used for auxiliary spray to cool the pressurizer in the event reactor coolant pumps are secured.

Connections have been provided to allow for RCS cleanup while on shutdown cooling with the RCS depressurized.

9.3.4.2.4 Corrosion Control by Reactor Coolant System Chemistry

Chemistry control of the reactor coolant consists of removal of oxygen by hydrazine/carbohydrazide scavenging during startup, reduction of oxygen concentration during power operation by maintaining excess hydrogen concentration in the reactor coolant, and pH control by control of lithium. A chemical addition tank uses reactor makeup water to transfer hydrazine/carbohydrazide or lithium hydroxide to the suction side of the charging pumps for injection into the RCS, while hydrogen concentration in the RCS is controlled by maintaining a hydrogen overpressure in the volume control tank.

During the preoperational test period, 30 to 50 ppm hydrazine was maintained in the reactor coolant whenever the reactor coolant temperature was below 150 °F. This was done to prevent the halide-induced corrosion attack of stainless steel surfaces which can occur in the presence of significant quantities of dissolved oxygen. During the initial heatup, any dissolved oxygen is scavenged by hydrazine, thus eliminating one necessary ingredient for halide-induced corrosion. Elimination of oxygen on heatup also minimizes the potential for general corrosion. At higher temperatures, hydrazine decomposes, not necessarily completely, producing ammonia and a high pH which aids in the development of passive oxide films on RCS surfaces that minimize corrosion product release. This high pH was maintained throughout the preconditioning period by maintaining 1-2 ppm lithium in the RCS. The corrosion rates of Ni-Cr-Fe Alloy-600 and -300 series stainless steels decrease with time when exposed to prescribed reactor coolant chemistry conditions. Rates approach low steady state values within approximately 200 days. The high pH condition produced by high ammonia concentration (to 50 ppm) and lithium (1-2 ppm) minimizes corrosion product release and assists in the rapid development of the passive oxide film. Most of the film is established within seven days at hot, high pH conditions.

High hydrazine concentration is currently not required to inhibit halide-induced corrosion, but hydrazine/carbohydrazide, added in appropriate concentrations, is still used during heatup to scavenge oxygen. This assures complete removal of oxygen on heatup while minimizing ammonia and nitrogen generation when hot and at power. When at power, oxygen is controlled

to a very low concentration by maintaining excess dissolved hydrogen in the coolant. The excess hydrogen forces the water decomposition/synthesis reaction in the reactor core to water rather than hydrogen and oxygen. Any oxygen in the makeup water is also removed by this process.

Since operating with a basic pH control agent results in lower general corrosion release rates from the RCS materials and because the alkali metal lithium is generated in significant quantities by the core neutron flux through the reaction B-10 (n,alpha) Li-7, lithium is selected as the pH control agent. The production rate of lithium from this reaction is higher at the beginning of core life and decreases with core lifetime in proportion to the decrease in boron concentration. However, even though lithium is the choice for pH control, there exists a threshold for accelerated attack on zircaloy at approximately 35 ppm lithium. Therefore, the lithium concentration is controlled within a coordinated boron/lithium band that at the highest concentration is at least a factor of 10 below the threshold. This provides a wide margin between the upper operating limit and the threshold for attack in the event any concentrating phenomena exist. In the case of replacement steam generators, Westinghouse has evaluated starting a refueling cycle with lithium values higher than 3.5 ppm for a limited time (≤17 EFPDs). As long as lithium does not exceed 3.8 ppm there are no adverse effects on zircaloy corrosion. There is a positive effect on reduction of nickel transport from the new steam generators.

Early in core life, lithium production is the greatest and periodic removal by ion exchange is required to control the concentration below the upper limit. Late in core life lithium additions can be necessary to maintain lithium in the control band. Lithium is removed along with cesium by intermittent operation of an ion exchanger while a second ion exchanger is operated continuously for the removal of fission and corrosion products.

Concentrations of fluorides and chlorides in the coolant are maintained at low levels by reactor coolant purification and demineralized makeup water addition.

The resin beds remove soluble nuclides by the ion exchange mechanism. Insoluble particles are removed by a cartridge type prefilter located upstream of the ion exchanger. A strainer downstream of the ion exchangers protects against the gross release of resin to the coolant in the event of an ion exchanger retention element failure.

9.3.4.2.5 Reactivity Control

The boron concentration is controlled to obtain optimum CEA positioning; to compensate for reactivity changes associated with changes in coolant temperature, core burnup, and xenon concentration variations; and to provide shutdown margin for maintenance and refueling operations or emergencies.

To change boron concentration, the makeup system supplies either reactor makeup water or concentrated boric acid to the charging pump suction header or the volume control tank. If needed to maintain an appropriate level in the VCT, the letdown stream is diverted to the BMS (“feed and bleed” technique). Toward the end of a core cycle, to minimize the quantities of waste water produced due to feed and bleed operations, one of the letdown ion exchangers is used to reduce the RCS boron concentration. The capability of the CVCS for changing the RCS boron concentration is shown in Table 9.3-5.

Two boric acid makeup tanks and two boric acid pumps are available to supply boric acid to the RCS via the volume control tank and/or charging pumps. There are four modes of makeup system operation, all of which supply either the VCT or the charging pump suction header. In the dilute mode, a preset quantity of reactor makeup water is added at a preset rate. In the borate mode, a preset quantity of concentrated boric acid is introduced at a preset rate. In the manual mode, the flow rates of the reactor makeup water and the concentrated boric acid are preset manually to give any boric acid solution between zero and concentrated boric acid. This mode is normally used to makeup to the RCS at the existing RCS boron concentration. An automatic mode also exists, although it is normally not used. In this automatic mode, a preset boric acid solution would be automatically mixed and added when the VCT automatic makeup setpoint is reached. The preset solution concentration would be adjusted periodically by the operator to match the boric acid concentration being maintained in the RCS.

Boron is initially added to the CVCS using the boric acid batching tank. Reactor makeup water is added to the tank via the reactor makeup water pumps, and the fluid is heated by immersion heaters. Boric acid powder is added to the heated fluid while the mixer agitates the fluid. The tank design allows preparation of a boric acid concentration as high as 12 weight percent; however, the control point for the discharge piping heat trace is selected for a maximum concentration of 8.1 w/o.

Electric immersion heaters maintain the temperature of the solution in the boric acid batching tank high enough to preclude precipitation. The boric acid is then gravity drained to one of the boric acid makeup tanks. A schedule of waste generation is given in Table 9.3-6.

9.3.4.3 System Description

The major components of the CVCS are discussed in this section. The original design transients for the regenerative and letdown heat exchangers are listed in Table 9.3-8.

9.3.4.3.1 Regenerative Heat Exchanger

The regenerative heat exchanger, located in the containment above floor Elevation 352 feet conserves RCS thermal energy by transferring heat from the letdown stream to the charging stream. The heat exchanger is designed to maintain a letdown outlet temperature below 450 °F under all normal operating conditions. The design characteristics of the regenerative heat exchanger are given in Table 9.3-9.

9.3.4.3.2 Letdown Heat Exchanger

The letdown heat exchanger, located in the auxiliary building on floor Elevation 335 feet, uses component cooling water to cool the letdown flow from the outlet temperature of the regenerative heat exchanger to a temperature compatible with long-term operation of the purification system ion exchangers. The unit is sized to cool the maximum letdown flow rate from the maximum outlet temperature of the regenerative heat exchanger (450 °F) to the maximum allowable temperature of the ion exchanger resins (140 °F). To prevent possible damage to the heat exchanger by excessive component cooling water flow, the flow control valves are preset to limit the flow to 1,200 gpm maximum. The cooling water flow rate is indicated locally and alarmed on high flow in the control room. The design characteristics of the letdown heat exchanger are given in Table 9.3-10.

9.3.4.3.3 Purification Filters

The purification filters, located in the auxiliary building on floor elevation 335 feet, remove insoluble particulates from the reactor coolant prior to entering the ion exchanger. Only one unit at a time is used. The units are designed to pass the maximum letdown flow without exceeding the allowable differential pressure across the filter cartridge in the maximum fouled condition. Parallel filters are provided to assure cleanup capability following a crud burst. Due to the buildup of high activity levels during normal operation, the units are designed for remote removal of the contaminated cartridge assembly. The design characteristics of the filters are given in Table 9.3-11.

9.3.4.3.4 Purification and Deborating Ion Exchangers

The three mixed bed letdown ion exchangers are each sized for the maximum letdown flow rate. Two of the ion exchangers perform purification of the RCS letdown. One ion exchanger is used intermittently to control the lithium and cesium concentration in the RCS and another for normal operation. The units contain both anion and cation resins in a ratio specified by Chemistry and are provided with all connections required to replace and mix the resins by liquid and air sluicing. The third letdown (deborating) ion exchanger is identical to the purification ion exchangers in size and construction and is sized to contain sufficient anion resin (if needed) to control the RCS boron concentration from 30 ppm to the concentration at the end of core cycle. The design characteristics of the ion exchangers are given in Table 9.3-12. The three ion exchangers are located in the auxiliary building on floor Elevation 335 feet.

9.3.4.3.5 Volume Control Tank

The volume control tank, located in the auxiliary building on floor Elevation 354 feet, accumulates letdown water from the RCS to maintain the desired hydrogen concentration in the reactor coolant and to provide a reservoir of reactor coolant for the charging pumps. The tank is sized to store sufficient liquid volume below the normal operating band to allow a swing from full power to zero power without makeup to the volume control tank and such that sufficient useful volume is above the normal operating band to permit the accumulation of approximately 500 gallons of water during dilution operations. The accumulated water is normally sufficient to provide normal plant leakage makeup between dilution operations. The tank is provided with hydrogen and nitrogen gas supplies and a vent to the GWS to enable venting of hydrogen, nitrogen and fission product gases.

The volume control tank is initially purged with nitrogen or hydrogen and a hydrogen overpressure is established. The design characteristics of the volume control tank are given in Table 9.3-13. The Unit 2 volume control tank hydrogen supply is provided by a connection to the high purity hydrogen supply located in Unit 1.

9.3.4.3.6 Charging Pumps

The charging pumps, located in the auxiliary building on floor Elevation 335 feet, take suction from the volume control tank on the floor level above and return the purification flow to the RCS during plant steady state operations. Normally one pump is running to balance the letdown purification flow rate plus the reactor coolant pump controlled bleedoff flow rate. The second and third pumps are automatically started or stopped as pressurizer level decreases or increases due to plant load transients.

The pumps are positive displacement type with an integral leakage collection system. Vent, drain and flushing connections are provided to minimize radiation levels during maintenance operations. The pressure containing portions of the pump and internals are austenitic or precipitation hardened stainless steel materials for compatibility with boric acid. The pump design characteristics are given in Table 9.3-14. Flow from these pumps is immediately available. This allows the operator finer control over pressurizer level.

9.3.4.3.7 Boric Acid Makeup Tanks

Two boric acid makeup tanks, located on auxiliary building floor level 386 feet, provide a source of boric acid solution for injection into the RCS and for makeup to the spent fuel pool and the refueling water tank. Each tank normally stores boric acid in concentrations up to 3.5 weight percent. The combination of the boric acid makeup tanks and the RWT contain sufficient boric acid to bring the plant to a cold shutdown condition. The design characteristics of the tanks are given in Table 9.3-15.

9.3.4.3.8 Boric Acid Batching Tank

The boric acid batching tank, located on auxiliary building floor level 404 feet, and above the boric acid makeup tanks, is used for the preparation of concentrated boric acid which is batch gravity drained to the makeup tanks. The tank is designed to permit handling of up to 12 weight percent boric acid. An intertie is provided to the Unit 1 boric acid mix tank to prevent delays caused by limited boric acid batching capacities on Units 1 and 2.

The tank is heated and insulated and receives demineralized water for mixing the boric acid solution. Sampling provisions, mixer, temperature controller and electric immersion heaters are an integral part of the batching system. The design characteristics of the tanks are given in Table 9.3-16.

9.3.4.3.9 Boric Acid Makeup Pumps

The boric acid makeup pumps, located in the auxiliary building on the floor at Elevation 369 feet, take suction from the overhead boric acid makeup tanks and provide boric acid to the makeup subsystem and to the charging pump suction header. The capacity of each pump is greater than the combined capacity of all three charging pumps. The boric acid makeup pumps are also used to recirculate makeup tank contents, to pump from one makeup tank to the other, and to supply makeup to the RWT and the spent fuel pool. The pumps are single stage centrifugal pumps with mechanical seals and liquid and vapor leakage collection connections. The design characteristics of the pumps are given in Table 9.3-17.

9.3.4.3.10 Chemical Addition Tank

The chemical addition tank, located on auxiliary building floor Elevation 404 feet, provides a means to inject chemicals into the charging pump suction header. Reactor makeup water is supplied for chemical dilution and flushing operations. The design characteristics of the tank are given in Table 9.3-18. The tank size and reactor makeup water pump capacity are based on the maximum service requirement of hydrazine/carbohydrazide injection for oxygen scavenging on plant startup, and limiting CVCS lithium concentrations to acceptance levels.

9.3.4.3.11 Process Radiation Monitor

The process radiation monitor, described in Section 11.4, is in the one-half inch line bypassing the purification filter, and provides a continuous recording in the control room of reactor coolant gross gamma radiation and specific fission product gamma activity. A high alarm indicates an increase in coolant activity above the setpoint within five minutes of the event. This monitor is sensitive enough to provide for early detection of fuel element failure. Table 9.3-19 gives the design characteristics of the pressure boundary of the monitor.

9.3.4.3.12 Boronometer

This section has been deleted.

9.3.4.3.13 Relief Valves

To assure safe operation of the CVCS, overpressure protection is provided by relief valves throughout the system. The following is a description of the relief valves in the system.

A. Intermediate pressure letdown relief valve, 2PSV-4822

   The relief valve downstream of the letdown control valves protects the intermediate pressure letdown piping and letdown heat exchanger from overpressure. The valve has sufficient capacity to pass flow from the upstream components. The relief valve set pressure is 600 psig, 50 psi below the design pressure (650 psig) of the intermediate pressure letdown piping and letdown heat exchanger.

B. Low pressure letdown relief valve, 2PSV-4800

   The relief valves downstream of the letdown backpressure control valves protect the low pressure piping, purification filters, ion exchangers and letdown strainer from overpressure. The valve capacity is equal to capacity of intermediate pressure letdown relief valve 2PSV-4822. The set pressure is equal to the design pressure (200 psig) of the low pressure piping and components.

C. Charging pump discharge relief valves, 2PSV-4855, 2PSV-4845, 2PSV-4835

   The relief valves on the discharge side of the charging pumps are sized to pass the maximum rated flow of the associated pump with maximum backpressure without exceeding the maximum rated total head for the pump assembly. The valves are set to open when the discharge pressure exceeds the RCS design pressure (2485) by 10 percent.

D. Charging pump suction relief valves, 2PSV-4834, 2PSV-4844, 2PSV-4854

   The relief valves on the suction side of the charging pumps are sized to pass the maximum fluid thermal expansion rate that would occur if the pump were operated with the suction and discharge isolation valves closed. The set pressure is less than design pressure of charging pump suction piping.

E. Charging line thermal relief valve

The relief valve on the charging line downstream of the regenerative heat exchanger is sized to relieve the maximum fluid thermal expansion rate that would occur if hot letdown flow continued after charging flow was stopped by closing the charging line distribution valves. The valve is a spring-loaded check valve.

F. Volume control tank relief valve, 2PSV-4867

The relief valve on the volume control tank is sized to pass a liquid flow rate equal to the sum of the following flow rates: the maximum operating flow rate from the reactor coolant pump controlled bleedoff line; the maximum letdown flow rate possible without actuating the high flow alarm on the letdown flow indicator; the design purge flow rate of the sampling system; and the maximum flow rate that the boric acid makeup system can produce with relief pressure in the volume control tank. The set pressure is equal to the design pressure of the volume control tank.

G. Reactor makeup water relief valve, 2PSV-4943

The relief valve on the reactor makeup water system is sized to pass the maximum capacity of the reactor makeup water pumps with the volume control tank pressure at its design value. The set pressure is less than the volume control tank design pressure (75 psig) to ensure that the valve will open before the volume control tank relief valve opens.

H. Volume control tank gas supply relief valve, 2PSV-4838

The relief valve is sized to exceed the combined maximum capacity of the nitrogen and hydrogen gas regulators. The set pressure is lower than the volume control tank design pressure.

I. Reactor coolant pump controlled bleedoff header relief valve, 2PSV-4836

The relief valve at the reactor coolant pump controlled bleedoff header allows the controlled bleedoff flow to continue to the quench tank in the event that a valve in the line to the volume control tank is closed and does not serve an overpressure protection function. The valve is sized to pass the flow rate required to assure closure of one excess flow check valve in the event of failure of the seals in one reactor coolant pump plus the normal bleedoff from the other reactor coolant pumps. The maximum relief valve opening pressure is less than the controlled bleedoff high pressure alarm.

J. Heat traced piping thermal relief valves

Relief valves are provided for portions of the CVCS that are heat traced and which can be individually isolated. Other areas of the piping have been analyzed to show that thermal relief valves are not required. The set pressure is equal to or less than the design pressure of the system piping. Each valve is sized to relieve the maximum fluid thermal expansion rate that could occur if maximum duplicate heat tracing power were inadvertently applied to the isolated line.

9.3.4.3.14 Piping and valves

The piping of the CVCS is austenitic stainless steel. The cooling water side of the letdown heat exchanger is carbon steel. All piping is in accordance with ASME Code Section III, Class 2 or ANSI B31.1.0, as applicable.

All valves except the diaphragm-type have backseats which can be used to limit steam leakage when in the open position. Diaphragm-type valves are used to prevent radioactive gas leakage from the volume control tank and also for resin sluicing operations for the ion exchangers. Manually operated valves for radioactive service with nominal sizes larger than two inches are provided with a double-packed stem and intermediate lantern ring with a leakoff connection. All actuator operated valves for liquid service with a double-packed stem and intermediate lantern ring are provided with stem leakoffs.

9.3.4.3.15 Electrical Heaters

Redundant electrical heat tracing is installed on all piping, valves, and other line-mounted components that may potentially contain concentrated boric acid solution for a significant period of time. The heat tracing is designed to prevent precipitation of boric acid due to cooling. The boric acid system requires heat tracing only in the boric acid batching tank, the piping through the batching strainers and the piping up to the boric acid makeup tanks.

The heat tracing is designed to maintain the fluid temperature of the traced components above the saturation temperature of 103 °F for an 8.1 w/o boric acid solution. A heat trace control setpoint of 120 °F was selected to maintain the boric acid solution approximately 17 °F above this saturation temperature.

Two independent full capacity strap-on heater banks are installed on each boric acid makeup tank. The heaters are sized to compensate for heat loss through the tank insulation to the surroundings when the tank is filled to its maximum operating level with boric acid at its maximum temperature. Each heater bank is operated by an independent controller. The maximum boric acid concentration has been limited to 3.5 w/o so the heaters are not required for a makeup tank to be considered operable.

The batching tank is provided with corrosion resistant electrical immersion heaters. The heaters are sized to supply sufficient heat in six hours to increase the temperature of 500 gallons of 12 w/o boric acid solution from 40 °F to 160 °F, including the heat of solution required to dissolve the boric acid granules. The boric acid is not added to the tank until the demineralized water temperature exceeds the final saturation temperature by at least 20 °F.

9.3.4.3.16 Thermal Insulation

Thermal insulation is required for conservation of heat and to protect personnel from contact with high temperature piping, valves, and components. Equipment and sections of the system that are insulated are the regenerative heat exchanger, the charging and auxiliary spray lines downstream of the regenerative heat exchanger and the letdown line from the reactor coolant loop to the letdown heat exchanger. Thermal insulation on these sections is designed to limit the insulation surface temperature to 140 °F based on ambient temperature of 80 °F and the maximum expected piping and component temperature. Electrically heat traced piping, valves, pumps and other components are insulated to limit the insulation surface temperature to 140 °F based on an ambient temperature of 80 °F and the controlled component temperature.

Thermal insulation on the batching tank is designed to limit heat losses to 15.0 Btu/hr-ft² based on a tank temperature of 160 °F and an ambient temperature of 70 °F. Thermal insulation that does not cause chloride stress corrosion or that contains a chloride stress corrosion inhibitor is used on all stainless steel surfaces and on any insulated surfaces adjacent to stainless steel surfaces where moisture from that insulation could reach the stainless steel.

9.3.4.4 System Evaluation

9.3.4.4.1 Performance Requirements and Capabilities

The normal amount of boric acid stored solution contained in the combined volumes of the BAMTs and the RWT is sufficient to bring the plant to a cold shutdown condition at any time during plant life. The RWT is also an emergency source of borated water.

The charging pumps are used to inject concentrated boric acid into the RCS. With one pump normally in operation, the other charging pumps are automatically started by the pressurizer level control or by the SIAS.

During normal operation, the charging pumps draw suction from the VCT. However, upon initiation of a SIAS, valves 2CV 4820-2 and 2CV 4821-1 automatically close isolating letdown which feeds into the VCT. Any charging pumps that are not already operating automatically start and charging pump suction is switched to the boric acid makeup pump discharge. The SIAS signals both boric acid makeup pumps to start and opens 2CV-4916-2 (the emergency boration valve) and 2CV-4920-1 and 2CV-4921-1 (the gravity feed valves). Therefore, if the boric acid makeup pumps are not available, the charging pumps are lined up for gravity feed from the boric acid makeup tanks. This system is shown on Figures 9.3-4. Should the charging line inside the containment be inoperative for any reason, the line may be isolated outside of the containment, and the charging flow may be injected via the SIS. The malfunction or failure of one active component does not reduce the ability to borate the RCS since an alternate flow path is always available for emergency boration.

The capability of the CVCS to borate is not compromised by stopping letdown flow. Because safe shutdown can be achieved without letdown flow, this portion of the CVCS, which includes the letdown heat exchanger, has no specific requirement to function for post-accident operation. It is for this reason that the component cooling water system serving the letdown heat exchanger is designated Seismic Class 2 and not Class 1. Further, for accidents which involve an SIAS or CIS, the letdown line is automatically isolated by these signals.

The following discussion demonstrates that the letdown loop of the CVCS is not required to achieve cold shutdown.

Three effects must be accounted for in any cooldown. These are: a) accommodating the reactivity change caused by reducing the moderator temperature, b) accommodating the reactor coolant shrink, and c) ensuring sufficient coolant is available for pressurizer control. Without the letdown loop, these effects are handled as follows:

A. At End of Cycle (EOC) (the limiting case), the initial RCS boron concentration is small (assumed to be 0 ppmB) and the RCS boron concentration necessary to meet shutdown margin requirements at hot shutdown is on the order of 800 ppmB (this value is determined for each reload cycle and shown to be less than the concentration

that can be achieved by the CVCS). During cooldown, the RCS is brought to the required boron concentration by charging from the Boric Acid Makeup Tank (BAMT) and the RWT. Below 275 °F the shutdown cooling system is placed into operation and further boron additions may be accomplished by feed and bleed.

B. The total RCS shrink from power operation to the hot shutdown cooling window is approximately 15,000 gallons. The required volumes from the BAMTs and the RWT that make up this volume depend on the concentrations of these sources. The BAMT concentration ranges from 3.0 to 3.5 w/o boric acid. The RWT concentration ranges from 2500 - 3000 ppmB. When the concentrations of both sources are at their minimum values, about 10,870 gallons from the BAMTs are required prior to shifting to the RWT. With the maximum concentrations in both sources, only about 7,170 gallons are required from the BAMTs. These required volumes, adjusted to accommodate instrument uncertainty and tank residual volume are specified in the ANO-2 Technical Requirements Manual.

C. The pressurizer level is maintained at the hot standby level during the cooldown, and therefore pressurizer pressure control is accomplished. The necessary coolant to satisfy the requirements for pressurizer spray (depressurization) is supplied from the BAMTs or the RWT via the charging pumps through the auxiliary spray line, and is included in the volumes cited above.

The assumptions used to demonstrate the ability to place the unit on shutdown cooling without the letdown loop are as follows:

A. The limiting case is at EOC, because rod worth and boron worth are less, hence more boron addition is required to attain the necessary shutdown margin. The initial RCS boron concentration is assumed to be 0 ppmB, and the reactor is assumed to have been at 100 percent steady state power immediately prior to shutdown.

B. The pressurizer level during power operation prior to shutdown is assumed to be 910 cubic feet.

C. The reactor coolant pumps are not available.

D. The RWT is available with a volume as required by Technical Specifications and a boron concentration of ≥ 2,500 ppmB.

E. RCS temperature control is accomplished by use of the atmospheric dump valves.

F. The combined volume of the two BAMTs contain between 7,170 gallons (3.5 w/o boric acid in BAMT with 3000 ppmB in RWT) and 10,870 gallons (3.0 w/o boric acid in BAMT with 2500 ppmB in RWT).

G. Pressurizer pressure control is accomplished via the auxiliary spray line.

H. Boric acid entering the pressurizer is not assumed to mix with the reactor coolant.

I. The most reactive CEA is stuck out of the core.

J. Off-site power is lost and not regained.

K. Cooldown is slow enough so that the pressurizer remains at saturated conditions.

An adequate procedure to place the unit on shutdown cooling is outlined below. This procedure relates to the preceding discussion of requirements and assumptions used to evaluate the loss of letdown during a plant cooldown. It is not intended to be a generic method for cooldown to cold shutdown.

A. The required BAMT volume, based on the total RCS shrink volume, to achieve cold shutdown is calculated. The volumes to be provided from the BAMT and RWT necessary to supply the RCS contraction volume vary, based on the concentrations of these boric acid sources.

B. Charging of the calculated BAMT feed volume is initiated via the charging pumps, and a plant cooldown is initiated.

C. After all the BAMT feed volume is introduced to the RCS, charging pump suction is shifted to the RWT, and the remaining RCS shrink is accommodated from the RWT.

D. Throughout the cooldown, charging to the RCS will be intermittent as necessary to maintain pressurizer level.

E. The RCS is placed on shutdown cooling at < 275 °F, 280 psia.

F. After shutdown cooling is initiated, boration to the cold shutdown boron concentration may be completed by charging from the BAMTs or the RWT.

G. On shutdown cooling, only water with a greater boric acid concentration than that of the RCS is supplied, thus the RCS concentration will increase and remain above the Technical Specification required shutdown boron concentration (not necessary as long as Technical Specification requirements are met).

Utilization of the procedure above assures that greater than the minimum shutdown margin is maintained throughout the cooldown cycle.

If the letdown temperature exceeds the maximum operating temperature of the resin in the ion exchanger (140 °F) the flow will automatically bypass the ion exchangers and the process radiation monitor.

The charging pumps, boric acid makeup pumps, boric acid makeup tank heaters and all related automatic control valves are connected to an emergency bus should the normal power supply system fail. There are two emergency diesel generator sets available for this service and the components are aligned to the diesels as designed below:

Component	Diesel 1	Diesel 2
Charging Pump 2P36A	X	
Charging Pump 2P36B		X
Charging Pump 2P36C	(1 or 2)	
Boric acid pump No. 2P39A		X
Boric acid pump No. 2P39B		X
Boric acid gravity feed valve 2CV-4921-1	X	
Boric acid gravity feed valve 2CV-4920-1	X	

Component	Diesel 1	Diesel 2
Boric acid makeup tank No. 2T6A heater No. 2M43A		X
Boric acid makeup tank No. 2T6A heater No. 2M43C	X	
Boric acid makeup tank No. 2T6B heater No. 2M43B	X	
Boric acid makeup tank No. 2T6B heater No. 2M43D		X
Heat tracing system No. 1	X	
Heat tracing system No. 2		X
Boric acid makeup pump supply valve 2CV-4916-2		X
Volume control tank discharge valve 2CV-4873-1	X	
Letdown stop valve 2CV-4820-2		X
Letdown stop valve 2CV-4821-1	X	
Controlled bleedoff stop valve 2CV-4847-2		X
Boric acid recirculation valve 2CV-4903-2		X

Heat tracing is required only in those sections of the boric acid makeup system that normally contain greater than 3.5 w/o boric acid solution. The boric acid batching tank, the piping through the batching strainer and the piping up to the BAMTs is heat traced. Automatic temperature controls and independent alarm circuits are included in the heat tracing system.

The heat tracing is appropriately sectionalized taking into account system redundancy requirements and components that may be removed from the system for maintenance. Each heat tracing section has a duplicate full capacity set of heater elements and controls. An independent alarm system is provided with temperature sensors appropriately spaced within each section to detect a malfunction of the operating heat tracing anywhere within that section. Each sensor is annunciated separately on a local panel. A malfunction anywhere in the heat tracing annunciates an alarm in the control room. In the event of a malfunction, switchover to the redundant heat tracing for the affected section is done manually. The separate alarm system provides annunciation at the control room in the event of loss of electric power to the heat tracing.

Flush and back flush connections are provided to prevent crud buildup in tank bottom lines.
Frequently used, manually operated valves located in high radiation or inaccessible areas are provided with extension stem handwheels terminating in low radiation and accessible control areas. Manually operated valves are provided with locking provisions if unauthorized operation of the valve is considered a potential hazard to plant operation or personnel safety.

Leakage can be detected by the gamma sensitive area radiation monitors which are located in strategic areas throughout the plant. The gamma flux level seen by each detector is indicated, annunciated and recorded in the control room. Any significant leakage from the CVCS annunciates one of these alarms.

The CVCS can also monitor the total RCS water inventory. With no leakage in the RCS, the level in the volume control tank remains constant during steady state plant operation. Therefore, a decreasing level in the volume control tank alerts the operator to a possible leak. A more detailed discussion of leakage detection systems is presented in Section 5.2.7.

9.3.4.4.2 Single Failure Analysis

A single failure analysis for the CVCS is shown in Table 9.3-21. At least one failure is postulated for each major component. Additionally, various line breaks throughout the system are also considered. In each case the possible cause of such a failure is presented as well as the local effects, detection methods and compensating provision.

9.3.4.4.3 Testing and Inspection

Each component is inspected and cleaned prior to installation in the system. Demineralized water is used to flush the system.

Instruments were recalibrated during startup testing. Automatic controls were tested for actuation at the proper setpoints. Alarm functions were checked for operability and limits during preoperational testing. The safety valve settings were checked.

The system was operated and tested initially with regard to flow paths, flow capacity and mechanical operability. Pumps were tested at the vendor's plant to demonstrate head and capacity.

Prior to preoperational testing, the components of the CVCS were tested for operability. The components and subsystems checked include the following:

A. operation of all automatic and remote controlled valves;

B. operation of boric acid makeup pumps;

C. operation of nitrogen and hydrogen pressurization systems;

D. charging pump operational check;

E. check of miscellaneous valve function, alarms and interlocks;

F. instrumentation on the boric acid makeup tanks, volume control tank and boric acid batching tank; and

G. inspection of all valves for proper flow direction.

The system was tested for integrated operation during preoperational testing. Any defects in operation that could affect plant safety were corrected before fuel loading. As part of normal plant operation, tests and inspections, data tabulation and instrument calibrations are made to evaluate the condition and performance of the CVCS equipment. Data are taken periodically during normal plant operation to confirm heat transfer capabilities and purification efficiency.

The charging pumps permit leak testing of the RCS during plant startup operations and connections are provided to install a hydrostatic test pump in parallel with the charging pumps.

A charging pump can be used to check the operability and leak tightness of the check valves which isolate the RCS from the SIS.

9.3.4.4.4 Natural Phenomena

The CVCS components are located in the auxiliary building and the containment and, therefore, would not be subject to the natural phenomena described in Chapter 3 other than seismic which is discussed in Section 3.7. The auxiliary building arrangement of major CVCS components is shown in the floor plan figures in SAR Chapter 1.

9.3.4.5 Instrument Application

Table 9.3-22 lists the parameters used to monitor the CVCS.

9.3.5 FAILED FUEL DETECTION SYSTEM

Prompt detection of failed fuel is accomplished by the process radiation monitor in the letdown stream of the CVCS (see Section 9.3.4.3.11).

9.3.6 SHUTDOWN COOLING SYSTEM

9.3.6.1 Design Bases

9.3.6.1.1 Functional Requirements

The Shutdown Cooling (SDC) System in conjunction with the main steam and main or emergency feedwater systems is designed to reduce the temperature of the reactor coolant in post-shutdown periods from normal operating temperature to the refueling temperature.

The steam and feedwater systems are utilized in the initial phase of cooldown. SDC functions to reduce the coolant temperature to the refueling temperature.

The SDC heat exchangers are used during recirculation following a LOCA. Heat is removed from the recirculating containment sump water by means of shutdown cooling heat exchangers. Flow through the heat exchanger is provided by the containment spray pumps.

9.3.6.1.2 Design Criteria

The design requirements for the SDC System (in conjunction with the main steam and feedwater system) are as follows.

A. The functional requirements (Section 9.3.6.1.1) must be met assuming the failure of a single active component during injection or the single failure of an active or passive component during recirculation following a LOCA.

B. System components whose design pressure and temperature are less than the RCS design limits are provided with overpressure protection devices and two isolation valves in series. System discharge from overpressure protection devices is collected in a closed system.

C. The components of the SDC System are designed in accordance with ASME Code, Section III as shown in Section 3.2.2.

D. Materials are selected to preclude system performance degradation due to the effects of short and long-term corrosion.

General Design Criterion 34 requires that a residual heat removal system capable of performing its design function in the event of a single failure be provided. Both the redundant safety-related EFW system, described in Section 10.4.9, and the SDC System are designed to provide this residual heat removal capability. The operating relationship between these two systems in meeting the General Design Criterion 34 requirement is described in Section 9.3.6.2.1.

9.3.6.2 System Description

9.3.6.2.1 Functional Description

The historical system design parameters are given in Table 9.3-23.

The SDC System, in part, is shown on Figures 5.1-3, 6.3-2, and 6.2-17.

During shutdown cooling, reactor coolant is circulated by a LPSI pump through a shutdown cooling heat exchanger to the LPSI header and returned to the RCS through the four safety injection nozzles. The circulating fluid flows through the core, out the shutdown cooling nozzle in the reactor vessel outlet (hot leg) pipe, and back to the LPSI pumps. Shutdown cooling is initiated after the RCS conditions drop below the design pressure and temperature of the shutdown cooling equipment. At this time, the system is aligned for shutdown cooling.

The two valves in the suction line nearest the RCS are interlocked to prevent opening whenever the RCS pressure is above the design pressure of the SDC System. Each valve is independently controlled by separate instrumentation channels. The interlocks on these valves are further described in Section 7.6.

The SWS is the heat sink to which the reactor coolant residual heat is rejected. Each shutdown heat exchanger receives cooling water to its shell side from a separate SWS essential header.

To minimize thermal shock on the LPSI pumps, shutdown heat exchangers and piping, a low flow can be established by opening the warmup recirculation valve. The LPSI pumps are then warmed to reactor coolant temperature by cracking open one low pressure injection valve. The shutdown cooling heat exchangers are warmed by slowly opening the heat exchanger discharge throttle valve. When the shutdown cooling heat exchangers are warmed up (approximately 15 minutes), the remaining three low pressure injection valves are opened.

The SDC System may be placed in operation when RCS temperature is less than 275 °F, and the cooldown rate is limited to the rates allowed by the Technical Specifications. The cooldown rate is controlled by adjusting the flow rate through the exchangers with the throttle valve on the discharge of heat exchangers. The shutdown cooling flow indicator-controller maintains a constant total shutdown cooling flow rate to the core by adjusting the heat exchanger bypass flow to compensate for changes in flow rate through the heat exchangers. During initial cooldown the temperature differences for heat transfer are large, thus only a portion of the total shutdown flow is diverted through the heat exchangers. As cooldown proceeds the temperature differences become less and the flow rate through the heat exchangers is increased. The flow is increased periodically until the system reaches refueling temperature.

Shutdown cooling is continued through the entire period of plant shutdown to maintain RCS temperatures within Technical Specification requirements.

9.3.6.2.2 Components

The shutdown cooling heat exchangers are used to remove decay and sensible heat during cooldowns and cold shutdown. The characteristics of heat exchangers in the shutdown cooling mode are given in Table 9.3-24.

The design temperature and pressure for the shutdown cooling heat exchangers are established on the same basis as the LPSI pumps (see Section 6.3).

The LPSI pumps are used as part of the SDC System. During all periods of plant operation when SIS operability is required, the LPSI pumps are aligned for emergency core cooling operation.

Manual isolation valves are provided to isolate equipment for maintenance. Throttle valves are provided for remote control of heat exchanger tube side flow. Check valves in the discharge of the LPSI pumps prevent shutdown cooling reverse flow through the LPSI pumps. Manual valves have backseats which can be used to limit stem leakage when in the open position.

Pressure relief valves are provided to protect sections of piping from overpressure.

All SDC piping is austenitic stainless steel. All piping joints and connections are welded except for a minimum number of flanged connections which are used to facilitate maintenance.

9.3.6.2.3 Interface with Other Systems

A. Safety Injection System - During the shutdown cooling mode of heat removal the LPSI pumps are aligned to take suction from the reactor hot leg pipe and discharge through the shutdown cooling heat exchangers. The LPSI header returns flow to the RCS.

B. Reactor Coolant System - Temperature control during plant cooldown and refueling is accomplished by recirculating reactor coolant through a shutdown cooling heat exchanger. During normal operation, two closed valves provide isolation from the RCS. The two isolation valves are also provided with pressure interlocks which prevent opening these valves whenever the RCS pressure increases above the design pressure of the SDC System.

C. Service Water System - The SWS provides the heat sink to which the residual heat is rejected. Service water flows through the shell side of the shutdown cooling heat exchangers and also functions to cool the shaft seals on the LPSI pumps as they circulate the heated reactor coolant.

D. Containment Spray System - During normal operation the containment spray pumps are aligned to discharge through the shutdown cooling heat exchangers. This is the required alignment for emergency operation (operation following a LOCA). During shutdown cooling, the heat exchangers are isolated from the containment spray system.

9.3.6.3 Safety Evaluation

No single failure of an active component during residual heat removal will result in permanent loss of cooling capability. The RCS can be brought to refueling temperature using a LPSI pump and one shutdown heat exchanger.

An analysis of the SDC System has been performed to verify system capability to bring the reactor to a cold shutdown condition (less than 200 °F) within the Technical Specification time requirements of 36 hours, assuming the most limiting single active failure. The failure assumed is the loss of one emergency diesel generator and results in a one pump/one shutdown heat exchanger condition which is the slowest cooldown mode.

The total time required to bring the RCS from hot standby to cold shutdown was determined to be less than the Technical Specification requirement of 36 hours.

If one of the valves in the suction line to the LPSI pumps is closed when either LPSI pump is started or if one of the suction valves is closed while either LPSI pump is running, such condition will be alarmed in the control room. The operator can then open the valve to correct the situation. Similar pumps at another facility have been known to operate without suction for about an hour with only non-catastrophic damage to the seals.

A loss of instrument air to the shutdown cooling system will not result in a loss of cooling ability. The air-operated shutdown cooling valve 2CV-5093 is equipped with a hand wheel which permits its opening upon loss of instrument air. In addition, a manual bypass valve is provided.

A single failure of a passive component in the low pressure portion of the SDC System during residual heat removal may result in the interruption of the cooldown but will not result in a loss of core cooling. In the event of such a failure, SDC can be isolated and decay heat removed by the main steam and feedwater systems. The RCS may be maintained in this condition while repairs are effected.

With the reactor vessel head removed, continued core cooling in the event of a passive failure in the low pressure portion of the SDC System is provided by manual alignment and initiation of the SIS to fill the refueling canal. The safety injection tank isolation valves and High Pressure Safety Injection (HPSI) control valves may be opened, the HPSI pumps started and SDC isolated until the failure is repaired. The temperature of the refueling canal water rises until the evaporative loss equals core decay heat. The containment fan coil units may be used to remove the evaporative heat. These actions are initiated from the control room and will provide the continuation of core cooling.

For long-term performance of SDC without degradation due to corrosion, only materials compatible with the pumped fluid and with the CSS chemical additives are used. The possibility of chloride-induced stress corrosion of austenitic stainless steel is minimized by water chemistry control and the use of insulation material with a low soluble chloride content. During long-term operation following a LOCA, potential chloride stress corrosion due to recirculation of the containment sump water is minimized since SDC is not highly stressed.

Since SDC is essential for a safe shutdown of the reactor, it is a Seismic Category 1 system and designed to remain functional in the event of a design basis earthquake.

Components of the system are located within the auxiliary building and the containment and therefore are not subject to natural perturbations other than seismic.

Inadvertent overpressurization of the SDC suction piping is precluded by the use of interlocks installed on the two shutdown cooling isolation valves providing the boundary with the RCS. The instrumentation, control, and electric equipment pertaining to shutdown cooling valves have been designed to those portions of IEEE 279-1971 and IEEE 308-1971 that are applicable. Redundant and diverse pressure sensors (2PC-4623-1 and 2PS-4623-2), which are physically and electrically separated, are used to prevent opening the motor-operated valves to prevent over-pressurization of SDC. This instrumentation also provides an alarm when the isolation valves are opened and RCS pressure is rising to ensure a double boundary exists during operation. The power to the valve motors, sensors, and control system electronics are from physically and electrically separated and redundant power supply systems as required in IEEE 308-1971. See Sections 7.6.2.1, 8.3.1.2, 8.3.1.4 and 8.3.2.2 for further details.

Initiation of shutdown cooling is under strict administrative controls. For this reason, the ability to place SDC into operation solely from the control room is not provided. Prior to initiation of SDC, communication is established between the local operator and the control room operator. The valve lineup must be accomplished locally. The LPSI pumps and the shutdown cooling flow control valves (used to maintain proper flow through the reactor core and to maintain the proper cooldown rate) are controlled from the control room.

Because of the redundancy of the EFW system, the ability to place SDC into operation in the event of a single failure within SDC is not required. A passive failure of the shutdown cooling line would interrupt normal shutdown cooling via the shutdown cooling heat exchangers. Such an occurrence would not present any safety problems. Should the event occur prior to initiation of shutdown cooling, the plant may still be cooled to 300 °F and held at that temperature until a repair can be affected. Should the event occur while SDC is in operation, the RCS may be pressurized as required to permit operation of a reactor coolant pump; when coolant temperature approaches 300 °F due to residual decay heat input, the steam generators may be used to control system temperature by dumping steam as necessary until the inoperative line is repaired.

In addition to the above, it should be noted that, of the components required to operate in initiating shutdown cooling, only the two shutdown cooling isolation valves, 2CV-5084-1 and 2CV-5086-2 (shown in Figure 6.3-2) are located inside the containment building. Handwheels are provided on these valves to allow for local operation in the event an electrical failure in the valve operators or the associated cabling precludes remote operation of these valves. These valves are located such that shutdown dose rates will not preclude local operation.

9.3.6.4 Testing and Inspection

Historical data removed; refer to Section 9.3.6.4 of the FSAR.

To ensure availability of SDC, components of the system are periodically tested. As described in Section 6.3.4, the LPSI pumps and valves associated with the SIS are tested in accordance with the Edition and Addenda of the ASME Operation and Maintenance Code specified by 10 CFR 50 Section 50.55a(f). These system and component tests together with shutdown cooling heat exchanger thermal performance data taken during refueling are sufficient to demonstrate the operability of SDC.

9.3.6.5 Instrumentation Application

The operation of the SDC System is controlled and monitored using installed instrumentation. The instrumentation is used to monitor heat removal, cooldown rate, and shutdown cooling flow. The following instrumentation is provided with control room indication:

A. Temperature measurement at the shutdown cooling heat exchanger inlet and heat exchanger outlet; temperature of the common mixed flow from the heat exchanger outlet and the heat exchanger bypass. A two channel recorder tracks the temperature of the heat exchanger bypass flow and the mixed bypass and heat exchanger outlet flow to facilitate control of the RCS cooldown rate.

B. Pressure measurement at the LPSI header and shutdown cooling heat exchanger inlet.

C. Shutdown cooling flow rate is automatically controlled by a flow indicating controller. Total shutdown cooling flow is measured and the shutdown cooling heat exchanger bypass flow automatically adjusted to maintain a constant total flow in response to operator control of heat exchanger flow. A high/low flow alarm is produced by the indicating controller to the annunciator. The alarm warns the operator of possible vortexing which could result in a loss of suction to the LPSI pumps.

D. A common high/low level alarm is provided for two independent RCS level loops.

E. A CET indicator will give the operator indication of the reactor coolant temperature in the reactor vessel up until the time the head is removed for refueling. A CET high temperature alarm will be produced by the indicator.

F. LPSI pump suction pressure (0-50 psig only) and LPSI pump discharge header pressure. These indications are alarmed to warn the operator of unacceptable pressure fluctuations that may be indicative of a degradation or loss of SDC. LPSI pump delta-P is also indicated.

G. LPSI pump motor current. This parameter will be alarmed to warn the operator of unacceptable fluctuations in motor current which signify possible vortexing conditions that could result in a loss of suction to the LPSI pump.

Instrumentation used to monitor shutdown cooling is listed in Table 9.3-25.

9.4 AIR CONDITIONING, HEATING, COOLING, AND VENTILATION SYSTEMS

9.4.1 CONTROL ROOM

9.4.1.1 Design Bases

The heating, ventilating, and air conditioning systems for the control room are designed to provide a suitable environment for equipment and station operator comfort and safety.

The ventilation systems and equipment are designed in accordance with the recommended practices of the American Society of Heating, Refrigerating, and Air Conditioning Engineers Guide, the Air Moving and Conditioning Association, and the National Fire Protection Association. The ductwork is designed and fabricated in accordance with the Sheet Metal and Air Conditioning Contractors' National Association (SMACCNA) standards. Radioactivity limits and radiation protection are discussed in Section 12.1.

Full capacity redundant systems are provided to ensure that the failure of any single component will not prevent the fulfilling of the design functions. Protection against tornado missiles is described in Table 3.5-1.

9.4.1.1.1 Normal Conditions

The normal control room air conditioning system serves the control room and computer room. The control room and computer room air is recirculated in order to maintain cleaner air and to economize on cooling and heating loads. The free air space serviced by the normal ventilation system is estimated to be 41,500 cubic feet. Adequate filtered fresh air makeup is provided in the system. The control room and computer room air conditioning system design is based on the wall transmission, lighting, occupancy, and equipment loads with a room ambient temperature of 75 °F Dry Bulb (DB) and 50 percent Relative Humidity (RH).

The control room recirculation exhaust fans provide a means for clearing smoke or other airborne contaminants from within the room, and are designed to exhaust the room at the rate of 10 air changes per hour.

9.4.1.1.2 Emergency Conditions

On detection of high radiation or high chlorine concentration, the common control room for Units 1 and 2 is isolated by dampers on all supply and return ducts, except for the filtered outside air used for pressurization to minimize unfiltered air inleakage. The control room emergency ventilation system design is based on the combined Unit 1 and Unit 2 heat gains from safety-related control equipment, occupancy and lighting load. The free air space serviced by the emergency ventilation system is estimated to be 40,000 cubic feet.

The wall transmission load is included based on a 105 °F DB temperature for areas surrounding the control rooms. The emergency air conditioning system provides a recirculation rate of 15 air changes per hour.

The control room emergency air filtering system is based on a minimum of three room air changes per hour for the combined control room volume. The filter banks are sized for maximum efficiency.

The original DBA maximum emergency cooling pond temperature of 129.5 °F discussed in Section 9.2.5.3 exceeded preliminary estimates of the peak pond temperature. The Change required the replacement of the Unit 1 and Unit 2 emergency air conditioning units VUC-9 and 2VUC-9 with larger units capable of operating with 129.5 °F cooling water. The new control room emergency air conditioning units (2VUC-27A & B), are located in the Unit 2 control room and provide emergency air conditioning to both Unit 1 and Unit 2 control rooms. Seismically supported duct work has been added for air distribution to the Unit 1 control room.

In conjunction with installation of new control room emergency air conditioning units, an intertie has been provided from loop #2 of the Unit 1 service water system to the air conditioning condensing units 2VE-1A & B, to provide an alternate source of service water to the emergency air conditioning system.

Redundant, quick acting chlorine detectors are provided at the control room outside air intake. Detector signals initiate automatic isolation of the common control room and provide an audible alarm in both sections of the control room in case of high chlorine gas concentration in the air. These detectors are able to detect and signal a step increase in chlorine concentration of zero to 15 ppm within five seconds (based upon 66 percent response). Control room isolation is accomplished within five seconds after the detector trip signal is received. The emergency air filtration system is manually initiated.

The two chlorine detector loops are separated and channelized to meet IEEE 279-1971 requirements. One detector is also located in the sodium bromide & sodium hypochlorite building. An alarm is initiated locally at the entrance door.

Chlorine detection system design features are consistent with the recommendations of Regulatory Guide 1.95, “Protection of Nuclear Power Plant Control Room Operators Against an Accidental Chlorine Release,” February, 1975. However, since elemental chlorine is no longer stored or used on site or within a 5 mile radius of the plant site, the Reg Guide recommendation for Seismic Category I designation is not necessary for ANO design requirements. A postulated seismic event concurrent with transport failure and release of chlorine or other toxic gas offsite is considered an incredible event.

The control room is designed to minimize air inleakage by pressurizing the room with of outside air through either of the two emergency air filter trains. Self-contained breathing apparatus are available in the control room for use during an emergency.

Total unfiltered air leaking into the control room for the condition of control room isolation is assumed to be 250 cfm consistent with NRC letter 2CAN031001. This leakage includes 10 cfm inleakage attributed to ingress and egress of plant personnel through the control room doors during accident conditions.

The control room emergency air conditioning system and the emergency air filtering system are designed to meet the following criteria:

A. The systems are designed as Seismic Category 1 systems.

B. The systems are designed to include the capability of withstanding a single failure without loss of function.

9.4.1.2 System Description

9.4.1.2.1 Normal Conditions

The system schematic is shown on Figure 9.4-1. The control room and computer room are normally air conditioned by two 100 percent capacity air conditioning units receiving chilled water from two 100 percent capacity chillers. One air conditioning unit and one chiller are normally running, with the others in standby status isolated from the system by shutoff dampers and valves. The standby system is available for manual actuation in the event of failure of the operating system. Fan failure is monitored by a flow switch at the unit with an indicating light in the control room.

Adequate air flow is diverted to the false ceiling above the control room to aid in cooling the annunciator panels.

9.4.1.2.2 Emergency Conditions

The control room emergency air conditioning system consists of two unit coolers in the control room and two water cooled compressor condensing units near the control room to serve both Unit 1 and Unit 2 control rooms and the Electrical Equipment Room No. 2150. Although essential control room equipment is qualified for long term operation in temperatures at least as high as 104 °F (see section 3.11), the control room emergency cooling system was originally sized to provide much lower temperatures. As originally sized, either combination of unit cooler and compressor condensing unit would maintain 84 °F DB maximum temperature during control room isolation and/or loss of off-site power. In the event of a DBA, or sensing of high radiation or chlorine, either unit cooler and its respective condensing unit is manually started. In the event of high radiation or chlorine the control room is completely isolated from both the outside air and adjacent rooms, except for the filtered outside air used for pressurization to minimize unfiltered air inleakage.

The control room isolation dampers in the supply and return ductwork are spring loaded such that they fail closed upon loss of air or power. The single supply and single return isolation dampers are each actuated by either of two solenoid valves. Each of the two solenoid valves is supplied by separate Engineered Safety Features (ESF) DC power. This arrangement is shown in Figure 9.4-1.

The emergency air filtering system consists of two redundant filter trains, both of which are located outside the Unit 1 section of the control room. Due to space limitations, the two filter trains are designed differently. One filter train (2VSF-9) consists of a centrifugal fan, roughing filters, HEPA filters, and a 4-inch deep bed charcoal adsorber rated for 2,000 cfm. The other train (VSF-9) consists of a centrifugal fan, one filter unit assembly rated for 2,000 cfm with an outside air filter unit rated for 333 cfm, each with the necessary roughing filters, HEPA filters and 2-inch charcoal tray adsorber. Both VSF-9 and 2VSF-9 were originally designed to provide ~333 cfm outside air to minimize unfiltered air inleakage to the combined control room envelope (CRE), which was in turn based upon providing greater than or equal to 0.5 volume changes per hour based upon Standard Review Plan 6.4, Rev. 2 (July 1981). However, the actual outside air drawn by 2VSF-9 is ~465 cfm, as measured during control room tracer gas testing. Calculations have been performed that indicate that even with the higher 2VSF-9 makeup air flow rate, operation of VSF-9 with 333 cfm makeup air is still limiting in terms of control room radiation dose (1CAN060302). For either train, the outside air will be filtered through four inches of charcoal adsorber and the recirculation air will go through at least two inches of charcoal bed. The emergency air filtering trains are isolated by shutdown dampers during plant

normal operation. To prevent loss of pressurization, the outside air dampers on the filter trains are each equipped with a bottled reserve air supply which ensures that in the event an emergency recirculation fan fails, the outside air damper can be closed even with loss of instrument air. The emergency air filtering system is started automatically when the control room is isolated on a high radiation signal or a high chlorine signal. Since the air in the combined control room is mixed by the emergency air conditioning system, contamination entering any section of the control room will be cleaned up by the emergency air filtering system. This arrangement is shown on Figure 9.4-1.

9.4.1.2.3 **Component Descriptions**

A description of the major system components is given below:

Normal Control Room Air Conditioning System	
Fans	
Type	Centrifugal
Capacity, cfm	21,300
Motor	
Type	Induction
Horsepower rating, hp	30
Voltage, V	460
Phase	3
Enclosure	Open drip-proof
Insulation class	B
Heating Coil	
Type	Hot water
Capacity, Btu/hr	119,000
Cooling Coil	
Type	Chilled water
Capacity, Btu/hr	800,000
Reheat Coil	
Type	Electric
Capacity, kW	11.2
Computer Room	
Heating Coil	
Type	Hot water
Capacity, Btu/hr	101,500
Reheat Coil	
Type	Electric
Capacity, kW	11.2

Normal Control Room Recirculation - Exhaust System

Fans	
Type	Vaneaxial
Capacity, cfm	20,000
Motors	
Type	Induction
Horsepower rating, hp	10
Voltage, V	460
Phase	3
Enclosure	Open drip-proof
Insulation class	F

Control Room Emergency Air Conditioning System

Fans	
Type	Centrifugal
Capacity, cfm	9,900
Motor	
Type	Induction
Horsepower rating, hp	7.5
Voltage, V	460
Phase	3
Enclosure	Open drip-proof
Insulation class	B
Heating Coil	
Type	Electric
Capacity, kW	40
Cooling Coil	
Type	Direct Expansion
Capacity, Btu/hr	316,000
Compressor Condensing Unit	
Capacity, tons	29 tons
Refrigerant	R-12
Condenser	Water cooled
Compressor power rating, kW	37

Control Room Emergency Air Filtering System

Fans	
Type	Centrifugal
Capacity, cfm	2,000
Motors	
Type	Induction
Horsepower rating, hp	5
Voltage, V	460
Phase	3
Enclosure	Open drip-proof
Insulation class	B
Roughing Filter	
Quantity per assembly	2 (2VFP-35) 1 (VFP-15) 1 (VFP-15A)
Rated flow per filter cell, cfm	1,000 (2000 for VFP-15)
Type	Replaceable
Media	Glass fiber
Average efficiency, %	80
Rating basis	ASHRAE Std. 52-68 test method (current revision for VFP-15)
Rated pressure drop, unloaded, in.W.G.	0.45 (0.57 for VFP-15)
HEPA Filters	
Quantity per assembly	2 (2VFA-10) 2 (VFA-3) 1 (VFA-3A)
Rated flow per filter cell, cfm	1000 (2VFA-10) 1000 (VFA-3) 333 (VFA-3A)
Type	High efficiency, dry
Media	Glass fiber (water-proof, fire retardant)
Frame	Chromized steel original, T-409 for replacements
Face guards	4X4 mesh galvanized hardware cloth
Seal	Polyurethane
Efficiency	99.97% with 0.3 micron diameter DOP
Rating basis	MIL-STD-282
Rated pressure drop, unloaded, in. W. G.	1.0
Codes	Health and Safety Bulletin 306 (not applicable to VFA-3) Replacements for VSF-3 meet UL-586 and Design Basis of ASME AG-1 MIL-F-51079A (original only for VFA-3) MIL-F-51068D (original only for VFA-3) MIL-STD-282

Charcoal Adsorbers

	2VFC-10	VFC-2	VFC-2A
Design	4" Vert bed	2" tray	2" tray
Quantity per assembly	1	6	1
Rated flow per filter cell, cfm	2,000	333	333
Type (all)	Activated coconut shell, impregnated		
Granular size (all)	10-14 mesh		
Ignition temperature (all)	360 °C		
Gasketing material (all)	ASTM-D-1056, GR SCE-43		
Casing material (all)	304 stainless steel		
Efficiency % at 25 °C, 70% RH			
elemental iodine	99.99	99.9	99.9
methyl iodide	99.8	99.5	99.5
Rating basis (all)	RDT-M16-IT		
Retention time per 2" bed, sec	0.25	0.25	0.25
Rated pressure drop, inches W.G.	1.5	1.0	1.0
Codes (all)	AEC-DP-1082, July 1967 RTD-M16-IT AEC-DP-1075		

9.4.1.3 Safety Evaluation

In the event that both of the normal air conditioning systems fail, they will be shut down. As originally sized, the emergency unit cooler and compressor condensing units would then maintain a maximum temperature in the combined Unit 1 and Unit 2 control rooms of 84 °F DB. Control room equipment is qualified to operate at long term temperatures of a least 104 °F (see Section 3.11).

The normal control room air conditioning system is continuously monitored with alarms for high radiation and high chlorine. In the event of high radiation or high chlorine, the normal air conditioning systems of both Unit 1 and Unit 2 automatically de-energize and the common control room is completely isolated from both the outside air and adjacent rooms, except for the filtered outside air used to pressurize the control room to minimize unfiltered air inleakage.

The actuation level for high radiation is sufficiently below hazardous radiation levels (see Section 12.2) to minimize operator dose during an accident and is sufficiently above normally experienced background levels to minimize spurious actuations. For detection of chlorine in the supply ducts, see the detailed description in section 9.4.1.1.2.

Filtration of the air inside the control room is accomplished by the emergency air filtering system so that the limits of Criterion 19 of 10 CFR 50, Appendix A are not exceeded. An alarm for excessive pressure drop across the filters of the emergency filtering system will be actuated at one inch across the roughing filter, three inches across the HEPA filter or 1.15 inches across the charcoal adsorber. Fan failure is monitored by a flow switch with an indicating light in the Control Room. On an indication of fan failure, the standby unit will be manually started.

The control room supply and return air ductwork is equipped with ionization type detectors to alarm in the control room on the presence of visible or invisible products of combustion in the ventilation system. If smoke is present in the supply duct, the detector will initiate a signal to close the control room isolation dampers and de-energize the supply and recirculation fans. If smoke is trapped in the control room after isolation, the operator may override the exhaust isolation damper to open and purge the room with the exhaust air. If smoke is generated from within the control room, the detector in the return duct will initiate a signal to open the exhaust dampers for purging the control room.

These automatic features associated with the ventilation smoke detectors are considered to be system enhancements that are not essential to supporting the habitability safety function. Protection from prolonged exposure to smoke and/or noxious vapors is assured by the availability of self-contained breathing apparatus in the control room and the ability of control room operators to detect smoke or other vapors, manually isolate the control room envelope, and then restore the control room atmosphere by manipulating the control room ventilation system.

The Unit 1 control room, which is adjacent to the Unit 2 control room, is protected by a Halon 1301 flooding system in the subfloor and false ceilings. In the unlikely event Halon 1301 should enter the control room environment, it will not adversely affect the charcoal beds. It is also highly unlikely that the charcoal beds would be exposed to Halon 1301 since the emergency filter systems designed to remove radioactivity from the control room air following an accident are equipped with dampers in the closed position both upstream and downstream of the filter assembly.

A highly unlikely total discharge of Halon 1301 into the communicating Unit 1 and Unit 2 control room area atmospheres, with subfloor covers and false ceiling tiles removed, would result in a concentration of 1.96 percent if no ventilation or leakage existed. This would have no adverse affects; even the design concentration of six percent in the ceiling and subfloors is considered to be a very low level of toxicity and can be breathed for four or five minutes by personnel with no observable effects. After investigation of the cause of the discharge, the Halon can be released to the atmosphere by the ventilation system. The ventilation of control room areas will dilute the concentration to undetectable proportions. In the event of a slow leak to the system discharge header, the normal ventilation will dilute the concentration to undetectable proportions.

A small fraction of Halon 1301 will be pyrolyzed when the fire is extinguished, resulting in hydrogen fluoride and hydrogen bromide concentrations of less than 100 ppm. The decomposition products and the remaining Halon 1301 will be evacuated and exhausted to the atmosphere outside the building.

The emergency control room air conditioning system and the emergency air filtering system are designed to include the capability of withstanding a single failure without loss of function (see Table 9.4-1). Conformance to Regulatory Guide 1.52 is provided in Table 9.4-3.

9.4.1.4 Inspection and Testing Requirements

All components of the control room air conditioning system are accessible for periodic inspection and maintenance during plant operation.

Periodic visual inspections, during plant operation, will be performed on the components of all operating systems to check for damaged filters, faulty bolting and gasketing, excessive fan vibration, motor overheating, control malfunctioning, etc.

Periodic operational tests will be performed on all the standby components for normal plant operation to assure their proper functional capability.

Operational tests will be performed, during plant shutdown, on all the ESF unit coolers and related control systems to assure their proper functional capability.

The HEPA filter and charcoal adsorber of the control room emergency air filtering system are tested and qualified in the shop and after installation in the same manner as the filtering systems furnished for the penetration rooms ventilation system (Section 6.5.4).

Historical data removed; see Section 9.4.1.4 of the FSAR.

9.4.2 AUXILIARY BUILDING

The auxiliary building is served by separate ventilation systems for each of the following areas:

A. fuel handling floor radwaste areas
B. auxiliary building radwaste areas
C. non-contaminated areas
D. emergency diesel generator rooms
E. control room and computer room
F. battery rooms and battery equipment rooms
G. switchgear rooms
H. cable spreading room and Electrical Equipment Room No. 2108
I. CPC Room No. 2098-C
J. Electrical Equipment (MG) Room No. 2076
K. ventilation equipment room
L. main steam line enclosure
M. elevator-machine room
N. boiler room area
O. heat exchanger and pipeway area
P. Electrical Equipment Room No. 2091

Series isolation dampers are not provided for the ventilation systems in the Emergency Core Cooling System (ECCS) and auxiliary building rooms since no credit is taken for such isolation in the accident analysis described in Section 15.1.13. These ventilation systems are not Seismic Category 1 based on the fact that a seismic event and a fuel handling accident were not postulated to occur simultaneously. In addition, the building siding is not Seismic Category 1.

To meet the requirement of NUREG-0578, Item 2.1.8.b, stack radiation monitoring capability was installed on the auxiliary building ventilation exhaust stack. The installation consists of an isokinetic probe installed in the exhaust stack, necessary piping (3/4-inch) to the sampling station, valving, charcoal and particulate filters, a radiation monitor, pump, and flow indicator. The radiation monitor is mounted external to the pipe and consists of a radiation detector, preamplifier and a remote power supply/readout device.

9.4.2.1 Fuel Handling Floor Radwaste Area

See Section 9.4.3 for a detailed description.

9.4.2.2 Auxiliary Building Radwaste Area

See Section 9.4.3 for a detailed description.

9.4.2.3 Non-Contaminated Areas

The non-contaminated areas include the outage control center, SPDS computer room, and the health physics offices. The air from the work areas, the health physics offices, the storage rooms and the false ceiling area is recirculated through an air conditioning multi-zone unit while the air from all the other areas is exhausted to the atmosphere. Makeup air is supplied from the turbine building and the atmosphere.

9.4.2.4 Emergency Diesel Generator Rooms

Each of the two emergency diesel generator rooms has a separate ventilation system (two exhaust fans for each room) to ensure adequate ventilation and safe operation of the diesel generators. The air from the diesel generator rooms is discharged directly to the atmosphere through the roof. The air intakes, shutoff dampers, exhaust fans, ductwork supports and the temperature controls are designed to meet Seismic Category 1 requirements and are protected from tornado generated missiles. The exhaust fans discharge air directed away from the air intakes at a sufficiently high velocity (28 fps) to preclude short circuiting of exhaust air into the room.

The exhaust fans in the emergency diesel generator rooms are started and the outside air dampers open at any time the room air temperature is above the setpoint.

In case one exhaust fan in either room fails the second fan will maintain the room at 115 °F DB with an outside air temperature of 95 °F or 120 °F with an outside air temperature of 100 °F.

A single failure analysis has been made on all active and passive components of the emergency diesel generator room ventilation systems to show that failure of any single component will not prevent fulfilling of the design functions. This analysis is shown in Table 9.4-2.

9.4.2.5 Control Room and Computer Room

See Section 9.4.1 for a detailed description.

9.4.2.6 Battery Rooms and Battery Equipment Rooms

The supply air to the two battery rooms is transfer air from the auxiliary building. The supply air to the two corresponding equipment rooms is from one of the two auxiliary building radwaste area supply air handling units. Each battery room and its corresponding equipment room is served by an independent battery room exhaust system. The exhaust systems are designed to remove air from the high point of each battery room at the minimum rate of 11 air changes an hour. Each exhaust system is equipped with an air flow switch to alarm in the control room when the exhaust fan is operating and the discharge air flow is not established. An indicating light in the control room shows each exhaust fan status. With either exhaust system out of

service, it would take approximately 1½ days (worst case) for battery room hydrogen concentrations to approach the four percent flammability limit. The air flow alarms will therefore provide the operator with sufficient time to investigate the cause of the alarm and take necessary measures to restore exhaust flow well before flammable limits would be approached.

The exhaust systems also provide ventilation to maintain 105 °F in the rooms during normal plant operation. Some of the ESF equipment in Battery Equipment Room Nos. 2097 and 2099 is designed to operate in maximum ambient temperature of 122 °F. The exhaust systems for these rooms are designed to Seismic Category 1 requirements. They are protected from tornado missiles and the effects of high energy pipe ruptures and will maintain the room at 120 °F maximum during emergency conditions.

9.4.2.7 Switchgear Rooms

Each of the two cooling units (designed as Seismic Category 1) located in each of the two switchgear rooms consists of a low efficiency filter, a cooling coil (constructed in accordance with ASME Code Section III, Class 3) and a centrifugal type direct-driven fan. The unit takes air from the switchgear room and returns cooled air to the same area. One of the two cooling units in each switchgear room is a standby. The unit coolers in one switchgear room are connected to one SWS loop and the unit coolers in the other room are connected to the other SWS loop. The unit coolers utilize service water with welded guard piping on the service water supply and return lines to the units. The coolers are designed to maintain normal room temperature at 110 °F DB maximum in case the 85 °F service water is available.

Each switchgear room is also equipped with an exhaust fan designed to Seismic Category 1 requirements. In the event the switchgear room temperature rises above 120 °F, an annunciation will be received in the control room and operations will start the exhaust fan to ventilate the air from the switchgear room to the health physics office area. The exhaust fans are not required for safe shutdown after a tornado.

9.4.2.8 Cable Spreading Room and Electrical Equipment Room No. 2108

The cable spreading room air conditioning package unit is located outside of the room and was originally designed to take air from the turbine building and returns cooled air to the cable spreading room. The cable spreading room cooling unit has since been abandoned in place. The electrical equipment room package unit takes air from the room and returns cooled air to the same area. Each of these units consist of a centrifugal type fan, a refrigerant cooling coil and a water cooled compressor condensing unit. The electrical equipment unit is designed to utilize auxiliary cooling water and is designed to maintain the room at the temperature of 95 °F DB maximum.

9.4.2.8.A CPC Room No. 2098-C

Two package computer room HVAC units provide environmental control by recirculating air within the room. Each of the units consist of a centrifugal type fan, a refrigerant cooling coil, electric reheater coil, self generating humidifier, two compressors, and a remote located air cooled condenser. Each unit is sized to meet the room cooling load. Two units are used to provide redundancy. A microprocessor controller, mounted integral to the units, controls the units to maintain the desired room temperature and humidity conditions.

9.4.2.9 Electrical Equipment (MG) Room No. 2076

Each of the two MG room unit coolers takes air from the room and returns cooled air to the same area. The units utilize chilled water and are on the control and computer room chilled water system. The unit coolers are designed to maintain the room at the temperature of 105 °F DB maximum.

9.4.2.10 Ventilation Equipment Room

The ventilation equipment room is equipped with a centrifugal supply fan that starts when an increase in room air temperature above 75 °F DB is sensed by an electric temperature controller and through interlock starts an exhaust fan. The room is equipped with two electric heaters to maintain the room temperature of 60 °F during shutdown periods.

9.4.2.11 Main Steam Line Enclosure

The main steam line enclosure is equipped with a vaneaxial type exhaust fan that starts when the air temperature within the enclosure is above 100 °F DB as sensed by an electric air temperature controller. The fan stops when the air temperature drops to 95 °F DB. Outside air is supplied through a wall louver.

9.4.2.12 Elevator-Machine Room

The elevator-machine room ventilation unit consists of a mixing box with mixing dampers, a roll type filter, an electric heating coil and a centrifugal type supply fan. The air from the room is exhausted to the atmosphere through a relief damper. The electric heating coil is a 2-stage type coil. The room air temperature is sensed by a 2-stage electric thermostat. With a decrease in room temperature below 50 °F DB, Heating Stage 1 is energized. Heating Stage 2 is energized when the room temperature drops to 45 °F DB. The supply fan runs all the time. The air is recirculated during the winter and the room is supplied with 100 percent outside air during summer.

9.4.2.13 Boiler Room Area

The boiler room is equipped with two exhaust fans controlled by separate thermostats. On an increase in room temperature above 88 °F DB, one of the exhaust fans in the boiler room starts. The second fan starts when the room temperature reaches 100 °F DB. Outside air is drawn into the room through wall louvers. The boiler room area is maintained at a minimum of 60 °F DB by means of hot water unit heaters mounted on the inside surface of exterior walls.

9.4.2.14 Heat Exchanger and Pipeway Area

The heat exchanger and pipeway area ventilation system is equipped with a supply air handling unit and a vaneaxial type exhaust fan. The supply unit consists of a roll type filter, a heating coil, a cooling coil and a centrifugal fan. The unit takes air from the atmosphere and serves these areas through a ductwork system. The ventilation air from these areas is exhausted through a ductwork system by the vaneaxial exhaust fan.

The ventilation system for these areas is designed to maintain suitable ambient temperatures of 60 °F DB minimum and 105 °F DB maximum during winter and summer, respectively. The supply air handling unit and exhaust fan are interlocked such that the exhaust fan will not start unless the supply unit is running.

9.4.2.15 Electrical Equipment Room No. 2091

There are two unit coolers in Electrical Equipment Room No. 2091 (one standby). Both units are connected to one electrical bus. In the event of a Design Basis Accident (DBA), a SIAS signal will start both unit coolers and one unit cooler is manually stopped from the control room.

In addition, there are two redundant ventilation fans in Room No. 2091 to provide emergency cooling. Both fans will start on an increase in room temperature above 120 °F DB, and will stop when the room temperature is cooled down to 115 °F.

9.4.2.16 Component Descriptions

Non-Contaminated Area Supply System

Fan (2VSF-10)	
Type	Centrifugal
Capacity, cfm	5100
Motor	
Type	Induction
Horsepower rating, hp	10
Voltage, V	480
Phase	3
Enclosure	Open drip-proof
Heating Coil	
Type	Hot water
Capacity, Btu/hr	169,000
Pre-Cooling Coil	
Type	Chilled water
Capacity, Btu/hr	165,000
Cooling coil	
Type	Chilled water
Capacity, Btu/hr	175,000
Filter	
Type	Automatic roll
Media	Glass fiber blanket
Efficiency, %	85

Controlled Access Entry Area Supply System

Fan (2VSF-51)	
Type	Centrifugal
Capacity, cfm	1525
Motor	
Type	Induction
Horsepower Rating, HP.	1
Voltage, V	480
Phase	3
Cooling Coil	
Type	Chilled Water
Capacity, Btu/hr.	120,000

Non-Contaminated Area Exhaust System

Fan (2VEF-9)	
Type	Centrifugal
Capacity, cfm	1605
Motor	
Type	Induction
Horsepower rating, hp	1/3
Voltage, V	480

Enclosure	TEAO

9.4.3 RADWASTE AREA

The radwaste area consists of the auxiliary building radwaste area and the fuel handling floor radwaste area.

9.4.3.1 Design Bases

The fuel handling floor radwaste area and the auxiliary building radwaste area have similar design bases.

Each of the above two areas is served by a separate ventilation system.

The supply systems are designed to maintain the temperature of all areas inside the building at 105 °F DB when outdoor air is at summer design conditions of 95 °F DB and 50 percent relative humidity and at 60 °F DB when outdoor air is at winter design condition of 6 °F DB.

The systems are designed to maintain the temperature at a minimum of 60 °F DB, using electric heaters mounted on the inside surface of exterior walls, when the outdoor air is at winter design condition and the plant is shut down.

The exhaust systems are designed to prevent release of airborne radioactive material to the environment. They are designed to maintain the preferred direction of air flow from spaces with low potential radioactivity into spaces of progressively higher potential radioactivity.

The systems are designed to treat exhaust air before releasing it to the atmosphere. Automatic continuous radiation monitoring is provided for the exhaust ducts as described in Section 11.4.2. The systems are designed for continuous operation.

See Section 6.5.2 for the basic design criteria of the roughing filter, HEPA filter, and charcoal adsorber, with the following exceptions. Replacement medium efficiency roughing filters are 80% efficient with initial resistance not to exceed 0.56 inch W.G. clean and a face area of 23-3/8" x 23-3/8". Replacement HEPA filters are in compliance with and meet the basic design criteria of ASME AG-1 in lieu of AEC-HSB-306, MIL-F-51079A, and MIL-F-51068D and are not evaluated for dust holding capacity.

9.4.3.2 System Description

9.4.3.2.1 Auxiliary Building Radwaste Area

Two Radwaste Supply Fans (2VSF-7A and 2VSF-7B) supply the Unit 2 Auxiliary Building Radwaste Area. 2VSF-7A serves Elevations 354, 372, 386, as well as both DC Bus Equipment Rooms, 2B63 Room, and the Boric Acid Makeup Pump Area. 2VSF-7B serves Elevations 317, 335 and the corridor behind Door 340.

Each unit consists of a roll type filter, a heating coil, a cooling coil and a centrifugal type fan. The unit takes air from the atmosphere and serves the different elevations through a ductwork system.

The ventilation air from the spaces is exhausted to a containment flute (vent) through a multi-filter unit consisting of a roughing filter, a HEPA filter, a charcoal adsorber and two vaneaxial type fans, one of which serves as a standby.

The exhaust duct system is equipped with isolation dampers in order to isolate the multifilter unit and the fans for maintenance purposes.

The supply air handling units and exhaust fans are interlocked such that the supply fans will not start unless one of the exhaust fans is running.

The auxiliary building radwaste area is also equipped with the following Engineered Safety Features (ESF) unit coolers which are designed as Seismic Category 1:

A. Shutdown heat exchanger rooms unit coolers (Elevation 317 feet)
B. High Pressure Safety Injection (HPSI) pump room unit coolers (Elevation 317 feet)
C. Charging pumps area unit coolers (Elevation 335 feet)
D. Emergency feedwater pumps area unit coolers (Elevation 335 feet)
E. Electrical Equipment Room No. 2096 unit coolers (Elevation 372 feet)
F. Electrical Equipment Room No. 2150 unit coolers (Elevation 404 feet)

Each of the above unit coolers consists of a fan-coil unit containing a low efficiency filter, a cooling coil and a centrifugal type direct-driven fan. The unit coolers take air from the area served and return cooled air to the same area.

There are two shutdown heat exchanger rooms. Three unit coolers (one standby) are located in each room. The standby unit in each room is manually operated from the control room. The other two unit coolers in each room are interlocked with the pumps inside the room and are connected to one SWS loop and one electrical bus in one room and to the other SWS loop and electrical bus in the second room.

There are two unit coolers in the HPSI pump room. The unit coolers are interlocked with the pump inside the room and one unit cooler is connected to one SWS loop and one ESF bus and the second unit cooler is connected to the other SWS loop, and the other ESF bus.

The purge air systems of the two shutdown heat exchanger rooms and the HPSI pump room are aligned during normal plant operation. In the unlikely event of a DBA, the isolation is assured by a Safety Injection Actuation Signal (SIAS) to each isolation valve. The purge air system will be put in operation if personnel access into the rooms is desired. After purging is completed, the radiation level inside the room is verified with portable monitors before entering. The purge air is obtained from the surrounding controlled access area and is exhausted through the Radwaste Area Ventilation System. The Purge Air System is designed to purge each room independently.

There are three rooms in the charging pump area with one unit cooler in each room. The unit coolers are interlocked with the pumps inside the area. In two of the three rooms, one unit cooler is connected to one SWS loop and one electrical bus, and the other unit cooler in the third room is connected to both SWS loops mentioned above and can be manually switched from the control room to either one. This unit is also connected to both electrical buses.

There are two unit coolers in the emergency feedwater pumps area. These unit coolers are interlocked with the pumps in the area with one unit cooler connected to one SWS loop and one ESF bus and the second unit cooler connected to the other SWS loop and ESF bus.

There are two unit coolers in Electrical Equipment Room No. 2096 (one standby). Both units are connected to one electrical bus. In the event of a DBA, an SIAS signal will start both unit coolers and one unit cooler is manually stopped from the control room.

There are two unit coolers in Electrical Equipment Room No. 2150 which utilize refrigerant from the two water cooled compressor condensing units for the control room (2VE-1A, B). In the event of a DBA, either unit cooler can be manually started and is interlocked to automatically start the associated compressor condensing unit. Either unit cooler and its associated condensing unit will maintain a 95°F DB maximum ambient temperature during a DBA.

Electrical Equipment Room 2150 also contains an air conditioning packaged unit for use during normal operation to provide more efficient cooling for cabinets containing terminal connections for the Core Protection Calculators (CPCs) and other systems.

9.4.3.2.2 Fuel Handling Floor Radwaste Area

The fuel handling and storage floor is served by a separate ventilation system. The ventilation system maintains a slight vacuum in this area. In the event of high radiation measured on the floor, the ventilation system will continue to operate to remove the contamination from the space to avoid the spread of airborne radioactive particles to other areas.

One supply air handling unit serves the fuel handling floor radwaste area.

The unit consists of a roll type filter, a heating coil, and a centrifugal type fan. The unit takes air from the atmosphere and serves the fuel handling floor radwaste area through a ductwork system.

The ventilation air from the spaces is exhausted to a containment flue (vent – see Figure 11.2-2) through a multi-filter unit consisting of a roughing filter, a HEPA filter, and a charcoal adsorber, and two vaneaxial type fans, one of which serves as a standby.

9.4.3.2.3 Component Description

Fuel Handling Floor Radwaste Area Supply System

Fan (2VSF-4)	
Type	Centrifugal
Airflow, cfm	See P&ID M-2262
Motor	
Type	Induction
Horsepower rating, hp	40
Voltage, V	480
Phase	3
Enclosure	Open drip-proof
Insulation class	B

Heating Coil	
Type	Hotwater
Original design capacity, Btu/hr	2,332,800
Filter	
Type	Automatic roll
Media	Glass fiber blanket
Efficiency, %	85

Fuel Handling Floor Radwaste Area Exhaust System

Fans (2VEF-14A&B)	
Type	Vaneaxial
Airflow, cfm	See P&ID M-2262
Motors	
Type	Induction
Horsepower rating, hp	100
Voltage, V	460
Phase	3
Enclosure	Totally enclosed air over
Insulation class	F
Roughing Filters	
Quantity per assembly	21
Design rated flow per filter cell, cfm	2,000
Type	Replaceable
Media	Glass filter
Average efficiency %	80
Rating basis	ASHRAE STD 52-68 Test method original, current revision for replacements
Design rated press. drop, unloaded, in. W.G.	0.54 original, ≤ 0.56 for replacements
HEPA Filters	
Quantity per assembly	27
Design rated flow per filter cell, cfm	1,500
Type	High efficiency, dry
Media	Glass fiber (waterproof, fire retardant)
Frame	Chromized steel original, T-409 for replacements
Face guards	4 x 4 mesh galvanized hardware cloth
Separator	None
Seal	Neoprene
Efficiency, %	99.97% with 0.3 micron diameter DOP

Rating basis	MIL-STD-282
Design rated pressure drop, unloaded, in. W.G.	1.0 original, ≤ 1.3 for replacements
Codes or Standards	Health and Safety Bulletin 306 original, ASME AG-1 for replacements UL-586 MIL-F-51079A original, ASME AG-1 for replacements MIL-F-51068D original, ASME AG-1 for replacements MIL-STD-282, ANSI-101.1-1972
Charcoal Adsorbers	
Quantity per assembly	2" Vertical Bed
Flow per filter cell, cfm	See Figure 9.4-2
Type	Activated coconut shell, impregnated
Granular size	10-14 mesh
Ignition temperature	360 °C
Charcoal per cell, lbs	7,560
Maximum moisture content, %	3
Casing material	304 stainless steel
Efficiency, %	99.9% elemental iodine at 25 °C, 70% RH 99.5% methyl iodide at at 25 °C, 70% RH 99.9% Freon-112
Rating basis	RDT-M16-1T
Retention time, sec	0.25
Rated pressure drop, inches W.G.	1 ± 0.2
Codes	AEC-DP-1082, July 1967 RTD-M 16-IT, June 1972 AEC-DP-1075

Auxiliary Building Radwaste Area Supply System

Fans (2VSF-7A&B)	
Type	Centrifugal
Airflow, cfm	See P&ID M-2262

9.4.3.3 Safety Evaluation

9.4.3.3.1 Auxiliary Building Radwaste Area

In case of failure of either of the two supply systems, the exhaust system will remain in operation to prevent leakage of air to adjacent areas and provide the desired direction of air movement. The standby exhaust fan provides additional reliability by ensuring continuous ventilation of the areas, and precluding any overheating of the charcoal filter.

The fans are statically and dynamically balanced. Fan ratings are in accordance with AMCE Standard Test-Code 210. The ductwork is leak tested, and the entire systems are balanced, adjusted, and tested for performance.

Allowable leakage in percentage of the designed flow is an follows:

Radwaste Area Exhaust Ductwork	2% or less
Radwaste Area Supply Ductwork	5% or less

The standby ESF unit coolers in the auxiliary building radwaste area ensure continuous cooling in the areas where they are located following a DBA.

The containment flue (vent – see Figure 11.2-2) for the auxiliary building radwaste area exhaust is monitored for gaseous and particulate radioactivity as discussed in Section 11.4. The radiation levels are indicated, recorded and alarmed in the control room. In the event of high radiation, the operator can stop both supply and exhaust systems and isolate the multi-filter unit via hand switches located in the control room.

9.4.3.3.2 Fuel Handling Floor Radwaste Area

The safety evaluation of the fuel handling floor radwaste area is similar to that of the auxiliary building radwaste area except that the former has only one supply system and is not equipped with any ESF unit coolers.

9.4.3.4 Inspection and Testing Requirements

See Section 6.5.4 for testing requirements of the HEPA filters and charcoal adsorbers.

The systems were given a preoperational test before the station produced power. The components of the systems are accessible for periodic inspection.

Periodic visual inspections during plant operation, will be performed on the components of all operating systems to check for damaged filters, faulty bolting and gasketing, excessive fan vibration, motor overheating, control malfunctioning, etc.

Periodic operational tests will be performed on all the standby components for normal plant operation to assure their proper functional capability.

Operational tests will be performed, during plant shutdown, on all the ESF unit coolers and related control systems as described in Section 14.1 to assure their proper functional capability.

9.4.4 TURBINE BUILDING

9.4.4.1 Design Bases

The heating, ventilating and air conditioning systems for the turbine building are designed to provide a suitable environment temperature between 60 °F DB and 105 °F DB for equipment and personnel. Airborne radioactivity levels inside the turbine building are not considered significant (see Section 12.2.2.4). The exhaust air from this area is released into the atmosphere without any special treatment.

Summer outside design conditions is 95 °F DB and 79 °F WB. For winter they are 6 °F DB.

The ventilating systems and equipment are designed in accordance with the recommended practices of the American Society of Heating, Refrigerating, Ventilating, and Air Conditioning Engineers Guide, the Air Moving and Conditioning Association, and the National Fire Protection Association. The ductwork is designed and fabricated in accordance with the Sheet Metal and Air Conditioning Contractors National Association (SMACCNA) standards.

9.4.4.2 System Description

Ventilation air for the turbine building is supplied by 34 supply fans. All supply fans are equipped with roll type filters and mixing dampers.

Fourteen of the supply fans are equipped with heating coils. The turbine building is also provided with hot water unit heaters mounted on the inside surface of exterior walls. These heaters will operate during winter shutdown to maintain the building at 60 °F DB. The building is also equipped with six chilled water unit coolers serving various areas (condensate pumps, main feed water pumps and feedwater heater drain pumps).

Air in the building is exhausted through roof ventilators and through exhaust fans in various areas (switch gear, lube oil, pumps area and store room) within the building. The fans are manually controlled from motor control centers located in the turbine building.

9.4.4.3 Inspection and Testing Requirements

The systems were given a preoperational test before the station produced power.

All temperature controls were tested and calibrated before operation.

The fans were statically and dynamically balanced. Fan ratings are in accordance with AMCA Standard Test-Code 210. The ductwork is leak tested, and each system is balanced, adjusted, and tested for performance.

The components of the systems are accessible for periodic inspection.

Periodic visual inspections, during plant operation, will be performed on the components of all operating systems to check for damaged filters, faulty bolting and gasketing, excessive fan vibration, motor overheating, control malfunctioning, etc.

Periodic operational tests will be performed on all the standby components for normal plant operation to assure their proper functional capability.

9.4.5 CONTAINMENT BUILDING

9.4.5.1 Design Bases

The Containment Cooling System (CCS) design is based on equipment and piping heat gain to maintain an ambient air temperature in the containment within the limits of Technical Specifications during normal plant operation. For capacity see Section 9.4.5.2.

The CCS will also remove heat energy from the containment atmosphere in the event of a LOCA in order to suppress any resultant increase in containment pressure and temperature. For capacity see Table 6.2-22.

During shutdown conditions a containment purge is made to lower containment atmosphere activity below 10 CFR 20 limits for personnel access to the containment building. The purge duration required to reduce containment atmosphere activity to ambient levels is affected by such factors as failed fuel, RCS leakage, and duration of activity accumulation. Section 11.3.6.2 discusses the original estimated annual releases from containment purges.

9.4.5.2 System Description

The system schematic is shown on Figure 9.4-4.

The CCS utilizes four cooling units located in the containment outside the secondary shielding. Each cooling unit is equipped with a vaneaxial type fan and two sets of coils. One is a chilled water coil for normal cooling and the other is a service water coil for emergency cooling following a postulated DBA. Ductwork distributes air from the cooling units to lower areas of the building, steam generator cavities and the reactor cavity. The air then flows upward through the building and is picked up by return ductwork just below the crane rail. Three drain ports are provided on the bottom of each cooling unit for normal condensate removal. Emergency condensate is removed via a sump, located in the fan section of the unit. The drains are sized to remove condensate from the units during normal and post-accident operation.

A single vaneaxial fan is mounted vertically on top of each cooling unit. The fan motors are of the type that have been tested in accordance with IEEE Report No. NSF/TCS/SC2-A, "Proposed Guide for Qualification Tests for Class 1 Motors Installed within the Containment of Nuclear Fueled Generating Stations." A bypass damper is provided on top of the unit between the chilled water coils and the service water coils. The damper is a positive opening type that will open on a Containment Cooling Actuation Signal (CCAS) when the containment pressure reaches a nominal value of 18.3 psia. The damper allows the steam-air mixture in the containment to bypass the return air duct and the chilled water cooling coils and to go through only the service water coils. The position of the damper is indicated in the control room. The decrease in pressure drop due to the bypassing of the return air ducts and chilled water cooling coils will permit the fan in the unit to handle the necessary quantity of air for cooling purposes at the same speed as required for normal operation.

The containment has four recirculation fans with separate duct systems. The fans take suction from the dome and discharge air to a minimum elevation of 376 feet. The fans are started by the operator with control switches located in the control room. The ducts are provided with duct relief valves, designed in accordance with AAF TR-7101, for protection from pressure transients. The fans, the fan supports and the duct supports were originally designed to meet Seismic Category 1 requirements, however, they are not being maintained as seismic Category 1. The containment recirculation system is not credited in any accident or transient analysis. It is not credited for the hydrogen mixing function in the ANO-2 probabilistic risk assessment (see Section 6.2.5).

The normal purge supply system for containment accessibility consists of a centrifugal type fan, a hot water heating coil and roll type filter. The purge exhaust system consists of a vaneaxial fan, a roughing filter, a HEPA filter and a charcoal absorber. All components of the purge system, except interior ducts and two isolation valves, are located outside the containment. Ducts are provided inside the containment for adequate distribution. The normal purge system discharge to the atmosphere is monitored for radioactive material and alarmed to prevent release exceeding acceptable limits.

The containment is equipped with four cooling units to cool the Control Element Drive Mechanism (CEDM) shroud. The units are mounted on the removable missile shield at Elevation 426 feet, 6 inches and are ducted down to the shroud. Three units operate continuously during normal conditions with one unit as a standby. The cooling units consist of a fan-coil unit containing a cooling coil and a centrifugal type fan. The units use chilled water and are on the main chilled water system.

The reactor cavity cooling system is designed to take air from the CCS ductwork and supply it around the reactor cavity area. The system is equipped with two vaneaxial type fans. One fan operates continuously with the other as a standby.

Following the postulated DBA, a potentially major source of hydrogen production results from the decomposition of water by radiolysis. The elimination of the hydrogen in the containment is accomplished by two hydrogen recombiners (see Section 6.2.5). Hydrogen samplers indicate the concentration of hydrogen in the containment.

A description of the major system components is given below:

Containment Purge Supply System

Fan (2VSF-2)	
Type	Centrifugal
Capacity, cfm	40,000
Motor	
Type	Induction
Horsepower rating, hp	60
Voltage, V	480
Phase	3
Enclosure	Open drip-proof
Insulation class	B
Heating Coil	
Type	Hot water
Capacity, Btu/hr	2,332,800
Filter	
Type	Automatic roll
Media	Glass fiber blanket
Efficiency, %	85

Containment Purge Exhaust System

Fan (2VEF-15)	
Type	Vaneaxial
Capacity, cfm	40,000
Motor	
Type	Induction
Horsepower rating, hp	75
Voltage, V	480
Phase	3
Enclosure	Totally enclosed air over
Insulation class	F
Roughing Filter	
Quantity per assembly	21
Rated flow per filter cell, cfm	2,000
Type	Replaceable
Media	Glass fiber
Average efficiency %	80
Rating basis	ASHRAE STD 52-68 Test Method original, current revision for replacements
Rated pressure drop, unloaded, in. W.G.	0.54 original, ≤ 0.56 for replacements
HEPA Filter	
Quantity per assembly	27
Rated flow per filter cell, cfm	1,500
Type	High efficiency, dry
Media	Glass fiber (waterproof, fire retardant)
Frame	Chromized steel original, T-409 for replacements
Face guards	4 x 4 mesh galvanized hardware cloth
Separator	None
Seal	Neoprene
Efficiency, %	99.97% with 0.3 micron diameter DOP
Rating basis	MIL-STD-282
Rated pressure drop, unloaded, in. W.G.	1.0 original, ≤ 1.3 for replacements

Capacity, Btu/hr	729,200

Reactor Cavity Booster Fans

Fans (2VSF-34A&B)	
Type	Vaneaxial
Capacity, cfm	12,000
Motors	
Type	Induction
Horsepower rating, hp	40
Voltage, V	460
Phase	3
Enclosure	Totally enclosed air over
Insulation class	RN

9.4.5.3 Safety Evaluation

The CCS, along with the CSS, provides the design heat removal capacity for the containment following a postulated LOCA as described in Section 6.2.2.

A single failure analysis is presented in Section 6.2.2.

The casing design for the cooling units is of a special nature to preclude the possibility of pressure wave collapse as described in Section 6.2.2.2.2 with quick opening relief valves incorporated into the design to maintain post-accident operability. The relief valves are provided on the unit housing and the supply air ducts. They are designed to relieve the housing when pressure differential exceeds 0.3 psid. The cooling units are located outside the secondary shield at elevations above the water level in the containment at post-accident conditions and below concrete floor slabs. In these locations, the cooling units are protected from missiles, flooding, and from foreign objects falling into or being sucked into the units through the bypass damper. The concrete floor slabs shield the bypass damper openings from the spray water. The condensate is removed in a manner that allows for the required heat removal capacity of the coils to be maintained.

Also, the locations provide shielding so that the design radiation dose level allows maintenance, repair, and inspections to be performed during power operation.

The containment purge system will operate only if required. The containment isolation valves of the purge system will be closed otherwise. The containment isolation functions of these valves are discussed in Section 6.2.4.

9.4.5.4 Inspection and Testing Requirements

Active components of the cooling units will normally be inservice. Valving on the cooling coils can be periodically cycled, thus placing the standby coils into service periodically during power operation.

Periodic visual inspections, during plant operation, will be performed on the components of all operating systems to detect excessive fan vibration, motor overheating, control malfunctioning, etc.

Operational tests will be performed, during plant shutdown, on all the ESF containment cooling units and related control systems to assure their proper functional capability.

The HEPA filter and charcoal adsorber are tested in the same manner as that furnished for the penetration rooms ventilation system (see Section 6.5.4).

9.4.6 INTAKE STRUCTURE

The Intake Structure Ventilation System utilizes 100 percent outside air. During normal operation, the intake structure can be ventilated by exhaust fans 2VEF-25A&B at 20,000 cfm each in the summer or by 7000 cfm fan 2VEF-32 in the winter. Both vaneaxial fans are located in a missile shield on the roof and exhaust air from the upper level ductwork.

Exhausted air is replaced by outside air entering a missile protected opening in the roof and fully louvered doors. The fans are switched automatically by indoor thermostats.

Electric unit heaters 2VUE-39 through 2VUE-42 on the upper level and 2VUE-43 through 2VUE-46 on the lower level are set to prevent the rooms from dropping below 60 °F in the winter although the safety-related equipment is qualified down to 6 °F.

During a DBA, engineered safeguard signals (MSIS and SIAS) automatically start both 2VEF-25A & B to ventilate the rooms to maintain safe equipment operating temperature.

Natural convection cooling is credited for events where forced ventilation is not available.

9.4.7 ALTERNATE AC GENERATOR BUILDING

Refer to Section 8.3.3 for the description of the HVAC system for the AAC Generator Building.

9.5 OTHER AUXILIARY SYSTEMS

9.5.1 FIRE PROTECTION SYSTEM (FPS) - CODES AND STANDARDS

The FPS is designed in accordance with applicable codes and regulations of the State of Arkansas and applicable sections of Title 29, Chapter XVIII, Part 1910 (Occupational Safety and Health Standards) of the Code of Federal Regulations, as set forth in the Federal Register Volume 37, Number 202, and dated October 18, 1972. It is designed in substantial compliance with the requirements of the Nuclear Energy Property Insurance Association (NEPIA), the National Fire Codes of the National Fire Protection Association, General Design Criterion 3 of 10 CFR 50, Appendix A, and NFPA 805, "Performance-Based Standard for Fire Protection for Light Water Reactor Electric Generating Plants, 2001 Edition," in accordance with 10 CFR 50.48(c).

9.5.1.1 Design Bases

Fire protection for ANO-2 was originally designed and installed to satisfy requirements of building codes, and portions of OSHA, NFPA and NEPIA guidelines. This resulted in the use of fire barriers, fire doors, fire and smoke detectors, sprinkler and deluge water systems, and hose stations. As a result of the Browns Ferry fire of March 1975, the ANO fire protection program has been improved. Many changes were made to satisfy NRC criteria in BTP9.5-1 (1976) and other staff positions including 10 CFR 50, Appendix R, Sections G, J, O, and L by reference from G.3. Subsequently, a license amendment request was submitted and approved to transition from Appendix R to the requirements of NFPA 805.

The ANO-2 fire protection program includes the following:

A. Structures, systems and components important to safety are designed and located to minimize, consistent with other safety requirements, the fire hazard. Noncombustible and heat resistant materials are used wherever practical throughout the unit. This requirement is in compliance with 10 CFR 50, Appendix A, General Design Criterion 3, Fire Protection.

B. The Fire Protection System (FPS) is designed to minimize the effects of fires on structures, systems and components important to safety, in accordance with 10 CFR 50, Appendix A, General Design Criterion 3, Fire Protection. It is designed to provide adequate capability to fight the fire hazard encountered in all plant areas.

C. The FPS is designed so that pipe rupture or inadvertent operation does not cause loss of function of plant structures, systems and components important to safety, in compliance with 10 CFR 50, Appendix A, General Design Criterion 3, Fire Protection.

D. Procedural controls are established to limit the use of combustible materials and to prevent potentially hazardous situations. A description of these controls is contained in Section 9.5.1.5.4.

E. Hydraulically balanced automatic sprinkler systems, ordinary or extra hazard automatic sprinkler systems, and hydraulically designed automatic water spray systems are installed in all areas with a high fire potential, or where such protection is required due to a high concentration of safe shutdown related cabling.

F. Inside hose connections, hose reels, and manual fire-fighting equipment are provided. A fire brigade is staffed and trained in order to provide prompt response to fires and to backup automatic suppression systems. A description of the fire brigade training and staffing is contained in Section 9.5.1.5.2.

G. Portable fire extinguishers are provided throughout normally accessible areas of the plant in accordance with applicable NFPA, OSHA, property insurer and NRC regulations and recommendations.

H. Alarms are provided in the control room upon activation of automatic fire protection systems. Fire and smoke monitoring and detection systems are installed in safety-related areas and in ventilation exhaust ductwork. These systems alarm in the control room and, if personnel can be in the vicinity, locally.

I. In areas where redundant safe shutdown related cabling are in close proximity to each other such that they could both be damaged in a fire, additional protective measures are provided such as thermal barriers, cable coating, or extensive fast-acting directed water spray systems.

J. A fire protection water supply system jockey pump is provided to minimize cycling of the main fire pumps.

9.5.1.2 System Description

9.5.1.2.1 General Description

The plant fire protection system is comprised of diversified monitoring, detection, alarm, suppression, and extinguishment facilities particularly selected to protect the area or equipment from damage by fire, and include, among other things, the following major features:

A. Fire protection water supplies, yard mains and hydrants.

B. Automatic wet sprinklers, hydraulically designed, ordinary and extra hazard.

C. Deluge and pre-action systems, hydraulically designed.

D. Water spray systems, hydraulically designed.

E. Standpipes and hose reels.

F. Automatic CO_2 extinguishing system and automatic Halon 1301 suppression system.

G. Portable fire extinguishers.

H. Fire and smoke monitoring, detection and alarm systems.

I. Fire barriers, seals, and penetrations.

A simplified schematic is provided in Figure 9.5-1.

Equipment and components that are required for fire protection have been designated as “F Listed” in the controlling plant database (such as equipment database/component database).

9.5.1.2.2 Component Description

The components of the plant fire protection system are selected to provide comprehensive protection against fire hazards throughout the plant with greatest emphasis placed on the risk of fire in the component's immediate location. The following provides a general description of the plant fire protection systems that may be credited to support a basis for engineering equivalency evaluations (EEEE), defense-in-depth (DID), or risk. Detection and suppression systems required for EEEE, DID, or risk are specifically noted in the Fire Hazards Analysis.

FIRE PROTECTION WATER SUPPLIES, YARD MAINS, AND HYDRANTS - The fire protection water supplies and pumps are shared between the two plants. Water for fire protection service is supplied at 125 psig to the 12-inch cast iron, cement-lined yard main encircling the plant. The fire water pumps, one 2,500 gpm automatic electric motor driven pump and one automatic diesel engine driven pump draw suction from the Dardanelle Reservoir or Emergency Cooling Pond (ECP) for fire protection. The diesel engine driven pump has a day tank containing enough diesel oil for eight hours of operation. The day tank has provisions for refilling from the 185,000 gallon diesel oil bulk storage tank (T25). A jockey pump automatically maintains yard main pressure between 118 and 134 psig. Should pressure fall to 110 psig, the motor driven pump will start automatically. Should system pressure fall to 90 psig, the engine driven pump will start automatically. Both pumps will continue to run until shut off manually. Fire water pump data is provided in Table 9.5-1. The yard main is provided with post indicator valves for sectional control. Two-way hydrants, with individual curb box valves are provided at 250 to 300-foot intervals. Hose houses and equipment (with the exception of fire axes), under guidance contained in NFPA 24, "Standard for the Installation of Private Fire Service Mains and Their Appurtenances," (1995), are provided at each hydrant.

WET PIPE SYSTEMS - Automatic wet sprinklers, hydraulically designed under guidance contained in NFPA 13, "Standard for Installation of Sprinkler Systems," (several editions), are provided for areas under the turbine generator operating floor. The system is hydraulically balanced to provide a 0.30 gpm per square foot density for any, including the most remote, 3,000 square feet of floor area and at the same time be capable of providing a minimum of 0.20 gpm per square foot density for any area up to a maximum of 10,000 square feet. (2CAN087706)

Wet pipe systems, arranged on ordinary hazard pipe schedule with 100 to 130 square feet per head spacing, except as noted above, are provided under guidance contained in NFPA 13, (several editions), to protect the following areas and equipment:

A. the clean and dirty lube oil storage tanks room;

B. the storage rooms at Elevations 354 and 335 feet in the turbine building between Columns A2 and B2;

C. the area under the turbine generator on the side of the turbine pedestal where oil piping runs are located, under all intermediate floors, and all areas to which oil may spread in the event of an oil line break;

D. heating and boiler room;

E. secondary chemistry lab;

F. storage and janitor rooms;

G. waste filler storage room;

H. chemistry laboratory;

I. secondary sampling system room;

J. the Pit No. 1 containing the turbine hydraulic oil coolers and reservoir in the turbine building basement Elevation 320 feet;

K. the area from Column line D to F and Column line 5 to 6, including the area under the platforms for the main feedwater pumps in the turbine building basement;

L. the turbine generator lube oil reservoir;

M. hot instrument shop;

N. decontamination room;

O. chemical storage area;

P. storage area Elevation 354 feet in the auxiliary building between Column lines K2 and J2, and 1 and 2.6

Q. general access area, Elevation 317 feet (east wall area), protection of SWS pump motor cables;

R. HPSI, LPSI, containment spray pump, Elevation 317 feet (east wall area), protection of SWS pump motor cables; and,

S. the west wall of general access area 2073, Elevation 354 feet, auxiliary building, in the vicinity of the Emergency Diesel Generator Jacket cooler valves.

The Technical Requirements Manual (TRM) includes a listing of the required sprinkler systems.

The wet-pipe sprinkler systems have fusible heads that activate when exposed to excessive heat. The activation temperature is 160 °F where the ceiling temperature is not expected to exceed 100 °F and 212 °F in rooms where higher temperatures are expected. Flow of water through alarm check valves energizes local alarms and registers an alarm condition on the audible-visual fire annunciator panel in the control room. Once initiated, wet sprinkler system operation is terminated manually by shutting an external gate valve.

DELUGE AND PREACTION SPRINKLER SYSTEMS, AND FIXED WATER SPRAY SYSTEMS - Deluge and Preaction Sprinkler Systems, and Fixed Water Spray Systems are hydraulically designed in accordance with NFPA 13 and NFPA 15, "Standard for Water Spray Fixed Systems for Fire Protection," (several editions). These systems are provided to protect the following equipment:

A. Deluge Sprinkler Systems

  1. The hydrogen seal oil unit;

  2. The diesel fuel tank storage vaults

B. Preaction Systems

1. The emergency diesel generator rooms and associated day tank enclosures;
2. The turbine generator bearings;
3. The four auxiliary building electric penetration rooms;
4. The four ESF penetration areas in the containment; and
5. The Service Water System (SWS) pump motors in the Intake Structure.

C. Fixed Water Spray Systems

1. Cable spreading room;
2. Corridor #2139 (behind control room) manual operation;
3. Corridor 2104, 2105, and 2109 (diesel generator room and lower south electrical penetration room access corridors);
4. The unit auxiliary transformer;
5. Startup Transformer 3;
6. Main Transformers A, B, C; and
7. The feedwater pumps lube oil reservoir.

The TRM includes a listing of the required sprinkler systems.

Automatic deluge and water spray system operation is initiated by various means for each system. The following summarizes the actuation method for control valves on deluge, preaction, and water spray systems in safety-related areas:

System	Method of Actuation
Cable spreading room spray system	Any one line heat detector and one smoke detector
Corridor 2104, 2105, and 2109 spray system	Any one line heat detector and one smoke detector
Diesel generator rooms preaction	Any one smoke detector and one systems flame detector
Auxiliary building electrical penetration rooms preaction systems	Any one smoke detector
Containment penetration areas preaction system valve	Any one smoke detector and any one heat detector for the outside control; the outside motor operated valve must be actuated from the Control Room

A manual preaction system for the four containment penetration areas is utilized to prevent diluting the borated containment sump inventory with unborated water.

CO_2 TOTAL FLOODING SYSTEM - The CO_2 total flooding system for the turbine generator exciter housing (not required for compliance with 10 CFR 50.48) is designed under guidance contained in NFPA 12, “Standard on Carbon Dioxide Extinguishing Systems,” and NFPA 70, “National Electric Code,” (1977). The system is activated automatically in response to heat actuated detectors or manually and will flood the exciter housing with CO_2 to extinguish the fire. The system is designed to provide a 35 percent CO_2 concentration, as required by NEPIA, for the duration of the turbine spindown. The system is connected to and supplied from CO_2 storage tank, T-108 in Unit 1.

HALON 1301 SUPPRESSION SYSTEM - The HALON 1301 Suppression System for the CPC Room (No. 2098-C) is designed under guidance contained in NFPA 12A, “Standard on Halon 1301 Extinguishing Systems,” 1985. The system is activated automatically in response to smoke detectors, or manually, and will flood the CPC room with HALON 1301 to extinguish the fire. The system is designed to provide a 5 percent HALON 1301 concentration for a duration of ten minutes. The system is connected to and supplied from HALON storage tanks, 2T-158A and 2T-158B.

STANDPIPES AND HOSE REELS - Wet standpipes for fire hoses are designed under guidance contained in NFPA 14, “Standard of the Installation of Standpipe and Hose Systems,” (1983). Standpipes are installed within or adjacent to stair towers and other points not greater than one hundred feet apart in all normally accessible areas in plant buildings. Four-inch standpipes are provided for multiple hose connections and two and one-half inch standpipes are provided for single hose connections. The standpipe hose connections are equipped with one and one-half inch hose valves, reducers, and not more than 100 feet of one and one-half inch woven jacket lined hose. Except in areas of potential electrical fire, adjustable spray nozzles are provided; in areas of electrical fire potential, spray nozzles are the type rated by Underwriter's Laboratories for electrical fires. The hose stations in containment are supplied by standpipes that are dry and normally isolated by valves outside containment. These valves can be opened locally or by remote control from the control room. Wet standpipe supplying hose reels through manually operated hose valves are available for manual control of fire; however, hose stations in containment are dry pipe.

Fire hose station locations are identified in the Fire Zone Summaries Section of the FHA.

PORTABLE FIRE EXTINGUISHERS - Portable fire extinguishers for manual extinguishment of fires are provided throughout normally accessible areas of the plant in accordance with OSHA regulations and NFPA 10, “Standard for Portable Fire Extinguishers,” (2007 Edition) and NEPIA recommendations.

FIRE AND SMOKE MONITORING, DETECTION AND ALARM SYSTEM - Fire and smoke monitoring, detection, and alarm is accomplished by ionization (I), infrared flame (F), photoelectric (High Sensitivity Smoke Detectors), air sampling, and heat responsive or heat actuated devices (HAD). Required fire or smoke detectors are listed in the TRM.

Heat and smoke collectors have been installed over the smoke detectors in containment to improve their sensitivity.

The fire and smoke monitoring, detection, and alarm devices are activated by the several stages of fire. Ionization detectors alarm at the presence of invisible combustion gases during the incipient stage of fire. Thermal detectors react to the attainment of a high fixed temperature or rapid rise in ambient temperature (in excess of 15 °F per minute) and provide alarm service as

well as release service for certain automatic systems as discussed above. The protecto-wire line type heat detectors actuate when the wire reaches 190 °F; the protecto-wire is crisscrossed on top of the cable trays and clamped to alternate sides of the tray every 18 inches. (1CAN037914) Infrared flame detectors respond to the infrared energy and flicker rate generated by a flame. These detectors have a 5-second time delay to minimize false actuations. Air sampling detection systems detect invisible particulates created by thermal degradation during the true incipient or overheating stage of a fire, providing very early warning detection. The selection, placement, and spacing of fire monitoring, detection, and alarm devices is based on the design configuration and employment of the area together with draft condition due to natural or forced ventilation. All fire monitoring, detection and alarm devices are supervised for reliability. Monitoring circuits are provided for each of the electric motor driven and diesel driven fire pumps. Such alarm signals register on the audible-visual fire annunciator panel in the control room.

MANUAL FIRE FIGHTING EQUIPMENT - In addition to hose stations and portable extinguishers, manual fire-fighting equipment has been provided to assist fire brigade fire fighting activities. This equipment includes:

A. Portable radio communication equipment;

B. Portable smoke exhaust units with flexible ductwork;

C. Emergency self-contained breathing apparatus;

D. Battery powered sealed beam portable lights; and,

E. Fire-fighting foam and foam nozzle.

The use of this equipment in specific fire areas/zones is contained in the ANO Pre-Fire Plan.

SAFETY EQUIPMENT AREA COMPONENTS - Plant fire protection equipment located in areas containing safety-related equipment is provided with components which have been selected to minimize the risks of inadvertent operation. (Additionally, drip-proof or weather protected motors are installed on safety-related equipment pumps and electrical equipment where feasible to minimize the possibility of damage should fire-fighting operations be required.) Wet pipe sprinkler systems are not used in safety-related system pump rooms.

9.5.1.3 Safety Evaluation

9.5.1.3.1 Design Considerations Minimizing the Potential for Fires

In accordance with NFPA 805, a risk-informed, performance-based analysis was performed that ensures key safety functions (i.e., reactivity control, inventory and pressure control, decay heat removal, and vital auxiliaries) will be maintained in the event of a fire. See the Fire Hazards Analysis for more detail.

The design of the FPS was considered in the analysis as a means to minimize the effects of fires and to provide the capability to extinguish a fire encountered in any of the plant fire hazard areas. The basic fire prevention and protection is achieved by physical separation of systems or by fire barriers between such installations.

Non-combustible and fire resistant materials are used wherever practical throughout the plant buildings, particularly in areas containing critical portions of the plant such as the containment, control room and components of the ESF. Fire barriers which are adequate for the hazard isolate the lube-oil room, control room, cable spreading room, computer room, emergency diesel generator rooms, battery rooms, auxiliary boiler room, fuel oil storage, and the principal electrical switchgear areas. Fire barriers which are adequate for the hazard also separate the Unit 2 turbine generator from the Unit 1 turbine generator below the operating floor (Elevation 386 feet), Unit 2 auxiliary building from Unit 1 auxiliary building below Elevation 386 feet, and Unit 2 turbine building from Unit 2 auxiliary building in Seismic Category 1 areas. Precast concrete fire barriers separate the three main transformers and the Unit Auxiliary Transformer (UAT) from the Startup Transformer 3 and both the Unit Auxiliary and Startup Transformers 3 from the adjacent turbine building wall. Fire resistant fluid is used in switchgear, transformers, and hydraulic systems inside buildings. The high pressure turbine generator lube oil lines are enclosed within guard piping. The battery rooms are ventilated as described in Section 9.4.2.6 preventing the buildup of explosive mixtures of hydrogen and oxygen.

Combustible loading calculations that provide an estimate of current fire zone/area combustible loading are listed in the corresponding fire zone/area summaries contained in the FHA, SAR Appendix 9B.

The reactor coolant pumps are provided with oil collection drip pans, spray deflectors and drain lines with a holding tank to collect and drain oil that might leak from reactor coolant oil reservoirs, external piping, flanged connections, oil gauges, or filler lines.

In general, redundant components of ESF are installed in locations physically separated from each other in order to prevent fire, should it occur, from spreading from one train to the other. In many cases, redundant ESF components are separated from each other by fire barriers that prevent the spread of fire from one component to its redundant counterpart. Penetrations of fire barriers are protected to a fire rating equivalent to that of the fire barrier or evaluated using the guidance of Generic Letter 86-10. Ventilation penetrations of fire barriers are provided with 3-hour rated dampers or fire doors, when necessary. Doorway penetrations have 3-hour fire rated doors, or have evaluations to confirm they are adequate for the hazards. Cable tray penetrations are protected with fire seals of a design that has passed tests for a 3-hour rating, or have evaluations to confirm they are adequate for the hazards. Piping and conduit penetrations are sealed around the outside. Large conduits are also sealed on the inside. Critical fire doors are locked or provided with electrical supervision to alarm if left opened or they are surveilled to verify they are closed. The prevention of the spread of fire is based on the hazards involved, or to allow time for manual suppression response.

In the unlikely event that the FPS does not function, fire barriers would contain the fire within the hazard area and prevent the spread of fire to other areas.

The potential magnitude of a fire in the control room is limited by the following factors:

A. Materials used in control room construction are noncombustible.

B. ESF and RPS control cables and switchboard wiring are constructed of materials that have passed the flame tests described in Insulated Power Cable Engineers Association Publication S-61-502 and National Electric Manufacturers Association Publication WC 5-1961.

C. Furniture in the control room is of mostly metal construction.

D. Combustible supplies such as log books, records, procedures, manuals, etc., are limited to those required for plant operation.

E. Smoke detectors are provided in the control room.

F. All areas of the control room are readily accessible for fire extinguishing.

G. Adequate fire extinguishers are provided, and a hose station is conveniently located near the control room.

H. The control room is occupied at all times by a qualified person who has been trained in fire extinguishing techniques.

Flammable materials in the control room are distributed to the extent that a fire is unlikely to spread. A fire, if started, will be of such a small magnitude that it can be extinguished by the operator using a hand fire extinguisher. The resulting smoke and vapors will be removed by the control room ventilation system.

Fire in a section of a control board or critical instrument equipment is considered credible; however, due to use of barriers or physical separation, and the limited amount of combustible material in an isolated section, evacuation of the control room will most likely not be required following any fire.

To prevent a fire, or the effects of a fire, originating outside the control room from spreading inside, all wall and floor openings are sealed to preclude the free passage of products of combustion into the room.

9.5.1.3.2 Prevention of Unsafe Conditions

Requirements to ensure that operation of the FPS will not produce conditions unsafe to personnel or detrimental to the equipment protected are as follows:

A. All areas within the plant served by sprinkler or water spray systems are adequately drained to prevent water flooding.

B. The shutoff head of the fire pumps (165 psig for the main and diesel fire pumps and 175 psig for the jockey fire pump) is below system static test pressure (200 psig).

Design features to minimize conditions unsafe to personnel are provided as follows:

A. Rooms and areas relying on manual fire protection are accessible with respect to radiation, such that personnel fighting the fire will not be exposed to radiation in excess of that expected for the zone or area in which the safety equipment is located.

B. None of the above areas contain enough combustible material to produce heat that would render the room or area inaccessible.

C. Thermal anti-sweat insulation, with U.L. listings of 25 for flamespread, 5 for fuel contributed, and 40 for smoke generated, is provided for service to the emergency feedwater pump rooms and switchgear rooms serving ESF. The emergency feedwater pump turbine is covered with an insulated, removable galvanized steel shell.

D. Insulation, with U.L. listings of 25 for flamespread and for fuel contributed and 50 for smoke generated, is provided for ductwork above the ceiling of the control room.

E. The ventilation system of the control room is arranged to isolate the control room from the effects of fire or toxic agents originating outside the control room. Penetrations are sealed to preclude the free passage of products of combustion into the room. The control room is equipped with Halon 1211 and carbon dioxide portable fire extinguishers for manual extinguishing of fires in the panels and elsewhere in the control room. Each portable extinguisher has a capacity of 20 pounds of carbon dioxide and are U.L. listed. The total discharge of carbon dioxide from these extinguishers would result in a concentration of approximately one percent carbon dioxide by volume if no ventilation or leakage existed. The ventilation of the control room area will dilute the concentration to undetectable proportions.

   Ventilation provided for the control room, computer room and Control Element Drive Mechanism (CEDM) equipment room protects occupants against toxic agents and is discussed in Section 9.4.1. Ventilation for the turbine and auxiliary buildings is discussed in Section 9.4.

F. The turbine building roof is equipped with U.L. listed automatic smoke and heat vents on the ratio of one square foot of venting area to each 100 square feet of turbine floor area.

9.5.1.3.3 Fire Hazards Analysis

The purpose of the Fire Hazards Analysis (FHA) is to evaluate potential fire hazards and appropriate fire protection systems and features used to mitigate the effects of fire in any plant location.

In order to evaluate the potential effects of major fires on redundant safe shutdown equipment, the plant was divided into fire areas that are separated by 3-hour or adequate for the hazard fire rated barriers. The fire areas were further divided into fire zones by masonry partitions, non-combustible partitions, or clear space. All safety-related circuitry and equipment within each fire zone was analyzed along with the potential fire loading within the zone. The potential for a fire to cause loss of safe shutdown functions was evaluated.

If needed, modifications were made to assure that a fire during any operational mode and plant configuration will not prevent the plant from achieving and maintaining the fuel in a safe and stable condition.

As allowed by 10 CFR 50.48(c), ANO-2 revised the fire protection licensing basis to comply with NFPA 805 (2CAN121202). The NRC issued a Safety Evaluation Report approving the revised license (2CNA021502).

For additional information see SAR Appendix 9B.

9.5.1.3.4 Seismic Design Criteria

Those portions of the FPS installed within ESF equipment rooms and Corridor No. 2139, west of the Control Room are supported in accordance with Seismic Category 1 requirements. All other portions of the FPS are designed to meet Seismic Category 2.

9.5.1.3.5 Potential Adverse Effects of Fire System Operation

An analysis has been performed to demonstrate that actuation of an auxiliary building sprinkler system or a rupture of a fire water pipe will not result in impairment of redundant safety-related equipment or jeopardize the ability to bring the plant to a safe shutdown condition.

To minimize the likelihood of inadvertent actuation, fire protection actuation circuits are provided with diverse detection methods, such as use of preaction systems requiring heat to open the fusible link heads and then a separate signal from smoke, heat, or flame detectors to actuate the control valve. Water spray systems will require a signal from both of two diverse detection circuits to open the control valve; these systems use smoke detectors and line type heat detectors. For any of these suppression systems, a signal from any one of the detection circuits alarms in the control room so operator action can be taken.

ESF redundant trains are physically separated so that the probability of losing more than one train of an ESF system because of an external event, such as a fire, is reduced.

If a fire were to occur in one diesel generator room, the fire wall between the diesel generators will protect the other diesel generator room. Redundant ESF pumps are located in separate compartments in the auxiliary building. Redundant ESF piping and electrical circuitry are physically separated. Redundant channels of reactor protection circuitry are also physically separated. As noted in Section 9.5.1.3.3, additional protective features were provided to preserve the separation between redundant safety-related cabling.

The design of fire fighting systems is such that their rupture or inadvertent operation will not jeopardize the capability of safety-related structures, systems, and components.

Operation of a section of the auxiliary building sprinkler system will not result in safety equipment impairment, since wet sprinkler system protection is excluded from rooms containing ESF switchgear or safety features pumps and motors. Since each section of the sprinkler system is independently activated, the operation of all or a significantly large group of auxiliary building sprinklers is not a likely event.

Spray shields have been installed in fire zones 2109-U and 2137-I to protect Motor Control Centers (MCCs) 2B51 and 2B61, respectively, from damage due to water spray.

The drainage from the secondary sampling room, chemistry leak system, and waste filler storage area are combined. Additionally, the secondary chemistry lab, storage and janitor room drainage are combined. As a result of these combinations, annunciators indicate the actuation of fire systems for the combined areas.

The potential for degradation of ESF equipment by flooding due to failures in fire water piping was considered in the design of the FPS and in the design of the rooms and buildings containing ESF equipment. Outflows from fire water piping can be stopped by shutting down the fire pumps from the control room or the intake structure. A system failure causing more

water loss than the jockey pump could replenish (90 gpm) will be detected in the control room by the annunciation of fire pump actuation without any indication of sprinkler or deluge system actuation.

The indications available to the operators which would indicate a fire main rupture condition are:

A. operation of one or both fire pumps without a central fire annunciator control panel alarm;

B. fire main water flow alarm without a central and local fire annunciator control panel alarm; or

C. operation of auxiliary building sump pumps followed by a high sump level alarm.

Any oil-water mixture in the diesel generator rooms is drained away by the floor drainage system. Back flow preventers are installed in the drain line from each room to prevent the possibility of oil and water flow from one room to the other. The only situations in which automatic or inherent design features might require supplementary operator action to ensure protection of safety-related systems are a fire main rupture in the auxiliary building, or actuation of water spray systems. The following describes how the failure or system actuation would be detected and corrective steps taken by operators:

A. The auxiliary building fire main is generally routed through the central corridors of each floor of the auxiliary building. If a fire main rupture occurred on any floor at or above grade level, it is anticipated that no substantial water accumulation would occur on these floors since most of the water would drain down the stairwells to below grade. Floor drains further limit water accumulation. The limiting safety-related components located below grade, for which flooding protection must be provided, are the safety injection pump and spray pump motors. Flooding protection is provided by compartmentalization of safety injection pumps and spray pumps into separate rooms to prevent loss of more than one redundant train. The operators will have sufficient time to determine that a fire main rupture has occurred and then isolate the ruptured portion of the fire main before any safety-related system has been degraded below minimum requirements.

B. Actuation of water sprays will alarm in the control room. The safety concern is the same as for the fire main break; however, considerable time would be required before flooding could occur. The operators will have more than enough time to verify that no fire exists or that the fire has been extinguished and then close the isolation valve to the system.

9.5.1.4 <u>Tests and Inspections</u>

Historical data removed - To review the exact wording, please refer to Section 9.5.1.4 of the FSAR.

9.5.1.4.1 <u>Fire Pumps</u>

The pumps are given periodic operational and performance surveillance tests as required by Appendix 9D.

9.5.1.4.2 Post-Operational Testing

The plant fire protection system is inspected and tested in accordance with surveillance requirements and frequencies specified in Appendix 9D.

9.5.1.5 Fire Protection Plan

The Arkansas Nuclear One Fire Protection Program was developed to define the organizational responsibilities, procedural controls, fire brigade staffing and training, and the quality assurance provisions that have been established for both Unit 1 and Unit 2. The following sections comprise the elements of the Arkansas Nuclear One Fire Protection Plan.

9.5.1.5.1 DELETED

9.5.1.5.2 Fire Brigade Training

The Arkansas Nuclear One Fire Brigade Training Course assures that the capability to fight potential fires is established and maintained. The program consists of initial classroom instruction outlined in the Plant Procedures and periodic instruction in the form of classroom sessions, fire drills and practice in fire fighting. This training is intended for all Fire Brigade members.

9.5.1.5.2.1 Classroom Instruction

A. The initial classroom instruction includes the following:

1. The course identifies the various classes of fires and types of combustibles involved, citing examples of specific materials in each class. This identification and location of all such hazards cannot be realistically covered in the initial classroom training. The training does cover some specific hazard locations but its thrust is to generate awareness in the training of what types of materials constitute a hazard. The trainee can then relate this information to materials he sees in the plant during his normal work.

2. The course covers the types of fire fighting equipment utilized on site and explains the use of each type. The general locations of the equipment are also discussed. Familiarization of the trainees with plant layout including access and egress routes to each area is discussed.

3. The course discusses or demonstrates the use of available fire-fighting equipment and each trainee has the opportunity to utilize the equipment. The curriculum includes training in fighting structural fires and flammable liquid fires. The principles utilized in planning a fire attack are discussed also. The instruction includes a discussion of utilizing water in combating electrical fires. The proper extinguishing methods and agents to be utilized in combating all four classes of fires are covered and specific examples are cited where appropriate to illustrate techniques.

4. The course discusses in detail the action to be taken when a fire is discovered, the reporting requirements for fires, the actions to be taken by the individuals or groups on site at the time and provides information on contacting appropriate outside fire-fighting organizations, as outlined in the Plant Procedures.

5. The proper use of the installed communications equipment is either common knowledge, e.g. telephone use, or is covered during the new employee's initial orientation, e.g. public address system use. The installed plant lighting system is normally on and in the event it is lost, the emergency lights activate automatically. Portable lights are available for firefighting use. The installed ventilation system is operated by qualified operators.

   The initial training addresses the principle of ventilation in the fire-fighting. The discussion includes vertical and horizontal ventilation, where to ventilate and distribution of personnel when ventilating.

   If the trainee does not routinely receive instruction outside the fire protection course, the following will be presented in the fire protection course:

   a. Hands-on training in the use of self-contained breathing equipment.

   b. Nomenclature, normal use, emergency use, donning, and storage of the breathing equipment.

   c. Changing out of air bottles on breathing equipment.

   The course discusses methods of escaping from a fire zone should the air supply become expended.

6. The initial training course discusses the need for organization and coordination in fire-fighting operations. More effectual leadership is developed through presentations on the tactics utilized in fire-fighting. This is done by discussing several different fire scenarios with the trainees once the concepts and considerations of making a fire attack have been covered. The pre-fire plans and procedures are used as a basis.

7. One part of the course consists of a discussion regarding smoke and toxic products of combustion. The use of self-contained breathing apparatus is emphasized.

8. Training is provided in fighting fires in windowless structures such as those that could occur in ANO.

9. Leadership training is provided such that any individual completing the course is capable of taking charge at the scene of the fire.

10. One part of the presentation includes the principles and techniques involved in structural fire-fighting. This includes types of fires -- incipient, free burning, smoldering; thermal balance; heat and smoke movements; types of attack; visibility; need for breathing apparatus; and, tactics. Utilizing the principles learned in this part of the course, the brigade members can apply them to an actual fire inside a structure.

11. The course covers in detail the provisions of the procedure on fire brigade organization and training in the general fire plan. The provisions of those procedures not related to fire-fighting are not discussed nor are the various pre-fire plans. The periodic training program is the form utilized for familiarization with the pre-fire plan.

12. The initial fire brigade training course is maintained up-to-date with regard to modifications to the fire-fighting equipment provided and to the installed fire protection systems. Changes in pre-fire plans are covered in the periodic training course.

B. The instruction is provided by individuals who are knowledgeable, experienced and trained in the subject matter presented.

C. The initial training course is intended for Fire Brigade members. No individual will be placed on the Fire Brigade unless he has completed the Initial Classroom Training.

D. Training is conducted in accordance with Appendix 9D and will repeat the content of the Fire Brigade Training Course over a 2-year period.

9.5.1.5.2.2 <u>Practice</u>

Practice sessions are held for fire brigade members on the proper method of fighting various types of fires similar to those which could occur in Arkansas Nuclear One. These sessions provide fire brigade members with experience in actual fire extinguishment and the use of emergency breathing apparatus under strenuous conditions. These practice sessions are provided at intervals not exceeding one year for each fire brigade member.

9.5.1.5.2.3 <u>Drills</u>

Fire brigade drills are performed at the plant.

A. Each drill is assessed for effectiveness by a person knowledgeable in fire-fighting tactics. Among items considered are:

1. Time elapse from start of drill to announcing of fire, as appropriate.

2. Time required for minimum expected fire brigade members to respond.

3. Time required for full fire brigade response.

4. What equipment was broken out for use at the fire scene.

B. The drills also include observation of the brigade's performance in a discussion with the brigade members. The observation and discussions serve to provide the evaluator with an indication of each brigade member's knowledge in his role in a fire, conformance with plant procedures, and use of equipment.

C. The drills include simulated use of appropriate equipment in the areas, and types of fires or conditions are varied from drill to drill such that brigade members are trained in fighting fires in safety-related areas containing significant fire hazards (moderate or

greater heat loads) with the exception of the Containment Building. The pre-fire plans and procedures are used as a basis for these drills. Table top drills are not utilized in lieu of actual drills.

The situation selected for drills simulates the size and arrangement of a fire which could reasonably occur in the zone selected, allowing for fire development due to the time required to respond, to obtain equipment, and organize for the fire, assuming loss of the automatic protection system within the zone, if any.

D. Assessment of the Fire Brigade Leader's direction of the fire-fighting effort is performed as described in "B" above.

E. Fire drills are performed at varying intervals such that all fire brigade members participate in a drill at least semi-annually to meet the requirements of NFPA 600, "Standard for Industrial Fire Brigade." At least one drill per shift is scheduled to be performed on a "back shift." At least one drill per year is unannounced for each shift. At least once per year an attempt is made to hold a drill with the Fire Brigade and the London Fire Department.

F. The drills conducted at Arkansas Nuclear One are pre-planned to accomplish certain objectives. A critique of each drill is generated by an individual knowledgeable in fire-fighting tactics, and copies are distributed to appropriate management personnel. Drills are normally observed by an individual knowledgeable in fire-fighting tactics with the assistance of other selected personnel as required.

9.5.1.5.2.4 <u>Records</u>

Records of all formal training provided to each fire brigade member are maintained and are available for review.

9.5.1.5.2.5 <u>London Fire Department</u>

Information is available to the London Fire Department for use in their training programs. This information includes basic radiation principles, typical radiation hazards, and precautions to be taken in a fire involving radioactive materials in the plant.

9.5.1.5.3 <u>General Employee Fire Prevention Training</u>

Personnel are instructed on the proper handling of accidental events such as leaks or spills of flammable materials that are related to fire prevention. In addition, all plant contractor personnel are indoctrinated in appropriate administrative procedures which implement the Fire Protection Program and the emergency procedures relative to fire protection.

9.5.1.5.4 <u>Control of Combustibles</u>

Administrative controls minimize the amount of combustibles that a safety-related area may be exposed to. The following discussion describes the controls developed.

A. Plant Procedures govern the handling, use and storage of combustibles in the plant. They specify the quantities of flammable and combustible liquids which may be stored in various buildings and set requirements regarding the handling, storage, and use of all combustible materials.

B. The Plant Procedures contain guidance regarding location, allowable quantities, types of materials allowed, and other factors affecting the transit fire loading in the plant. All work in the NFPA 805 defined power block is reviewed to assess the impact of fire protection by the Cognizant Supervisor and/or Operations. Where any questions arise regarding additional fire protection measures needed, the suitability of materials, storage arrangement, etc., Fire Protection personnel are consulted.

C. The Plant Procedures contain specific requirements to minimize the fire hazard associated with waste, scrap, rags, oil spills, or combustibles resulting from work activity in the NFPA 805 defined power block. These requirements consider the type of hazards involved and specify one or more of the following actions as appropriate:

1. Timely removal of all waste, debris, scrap, rags, oil spills or other combustibles resulting from the work activity. Removal is effected upon the completion of the work activity or the end of the shift, whichever is sooner (NFPA 805 Section 3.3.1.2(3)).

2. Properly storing the material to minimize the hazard.

3. Insuring that the zone is continually manned or frequently inspected while the hazard is present.

4. Periodic surveillance is made throughout the plant in an effort to control the accumulation of combustibles.

5. Wood used in the plant is treated with a fire retardant or is pressure treated fire retardant lumber or evaluated by Design Engineering/Fire Protection.

9.5.1.5.5 Control of Ignition Sources

9.5.1.5.5.1 Administrative Controls

Administrative Controls are instituted to protect safety-related equipment from fire damage or loss resulting from work involving ignition sources, such as welding, cutting, grinding or open flame work. Controls prohibit the use of open flame or combustion smoke for leak testing. Smoking is prohibited in all Entergy enclosed facilities.

9.5.1.5.5.2 Control of Welding, Cutting, Grinding and Open Flame Work

A. The Plant Procedures control all cutting, welding, grinding, and other open flame operations. Prior to beginning any cutting, welding, burning, or other open flame operations, the workers must have a Hot Work Permit issued by the Cognizant Supervisor and/or Operations.

B. The Plant Procedures require that the Cognizant Supervisor and/or Fire Protection personnel be responsible for having the work site inspected prior to work commencement and determining the precautions necessary for the safe performance of the work. Where any questions arise in regard to fire protection, Fire Protection personnel should be contacted.

The Plant Procedures assure that the following precautions are accomplished:

1. The Cognizant Supervisor and/or Operations assure that all movable combustible material below and within a 35-foot radius of the cutting, welding, grinding, or open flame work is removed, if feasible to do so.

2. Where the above requirements cannot be met, the Cognizant Supervisor and/or Operations assures that all combustible materials within a radius of 35 feet and below the cutting, welding, grinding, or open flame work are protected in accordance with NFPA-51B, "Standard for Fire Protection During Welding, Cutting and Other Hot Work," Item 3-3.2.

   The Cognizant Supervisor has the option of requiring a fire watch, if needed, to meet the requirements of NFPA-51B or to satisfy himself that the job can be accomplished without undue hazard to equipment or personnel.

   In the event the Cognizant Supervisor determines a fire watch is not needed, concurrence must be obtained from the Shift Manager or Fire Protection personnel.

   If the fire watch is deemed necessary by the above paragraph, the duties of that person(s) are defined in accordance with NFPA-51B.

3. In accordance with the provisions of NFPA-51B, the Cognizant Supervisor assures himself that the cutting and welding equipment to be used is in satisfactory operating condition and in good repair.

4. Welding, cutting, grinding, or open flame work to be performed on any pressurized system or any tank, vessel, or piping which may contain residual combustible vapors, is performed in accordance with NFPA-51B. Where appropriate, the use of suitable instrumentation in verifying a safe atmosphere is required.

9.5.1.5.5.3 Leak Testing

The Plant Procedures provide for the strict control of open flame work, regardless of the purpose. Thus, no special procedure for a specific application is needed.

9.5.1.5.5.4 Smoking and Ignition Source Restrictions

Smoking is prohibited in all Entergy enclosed facilities.

9.5.1.5.6 Plant Procedures (Firefighting)

The Plant Procedures cover such items as notification of the fire, fire emergency procedures, and coordination of fire-fighting activities with off-site fire departments. The Plant Procedures identify:

A. Actions to be taken by individuals discovering the fire, such as, notification of control room, attempt to extinguish fire and actuation of local fire protection systems.

B. The specific actions required of the control room operator when a fire is reported.

C. The people required to report to the scene of the fire when a fire is announced.

D. Means of immediately alerting the Fire Brigade upon report of a fire or receipt of an alarm on the control room annunciator panel.

E. Actions to be taken by the Fire Brigade after notification, by the control room, of a fire, including location to assemble.

A set of pre-fire plans is available which provide the Fire Brigade Leader with information, which with his training, allows him to make intelligent fire ground decisions and specify the responsibilities to the fire brigade members for the selection of fire-fighting equipment and transportation to the scene of the fire.

The operation of installed fire protection systems is covered in the Fire Brigade Training Course. Pre-planned strategies, incorporated in the pre-fire plans, are available for all safe shutdown zones and zones presenting a hazard to safe shutdown equipment. Copies of the pre-fire plans are provided in the both unit control rooms, both unit simulators, and the fire brigade lockers. Other copies may be distributed as needed.

F. Pre-fire plans

1. Each plan identifies any hazardous combustibles located in the zone concerned or any combustibles of an unusual nature which might be encountered.

2. The plan lists fire-fighting equipment available in the vicinity of the fire zone and a plan of the area is incorporated to identify their location. No attempt is made to identify such extinguishers thus fitted for the particular material in the area, unless a material with unique extinguishing requirements is present. The fire brigade members receive training in the selection of extinguishing agents for various types of fires. The pre-fire plan should contain no more information than is absolutely necessary. To load it with information with which the plant personnel are quite familiar detracts from the usability of the document.

3. The pre-fire plans provide guidance in selecting the most favorable direction from which to attack fires in the particular zone. Specific instructions, as to which way to attack from, are not provided, due to the many different types of fire situations which may occur in a given zone.

   Many factors are considered when providing guidance regarding directions from which to attack the fire. Among these are accessibility, protection of personnel, drainage, ventilation, availability of equipment, potential fire configurations within the zone, etc.

   Each pre-fire plan includes a plan view of the fire area on which all means of access and egress are marked. Fire-fighting equipment locations are identified, major items of equipment are shown, and other significant features are depicted.

   Where locked doors are involved, they are specifically identified in the pre-fire plans and means of accessing them is specified.

4. The pre-fire plans include the location of the various systems and equipment controls which might be of value during a fire attack.

5. The pre-fire plans include a listing of exposures which may need to be protected or they are shown on attached arrangement drawings. In addition, the plan discusses hazards which might be present, such as drums of combustible liquids, and state what action is required to negate or minimize the hazards. For example, solvent drums should be kept cool to prevent overpressure rupture or an internal vapor air explosion.

6. The plant pre-fire plans provide the Fire Brigade Leader with the type of radiological hazards present. Any personnel hazards of toxic nature not included in the combustion gases or ordinary materials are either listed in the pre-fire plans or shown on attached drawings. In addition, the plant utilizes the hazardous materials identification system developed by NFPA, and as described in the NFPA Code 704M, "Standard System for the Identification of the Hazards of Materials for Emergency Response," where significant quantities of toxic materials are normally present.

7. The pre-fire plans discuss the means available for ventilating the zones concerned.

G. General instructions for operators and general plant personnel are set forth in the Plant Procedures.

Instructions for the control room operators have been discussed in "B" above. General plant personnel are required to report to their work center, or if that area is involved, to an alternate assembly area.

H. The validity of the pre-fire plans is tested by drills and at such drills all aspects of the plan are reviewed with the fire brigade and the discussion of the plan is concluded.

I. The Plant Procedures define the organization and outline coordination with outside fire departments.

J. The Plant Procedures assure that the responsibilities of each Fire Brigade position corresponds with actions required as outlined in the procedures.

K. The Plant Procedures assure that the responsibility of the Fire Brigade to the operation of the plant do not conflict with their responsibilities during a fire emergency.

9.5.1.5.7 <u>Fire Brigade – Organization and Composition</u>

The Fire Brigade consists of five trained individuals established each shift and is onsite 24 hours a day, seven days a week. The Fire Brigade consists of five personnel who have received full training. Upon arrival at the scene, the Fire Brigade Leader assesses the situation, instructs his brigade members and extinguishes the fire. He also reports his assessment to the control room. He requests the control room to supply him assistance if he does not think his team can control the situation. In this event, the control room operator contacts the London Fire Department and any other outside agency he believes should respond.

At the beginning of each shift, a Fire Brigade is selected. Each position of the brigade corresponds to a position title. Specific instructions as to command control, fire hose laying, applying extinguishant, advancing support supplies to the fire, communication with the control room coordination with outside fire department are covered in general in the initial classroom training course. Those fire zones which have pre-fire plans contain specific instruction in the areas above applicable for that specific zone.

The Fire Brigade Leader communicates directly with the Control Room. Response activities requiring coordination or authorization by Operations are provided in the Plant Procedures and/or Pre-fire Plans.

Each Fire Brigade member, at least once every two years, must satisfactorily complete a physical examination for performing strenuous duties. This requirement is enforced to effectively screen out personnel with heart or respiratory disorders and preclude these personnel from Fire Brigade duties.

The recommendation in NFPA 27 and the standards contained in the associated Appendix were considered in the organization, training, and functioning of the Fire Brigade.

9.5.1.5.8 Quality Assurance Program for Fire Protection

This quality program is to ensure that the fire protection systems for safety-related areas are controlled in accordance with applicable NRC regulations, industrial standards and codes, policies, rules, procedures, and licensing documents. The quality program is implemented through approved procedures. The effectiveness of the fire protection program is verified through surveillances and scheduled audits conducted by the Quality Organization, under the cognizance of the SRC. General requirements for this program are also described in Section G.1 of the QAPM. Personnel performing inspections need not be certified to ANSI N45.2.6, when inspections are performed on equipment not listed on the Q-list.

Employees whose duties and responsibilities are related to this fire protection program at or in support of the nuclear plant are to participate in appropriate training programs to assure that suitable proficiency is achieved and maintained in the work they are performing.

Fire protection training for plant personnel is included as part of industrial safety in the General Employee Training Program. Personnel are periodically retrained in industrial safety in accordance with approved procedures. Personnel assigned to the plant Fire Brigade are to receive additional indoctrination and training to assure their capability to fight fires is established and maintained. The Manager, Training has the overall responsibility for these training programs.

9.5.1.5.8.1 Design Control

Sections B.2 and B.3 of the QAPM are applicable for design control activities pertaining to fire protection systems.

9.5.1.5.8.2 Procurement Document Control

Sections B.4 and B.5 of the QAPM are applicable for procurement control activities pertaining to fire protection systems. When these items are not associated with the Q-list, the procurement document is to include the requirement that items be U.L. listed or F.M. approved for fire protection use, where applicable, in accordance with approved procedures.

9.5.1.5.8.3 Instructions, Procedures, and Drawings

Sections A.1.d and B.1.c of the QAPM are applicable to instructions, procedures and drawings pertaining to fire protection systems.

9.5.1.5.8.4 Document Control

Section B.14 of the QAPM is applicable for the control of quality program documents related to fire protection.

9.5.1.5.8.5 Control of Purchased Material, Equipment, and Services

The control of purchased fire protection-related materials, equipment, and services is described in Sections B.4 and B.5 of the QAPM, with the following exceptions. For the procurement of fire protection-related items or services not associated with the Q-list, the vendor/contractor qualification criteria (including periodic reassessment of their program) is not required. Non-conformances dispositioned repair or use-as-is by the vendor are to be submitted to and accepted by ANO only when so designated on the procurement document.

9.5.1.5.8.6 Identification and Control of Materials, Parts, and Components

Section B.6 of the QAPM is not applicable to the identification and control of materials, parts and components pertaining to fire protection systems. The identification and control of materials, parts, and components are conducted in accordance with existing procurement and materials management procedures and practices.

9.5.1.5.8.7 Control of Special Processes

Section B.11 of the QAPM is not applicable for the control of special processes, as applicable to fire protection systems. The control of special processes for the maintenance of the fire protection system is performed in accordance with applicable approved procedures and practices.

9.5.1.5.8.8 Inspection

Inspection activities applicable to the fire protection system are described in Section B.12 of the QAPM with the exception of Section G.1, when inspections are performed on equipment not associated with the Q-list. Personnel performing inspections need not be certified to ANSI N45.2.6.

In addition to the provisions of the QAPM, inspections and surveillances are addressed in applicable portions of the SAR for each nuclear unit.

9.5.1.5.8.9 Test Control

A test program is to be established and implemented to ensure that testing is performed and verified on applicable systems and components to demonstrate conformance with design and system readiness requirements. The tests are to be performed in accordance with written test procedures and test results evaluated for conformance to the test objectives.

The control of testing activities is described in Section B.8 of the QAPM. Surveillance testing requirements are identified in the Safety Analysis Report for each nuclear unit.

9.5.1.5.8.10 Control of Measuring and Test Equipment

Section B.9 of the QAPM is not applicable for the control of measuring and test equipment. No particular measuring and test equipment controls have been identified in BTP-APCSB 9.5-1, Rev. 2. Measuring and test equipment is controlled in accordance with applicable approved procedures and practices.

9.5.1.5.8.11 Handling Storage and Shipping

Section B.7 of the QAPM is not applicable for the handling, storage, and shipping of fire protection-related materials and equipment. Handling, storage, and shipping activities are controlled in accordance with applicable approved procedures and practices.

9.5.1.5.8.12 Inspection, Test, and Operating Status

Measures are established to provide for the identification of items that have satisfactorily passed required inspections and tests and are documented per approved instructions or procedures.

Section B.10 of the QAPM is applicable for identifying the inspection, test, and operating status of the fire protection system.

9.5.1.5.8.13 Nonconforming Material, Parts, and Components

The control of nonconforming materials, parts and components related to the fire protection system is described in Sections A.6, B.6, and B.13 of the QAPM. Vendor non-conformances are to be submitted to ANO only when so designated on the procurement document.

9.5.1.5.8.14 Corrective Actions

A corrective action system is established to ensure that conditions adverse to fire protection, such as failures, malfunctions, deficiencies, deviations, defective components, uncontrolled combustible materials, and non-conformances, are promptly identified, reported, and corrected.

Corrective action activities are controlled as described in Sections A.6 and B.13 of the QAPM with the exception that vendors furnishing fire protection items not associated with the Q-list are not required to be listed on the QSL.

9.5.1.5.8.15 Quality Assurance Records

Records which furnish evidence that the criteria enumerated in this program are being met for activities affecting the fire protection program are to be prepared and maintained as described in Section B.15 of the QAPM.

9.5.2 COMMUNICATION SYSTEMS

The communication systems are composed of internal (in-plant) and external services.

9.5.2.1 Design Basis

Voice and non-voice communication systems are provided for reliable communication during plant startup, operation, shutdown, and maintenance under normal conditions.

In-plant communications, including radio systems, are provided for use with the remote shutdown panel.

Since none of the communication systems are required for the actuation of any safety-related system, they have all been designed for non-Class 1E service.

9.5.2.2 Description

Communication systems provide audio and visual transmission of information, data exchange, and data gathering. Voice communications include:

A. In-plant Computerized Branch Exchange (CBX) and public address;

B. In-plant 4-channel intercommunications and public address;

C. Commercial telephone;

D. ANO radio system;

E. Entergy Dispatcher's Network;

F. Direct NRC telephone link (NRC ENS Hotline);

G. Direct NRC telephone link (NRC HPN Hotline).

H. Industrial two-way radios

Non-voice communications include:

A. Closed circuit television security system;

B. Plant evacuation warning system; and,

C. Plant security intrusion and entry alarms.

The CBX is a three switch, direct dial, private automatic telephone exchange powered by normal non diesel backed power with an 8 hour battery backup supply at each switch. The public address system is powered by a battery charger with battery backup. The following additional features have been incorporated:

A. Paging public address and page answer lines;

B. Conference lines; and,

C. "Meet-me" conference line.

The in-plant 4-channel intercommunication system is composed of local amplifier-loudspeaker-handset combinations. The entire system is solid-state.

The commercial telephone system is supplied by GTE.

Industrial two-way radios are mobile transceivers. Vehicle mounted and hand-held units, along with the base station, operate on FCC approved frequencies. The hand-held two-way units are available for use by the fire brigade. Fixed repeaters have been installed to assure adequate communication between all plant areas using the hand held two-way radios.

The Dispatcher's Network contains a direct line between ANO and the Dispatchers Center in Pine Bluff, Arkansas.

The Plant Evacuation Warning System is composed of electronic sirens and beacons (for areas with high background noise) manually controlled from the control room. The Plant Evacuation Warning System is further discussed in the Arkansas Nuclear One Emergency Plan.

Intrusion and entry alarms, as well as closed circuit television usage, are discussed in the Arkansas Nuclear One Security Plan.

9.5.2.3 Inspection and Testing

Most systems with the exception of the Plant Evacuation Warning System are in daily operation. This allows for testing to ensure that each system is operable. An administrative procedure provides for periodic testing of the Plant Evacuation Warning System in addition to procedures which require testing of the emergency communication equipment.

9.5.3 LIGHTING SYSTEMS

Lighting is provided to furnish illumination levels adequate for the safe performance of operating and maintenance duties. Emergency DC lighting is provided in all operating areas for the safety of personnel in case of the failure of AC power. Figure 8.3-17 shows the single line diagram of the lighting distribution system.

Lighting systems are not required for the safe shutdown of the reactor.

Alternate shutdown lighting is provided to facilitate access and egress to areas that require manual operator action in the event of a control room/cable spreading room fire.

9.5.3.1 Design Bases

Design of the lighting systems for the various buildings and areas of the plant is based on illumination levels that equal or exceed those recommended by the Illuminating Engineering Society for central stations.

Because of restrictions on the use of mercury or its compounds in certain areas, interior lighting of the containment and of the fuel handling area is incandescent except for high pressure sodium vapor lighting in areas which have been specifically evaluated and approved (such as the Spent Fuel Pool). Non-mercury based Light Emitting Diode (LED) lighting has also been evaluated for overhead use in the Spent Fuel Pool area.

9.5.3.2 System Description

Plant lighting is divided into four main systems which are defined as follows:

A. Normal: Lighting supplied by the normal plant AC source.

B. Essential: Lighting which is supplied by the normal plant AC source, but upon failure of this source, it is supplied from a diesel-generator.

C. Emergency: Lighting supplied by the station batteries following loss of both normal and essential AC lighting.

D. Alternate Shutdown: Lighting supplied by independent 8 hour battery packs following a loss of normal and essential AC lighting for the control rooms and other essential locations.

Normal and essential lights are mercury vapor, high pressure sodium, fluorescent, light emitting diodes (LEDs), or incandescent and operate at either 480/277-volt AC or 208/120-volt AC. Emergency lights are incandescent and operate at 125-volt DC. Alternate shutdown lighting fixtures are powered by self-contained batteries rated for eight hours of operation.

All lighting raceways are run in separate conduits. Emergency lighting raceway is run separately from the normal lighting raceway.

The emergency lighting supplied by the station batteries is brought into operation by an automatic transfer switch, actuated by the loss of essential AC lighting power. When power becomes available, essential lighting is restored and emergency lighting is discontinued.

Individual 8-hour battery powered emergency lighting units are provided in the control room and other strategic plant locations needed for operation of safe shutdown equipment and access and egress routes thereto. Upon loss of normal and/or essential area lighting power, these DC lighting units will be automatically switched on.

9.5.3.3 Tests and Inspection

AC lighting circuits are normally energized and require no periodic testing. The emergency DC and alternate shutdown lighting system will be inspected and tested periodically to prove the operability of the automatic transfer switch and other components in the system.

9.5.4 DIESEL GENERATOR FUEL OIL STORAGE AND TRANSFER SYSTEM

Figure 9.5-8 shows a schematic diagram of the diesel generator fuel oil storage and transfer system. This system provides adequate storage of diesel fuel and supplies it to the two emergency diesel generators.

9.5.4.1 Design Bases

The diesel generator fuel oil storage and transfer system is designed to provide independent sources of fuel oil for each emergency diesel generator.

The capacity of the above ground bulk storage tank was based on the quantity of fuel oil required for a Unit 1 startup. The startup boiler will use about 50,000 gallons of fuel oil per day for a period lasting from one to four days during startup of Unit 1 following a planned shutdown. The capacity of the bulk storage tank (185,000 gallons) plus the capacity of the Unit 1 startup boiler day tank (15,200 gallons) provides enough fuel oil for four days operation of the startup boiler. Fuel delivery to the plant site will be scheduled to replenish fuel consumed during this operation.

A fuel capacity of at least 22,500 gallons for one underground Emergency Storage Tank plus a fuel capacity of at least 520 gallons for one diesel day tank will be sufficient for not less than three and one half days of operation of one Emergency Diesel Generator loaded to its maximum continuous rating. Thus, in accordance with ANSI 59.51 and NRC Regulatory Guide 1.137, at least a seven day total diesel fuel inventory will be available onsite in the emergency storage tanks for operation of one Emergency Diesel Generator loaded to its maximum continuous rating during loss of electric power conditions. Each diesel generator day tank has a low level alarm capacity sufficient to power an Emergency Diesel Generator at 110% of its maximum continuous load for a period in excess of 60 minutes.

Under maximum flood conditions (no nuclear accident), the plant will be shut down and one diesel generator loaded to about 50 percent of its rating. Then, the emergency storage tank inventory will last for at least 7 days operation even if one emergency storage tank is considered unavailable. Emphasis has been placed on rigging emergency off-site power prior to the flood reaching the site as described in Section 8.2.1.4. After the Design Basis Earthquake (DBE) and a simultaneous nuclear accident, three and one-half days emergency supply of diesel oil will be available even in the unlikely event one emergency storage tank has failed. Within this period, additional fuel could be delivered to the plant site by any one of three methods: truck delivery, rail car delivery or delivery by barge from the river. In the highly unlikely event that all three of these normal supply routes are unavailable because of the earthquake, fuel could be airlifted to the plant site via helicopter. Based on conservative estimates from the Corps of Engineers it is expected that the probable maximum flood could be above plant grade (Elevation 353 feet) for two to five days.

9.5.4.2 System Description

The system consists of the following components:

A. two 22,500-gallon underground storage tanks (2T57A & B);

B. four fuel oil transfer pumps (P16A & B and 2P16A & B);

C. two 550-gallon fuel oil day tanks (2T30A & B);

D. one 185,000-gallon bulk storage tank (T25);

E. associated piping, valves and instrumentation; and,

F. hose cross connection (2-inch) and valves.

All of the above components except the bulk storage tank and piping from the bulk storage tank to the underground storage tanks meet Seismic Category 1 requirements.

The two storage tanks are located in underground vaults in the plant yard and the two smaller "day tanks" are located adjacent to the diesel generators in the auxiliary building. The emergency storage tank inventory is replenished from the conventional above-ground fuel oil bulk storage tank by gravity feed through a buried pipeline.

All other systems requiring fuel oil such as the plant heating boilers and the Unit 1 startup boiler take oil directly from the common fuel oil bulk storage tank. Thus, the inventory of diesel fuel oil in the emergency diesel fuel tanks is unaffected by other demands on the fuel oil bulk storage tank.

Because the bulk storage tank is not an essential fuel supply to the diesels, it is not designed to tornado, flood or single failure criteria.

The emergency storage tank vaults are of Seismic Category 1 design and, in addition, have been specifically designed to resist the loadings imposed by the probable maximum flood. This includes anchoring the vault to rock and providing ventilation openings above flood elevation. The outside door is of watertight construction.

The emergency storage tank vaults are equipped with a water spray fire protection system which is described in Section 9.5.1. In addition, each storage tank vault is separated from the other vault by 3-hour fire rated walls and doors. The volume of the vault below the door elevation is sufficient to contain the full inventory of oil in the unlikely event of a ruptured fuel tank. Each emergency storage tank vault has a sump which in turn is connected to a main sump equipped with a sump pump. The two Unit 2 sumps are kept isolated from the main sump by normally closed valves. Level switches in the sumps annunciate a high level alarm in the control room.

Each emergency storage tank is gravity connected to a transfer pump located in the underground vault. Strainers are provided at the pump inlet to prevent particulate matter from entering the pump. The transfer pumps discharge to the diesel "day tanks" through buried pipelines. The diesel fuel oil transfer piping from the emergency storage tanks to the day tanks is designed to ANSI B31.1.0 and is in accordance with the additional requirements of Seismic Category 1 and the Quality Assurance Program Manual (QAPM). The transfer pumps, 2P16A and 2P16B, are cross-connected at their suctions and discharges with two normally closed valves and are each capable of drawing diesel oil from either emergency storage tank and supplying it to either diesel engine. An additional modification was made based upon the Appendix R review. In performing the Appendix R analysis and review of July 1982, it was revealed that "red" and "green" power cables for the unit pumps are routed together in a manner which was not in compliance with Appendix R separation requirements. Therefore, a cross connection of the Unit 1 and Unit 2 transfer pumps was made in order that pumps from either unit may supply fuel oil to the diesel generator of the other unit. The system is depicted in FSAR Figure 9.5-8. Each emergency storage tank is vented by a Seismic Category 1 vent pipe with a flame arrester which penetrates that portion of the roof which is above the maximum flood elevation. To prevent oil from flowing over the emergency tank vents before the bulk storage tank T25 is completely filled, the vents on emergency tanks 2T57A and B were raised three feet in elevation (from Elevation 380 to 383 feet). This places them above the T25 overflow line. A high level alarm is provided on bulk storage tank T25.

The two emergency diesel generator fuel oil day tanks are located in the auxiliary building at Elevation 369 feet. Each day tank and its associated diesel generator unit are located in Seismic Category 1 enclosures and are isolated from the other diesel generator unit and

associated equipment by a fire wall. Each day tank is also isolated from all other associated equipment by a fireproof enclosure and is equipped with water spray fire protection and fire and smoke detection systems as described in Section 9.5.1. The atmospheric vents on the day tanks are fitted with flame arresters to prevent ignition of the fuel oil from an outside spark. The rotary fuel pump transfers the fuel from the day tank, through a duplex filter to further eliminate particulates, to the fuel metering injection pumps.

The day tanks can be supplied with diesel oil from the storage tanks by either manual or automatic operation of the transfer pumps. For the EDG 2K4A fuel transfer system, in the automatic mode of operation, level switches 2LS-2801-1 and 2LS-2804-1 will start fuel oil transfer pump 2P16A. Level switch 2LS-2804-1 will also open the fuel oil supply valve, 2SV-2802-1, on low level in fuel oil day tank 2T30A. Level switch 2LIS-2801-1 will close and activate an alarm on low level if the day tank level fails to rise. As an additional safeguard, an alarm will be activated if either of the two transfer pump discharge valves are closed while the pump is running. Level switch 2LS-2801-1 will stop the transfer pump and level switch 2LS-2804-1 will close the supply valve on high level in the day tank thus preventing a day tank overflow due to a single failure of a level switch. Level switch 2LS-2804-1 is wired in series with level switch 2LS-2801-1 in the automatic operation mode circuitry to provide a means to stop the transfer pump in the event that 2LS-2801-1 fails to operate. This provides backup protection against the transfer pump's operating with high day tank level. Similar controls are provided on the fuel oil transfer system for EDG 2K4B.

Further pertaining to EDG 2K4A, should pump 2P16A still fail to stop, a high-high level signal from 2LIS-2801-1 will activate a high-high level alarm. Level switch 2LIS-2800 closes and activates a low level alarm on low fuel oil level in underground storage tank 2T57A. Similar controls are provided on the fuel oil storage and transfer systems for EDG 2K4B.

All components of the electrical system provided for the diesel fuel oil system are Class 1E electric systems as described in Section 8.3. Electric power to the diesel fuel oil transfer pump (2P16A) and solenoid valve (2SV-2802-1) associated with the underground storage tank serving the 2K4A diesel generator is supplied from ESF Channel 1. Similarly, electric power to pump 2P16B and solenoid valve 2SV-2822-2 associated with the tank serving the 2K4B diesel generator is supplied from ESF Channel 2. ESF Channels 1 and 2 power supplies are accessible to their corresponding diesel generator.

The diesel fuel oil system is required to supply acceptable quality diesel oil to the emergency diesel generators in an emergency condition for safe shutdown of the plant.

Procedures have been developed to address the use of the Unit 1 transfer pumps, the materials required for the cross-connection, the method of performing the cross connection, including the alignment of valves, operation of the system to supply fuel to the diesel day tanks of either unit.

9.5.4.3 Design Evaluation

The diesel generator fuel oil storage and transfer system provides two independent sources of fuel oil supply. The pumps, tanks, and piping are so arranged that malfunction or failure of either an active or passive component in one source of supply will not impair the ability of the other source to supply fuel oil. Electrical power is supplied through two separate ESF channels, so that a single failure will not result in loss of both independent sources of fuel oil. The system therefore meets the requirements of the single failure criteria.

The system is designed to withstand environmental design conditions. The underground storage tanks are designed for outdoor, underground installation with a temperature range of 30 to 100 °F. The diesel generator day tanks are designed for indoor, above-ground installation with an ambient temperature range of 60 to 105 °F. The diesel oil transfer pumps are designed to handle oil in the temperature range 40 to 100 °F. The exterior surfaces of the underground storage tanks are commercially sand blasted, primed and finish painted to prevent corrosion. The interior surfaces of the tank up to 18 inches from the bottom are solvent cleaned, sand blasted and coated with two coats of polyamide cured coaltar epoxy at eight mils minimum dry film thickness per coat. The exterior surface of the underground fuel oil piping is cleaned by wire brushing, coated with a primer, and wrapped with coal tar tape in the field.

9.5.4.4 <u>Tests and Inspection</u>

Historical data removed - To review the exact wording, please refer to Section 9.5.4.4 of the FSAR.

The underground storage tanks are stamped in accordance with ASME Code, Section VIII. During periodic testing of the diesel generators proper operation of the fuel system is monitored as required by the Technical Specifications. Switches will also be exercised to confirm annunciation features.

9.5.5 DIESEL GENERATOR COOLING WATER SYSTEM

The diesel generator cooling water systems are shown in Figure 9.5-8.

9.5.5.1 <u>Design Bases</u>

The diesel generator jacket cooling water system is a closed loop system designed to supply clean water to the diesel engines in order to maintain proper operating temperatures of the cylinders and pistons. The diesel generator service water cooling system is designed to carry away waste heat from the jacket cooling water, lubricating oil, and the scavenging air.

9.5.5.2 <u>System Description</u>

The diesel generator jacket cooling water system consists of the following Seismic Category 1 equipment:

A. jacket cooling water expansion tank;

B. jacket cooling water circulating pump;

C. jacket cooling water heat exchanger;

D. electric standby heater;

E. standby circulating pump; and,

F. piping, valves, and instrumentation.

The jacket cooling water circulating pump is an engine driven centrifugal type water pump designed to provide cooling water flow at all engine loadings. The pump discharge flow is directed into the engine cooling passages. Each cylinder liner is fitted with a forged steel water jacket surrounding a symmetrical liner, and the liner adjacent to the jacket is machined to

provide circumferential and axial passages through which the cooling water flows. After passage through the engine, the cooling water is collected in a cooling water header and is then directed to a thermostatic bypass valve where a portion of the flow is diverted through the shell side of the jacket cooling water heat exchanger in order to maintain the required jacket water operating temperature. The bypass valve is of fail-safe type and will close on a malfunction, thereby providing full cooling capacity. The two flow paths again join at the heat exchanger outlet and flow back to the pump suction.

A connection to the cooling water circuit between the jacket water heat exchanger outlet and the pump suction leads to an expansion tank. The expansion tank compensates for changes in jacket cooling water volume as the engine heats up and cools down. The expansion tank has provisions for filling and corrosion inhibitor addition. Makeup water to the expansion tank is provided by the condensate transfer pumps (2P9A/B) which take suction from the condensate storage tanks (2T41A/B). The makeup water system is designed as Seismic Category 2 up to the expansion tank isolation valve. The makeup water pipe, including the isolation valve, to the expansion tank is designed as Seismic Category 1. The expansion tank is vented to atmosphere and is provided with local level indication and a low level alarm which annunciates at the diesel generator control panel and initiates a common alarm in the control room. The expansion tank is filled as required during routine testing of diesel.

The diesel engine Cooling Water (CW) system is designed as a leak tight system. The engine CW pump is provided with spring loaded carbon seals which are designed not to leak. Shop tests at full rated load continuous of similar model diesels as those provided at Unit 2 indicate no makeup water to the expansion tank is required due to leakage. Calculations indicate the evaporation loss from the CW expansion tank will be approximately seven gallons in seven days with the diesel operating at full rated load continuously. Therefore, the diesel can be operated for seven days without makeup to the CW expansion tank.

During periods of standby, the jacket cooling water and water passages are maintained at a warm "ready" condition by the electric standby heater and the motor driven standby circulating pump. Operation of the heater and standby circulating pump are not required under emergency start conditions.

The diesel generator service water cooling system consists of the following Seismic Category 1 equipment:

A. jacket cooling water heat exchanger;

B. lubricating oil heat exchanger; and,

C. air cooler heat exchanger.

The above three heat exchangers are mounted on the diesel generator skid and are piped with the tube sides (service water) in series. Service water enters the air cooler heat exchanger first, then flows through the lube oil cooler and finally through the jacket cooling water heat exchanger, carrying away the waste heat from the three respective engine systems. The SWS is described in Section 9.2.1.

9.5.5.3 Design Evaluation

The diesel generator cooling water systems have adequate capability to carry away the waste heat from the diesel generator units under all combinations of engine loadings and ambient conditions.

The jacket cooling water system has a sufficient volume of water to allow the engine to run at full load for three minutes without raw water cooling available, thus assuring that no engine damage will occur during the time interval between receipt of the Safety Injection Actuation Signal (SIAS) and the start of the service water pumps which supply the diesel generator cooling water.

Corrosion of the jacket cooling water system is reduced by using demineralized water from the PMU and by the addition of an inhibitor. The coolant space in each cylinder liner is coated after assembly at the factory with a Heresite coating to further prevent corrosion and to extend the life of the liner assembly. The engine is designed such that no water is in contact with the fabricated cylinder block, thus eliminating block damage from corrosion or freezing. All parts in the engine system in contact with the jacket coolant are readily renewable to facilitate maintenance and repair.

Corrosion of the service water cooling system is precluded by using Admiralty B-111 tubes in the three diesel generator skid mounted service water cooled heat exchangers. The service water is passed through traveling screens and 3/16-inch mesh basket strainers before reaching the heat exchangers, thus reducing the possibility of tube plugging by debris in the water.

If a failure occurs in the cooling water system of one diesel generator, the other diesel generator is available and is capable of bringing the plant to a safe shutdown in an emergency condition. There are no interconnections between the cooling water systems of the two diesel generators.

9.5.5.4 Tests and Inspection

The lube oil heat exchanger, air cooler heat exchanger, and the jacket cooling water heat exchanger are all built, tested, and stamped in accordance with ASME Section VIII. All skid mounted cooling water piping is fabricated in accordance with the manufacturers standard procedures, conforming generally with American Welding Society (AWS) requirements. In addition, the entire skid mounted cooling water system meets Seismic Category 1 requirements and is functionally tested in the manufacturer's factory prior to shipment. During periodic testing of the diesel generator, temperature and pressure readings are available to monitor proper operation of the cooling water system.

9.5.5.5 Instrumentation Applications

The following local alarm points are provided in the cooling water systems of each diesel generator:

A. jacket water low temperature;

B. jacket water level low;

C. jacket water high temperature;

D. jacket water low pressure; and

E. service water low pressure.

Operation of any one of the above A., B., or D. local alarms activates an "Engine/Gen Trouble" alarm in the control room. Operation of either the C. or E. local alarm activates a "Potential Engine Failure" alarm in the control room. In addition, pressure and temperature indicating devices are provided for local indication. Local flow indicating devices are provided for periodic surveillance testing and service water flow balancing.

9.5.6 DIESEL GENERATOR STARTING SYSTEM

The diesel generator air starting system is shown in Figure 9.5-8.

9.5.6.1 Design Bases

The diesel generator starting system is designed to store and supply an adequate source of compressed air to the diesel engine cylinders for fast, reliable cranking and starting under planned or emergency start conditions.

9.5.6.2 System Description

The starting system for each diesel generator consists of the following Seismic Category 1 components:

A. Two electric motor driven starting air compressors;

B. Two starting air receivers;

C. Two starting air strainers;

D. Two solenoid air admission valves;

E. Pilot air distributor valve;

F. Twelve cylinder air start valves; and,

G. Associated piping, valves, and instrumentation.

The starting air compressors, receivers, and associated accessories are located in the auxiliary building at Elevation 369 feet. Each starting system and its associated diesel generator unit are located in a Seismic Category 1 enclosure and are isolated from the other diesel generator unit and associated equipment by a fire and missile proof wall.

The starting air compressors take suction from the room air through compressor mounted air filters and each compressor discharges to its respective air receiver through a Seismic Category 1 pipe line. The air receivers are maintained at a pressure above 225 psig by automatic starting of the compressor at 225 psig receiver pressure and maintained below the receiver's relief setpoint of 250 psig. The compressor air inlet valves are held open on compressor motor starting by compressed air from the receivers until the motor is up to rated speed. Unloaded motor starting assures fast attainment of rated speed and prolongs compressor motor life.

Each air receiver is equipped with a safety valve, pressure indicator, drain valve, low pressure alarm, and shutoff valves. Either air receiver or compressor can be removed from service, repaired, or replaced without affecting the other, parallel, air supply system.

The air receivers are connected to each engine system via two parallel, Seismic Category 1 pipe lines fitted with a flexible hose for vibration isolation, stop valve, check valve, strainer, and air start solenoid valve. On receipt of a starting signal, both solenoid valves open simultaneously, delivering air to the timed pilot air distributor valve and the individual air start valves located in each cylinder. Pilot air delivered by the timed distributor valve opens the air start valves in proper sequence, admitting starting air directly into the engine cylinders for cranking. This air-over-piston starting system eliminates the need for starting air motors. Adequate cranking effort is obtained with only six air valves in the 12-cylinder engine operating; the additional six valves provide increased starting reliability.

Provisions for manual and automatic starting are provided. Manual operation from the control room (remote) or the diesel generator control panel (local) is possible, with the choice of operating location controlled by a "Local-Remote" selector switch located on the generator control panel. Placing the selector switch in the "Local" mode will permit manual starting of the unit from the local position only, and this mode is annunciated in the control room. With the selector switch in the "Remote" mode, manual starting can be accomplished from the control room only. Both diesel generators will start automatically on receipt of an Engineered Safety Features Actuation Signal (ESFAS) or by an undervoltage relay on the respective 4160-volt ESF bus, regardless of the position of the "Local-Remote" selector switch. In addition to the "Local-Remote" selector switch, there is a local, key operated, 3-position "Start-Auto-Lockout" control switch located on the diesel generator control panel. The key is removable in the "Auto" position only and turning the switch to the "Lockout" position is not possible unless the key is inserted. When in the "Lockout" mode, neither manual nor automatic starting of the diesel generator is possible. This mode is used only during engine or generator maintenance operations. Placing the selector switch in the "Lockout" position initiates an alarm in the control room to indicate that the diesel generator is not available. Additional information on this onsite power system is contained in Section 8.3.

9.5.6.3 <u>Design Evaluation</u>

Each diesel generator is equipped with two air compressors, air receivers, and solenoid air admission valves, either set of which is capable of starting the engine. Each of the two air receivers is sized to store enough air to crank and start the engine five times for the normal cranking duration without the use of the air compressors. All operations necessary to maintain the starting systems in a ready condition are entirely automatic and self-initiated. Sufficient instrumentation is provided to monitor the operation and status of each starting system. A means for local and remote starting and stopping are provided, with automatic starting capability provided regardless of previous status except when in "Lockout" position. When a SIAS signal is present, a running diesel generator can only be shut down locally. The system is designed to start the engine in such a time that the diesel generator unit can reach rated speed and voltage in a maximum of 15 seconds.

The starting system of each individual diesel generator is not required to meet the single failure criterion, as the two emergency diesel generators are redundant. If a failure occurs in the starting system of one diesel generator, the other diesel generator is available and is capable of bringing the plant to a safe shutdown in an emergency condition. There are no interconnections between the starting systems of the two diesel generators.

The diesel is designed to be accelerated to 150-180 rpm by the Air Starting System in less than two to five seconds at which time diesel ignition will commence. If the diesel is not up to a speed of 250 rpm in 10 seconds, the diesel will be shut down by the start failure relay (if both crank limit timers time out) and start failure will alarm in the control room.

The start failure setting is based on previous tests performed on similar diesels wherein it has been determined that if the diesel has not reached a speed of 250 rpm in 10 seconds then the diesel will not start with further cranking by the air start system.

It has been determined that sufficient reserve starting air capacity for cranking and starting the diesel two additional times will be available if the diesel is shutdown after 10 seconds of cranking. This will allow an operator to correct any malfunction, such as resetting the overspeed trip mechanism, and allow two additional attempts at starting the diesel.

The overspeed mechanism is mechanically linked with the fuel cut-out lever. An overspeed trip condition as a result of actual overspeeding of the engine will engage the overspeed trip mechanism which will close the fuel racks and stop the engine. This condition will annunciate and light the "Overspeed Trip" window on the generator local control panel and at the same time annunciate and light the control room "Engine/Exciter Shutdown" window.

The alarm horn will sound and the alarm window will flash until acknowledged. Then the alarm horn will silence and the alarm window will be lit steady. The alarm window will remain lit until the alarms are reset at the local EDG panel.

Low lube oil pressure will shut down the diesel through the shutdown relay if two out of three of the low lube oil pressure switches are actuated.

9.5.6.4 Tests and Inspection

All components in the emergency diesel generator starting systems meet Seismic Category 1 requirements. The air receivers are fabricated, tested, and stamped in accordance with Section VIII of the ASME Boiler and Pressure Vessel Code, and all piping is fabricated and tested in accordance with the manufacturer's standards, conforming to American Welding Society (AWS) requirements.

The diesel generator starting system is required to operate in an emergency condition for safe shutdown of the plant.

9.5.6.5 Instrumentation Applications

In addition to the instruments and controls discussed in Section 9.5.6.2, the following items are provided in the starting systems.

A. Starting air low pressure alarms for each air receiver and compressor inoperable alarms located in the local annunciator panel. Operation of any one initiates a "Start Air Trouble" alarm in the control room.

B. Diesel Engine "Start Failure" alarm in the control room which operates on any starting malfunction.

C. Diesel Generator "Auto Start Command" alarm in the control room.

9.5.7 DIESEL GENERATOR LUBRICATION SYSTEM

The lubricating oil system for the diesel generators is shown in Figure 9.5-8.

9.5.7.1 Design Bases

The diesel generator lubrication system is designed to supply lubricating oil to the diesel generator main bearings, thrust bearings, wrist pins, engine accessories, and the underside of the piston crown for piston cooling.

9.5.7.2 System Description

The diesel generator lubrication system consists of the following Seismic Category 1 equipment:

A. lube oil strainer;

B. lube oil cooler;

C. lube oil filter;

D. circulating oil pump;

E. pre-lube pump;

F. standby lube oil circulation pump;

G. electric standby heater; and,

H. piping, valves, and instrumentation.

The main circulating oil pump is an engine driven rotary gear type pump which maintains the required oil flow while the engine is running. The pump takes suction from the engine sump through a suction strainer and discharges through the full flow oil filter to the thermostatic bypass valve, where a portion of the oil flow is directed through the shell side of the lube oil cooler to maintain the required oil operating temperature. After the two flow paths again join at the cooler outlet, the lube oil passes through the lube oil strainer and into the engine main oil headers for distribution to the various engine components. A portion of the lube oil is circulated to the underside of the piston crown through drilled passages in the connecting rods to assist in cooling of the pistons.

During periods of standby, the lubricating oil is maintained at a constant elevated temperature by the electric standby heater and is circulated by the motor driven standby circulating pump to assure optimum viscosity and lubricating properties.

The diesel engines are periodically tested in accordance with Technical Specification requirements. To reduce wear on moving parts which would occur during engine startup before oil pressure is established, a motor-driven pre-lube pump is provided. Before a planned engine startup, the pump is manually switched on for the manufacturer recommended time to establish oil flow and pressure prior to engine cranking. Occasional EDG starts without pre-lube (i.e., actual demand tests) can be tolerated only on a limited basis. Pre-lube pump operation is not required under emergency start conditions.

9.5.7.3 Design Evaluation

The diesel generator lubrication systems have sufficient capacity to store, purify, and supply lubricating oil for the emergency diesel generators. Standby heaters and preoperational lube oil pumps are provided to ensure optimum startup conditions and reduce wearing of moving parts during engine exercising startups. The lubrication system of each individual diesel generator is not required to meet the single failure criterion as the two emergency diesel generators are redundant. If a failure occurs in the lubrication system of one diesel generator, the other diesel generator is available and is capable of bringing the plant to a safe shutdown in an emergency condition. There are no interconnections between the lubrication systems of the two diesel generators.

9.5.7.4 Tests and Inspection

The lubricating oil cooler, lubricating oil filter, lubricating oil strainer, and lubricating oil electric standby heater are built, tested, and stamped in accordance with ASME Section VIII. The lube oil piping is fabricated in accordance with the manufacturer's standard procedures. In addition, the entire lubricating oil system meets Seismic Category 1 requirements and is functionally tested in the manufacturer's factory prior to shipment.

9.5.7.5 Instrumentation Applications

The lubrication system is equipped with three low lube oil pressure switches; operation of any one sounds local and control room alarms; and, operation of any two shuts the engine down. Additional local alarms include high temperature, low temperature, and high crankcase pressure. Operation of the high temperature or high crankcase pressure alarm activates a "Potential Engine Failure" alarm in the control room. Operation of the low temperature alarm activates an "Engine/Gen Trouble" alarm in the control room.

Pressure and temperature indicating devices are provided for local indication, and may be used to confirm proper operation of the lube oil system during periodic testing of the diesel generator.

9.5.8 SEISMIC CATEGORY 1 VALVES

Information concerning all Seismic Category 1 valves is maintained current in the ANO Component Data Base.

9.5.9 DIESEL GENERATOR COMBUSTION AIR INTAKE AND EXHAUST SYSTEM

9.5.9.1 Design Bases

The diesel generator combustion air intake and exhaust system is designed to supply adequate combustion air to the diesel generator and exhaust the combustion products to the atmosphere.

9.5.9.2 System Description

Each diesel generator takes suction from the diesel generator room for its combustion air. The air is filtered at the engine before entering the combustion chambers. Intake air is drawn into the room through a louvered opening at the top of the room. The combustion products are exhausted by a muffler system and exhaust piping to the atmosphere at Elevation 425 feet.

9.5.9.3 Design Evaluation

The combustion air intake into the room is designed to Seismic Category 1 requirements, protected from tornado generated missiles, and shielded from direct wind, rain or snow.

The Combustion Products Exhaust System is also designed to Seismic Category 1 requirements. Failure of any of the exhaust system fans and the diesel generator room high temperature will actuate a "2DG1 RM TEMP HI/FAN TROUBLE" alarm in the control room. The flue gases are exhausted at an elevation 30 feet above the air intake at a sufficiently high velocity (116 feet per second) to avoid introduction of exhaust gases into the air intake. The sodium bromide/sodium hypochlorite, hydrogen, and carbon dioxide storage buildings are more than 300 feet away from the air intake. The nearest location where gaseous fire extinguishing media may be used is the cable spreading room, which is more than 100 feet away. Under any accident or meteorological conditions, the possibilities of diluting the oxygen content of the combustion air to the extent as to prevent the diesel generators from developing full rated power or causing the engines to shut down is minimal.

9.5.9.4 Test and Inspections

The diesel generators will be tested periodically per the Technical Specifications which will test the air intake and exhaust system.

Table 9.1-5

SINGLE FAILURE MODE ANALYSIS OF THE FUEL HANDLING EQUIPMENT

Component Identification	Failure Mode	Detrimental Effect On System	Corrective Action	Remarks
Refueling machine fuel hoist weight system	Electrical overload trip fails	None	Continue refueling, repair on non-interfering basis	Use visual presentation of load meter
	Complete system fails	None	As above	Maximum stall torque of motor will not damage bundle
Fuel carrier	Wheels lock in transfer tube	Transfer change not completed	Switch to 5 hp mode	Load sufficient to move fuel carrier with all wheels locked
Hydraulic power supply for upender	Line to cylinder on upender ruptures	None	Valve off defective line	Upender has two cylinders each of which is capable of raising upender
	Loss of hydraulic power	Process can continue on slower basis	Upend manually	Use tool provided
Brake on refueling machine fuel hoist	Does not provide required brake load	None	Continue, repair on non-interfering basis	Redundant brake system provided
Fuel carrier cable	Cable parts	Delays refueling	Move fuel carrier to safe position with manual tool	Remove fuel prior to repair

Table 9.1-5 (continued)

Component Identification	Failure Mode	Detrimental Effect On System	Corrective Action	Remarks
Refueling machine hoist motor	Power failure	Operation must be completed manually	Repair	Hoist using manual handwheel
Bridge drive motor	Power failure	Operation must be completed manually	Repair	Drive using manual handwheel
Electronic position indication	Power failure	None	Repair on non-interfering basis	Indexing can be accomplished by backup scale and pointer
Fuel carrier position sensing	Electrical failure	None	Repair on non-interfering basis	Winch motor stalls on overload
Refueling machine pressure	Loss of air	None	Repair	Continue using manual mode
Refueling machine TV camera	Electrical failure	None	Repair on non-interfering basis	Not mandatory for fuel handling
Refueling machine electronic hoist position indication	Electrical failure	None	Repair on non-interfering basis	Redundant mechanical counter
Fuel transfer tube isolation valve	Fails to close	None	Repair

TABLE 9.1-7

FUEL ASSEMBLY PARAMETERS USED IN SFP AND NFV CRITICALITY ANALYSES

Parameter	16 x 16 Standard	16 x 16 NGF
Fuel enrichment (wt. % U-235)	4.95	4.95
Number of fuel rods (per assembly)	236	236
Fuel Rod OD (inch)	0.382	0.374
Fuel Rod ID (inch)	0.332	0.329
Cladding thickness (inch)	0.025	0.225
Cladding material	Zircaloy-4	Optimized ZIRLO
Fuel pellet OD (inch)	0.325	0.3225
Stack density (g/cc)	10.412	10.522
Annular pellet inner diameter (inch)	0.16275	0.155
Fuel Rod pitch (inch)	0.506	0.506
ZrB_2 Coating Loading (mg ^{10}B/inch)	3.14 (Cycle 18) 2.95 (Cycle 19)	3.14
ZrB_2 Coating Thickness (inch)	.0004170 (Cycle 18) .0003920 (Cycle 19)	.0004170
Coating Length (inch)	134 (Cycle 18) 136 (Cycle 19)	138
Number of tubes (4 guide / 1 instrument per assembly)	5	5
Guide tube OD (inch)	0.98	0.98
Guide tube thickness (inch)	0.04	0.04
Active fuel height (inch)	149.61 – 150.0	150.0

NOTE: This table provides the values assumed in the criticality analyses documented in Reference 5. Variations in the pellet radius, fuel enrichment, stack density, and active fuel height occur for different reload batches.

Table 9.1-9 – DELETED

Table 9.1-10

Appendix B Supplement to Generic Licensing Topical Report EDR-1 for Spent Fuel Handling Crane L-3 Summary of Plant Specific Crane Data

Reg. Guide 1.104 Position	EDR-1 Topical Report Section	Information to be Provided	Specific Crane Data
C.1.a	III.C(C.1.a)	1. The actual crane duty classification of the crane specified by the applicant.	1. The trolley has a Class "C" crane duty classification in accordance with CMAA Specification #70. The bridge has a Class A crane duty classification.
C.1.b	III.C(C.1.b)	1. The minimum operating temperature of the crane specified by the applicant.	1. The trolley was designed and fabricated for a minimum operating temperature of 30 °F.
C.2.b	III.C(C.2.b) III.E.4	1. The maximum extent of load motion and the peak kinetic energy of the load following a drive train failure. 2. Provisions for actuating the emergency drum brake prior to traversing with the load, when required to accommodate the load motion following a drive train failure.	1. The Main Hoist was designed such that the maximum vertical load motion following a drive train failure does not exceed 1.5 feet and the maximum kinetic energy of the load is less than that resulting from one inch of free fall of the maximum critical load. 2. Provisions for automatically actuating the emergency drum brake prior to traversing with the load are not required since the maximum amount of load motion and kinetic energy has been factored into the facility design of the spent fuel pool floor (Elevation 404'-0"). This elevation can accommodate the load motion and the load will be administratively controlled by Procedure 1402.133 to maintain greater than or equal to 1.5 feet when traversing the Elevation 404'-0" floor.
C.3.e	III.C(C.3.e)	1. The maximum cable loading following a wire rope failure in terms of the acceptance criteria established in Section III.C(C.3.e).	1. The maximum cable loading following a wire rope failure in the Main Hoist meets the maximum allowed by the acceptance criteria established in Section III.C(C.3.e).

Table 9.1-10 (continued)

Reg. Guide 1.104 Position	EDR-1 Topical Report Section	Information to be Provided	Specific Crane Data
C.3.f	III.C(C.3.f)	1. Maximum fleet angle 2. Number of reverse bends 3. Sheave diameter	1. 3.5 degrees, Main Hoist. 2. None, other than the one between the wire rope drum and the first sheave in the load block. 3. 18 x wire rope diameter, Main Hoist.
C.3.h	III.C(C.3.h) III.E.11	1. The maximum extent of motion and peak kinetic energy of the load following a single wire rope failure.	1. The Main Hoist was designed such that the maximum load motion following a single wire rope failure is less than 1.5 feet and the maximum kinetic energy of the load does not exceed that resulting from one inch of free fall of the maximum critical load.
C.3.i	III.C(C.3.i)	1. The type of load control system specified by the applicant. 2. Whether interlocks are recommended by Regulatory Guide 1.13 to prevent trolley and bridge movements while fuel elements are being lifted and whether they are provided for this application.	1. A. Ederer AC flux vector, Main Hoist. B. Shepard Niles mechanical load brake, Aux Hoist. 2. The crane will not be used to lift fuel elements from the spent fuel racks. Therefore, interlocks to prevent trolley and bridge movements while hoisting have not been provided.
C.3.j	III.C(C.3.j)	1. The maximum cable and machinery loading that would result in the event of a high speed two blocking, assuming a control system malfunction that would allow the full breakdown torque of the motor to be applied to the drive motor shaft.	1. The energy absorbing torque limiter (EATL) was designed such that the maximum machinery load, which would result in the event a two-blocking occurs while lifting the rated load at the rated speed. This allows the full breakdown torque of the motor to be applied to the drive shaft and it will not exceed 3 times the design rated loading. In addition, the EATL design does not allow the maximum cable loading to exceed the acceptance criteria established in Section III.C(C.3.e) during the above described two-blockings.

Table 9.1-10 (continued)

Reg. Guide 1.104 Position	EDR-1 Topical Report Section	Information to be Provided	Specific Crane Data
	III.C(C.3.j) (continued)	2. Means of preventing two blocking of auxiliary hoist, if provided.	2. The 15 Ton Auxiliary Hoist has a geared upper limit switch and an arm actuated up over-travel switch.
C.3.k	III.C(C.3.k)	1. Type of drum safety support provided.	1. The alternate design drum safety restraint shown in Figure III.D.4 of EDR-1 is arranged to counter gear and brake forces as well as downward loads. These brackets act on the diameter of the ends of the drum on the Main Hoist.
C.3.o	NA	1. Type of hoist drive to provide incremental motion.	1. AC flux vector.
C.3.p	NA	1. Maximum trolley speed. 2. Maximum bridge speed. 3. Type of overspeed protection for the trolley and bridge drives.	1. 28 fpm. 2. 25 fpm. 3. Overspeed switches which actuate the brakes are provided for the trolley and bridge drives.
C.3.q	NA	1. Control station location.	1. The complete operating control system, including an emergency stop button, is located on the remote radio control station. An additional emergency stop button is located on the pendant station, permitting de-energization of the crane independent of the control station.
NA	III.D.1	1. The type of emergency drum brake used, including type of release mechanism. 2. The relative location of the emergency drum brake. 3. Emergency drum brake capacity.	1. A pneumatically released band brake is used for the Main Hoist. 2. The emergency drum brake engages the wire rope drum of the Main Hoist. 3. The Main Hoist emergency drum brake has a minimum capacity of 125% of that required to hold the design rated load.

Table 9.1-10 (continued)

Reg. Guide 1.104 Position	EDR-1 Topical Report Section	Information to be Provided	Specific Crane Data
NA	III.D.2	1. Number of friction surfaces in EATL. 2. EATL torque setting.	1. The main surface of the EATL has 21 friction surfaces. 2. The specified EATL torque setting is approximately 130% of the Main Hoist design rated load.
NA	III.D.3	1. Type of failure detection system.	1. A totally mechanical drive train continuity detector and emergency drum brake actuator have been provided in accordance with Appendix G of Revision 3 of EDR 1 for the Main Hoist.
NA	III.D.5	1. Type of hydraulic load equalization system.	1. The Main Hoist hydraulic load equalization system includes both features described in Section III.D.5.
NA	III.D.6	1. Type of hook. 2. Hook design load. 3. Hook load test.	1. Both the Main and Auxiliary Hooks have a single load path. 2. A. The Main Hook design critical lift load is 130 tons with a 10:1 factor of safety on ultimate. B. The Auxiliary Hook design lift load is 15 tons with a 5:1 factor of safety on ultimate. 3. The test load for each load path of the Main Hook is 260 tons.
NA	III.F.1	1. Design rated load. 2. Maximum Critical Load (MCL) rating. 3. Trolley weight (net). 4. Trolley weight (with load).	1. Main Hoist – 130 Ton Auxiliary Hoist – 15 Ton 2. Main Hoist – 130 Ton Auxiliary Hoist – NA 3. 74,000 lb (incl. Hooks) 4. 334,000 lb

Table 9.1-10 (continued)

Reg. Guide 1.104 Position	EDR-1 Topical Report Section	Information to be Provided	Specific Crane Data
	III.F.1 (continued)	5. Hook lift.	5. Main Hook – 80 feet, 0 inches Auxiliary Hook – 80 feet, 0 inches
		6. Number of wire rope drums.	6. The Main and Auxiliary Hoist each have one wire rope drum.
		7. Number of parts of wire.	7. Main Hoist – 4 parts per wire rope, 2 ropes, with (2) ropes off drum.
		8. Drum size (pitch diameter).	8. Main Hoist – 33 inches Auxiliary Hoist – 16 inches
		9. Wire rope diameter.	9. Main Hoist – 1-3/8 inches Auxiliary Hoist – 5/8 inch
		10. Wire rope type.	10. Main Hoist – Spelter Socket Williamsport Wire Ropes Works Royal Purple Plus Triple PAC Auxiliary Hoist – 6 x 37 EIPS/IWRC
		11. Wire rope material.	11. Carbon steel Main and Auxiliary Hoist.
		12. Wire rope breaking strength.	12. Main Hoist – 259,200 lb Auxiliary Hoist – 41,200 lb
		13. Wire rope yield strength.	13. Main Hoist – 207,360 lb Auxiliary Hoist – NA
		14. Wire rope reserve strength.	14. Main Hoist – 0.5777 Auxiliary Hoist – NA
		15. Number of wire ropes.	15. The Main Hoist has 2 ropes. The Auxiliary Hoist has one rope.

Table 9.1-10 (continued)

Reg. Guide 1.104 Position	EDR-1 Topical Report Section	Information to be Provided	Specific Crane Data
	III.C(C.1.b(1))	1. The extent of venting of closed box sections.	1. Closed box sections are not vented since the auxiliary building that houses the crane will not be pressurized.
C.1.b(3) C.1.b(4) C.4.d	III.C(C.1.b(3)) III.C(C.1.b(4)) III.C.(C.4.d)	1. The nondestructive and cold proof testing to be performed on existing structural members for which satisfactory impact test data is not available.	1. The procurement documents for the modified bridge structure did not invoke 10 CFR 50 Appendix B. An installation plan, to capture all of the critical characteristics of the structural members, is being used to ensure the structural members meet the requirements for the crane's intended function. Cold proof testing has been performed on the modified bridge, followed by a visual inspection of all accessible welds whose failure would result in the drop of a load. Visual inspections of structural degradation of the modified bridge were performed and no degradation was identified. Additional NDE of the critical welds on the bridge girder was performed. The ambient temperature when the 125% (+0%, -5%) static load test is performed is the minimum operating temperature for the crane. The minimum crane operating temperature has been established at 65 °F. In the event that the crane must be operated at a lower temperature, another 125% (+0%, -5%) static proof test will be performed at the lower temperature.

Table 9.1-10 (continued)

Reg. Guide 1.104 Position	EDR-1 Topical Report Section	Information to be Provided	Specific Crane Data
C.1.c	III.C.(C.1.c)	1. The extent the crane's structures which are not being replaced are capable of meeting the seismic requirements of Regulatory Guide 1.29.	1. The modified bridge structure and new trolley have been analyzed. Existing steel and concrete support structures have been analyzed for the design basis earthquake while supporting the maximum critical loads. This is documented in Entergy Calculation 61, Bechtel Book 21. Analysis methods and acceptance criteria are consistent with the ANO design basis for the support structure and runway girder, and meet the intent of Regulatory Guide 1.29, C.2.
C.1.d	III.C(C.1.d)	1. The extent welds joints in the crane's structures, which are not being replaced, were nondestructively examined 2. The extent the base material, at joints susceptible to lamellar tearing, was nondestructively examined.	1. Nondestructive examinations of the existing bridge structure were not required by existing regulations at the time of construction. However, the X-SAM® system provides additional overload protection, and the inspections of the existing structure described in C.1.b(3) above are adequate to ensure the structural integrity of the existing bridge. 2. The weld geometries used in (a) the existing bridge structure and (b) the replacement trolley structure are not considered to be susceptible to lamellar tearing.
C.1.e	III.C(C.1.e)	1. The extent the crane's structures, which are not being replaced are capable of withstanding the fatigue effects of cyclic loading from previous and projected usage, including any construction usage.	1. All past and projected uses of the modified structural components were assessed to ensure the crane is within the cyclic loading capability of the modified bridge structure and welds at 130 Tons for CMAA Class "A" service.

Table 9.1-10 (continued)

Reg. Guide 1.104 Position	EDR-1 Topical Report Section	Information to be Provided	Specific Crane Data
C.1.f	III.C(C.1.f)	1. The extent the crane's structures which are not being replaced, were post-weld heat treated in accordance with Sub article 3.9 of AWS D1.1, "structural welding code".	1. The material thickness of the modified bridge components are such that paragraph III.C(C.1.f) of EDR-1 does not require post weld heat treatment.
C.2.b	III.C(C.2.b) III.E.4	1. Provisions for accommodating the load motion and kinetic energy following a drive train failure when the load is being traversed and when it is being raised or lowered.	1. Administrative procedures will be used to assure that a minimum of 1.5 feet of clearance is maintained between the load and surfaces that cannot withstand the kinetic energy associated with one inch free fall of the load involved. The spent fuel pool floor laydown area (Elevation 404'-0") can withstand the kinetic energy associated with one inch free fall of the MCL, documented in Calculation 92-D-2001-62.
C.2.c	III.C(C.2.c)	1. Location of safe laydown areas for use in the event repairs to the crane are required that cannot be made with the load suspended.	1. The laydown areas that can be used in the event that repairs to the crane are required that cannot be made with the load suspended are the spent fuel pool floor and Elevation 404'-0" laydown area, documented in Procedure 1402.133.
C.2.d	III.C(C.2.d)	1. Size of modified components that can be brought into the building for repair of the crane without having to break the building integrity. 2. Location of area where repair work can be accomplished on the crane without affecting the safe shut-down capability. 3. Any limitations on operations that would result from crane repairs.	1. The X-SAM® trolley and modified bridge components can be brought in through the auxiliary building floor opening. The opening is 12'-0" x 24'-0". 2. Area is identified in Procedures 1402.133 and 1402.135. 3. No limitations for normal operations.

Table 9.1-10 (continued)

Reg. Guide 1.104 Position	EDR-1 Topical Report Section	Information to be Provided	Specific Crane Data
C.3.b	III.C(C.3.b)	1. The design margin and type of lifting devices that are attached to the hook to carry critical loads.	1. As an alternative to a dual load path system, the normal stress design factors have been doubled. The maximum critical load lifting device attached to the hook to carry critical loads will support a load six times the static plus dynamic load being handled without permanent deformation. The safety factor is 10:1 when compared to ultimate. This is in accordance with NUREG-0612, Section 5.1.6, Paragraph 1(a) and ANSI N14.6, Section 7.2.1.
C.3.t	III.C(C.3.t)	1. The extent construction requirements for the crane's structures, which will not be replaced, are more severe than those for permanent plant service. 2. The modifications and inspections to be accomplished on the crane following construction use, which was more severe than those for permanent plant service.	1. Prior use and load histories have been documented and reviewed for the modified bridge components as part of the final closeout information documented in Entergy MAI's and ER-ANO-2000-2688-02 associated with the spent fuel crane modifications. 2. Nondestructive examination of the accessible load bearing weld seams, and justification that the fatigue life of the modified components has not been compromised, were completed prior to the 125% design load test.
C.3.u	NA	1. The extent of installation and operating instructions.	1. The installation and operating instructions will be updated to fully comply with the requirements of Section C.3.u of Regulatory Guide 1.104 and Sections 7.1 and 9 of NUREG-0554.

Table 9.1-10 (continued)

Reg. Guide 1.104 Position	EDR-1 Topical Report Section	Information to be Provided	Specific Crane Data
C.4.a C.4.b C.4.c C.4.d	NA	1. The extent of assembly checkout, test procedures, load testing and rated load marking of the crane.	1. Prior to handling critical loads, the crane was given a complete assembly checkout, and then given a no-load test of all motions in accordance with updated procedures provided by Ederer. A 125% static load test and 100% performance test were also performed at this time in accordance with updated test procedures provided by Ederer. A no-load test of all motions and a two blocking test were performed by Ederer prior to delivery of the crane per Topical Report EDR 1. The maximum critical load is plainly marked on each side of the crane.
C.5.a	III.C(C.5.a)	1. The extent the procurement documents for the crane's structure's, which will not be replaced, required the crane manufacturer to provide a quality assurance program consistent with the pertinent provisions of Regulatory Guide 1.28.	1. The procurement documents for the components of the modified bridge structure did not invoke 10 CFR 50 Appendix B. However, these components were built to the manufacturer's quality control processes. Quality assurance provisions denoted in the procurement documents covered such items as design control, material selection and inspection and testing. The installation of the trolley and any structural modifications to the existing bridge is controlled by the Arkansas Nuclear One quality assurance plan and design change package ER-ANO-2000-2688.

SERVICE WATER SYSTEM SINGLE FAILURE ANALYSIS

COMPONENT	FAILURE	COMMENTS & CONSEQUENCES
Intake Structure	Blockage of water flow to service water pumps or loss of Dardanelle Reservior inventory due to dam rupture	Water is supplied to the system from the Emergency Cooling Pond by opening of 2CV-1471-1, 2CV-1473-5 and 2CV-1475-2, and closing of 2CV-1470-1, 2CV-1472-5 and 2CV-1474-2.
Service Water Pumps	One pump malfunctions	The other train will supply 100% of minimum requirements under all operating conditions, and the standby pump may be brought into service to supply an additional 100% of minimum requirements under all operating conditions.
Service Water Strainer	Blockage of water flow in one strainer	The other train will supply 100% of minimum requirements under all operating conditions, and the standby pump and strainer may be brought into service to provide an additional 100% of minimum requirements under all operating conditions.
System Pressure Boundary	Failure in Seismic Category 1 pressure boundary	The two trains are normally isolated from each other so that a failure in one train will not affect the other train. The trains can be isolated by operator action during other plant operating conditions.
Service water compartment sluice gates: 2CV-1471-1, 2CV-1473-5 2, CV-1475-2, 2CV-1470-1, 2CV-1472-5, or 2CV-1474-2	Valve fails to close or open with the hand switch	The other train will provide 100% of system requirements.

Table 9.2-5 (continued)

COMPONENT	FAILURE	COMMENTS & CONSEQUENCES
Auxiliary cooling system isolation valve: 2CV-1425-1 or 2CV-1427-2	Valve fails to close after SIAS or MSIS or RAS	The other valve 2CV-1427-2 or 2CV-1425-1 will close & isolate the auxiliary system.
Isolation valve serving "A" train ESF equipment in Aux. Bldg. pump rooms: 2CV-1400-1	Valve fails to open after SIAS	The other train will provide 100% of of system requirements.
Isolation valve serving "B" train ESF equipment in Aux. Bldg. pump rooms: 2CV-1406-2	Valve fails to open after SIAS	The other train will provide 100% of system requirements.
Inlet valves to Aux. Bldg. HPSI pump room unit coolers: 2CV-1407-1 or 2CV-1408-2	Inadvertent Valve Closure	The other train provides 100% of system requirements.
Inlet valve to shutdown cooling heat exchanger 2E35A: 2CV-1453-1	Valve fails to open after RAS	The other train will provide 100% of system requirements.
Inlet valve to shutdown cooling heat exchanger 2E35B: 2CV-1456-2	Valve fails to open after RAS	The other train will provide 100% of system requirements.
Inlet valves to switch gear rooms unit coolers: 2CV-1486-2, 2CV-1487-2, 2CV-1488-1, or 2CV-1489-1	Valve fails to open with associated fan start	The remaining unit cooler within the same train provides 100% of normal cooling requirements.
SWS discharge to Dardanelle Reservoir isolation valves: 2CV-1481-1 or 2CV-1480-2	Valve fails to close with hand switch	The other train will provide 100% of system requirements.
SW outlet valve from diesel generator "A": 2CV-1503-1	Valve fails to open with diesel generator start	The other train will provide 100% of system requirements.

Table 9.2-5 (continued)

COMPONENT	FAILURE	COMMENTS & CONSEQUENCES
SW outlet valve from diesel generator "B": 2CV-1504-2	Valve fails to open with generator start	The other train will provide 100% of system requirements.
SW inlet valves to Aux. Bldg charging pump room coolers: 2CV-1500-1, 2CV-1501-5, or 2CV-1502-2	Valve fails to open with associated fan start	The cooling capacity will be decreased about 35%. No credit is given to these coolers for safe shutdown of the plant under accident conditions.
SW outlet from "B" train containment Service Water Cooling Coils: 2CV-1513-2	Valve fails to open after CCAS	The other train will provide 100% of system requirements.
SW outlet from "A" train containment Service Water Cooling Coils: 2CV-1519-1	Valve fails to open after CCAS	The other train will provide 100% of system requirements.
SW inlet valves to the "B" train Aux. Bldg. electric equip. unit coolers: 2CV-1562-2 or 2CV-1564-2	Valve fails to open with associated fan start	The remaining unit cooler within the same train will provide additional 100% of system requirements.
SW inlet valves to the Aux. Bldg. emergency F.W. pump room unit coolers 2CV-1529-2 or 2CV-1532-1	Valve fails to open with associated fan start	The other train will provide 100% of system requirements.
SW inlet valves to the "A" train Aux. Bldg. electric equipment unit coolers: 2CV-1561-1 or 2CV-1563-1	Valve fails to open with associated fan start	The remaining unit cooler within the same train will provide additional 100% of normal system requirements. No credit is given to these coolers for safe shutdown of the plant under accident conditions.
SWS isolation valves supplying the CCW heat exchangers and main chillers: 2CV-1530-1 or 2CV-1531-2	Valve fails to close with SIAS or MSIS or RAS	The other train will provide 100% of system requirements.

Table 9.2-5 (continued)

COMPONENT	FAILURE	COMMENTS & CONSEQUENCES
SWS isolation valves supplying the Fuel Pool Heat Exchangers: 2CV-1525-1 or 2CV-1526-2	Valve fails to close with SIAS	The other train will provide 100% of system requirements.
SWS discharge line isolation valve in "A" loop: 2CV-1543-1	Valve fails to close with SIAS or MSIS or RAS	The other train will provide 100% of system requirements.
SWS discharge line isolation valve in "B" loop: 2CV-1542-2	Valve fails to close with SIAS or MSIS or RAS	The other train will provide 100% of system requirements.
SWS discharge to the Emergency Cooling Pond: 2CV-1560-2 or 2CV-1541-1	Valve fails to open with hand switch	The other train will provide 100% of system requirements.
Power Supplies	Failure of normal power source	The power supply automatically transfers to the preferred source.
	Failures of both normal and preferred power sources	The power supply automatically transfers to the diesel generators.
	Failure of power supply bus to one train	Other train is supplied from an independent and physically separate bus.
SW discharge control valves from control room emergency condensing unit (2VE1A or 2VE1B) 2CV-1509 or 2CV-1506	Valve fails to function	The other train will provide 100% of cooling requirements.

**SECONDARY SAMPLING SYSTEM
SAMPLE POINT DESIGN DATA**

Sample Name	Sample Conditions Normal/Max. Pressure (psig)	Sample Conditions Normal/Max. Temp (°F)
1. Makeup water mixed bed demineralizer tank outlet	15/100	60/100
2. Makeup water anion demineralizer tanks outlets	27/100	60/100
3. Makeup water cation demineralizer tanks outlets	40/100	60/100
4. Condensate storage tanks	10/60	100/140
5. Main steam headers	885/1085	529/556
6. 2E1A&B feedwater heater outlets	1085/1560	455/460
7. Feedwater into steam generators (grab sample only)	1085/1560	455/460
8. Emergency feedwater lines (grab sample only)	1200/1400	85/150
9. Heater drain pumps discharges (grab sample only)	630/835	386/390
10. Condensate pumps discharges	635/835	190/192
11. Condenser tube sheet leak detection trays	0/30	110/133
12. Cooling tower basin	5/10	97/110
13. Circulating water pumps discharge	45/85	97/110
14. Condenser hotwell	0/100	110/133

Note: The values listed represent historical operating conditions. The latest pressure-temperature analyses shall be utilized for determination of pressure-temperature design inputs.

Table 9.3-3

WASTE GAS ANALYZER SYSTEM SAMPLE POINT DESIGN DATA

Sample Name	Sample Conditions	
	Normal/Max. Pressure (psig)	Normal/Max. Temp (°F)
Volume Control Tank	15/50	120/150
Vacuum Degasifier	15/50	120/150
Waste Gas Decay Tanks (3)	250/380	120/150
Quench Tank	10/40	120/250
Reactor Drain Tank	10/40	120/250

Table 9.3-4

REACTOR COOLANT AND REACTOR MAKEUP WATER CHEMISTRY

Variable	Reactor Coolant		Reactor Makeup
	During Passivation	Operational	
Suspended solids ppm, max	0.5	0.35 (7)	---
pH at 77 °F	9.0-10.4	---	---
Chloride, ppm C1, max	0.15	0.15	0.15
Fluoride, ppm F, max	0.10	0.15	0.10
Hydrogen as H_2, cc/kg H_2O, (STP)	0 (1)	25-50 (7)	---
Dissolved O_2, ppm, max (2)	0.1	0.1	0.10 (5)
Lithium as Li-7, ppm	1.0-2.0	Consistent with Station Lithium Program	---
Boron as boric acid, ppm	0 (3)	(6)	---
Hydrazine, ppm	30-50		---
Ammonia (NH_3), ppm	50		---
Conductivity, μmhos/cm	(4)		
Silica, ppm, max	---	---	0.10
Zinc, ppb, max	---	≤ 40	
Zinc, ppb, excursions	---	≤ 80	

NOTES:

(1) Nitrogen overpressure is used in the CVCS volume control tank during passivation operations to exclude oxygen.

(2) At temperatures ≤ 250 °F, no upper limit on dissolved oxygen is specified.

(3) Boric acid should be added to the RCS as close as possible to fuel loading. Following the boric acid addition, hydrazine and ammonia concentrations should be reduced to maintain a primary coolant conductivity of less than 20 μmhos/cm.

(4) Depends on the concentrations of additives in the coolant.

(5) When degas tower is available.

(6) As required for reactivity control.

(7) Above cold shutdown conditions.

Table 9.3-5

CHEMICAL AND VOLUME CONTROL SYSTEM PARAMETERS

Normal letdown and purification flow, gpm	40
Normal charging flow, gpm	44
Reactor coolant pump controlled bleedoff, 4 pumps, gpm	4
Normal letdown temperature from reactor coolant system, °F	551
Normal charging temperature of reactor coolant system loop, °F	479
Ion exchanger operating temperature, °F	120
Soluble boron addition rate capability at end of cycle, one charging pump operating, (ppm/hr.)	277.8

Table 9.3-6

SCHEDULE OF WASTE GENERATION
(original design assumptions based on 12-month refueling cycle)

Source	Quantity, gal/yr
Refueling Shutdown and Startup	205,000
Cold Shutdowns and Startups	404,000
Hot Shutdowns and Startups	116,000
Boron Dilution	242,000
Average Daily Leakage to Reactor Drain Tank and Equipment Drain Tank	250 gal/day

Table 9.3-7

CHEMICAL AND VOLUME CONTROL SYSTEM PROCESS FLOW DATA

Values given are nominal based on Tcold at 550 °F; actual operating values may vary. The pressure drop across the purification prefilter, afterfilter, and ion exchanger varies with loading. The pressure drops shown are typical. The pressure in the volume control tank varies and affects the pressures at locations 5 through 11 and 14a through 14g proportionally.

REGENERATIVE HEAT EXCHANGER DESIGN DATA

1) Design Parameters

Quantity	1
Type	Shell and Tube, Vertical
Code	ASME Section III, Class 2
Tube Side – Letdown:	
Fluid	Reactor coolant, 1.5 w/o boric acid maximum
Design pressure, psig	2485
Design temperature, °F	650
Materials	Stainless Steel, Type 304
Pressure loss at 128 gpm, psi	100
Normal flow, gpm	40
Design flow, gpm	128
Shell Side – Charging:	
Fluid	Reactor coolant, 12 w/o boric acid maximum
Design pressure, psig	3025
Design temperature, °F	650
Materials:	
Shell	ASME SA-304, TP 304
Tubes	ASME SA-213, TP 304
Baffles	ASME SA-240, TP 304
Tube Sheet	ASME SA-182, F 304
Channel	ASME SA-312, TP 304
Pressure loss at 132 gpm, psi	70
Normal flow, gpm	44
Design flow, gpm	132

2) Operating Parameters

	Normal	Minimum Letdown/ Maximum Charging	Maximum Letdown/ Maximum Charging	Maximum Letdown/ Minimum Charging
Tube Side – Letdown				
Flow - gpm @ 120 °F	40	30	128	128
Inlet Temp. - °F	550	550	550	550
Outlet Temp.* - °F	218	152	366	442

* May vary with 551 °F inlet temperature.

	Normal	Minimum Letdown/ Maximum Charging	Maximum Letdown/ Maximum Charging	Maximum Letdown/ Minimum Charging
Shell Side – Charging				
Flow - gpm @ 120 °F	44	132	132	44
Inlet Temp. - °F	120	120	120	120
Outlet Temp. - °F	410	223	324	479

LETDOWN HEAT EXCHANGER DESIGN DATA

1) Design Parameters

Quantity	1
Type	Shell and Tube, Horizontal
Tube Side – Letdown:	
Code	ASME Section III, Class 2
Fluid	Reactor coolant, 1.5 w/o boric acid maximum
Design pressure, psig	650
Design temperature, °F	550
Pressure loss at 128 gpm, psi	50
Normal flow, gpm	40
Design flow, gpm	128
Materials:	
Shell	ASME SA-106 Gr.B
Tubes	ASME SA-213, Type 304
Cover	ASME SA-285, Gr. C F.B.Q.
Tubesheet	ASME SA-182, F 304
Channel	ASME SA-240, Type 304
Shell Side – cooling water:	
Code	ASME Section III, Class 3
Fluid	Component Cooling Water
Design pressure, psig	150
Design temperature, °F	250
Materials	Carbon Steel
Normal flow, gpm	180
Design flow, gpm	1200

2) Operating Parameters

	Normal	Minimum Letdown/ Maximum Charging	Maximum Letdown/ Maximum Charging	Maximum Letdown/ Minimum Charging
Tube Side – Letdown				
Flow - gpm @ 120 °F	40	30	128	128
Inlet Temp.* - °F	218	152	366	442
Outlet Temp. - °F	120	120	123	130

* Based on letdown temperature of 550°F, may vary with letdown temperature of 551 °F.

	Normal	Minimum Letdown/ Maximum Charging	Maximum Letdown/ Maximum Charging	Maximum Letdown/ Minimum Charging
Shell Side – Charging				
Flow - gpm @ 120 °F	121	35	1200	1200
Inlet Temp. - °F	100	100	100	100
Outlet Temp. - °F	133	129	127	134

Table 9.3-11

PURIFICATION FILTER DESIGN DATA

Quantity	2
Type Elements	Cartridges
Normal operating temperature, °F	120
Design pressure, psig	200
Maximum allowable pressure loss clean, psi @ 128 gpm	5
Maximum allowable pressure loss, loaded psi at 128 gpm	60
Design temperature, °F	250
Design flow, gpm	128
Normal flow, gpm	40
Code	ASME III, Class 3
Materials, wetted	SA-240 Type 304 Stainless Steel
Fluid, w/o boric acid, maximum	1.5

Table 9.3-12

PURIFICATION AND DEBORATING ION EXCHANGERS DESIGN DATA

Quantity	2 purification 1 deborating
Type	Flushable
Design pressure, psig	200
Design temperature, °F	250
Normal operating temperature, °F	120
Resin volume, cu. ft. each (total)	36.2
Resin volume, cu.ft. each (useful)	32.0
Normal flow, gpm	40
Maximum flow, gpm	1280
Code for vessel	ASME III, Class C
Retention screen size	80 U.S. Mesh
Material	Stainless Steel, SA-240, Type 304
Fluid, w/o boric acid, maximum	1.5
Resin type	Cation/anion mixed bed for purification and deborating

Table 9.3-13

VOLUME CONTROL TANK DESIGN DATA

Quantity	1
Type	Vertical, Cylindrical
Internal volume, gallons	4200
Design pressure, internal, psig	75
Design pressure, external, psig	15
Design Temperature, °F	250
Normal operating pressure, psig	15
Normal operating temperature, °F	120
Normal spray flow, gpm	40
Blanket gas - during plant operation	Hydrogen
Code	ASME III, Class C
Fluid, w/o boric acid, maximum	12
Material	ASME SA-240, Type 304

Table 9.3-14

CHARGING PUMPS DESIGN DATA

Quantity	3
Type	Horizontal, Positive Displacement, Triplex
Design pressure, psig	2735
Design Temperature, °F	250
Capacity, gpm	44
Normal discharge pressure, psig	2300
Normal suction pressure, psig	15 to 20
Normal temperature of pumped fluid, °F	120
NPSH required, psia (most limiting)	3.8
Driver rating, hp	100
Code	ASME P&V Code Class 2
Materials in contact with pumped fluid	SA-182, F 316, F 304 or F 304L; SA-479 TY-304; SA-705 TY-630 H1100
Fluid, w/o boric acid, maximum	12

Table 9.3-15

BORIC ACID MAKEUP TANKS DESIGN DATA

Quantity	2
Volume, gal each	11,700
Design pressure, psig	15
Design temperature, °F	200
Normal operating temperature, °F	70 – 80
Type heater*	6 electrical strap-on heaters, 2.25kW total each (2 banks of 3 each)
Fluid, w/o boric acid, maximum*	12
Material	ASME SA-240 Type 304
Code	ASME III, Class C

* Starting with Cycle 7, the maximum boric acid concentration in an operable tank is limited to 3.5 w/o to eliminate precipitation of boron at the ambient temperatures of the auxiliary building, thereby eliminating the need for tank heaters.

Table 9.3-16

BORIC ACID BATCHING TANK DESIGN DATA

Quantity	1
Internal volume, gal	630
Design pressure	Atmospheric
Design temperature, °F	200
Normal operating temperature, °F	110 – 160
Type heater*	Electrical Immersion
Number of heaters	3
Heater capacity, kw each	15
Fluid, w/o boric acid, maximum**	12
Material	ASME SA-240 Type 304
Code	None

** The control setpoint for the heat trace on the discharge piping is selected for a maximum boric acid concentration of 8.1 w/o.

Table 9.3-17

BORIC ACID MAKEUP PUMPS DESIGN DATA

Quantity	2
Type	Centrifugal, Horizontal
Design pressure, psig	150
Design Temperature, °F	250
Design head, ft	231
Design flow, gpm	143
Normal operating temperature, °F	70
NPSH required, ft	6
Motor horsepower	25
Motor voltage/phase/Hz	440/3/60
Fluid, wt % boric acid, maximum	12*
Material in contact with liquid	Austenitic Stainless Steel
Code	ASME III, Class 2

* Starting with Cycle 7, the maximum boric acid concentration in an operable flow path from the BAMT is limited to 3.5 wt % due to the elimination of heat tracing for this piping. This prevents boron precipitation at the ambient temperatures of the auxiliary building.

Table 9.3-18

CHEMICAL ADDITION TANK DESIGN DATA

Quantity	1
Internal volume, gals	8
Design pressure, psig	150
Design temperature, °F	150
Normal operating temperature, °F	Ambient
Materials	Austenitic Stainless Steel
Code	None

Table 9.3-19

CVCS PROCESS RADIATION MONITOR DESIGN DATA

Quantity	1
Type	Gamma scintillation
Design pressure, psig	200
Design temperature, °F	250
Normal operating temperature, °F	120
Normal flow rate, gpm	1.2
Measurement range, µCi/cc, I-135	10^{-4} to 10^{+2}
Code	ASME III, Class C

Table 9.3-21

SINGLE FAILURE ANALYSIS - CHEMICAL AND VOLUME CONTROL SYSTEM

Component	Failure Mode	Cause	Symptoms and Local Effects	Method of Detection	Inherent Compensating Provision(s)
Regenerative Heat Exchanger (RHX)	Decrease in ability to transfer heat	Excessive fouling or crud deposition	High temperature in letdown line	High temperature alarm from 2TAH-4820	Hot flow will automatically bypass IXs and PRM (2) 2TS-4820 will shut valve 2CV-4820-2 and stop letdown flow
Regenerative Heat Exchanger (RHX)	Shell to tube leakage	Corrosion and/or manufacturing defect	Eventual out of spec. boron concentration; heat exchanger temperature disparities	Isolate letdown and measure flow on 2FIS-4863 while charging. Perform only during shutdown	Safe plant shutdown not affected. Charging via SIS filling pressurizer, letdown via reactor coolant pumps
Letdown Heat Exchanger (LHX)	Decrease in ability to transfer heat	Excessive fouling or crud deposition	High temperature in letdown line or abnormally high cooling water flow rate	High temperature alarm from 2TAH-3805 and high temperature reading from 2TIC-4815	Hot flow will automatically bypass IXs
Letdown Heat Exchanger (LHX)	Cross Leakage	Corrosion and/or manufacturing defect	Radioactivity will be transferred to CCW	Activity monitor in CCW will sound alarm	Safe plant shutdown not affected

Table 9.3-21 (continued)

Component	Failure Mode	Cause	Symptoms and Local Effects	Method of Detection	Inherent Compensating Provision(s)
Line, between 2TE-4820 and 2CV-4811 (outside Containment)	Rupture	Faulty weld	High temperature in letdown line	High temperature alarm from 2TAH-4820 and low pressure alarm from 2PAHL-4812	2TS-4820 will shut valve 2CV-4820-2 and stop letdown flow
Line, between LHX and 2TE-4805	Rupture	Faulty weld	Loss of pressure in letdown line	Low pressure alarm from 2PAHL-4812 and high temp. alarm 2TAH-4820	2TS-4820 will close letdown stop valve 2CV-4820-2
Purification Filter	Clogs	Contamination	High differential pressure across filter	Sensor, 2PDIS-4802 will actuate alarm	Bypass Line will facilitate cartridge replacement
Purification Filter	Cartridge rupture	Excessive differential pressure	Contamination of IXs and PRM	None for small breaks, for larger breaks the reading of 2PDIS-4802 will be lower than normal also periodic sampling for activity buildup	Bypass line will facilitate cartridge replacement
Radiation Monitor	Fails to detect high levels radiation	Electrical malfunction	May allow a buildup of contamination	Laboratory analysis of coolant sample	Backup by sampling system and local samples
Radiation Monitor	False indication of high level of radiation	Electrical malfunction	Alarm	Laboratory analysis of coolant sample	Backup by sampling system and local samples

Table 9.3-21 (continued)

Component	Failure Mode	Cause	Symptoms and Local Effects	Method of Detection	Inherent Compensating Provision(s)
Letdown Ion Exchanger	Fails to remove contamination	Resin exhaustion	Buildup in RCS activity	Alarm from PRM and laboratory sample analysis	Bypass ion exchangers during replacement of resin
Letdown Ion Exchanger	Fails to remove boron from coolant	Resin exhaustion	Unable to maintain power at end of core cycle	Coolant sample and decreasing power	Bypass and replace during replacement of changer
Charging pumps	Fails to provide sufficient flow to RCS	Seal failure, electrical malfunction, or low NPSH	High letdown temp at 2TI-4820, and low charging flow rate at 2FIS-4863, and low pressurizer liquid level	Low level in pressurizer, low flow alarm at pump outlet (2FAL-4863)	Low level in pressurizer will start second and third pump
Line, Makeup to Volume Control Tank (VCT)	Rupture	Faulty weld	Possible loss of makeup, activity release from VCT, VCT low pressure	Low VCT level alarm, possible annunciation of area radiation monitors, VCT low pressure alarm	VCT level controller 2LS 4861-A will close VCT discharge valve2CV-48731 and open valve to refueling water tank
Boric Acid Batching Tank Heater and Controller	Fails off	Electrical malfunction	Precipitation, inability to mix boric acid	2TIC-4901 will indicate low temperature	Sufficient reserve in makeup tanks is available until malfunction is corrected
Boric Acid Batching Tank Heater and Controller	Fails on	Electrical malfunction	Overheating of boric acid in batching tank	2TIC-4901 will indicate high temperature	Isolate and repair, sufficient reserve in makeup tanks

Table 9.3-21 (continued)

Component	Failure Mode	Cause	Symptoms and Local Effects	Method of Detection	Inherent Compensating Provision(s)
Boric Acid Batching Tank Mixer	Fails to start	Electrical malfunction	Unable to batch boric acid solution	Visual	Isolate and repair, sufficient reserve in makeup tanks
Boric Acid Makeup tank	Leak	Faulty weld or connection	Loss of boric acid	Level indication and alarm	Redundant standby tank
Line, Discharge Boric Acid Makeup Tank	Leak	Faulty weld or connection	Loss of boric acid	Level indication alarm	Redundant standby tank
Boric Acid Makeup Pump	Fails to start	Electrical malfunction or shaft break	Loss of Flow	Pump discharge pressure low alarm	Redundant standby pump, gravity feed or use refueling water tank
Line, Boric Acid Pump Discharge	Rupture	Faulty weld	Loss of boric acid	Pump discharge pressure low alarm	Redundant standby pump, and boric acid from refueling water tank
Line, Gravity feed to charging	Rupture	Faulty weld	Loss of boric acid	Boric acid makeup tank level indication	Alternate flow path of boric acid available from refueling water tank
Heat Tracing	Fails off	Electrical malfunction	No adverse impact on system or system operation		

Table 9.3-21 (continued)

Component	Failure Mode	Cause	Symptoms and Local Effects	Method of Detection	Inherent Compensating Provision(s)
Volume Control Tank (VCT)	Rupture	Faulty weld	Loss of liquid and radioactive gases	Pressure and level indication and alarms on VCT, and radiation alarm in auxiliary building	Charging pump suction will automatically be supplied by refueling water tank on low level in VCT
Line, Discharge of VCT	Rupture	Faulty weld	Loss of coolant, radioactive gases and liquids released and low VCT pressure	Pressure and level indications and alarms in VCT	VCT discharge valve will close on low VCT level and charging pump suction will switch to refueling water tank
Line, Refueling Water Tank to CVCS	Rupture	Faulty weld	Loss of RWT contents	Level alarm in RWT	Ability to borate the RCS with contents of makeup tanks not affected. Isolation valve at tank
Line, Charging Pump Discharge	Rupture	Faulty weld	Loss of pressure, Loss of coolant	Low pressure alarm 2PAL-4870 and low flow alarm 2FAL-4863	Isolate and charge through HPSI header

ABBREVIATIONS

RHX - Regenerative heat exchanger
LHX - Letdown heat exchanger
IX - Ion exchanger
PRM - Process radiation monitor
SIS - Safety injection system

RCS - Reactor Coolant System
VCT - Volume control tank
RWT - Refueling water tank
CCW - Component cooling water (system)

SHUTDOWN COOLING SYSTEM INSTRUMENT APPLICATION

System Parameter and Location	Indication Local	Indication Control Room	Alarm[1] High	Alarm[1] Low	Recorder[1]	Control Function	Instrument Range	Normal Operating Range
Heat Exchanger Inlet Temperature, 2TI-5617, 2TI-5619	*						0-400 °F	90-120 °F
Heat Exchanger Outlet Temperature, 2TI-5618, 2TI-5620		*					0-400 °F	90-120 °F
Shutdown Cooling Return Temperature and Mixed Outlet and Bypass of Heat Exchanger, 2TR-5097					*		0-400 °F	90-120 °F
Heat Exchanger Inlet Pressure, 2PI-5622, 2PI-5625		*					0-600 psig	175-185 psig[2]
Shutdown Cooling Return Flow, 2FIC-5091		*	*	*		Heat Exchanger Bypass Valve	0-8000 gpm	Variable
Low Pressure Safety Injection Discharge Header 2PI-5092		*	*	*			0-600 psig	Variable
LPSI Pump Suction Pressure, 2PI-5039A		*	*	*			0-50 psig	~20 psig[2]
LPSI Pump ΔP, 2PI-5039A							0-300 psid	~130-140 psid[3]

Table 9.3-25 (Continued)

System Parameter and Location	Indication: Local	Indication: Control Room	Alarm[1]: High	Alarm[1]: Low	Recorder[1]	Control Function	Instrument Range	Normal Operating Range
LPSI Pump Motor Current, 2II-5018A	*						0-100 Amps	Variable
RCS Refueling Level, 2LI-4791, 2LI-4792							0-420"	Variable
RCS Refueling Level, Tygon Tubing							369'-1½" to 401'-5½"	Variable
CET Temperature, 2TI-4793							0-2300 °F	Variable

(1) All alarms and recorders are in the control room unless otherwise indicated.
(2) Reactor Vessel Head removed.
(3) LPSI Pump indicated ΔP includes pressure drop across 2FO-5090.

Table 9.4-1

SINGLE FAILURE ANALYSIS - CONTROL ROOM EMERGENCY AIR CONDITIONING SYSTEM

Component	Failure	Comments & Consequences
Off-site power	Not available	Emergency diesels start and supply electrical load to system.
Emergency diesels	One not available	The operative diesel supplies necessary power to one of the redundant system flow paths.
Control room emergency air conditioning system	One not available	The standby, full-capacity, control room emergency air conditioning system is available to provide suitable environmental conditions in the control room for operating personnel and safety-related control equipment.
Control room emergency air conditioning system	Rupture of equipment casings	The system is designed as a Seismic Category 1 System. The equipment and components are also inspectable and protected against credible missiles.
Control room emergency air conditioning system	Rupture of one loop of the service water piping system	The standby, full-capacity, control room emergency air conditioning system is supplied by the second loop of the service water piping system.

Table 9.4-2

SINGLE FAILURE ANALYSIS-EMERGENCY DIESEL GENERATOR ROOM VENTILATION SYSTEMS

Component	Failure	Comments & Consequences
Off-site power	Not available	Emergency diesels start and supply electrical load to systems.
Emergency Diesels	One not available	The operative diesel supplies necessary power to ventilation system serving the emergency diesel generator room in use.
Emergency Diesel Generator	One not available	The standby, full capacity, ventilation system is Room Ventilation Systems available to maintain a suitable environment for essential equipment to the second emergency diesel generator room.
Emergency Diesel Generator Room Ventilation Fans	One not available	The second fan will maintain the room at 115 °F DB with an outside air temperature of 95 °F or at 120 °F with an outside air temperature of 100 °F.
Emergency Diesel Generator Room Ventilation Systems	Rupture of equipment casings and/or ducts	The systems are designed as Seismic Category 1. The equipment and components are also inspectable and protected against credible missiles.

Table 9.4-3

CONFORMANCE OF ATMOSPHERE CLEANUP SYSTEMS (ACS) WITH RESPECT TO EACH POSITION OF U.S. NRC REGULATORY GUIDE 1.52 DATED JUNE 1973[(1)]

REGULATORY GUIDE POSITION 1: ENVIRONMENTAL DESIGN CRITERIA	Control Room Ventilation System[(2)]	Containment Purge System	Penetration Room Ventilation System	Auxiliary Bldg and Fuel Handling Floor Ventilation Systems
A) Each ESF atmosphere cleanup system is based on conditions resulting from DBA	Designed to maintain radiological dosage within limits of 10 CRF 50 Appendix A, Criterion 19	Originally designed to lower containment atmosphere activity below 10 CFR 20 limits for personnel access to the containment building (see Section 6.2.5.1)	Designed to collect and process potential containment penetration leakage after DBA	Non-ESF. Design based on assumptions in Regulatory Guide 1.25
B) System design based on 30 days integrated radiation dose	Yes	Yes	Yes	Yes, design based on assumptions in Regulatory Guide 1.25
C) Design of adsorber based on concentration and relative abundance of iodine species	Yes	Yes	Yes	Yes, design based on assumptions in Regulatory Guide 1.25
D) Compatibility of ACS with other ESF systems in containment	N/A	N/A	N/A	N/A
E) Components designed to lowest and highest outdoor temperature	N/A, Recirculation System	Yes	Yes	N/A

Table 9.4-3 (continued)

REGULATORY GUIDE POSITION 2: ENVIRONMENTAL DESIGN CRITERIA	Control Room Ventilation System(2)	Containment Purge System	Penetration Room Ventilation System	Auxiliary Bldg and Fuel Handling Floor Ventilation Systems
A) (i) ACS components consist of demister, prefilter, HEPA, iodine adsorber, HEPA filter after the adsorber, ducts and valves, fans and related instruments	No demister, no HEPA filter after the adsorber (no entrained moisture)	No demister, no HEPA filter after the adsorber (no entrained moisture)	No demister, no HEPA filter after the adsorber (no entrained moisture)	No demister, no HEPA filter after the adsorber (no entrained moisture)
(ii) Redundancy of ACS if required for mitigation of accident doses	Yes	No, single filter train	Yes	Single filter train, redundant fans
B) Physical separation and missile protection of redundant ACSs	Yes	N/A	Yes	No
C) Seismic Category 1 designation of ACSs	Yes	Yes	Yes	Yes
D) ACS pressure surge protection	N/A	N/A	N/A	N/A
E) Effect of radiation on ACS construction materials to perform intended function	Yes	Yes	Yes	Yes
F) Air flow rate of ACSs	2,000 cfm	40,000 cfm	2,000 cfm	See P&ID M-2262
G) Instrumentation provided in control room	Alarm for low flow and high pressure drop	Alarm for low flow and high pressure drop and high radiation in discharge air	Alarm for low flow and high pressure drop	Alarm for high pressure drop and high radiation in discharge air. Alarm for low flow on Fuel Handling Floor Ventilation

Table 9.4-3 (continued)

REGULATORY GUIDE POSITION 2: ENVIRONMENTAL DESIGN CRITERIA	Control Room Ventilation System(2)	Containment Purge System	Penetration Room Ventilation System	Auxiliary Bldg and Fuel Handling Floor Ventilation Systems
H) Electrical power supply and distribution in accordance with IEEE Standards	Yes	Yes	Yes	Yes
I) Design avoids bypassing of unfiltered air (except temporarily for tests)	All recirculating air flow through filter train	No bypass	No bypass	No bypass
J) Protection of workers from radiation during maintenance	Standard CVI design	Standard CVI design	Standard CVI design	Standard CVI design
K) Minimization of meteorological effects on outdoor air intakes		N/A	N/A	N/A
L) Maximum leakage rate of ACS housing and ductwork	Welded seam ductwork and housing, Seismic Category 1 design, zero-leakage	Seismic Category 1 design, zero-leakage	Piping constructed to ASME Section VIII requirement, Seismic Category 1, zero-leakage	2% leakage in exhaust ductwork
M) Performance of ACS not ESF classified	N/A	N/A	N/A	N/A

REGULATORY GUIDE POSITION 3: ENVIRONMENTAL DESIGN CRITERIA	Control Room Ventilation System(2)	Containment Purge System	Penetration Room Ventilation System	Auxiliary Bldg and Fuel Handling Floor Ventilation Systems
A) Demister performance and qualification requirement	No demister required	No demister required	No demister required	No demister required
B) Humidity control for adsorption units	None required	None required	None required	Exhaust air from conditioned space, no humidity control

Table 9.4-3 (continued)

REGULATORY GUIDE POSITION 3: ENVIRONMENTAL DESIGN CRITERIA	Control Room Ventilation System(2)	Containment Purge System	Penetration Room Ventilation System	Auxiliary Bldg and Fuel Handling Floor Ventilation Systems
C) Prefilter construction and efficiency	UL Class 1, 80% efficient by ASHRAE STD. 52-68 Test Method	UL Class 1, 80% efficient by ASHRAE STD. 52-68 Test Method original, current revision for replacements	UL Class 1, 80% efficient by ASHRAE STD. 52-68 Test Method original, current revision for replacements	UL Class 1, 80% efficient by ASHRAE STD. 52-68 Test Method original, current revision for replacements
D) HEPA filter construction and efficiency	Meets MIL-F-51068D, MIL-F-51079A and UL-586. Tested at 100% and 20% rated flow	Original meets MIL-F-51068D, MIL-F-51079A and UL-586. Replacements meet ASME AG-1 and UL586 and tested at 1000 cfm and 300 cfm flow rate	Meets MIL-F-51068D, MIL-F-51079A and UL-586. Tested at 100% and 20% rated flow.	Original meets MIL-F-51068D, MIL-F-51079A and UL-586. Original tested at 1000 cfm and 20% rated flow. Replacements meet ASME AG-1 and UL-586 and tested at 1000 cfm and 300 cfm flow rate
E) Filter and adsorber mounting frame design and construction	Designed to ORNL-NSIC-65	Designed to ORNL-NSIC-65	Designed to ORNL-NSIC-65	Vertical bed, designed to ORNL-NSIC-65
F) System filter housing design and construction	Designed to ORNL-NSIC-65	Designed to ORNL-NSIC-65	Designed to ORNL-NSIC-65	Designed to ORNL-NSIC-65
G) Water drains design	Designed to ORNL-NSIC-65	Designed to ORNL-NSIC-65	Designed to ORNL-NSIC-65	Designed to ORNL-NSIC-65
H) Consideration of radiation effect on material	Yes	Yes	Yes	Yes

Table 9.4-3 (continued)

REGULATORY GUIDE POSITION 3: ENVIRONMENTAL DESIGN CRITERIA	Control Room Ventilation System(2)	Containment Purge System	Penetration Room Ventilation System	Auxiliary Bldg and Fuel Handling Floor Ventilation Systems
I) Removal of iodine by adsorber material	CVI 4" deep tray type	CVI 2" vertical bed	CVI 2" deep tray type	CVI 2" vertical bed
J) Prevention of fire in adsorber resulting from decay heat	Auto ignition temp above 340 °C. Filter train is isolated. Fire detector provided	Auto ignition temp above 340 °C	Auto ignition temp not exceeded even with no convective or conductive heat removal for 30 days post LOCA	None
K) System fans provided with sufficient capacity and pressure	Yes	Yes	Yes	Yes
L) System fans capable of operation in post DBA environmental condition	Yes	Yes	Yes	No
M) Ductwork design	Designed to ORNL-NSIC-65 and industry standards	Designed to ORNL-NSIC-65 and industry standards	All steel piping	Designed to SMACNA, medium pressure high velocity
N) Ductwork and housing laid out with minimum of ledges, protrusions, crevices, etc., which impede personnel or create a hazard	Yes, all components are readily accessible	Yes, all components are readily accessible	Yes, all components are readily accessible	Yes, all components are readily accessible

Table 9.4-3 (continued)

REGULATORY GUIDE POSITION 4: ENVIRONMENTAL DESIGN CRITERIA	Control Room Ventilation System(2)	Containment Purge System	Penetration Room Ventilation System	Auxiliary Bldg and Fuel Handling Floor Ventilation Systems
A) Minimum radiation exposure to personnel during filter removal	Yes, standard CVI design	Yes, standard CVI design	Yes, standard CVI design	Yes, standard CVI design
B) Accessibility to components	All components are readily accessible without temporary ladder or scaffolding	Temporary platform required for access to prefilter and HEPA filter cells	All components are readily accessible without temporary ladder or scaffolding	Temporary platform required for access to prefilter and HEPA filter cells
C) Filter housing provided with adequately sized door with hinges	Filter housing provided with adequately sized door with hinges	Yes, at least one for each compartment	Yes, at least one for each compartment	Yes, at least one for each compartment
D) Adequate spacing between filter banks	Yes	Yes	Yes	Yes
E) Provision for alignment and support of elements during filter change	Standard CVI design	Standard CVI design	Standard CVI design	Standard CVI design
F) Adequate spacing between filter elements	Yes	Yes	Yes	Yes
G) Use of material handling facilities	Yes	Yes	Yes	Yes
H) Provision for permanent test probe with external connection	Yes	Yes	Yes	Yes
I) Periodic operation of ACS train	Yes	No, containment isolation valves must remain closed during power operation	Yes	Yes

Table 9.4-3 (continued)

REGULATORY GUIDE POSITION 4: ENVIRONMENTAL DESIGN CRITERIA	Control Room Ventilation System(2)	Containment Purge System	Penetration Room Ventilation System	Auxiliary Bldg and Fuel Handling Floor Ventilation Systems
J) Filter elements installed after active construction	Yes	Yes	Yes	Yes
K) Adequate vapor-tight lighting in filter housing	At least one in each compartment	At least one in each compartment	At least one in each compartment	At least one in each compartment
L) Electrical, water and compressed air services nearby but not inside housing	Yes	Yes	Yes	Yes
M) Ledges and sharp edges should be avoided	Yes	Yes	Yes	Yes

REGULATORY GUIDE POSITION 5: ENVIRONMENTAL DESIGN CRITERIA	Control Room Ventilation System(2)	Containment Purge System	Penetration Room Ventilation System	Auxiliary Bldg and Fuel Handling Floor Ventilation Systems
A) Even air flow distribution to filters	Yes	No, volumetric flowrate obtained per Section 8 of ANSI-N510-1980	Yes	Yes
B) In-place test of HEPA filter in conformance to ANSI Standard	Conform to ANSI-N101.1-1972	Conform to Section 10 of ANSI-N510-1980	Conform to ANSI-N101.1-1972	Conform to ANSI-N101.1-1972
C) In-place test of adsorber in accordance with USAEC Report	Conform to USAEC Report DP-1082 ORNL-NSIC-65	Conform to Section 12 of ANSI-N510-1980	Conform to USAEC Report DP-1082 ORNL-NSIC-65	Conform to USAEC Report DP-1082 ORNL-NSIC-65

Table 9.4-3 (continued)

REGULATORY GUIDE POSITION 6: ENVIRONMENTAL DESIGN CRITERIA	Control Room Ventilation System(2)	Containment Purge System	Penetration Room Ventilation System	Auxiliary Bldg and Fuel Handling Floor Ventilation Systems
A) If the activated carbon adsorber meets the regulatory requirement, the adsorber section should be assigned the decontamination efficiencies. If not, the carbon should not be used in ESF adsorbers	Carbon meets regulatory requirements as tested by manufacturer	Carbon meets regulatory requirements as tested by manufacturer	Carbon meets regulatory requirements as tested by manufacturer	Carbon meets regulatory requirements as tested by manufacturer
B) The efficiency of the adsorber should be determined by laboratory testing of representative samples of the activated carbon exposed simultaneously to the same service conditions as the adsorber section	Three test cannisters are provided in adsorber bank for periodic testing by supplier in laboratory	Three test cannisters are provided in adsorber bank for periodic testing	Three test cannisters are provided in adsorber bank for periodic testing by supplier in laboratory	Three test cannisters are provided in adsorber bank for periodic testing by supplier in laboratory
C) The user should prepare detailed procedures for each required field and laboratory test suggested by the regulatory guide	Yes	Yes	Yes	Yes

Note:

1. All of Table 9.4-3 is in response to NRC questions.
2. This column is applicable to 2VSF-9 and associated filters. Redundant unit is VSF-9 and is part of Unit 1. See Docket No. 50-313 for details of Unit 1 design.

APPENDIX 9A

FIRE PROTECTION PROGRAM

9A.1 PROGRAM DESCRIPTION

The Arkansas Nuclear One Fire Protection Program is defined as the following documents:

- section 9.5 of the Safety Analysis Report (SAR),
- the Operability, Surveillance, and Administrative Requirements (located in the SAR Appendix 9D),
- the 2012, 2013, and 2014 NFPA 805 submittals, and
- the 2015 NFPA 805 Safety Evaluation Report.

9A.2 SCOPE AND APPLICABILITY

The ANO Fire Protection Program has been incorporated into the SAR per Generic Letters 86-10 and 88-12. The Program is described in Section 9.5 and Appendices 9A through 9D.

The purpose of the Fire Protection Program is to extend the concept of defense-in-depth to fire protection in fire areas important to safety with the following objectives:

- To prevent fire from starting,
- To detect rapidly, control, and extinguish promptly those fires that do occur,
- To provide protection for structures, systems, and components important to safety so that a fire that is not promptly extinguished by fire suppression activities will not compromise the ability to achieve the safe shutdown of the plant.

The Fire Protection Program also delineates the responsibilities and the methods to be used to accomplish the objectives stated above. The Fire Protection Program will interface with other ANO manuals, plans and procedures to provide an effective and coordinated Fire Protection Program that encompasses all phases of operation, administration, and maintenance.

9A.3 ORGANIZATION AND RESPONSIBILITY

The personnel and organizations responsible for the oversight, implementation and maintenance for the ANO Fire Protection Program are described in SAR Section 13.1.1.

9A.4 ADMINISTRATIVE CONTROLS AND PROCEDURES

The ANO Fire Protection Program is controlled and maintained by various plant procedures that includes but not limited to implementing procedures, operational procedures, maintenance procedures, surveillance procedures, etc.

9A.5 FIRE HAZARDS ANALYSIS

The ANO Fire Hazards Analysis (FHA) is described in the SAR Appendix 9B.

9A.6 SAFETY EVALUATION REPORTS

ANO received a Safety Evaluation Report for the Fire Protection Program in 1978 and another one for Appendix R exemptions in 1988. These documents are numbered 2CNA087801 (2N-78-126) for 1978 and 2CNA108802 for 1988.

In 2012, ANO-2 submitted a request to revise the licensing basis from Appendix R to NFPA 805 as allowed by 10 CFR 50.48(c) (letter number 2CAN121202). ANO-2 received a Safety Evaluation Report for the revised Fire Protection Program in 2015 (letter number 2CNA021502)

9A.7 SAFE SHUTDOWN SYSTEMS

A listing of safe shutdown systems and the methodology used to ensure that modifications do not affect the ability to achieve a safe and stable condition following a fire are included in the FHA (SAR Appendix 9B).

9A.8 FIRE PROTECTION SYSTEMS

The ANO fire protection systems consists of fire pumps and distribution header, sprinkler systems, detection systems, hose reels, portable extinguishers, barriers, etc. A description of the fire protection systems may be found in the SAR Section 9.5.

9A.9 QUALITY ASSURANCE

Appropriate QA program controls ensure that the Fire Protection Program is maintained in accordance with the overall ANO QA Program.

9A.10 FIRE BRIGADE

Fire Brigade staffing, training, etc. may be found in the SAR Section 9.5.

APPENDIX 9B

FIRE HAZARDS ANALYSIS REPORT

The ANO Fire Hazards Analysis (FHA), maintained under separate cover, is considered part of the Fire Protection Program described in Appendix 9A of the SAR and as such is subject to the provisions of ANO Operating Licensing Condition 2.C.(3)(b).

APPENDIX 9C

SAFE SHUTDOWN CAPABILITY ASSESSMENT

DELETED

APPENDIX 9D

FIRE PROTECTION SYSTEM ADMINISTRATIVE REQUIREMENTS

Appendix 9D contains the Administrative Requirements related to Fire Protection Systems. These requirements were relocated from the ANO-2 Technical Specifications in accordance with Generic Letter 88-12. Other Fire Protection System requirements have been relocated to the ANO-2 Technical Requirements Manual.

9D.1 ADMINISTRATIVE REQUIREMENTS

9D.1.1 FIRE BRIGADE

A site Fire Brigade of at least 5 members shall be maintained onsite at all times. The Fire Brigade shall not include 3 members of the minimum shift crew necessary for safe shutdown of the unit and any personnel required for other essential functions during a fire emergency.

9D.1.2 TRAINING

A training program for the Fire Brigade shall be maintained and shall meet or exceed the requirements of Section 3.4.3 of NFPA 805, as approved in the NRC Safety Evaluation Report associated with the transition to NFPA 805.

10 STEAM AND POWER CONVERSION SYSTEM

This chapter provides information concerning the Steam and Power Conversion System (SPCS). The SPCS includes the steam system, turbine generator, main condenser and other auxiliary subsystems.

This description is provided to allow an understanding of the SPCS with an emphasis on those aspects of the design and operation of the system that affect the reactor and its safety features. Information is provided to show the capability of the system to function without compromising the nuclear safety of the plant under both normal operating or transient conditions. The radiological aspects of the normal operation of the system are summarized in this chapter, and are presented in detail in Chapter 11.

10.1 SUMMARY DESCRIPTION

The SPCS converts a portion of the thermal energy of the steam produced in the two steam generators into electrical energy. The steam is subsequently condensed and returned to the steam generators as heated feedwater.

The system also removes decay heat from the reactor core by bypassing steam to the main condenser or dumping to atmosphere prior to initiation of shutdown cooling.

The steam generated in the two generators is supplied to the high pressure turbine and to the second stage of the moisture separator reheaters. Upon leaving the high pressure turbine, it passes through the moisture separator-reheaters and then is admitted to the two low pressure turbines. A portion of the steam is extracted from the turbines for feedwater heating, first stage moisture separator reheaters, the main feedwater pump turbines, and the auxiliary steam system heating steam header. Main steam is also available to the emergency feedwater pump turbine, gland sealing steam, main feedwater pump turbine during startup, auxiliary steam system and the ANO Unit 1 auxiliary steam system via the boric acid concentrator (2M39) and the waste concentrator (2M41) supply header.

Exhaust steam from the low pressure turbines is condensed and deaerated in the main condenser. The heat rejected to the main condenser is removed by the closed loop circulating water system utilizing a natural draft cooling tower. The condensate pumps take suction from the condenser hotwell and deliver the condensate through two low pressure feedwater heater trains of five stages each to the suction of the main feedwater pumps. The main feedwater pumps discharge the feedwater through two high pressure feedwater heater trains of two stages each to the two steam generators. Drains from the moisture separator-reheaters and the two high pressure and one low pressure feedwater heater stages are collected in the heater drain tank and returned to the suction of the main feedwater pumps by the heater drain pumps. Drains from the remaining four low pressure feedwater heater stages are cascaded and ultimately returned to the condenser.

The flow diagrams, design performance characteristics, and safety-related design features of the SPCS are described in the remaining sections of Chapter 10.

10.2 TURBINE GENERATOR

The turbine generator receives steam from the two steam generators and converts a portion of the available enthalpy into electrical energy. Figures 10.2-1 10.2-3, 10.2-4, and 10.2-6 show the turbine generator design features and the related flow diagrams.

10.2.1 DESIGN BASES

The turbine generator is designed for variation in steam pressure as shown in Figure 10.2-1, and also for steam pressure and temperature transients which will occur following a sudden loss of electrical load.

"Base-load" operation is intended for the turbine generator unit. Turbine generator gross electrical output corresponding to nominal full reactor coolant system power output (3,044 MWt) and lowest anticipated condenser cooling water temperature (65 °F) was originally 958 MWe. During 2R14, the original steam generators were replaced with larger replacement steam generators (RSG) to accommodate the anticipated 107.5% power uprate to 3044 Mwt during 2R15. Concurrent with the RSG installation during 2R14, the high pressure (HP) and low pressure (LP) turbines were redesigned to optimize plant operation from Operating Cycle 15 forward.

Because the Nuclear Steam Supply System (NSSS) was designed with the capability of automatically accepting a step load change of 10 percent and ramp load change of five percent per minute over the load range of 15 to 100 percent, the rate of load change of the turbine generator is restricted to these values, although it has a capability of accepting load change at faster rates. In the current configuration which has the atmospheric dump valves (ADVs) located upstream of the main steam isolation valves (MSIVs) blocked closed, automatic operation of the SDBS can accept a load rejection of up to 49% power without a reactor trip.

The turbine generator and accessories are classified as Seismic Category 2 and are designed in accordance with industry standards and, where applicable, in accordance with the requirements of ANSI Code for Pressure Piping, TEMA Standards for Heat Exchangers, NEMA Standards, IEEE Standards, Hydraulic Institute Standards, and regulations of the National Board of Fire Underwriters.

To ensure continued conformance with these design bases, an inspection program has been established for the turbine. The turbines and valves will be disassembled for inspection, overhaul, and cleaning on a scheduled basis. The frequency of the inservice inspection of any piece of equipment depends on its operating history at Arkansas Nuclear One - Unit 2 as well as in other similar nuclear units.

10.2.2 SYSTEM DESCRIPTION

The turbine is a General Electric impulse-reaction, 1,800 rpm, tandem-component, 4-flow, 2-stage reheat unit with 43-inch last stage buckets. It is an indoor unit with a design throttle flow (valves wide open) of approximately 13.6 X 10^6 lb/hr at approximately 1.18"/2.05" Hga backpressure and zero makeup with initial steam conditions of approxmately 896.0 psia at 1194.9 Btu/lb. The design flow is 103 percent of rated flow at 900 psia to insure turbine Maximum Guaranteed Rating (MGR) is met. The turbine supplies extraction steam to seven stages of feedwater heaters, two main feedwater pump turbine drivers, and the auxiliary steam system heating steam header.

Steam leaving the high pressure turbine is dried and superheated by passing through two moisture separator-reheater units in parallel and then to two low pressure turbines. A portion of the main steam and the first stage extraction steam is bypassed to the 2-stage reheaters as the heat source.

The generator is a direct driven, 3-phase, 60-cycle, 22 kV, conductor cooled synchronous unit rated at 1,133,334 KVA at 60 psig hydrogen pressure, 0.95 power factor and 0.58 short circuit ratio. The exciter is direct-driven and is of the silicon diode rectifier type rated at 465 volts and 2,555 kW.

10.2.2.1 Turbine Generator Auxiliary Systems

The generator accessories include the following:

A. A seal oil system with shaft glands to prevent hydrogen leakage,

B. A closed loop hydrogen system to cool the generator field windings,

C. A closed loop demineralized water system to cool the stator windings,

D. An exciter air cooler,

E. A rectifier section,

F. An exciter field breaker, and

G. An automatic voltage adjuster and a manual voltage adjuster.

During degassing or hydrogen filling operations, the generator casing is purged using an inert gas (CO_2) to prevent fires or explosions. The purging operation is monitored utilizing a gas analyzer to insure the casing contains greater than 95 percent CO_2 when purging H_2 out of the generator and greater than or equal to 70 percent CO_2 when purging air out of the generator. During operation, H_2 purity is indicated in the Control Room and alarmed at 90 percent.

Accessories for the turbine include combination moisture separator-reheaters, steam seal system, bearing lubricating oil system, electrohydraulic control system and supervisory instruments.

The turbine has one double-flow, high pressure element in tandem with two double-flow, low pressure elements. Moisture separation and 2-stage reheating of the steam are provided between the high pressure and low pressure elements, with two horizontal-axis, cylindrical-shell, combined moisture separator reheater assemblies. One assembly is located on each side of the high pressure turbine element.

Steam from the two steam generators is supplied to the turbine generator unit. The steam enters the high pressure turbine through four stop valves and four control valves. The eight valves comprise the valve steam chest assembly with an equalizer line between the stop and control valves. After expanding through the high pressure turbine, steam flows through the combined moisture separators and 2-stage reheaters, and then through combined intermediate valves to two low pressure turbines.

The two moisture separators drain to separate drain tanks, which in turn discharge to the two high pressure heater drain tanks. The drains from these tanks are then pumped to the suction of the feedwater pumps. Extraction steam from the high pressure turbine is supplied to the first reheater stage tube bundle in each reheater. Each bundle drains to its drain tank and subsequently to the shell side of Feedwater Heater 2 in the appropriate heater train. Main

steam is supplied to the second reheater stage tube bundle in each reheater. Each second stage bundle also drains to its drain tank and subsequently to the shell side of Feedwater Heater 1 in the appropriate heater train.

To prevent reheater tube bundle flooding and consequent reheater drain instabilities, a scavenging steam system has been added to the moisture separator reheaters. This system has the effect of increasing steam flow through the tube bundle.

A turbine gland sealing system, using steam to seal the annular space where the shaft penetrates the casings, prevents steam outleakage or air inleakage along the shaft. A description of the turbine gland sealing system is given in Section 10.4.3.

The turbine generator bearings are lubricated by a pressurized lube oil system. During normal operation, bearing oil is provided from the discharge of one end of a double-ended oil turbine. The oil turbine is driven by high pressure (about 200 psig) oil supplied by a centrifugal pump mounted on the extension of the turbine generator shaft. During normal operation the other end of the oil turbine provides pressure to satisfy Net Positive Suction Head (NPSH) requirements of the shaft pump. During startup and shutdown (low shaft speed), an AC motor-driven turning gear oil pump and an AC motor suction pump supply bearing oil to the turbine generator and shaft oil pump, respectively. A DC motor-driven emergency bearing oil pump is provided to supply bearing oil in case of loss of AC power.

10.2.2.2 Electrohydraulic Control System

The turbine generator unit is equipped with an electrohydraulic control system to control the steam flow through the turbine. The control system consists of three major subsystems: a speed control unit, a load control unit, and a valve flow control unit.

The speed control unit compares actual turbine speed with a speed reference or actual acceleration with an acceleration reference and provides a speed error signal for the load control unit. The load control unit provides the proper bias and determines desired steam flow signals for the flow control units of the main stop valves, control valves, and intercept valves. The valve flow control units in turn position all the steam admission valves to obtain required steam flow through the turbine.

The flow control of the main steam entering the high pressure turbine is accomplished by the use of four parallel systems each of which consists of a stop valve and a governing control valve in series. Each stop valve is controlled by an electrohydraulic servoactuator so that it is either fully open or fully closed. The function of the stop valves is to shut off the flow of steam to the turbine when required. They close within three to five seconds by actuation of an emergency trip system which is independent of the electronic flow control units.

The turbine control valves are positioned by an electrohydraulic servoactuator in response to a signal from the flow control unit. The flow control unit signal positions the control valves for speed control during startup of the turbine and for load control after the turbine generator unit is synchronized.

The valves located in the crossover lines are combination reheat stop and intercept valves in one casing and control steam flow to the low pressure turbines. During normal operation of the turbine, the intermediate stop and intercept valves will be wide open. The intercept valve flow control unit positions the valve during startup and normal operations and closes the valves rapidly on turbine overspeed due to loss of load. The reheat stop valves close completely on any turbine trip.

The rate sensitive power-load unbalance relay in the load control unit acts to prevent a turbine generator overspeed trip following a sudden loss of electrical load. If a power load unbalance of 40 percent or greater exists, the power load unbalance relay will close the control valves until the power and load signals are back in balance. As the turbine accelerates, the control and intercept valves will be closed at the maximum rate by means of fast-acting solenoid valves, actuated by the power load unbalance relay, to prevent the unit from reaching the overspeed trip setting. Closure of the main and reheat stop valves on an overspeed trip is the second line of turbine protection.

10.2.2.3 Turbine Generator Overspeed Protection

Figures 10.2-3, 10.2-4, and 10.4-3 illustrate the steam path between the steam generators and the turbine. As shown, main and secondary steam inlets have two valves in series to control the flow of steam into the turbine. The operation of these valves to prevent excessive turbine overspeed is as follows.

A. Speed Sensing

1. The operating speed signal is obtained from two magnetic pickups on a toothed wheel at the high pressure turbine shaft. Increase of any one of the speed signals tends to close control and intercept valves.

   a. Loss of one of the speed signals will transfer control to the other speed signals.

   b. Loss of both speed signals will actuate the emergency trip system through two (redundant) trip signals. The operation of both speed signals is continuously monitored by the alarm system.

2. The mechanical overspeed trip will actuate the emergency trip system directly upon reaching its set speed (approximately 110 percent of rated speed).

   The overspeed trip mechanism consists of an eccentric weight mounted on the turbine shaft, which is held concentric with the shaft by a spring until the speed reaches approximately 110 percent of rated speed. Centrifugal force then overcomes the spring force and the weight flies out, striking a trigger which actuates the overspeed trip valve and releases the emergency trip system fluid to drain. The resulting decrease in emergency trip system fluid pressure causes the emergency trip valve to dump the hydraulic fluid pressure to drain, thereby closing the main stop and control valves and the combined intermediate stop and intercept valves. The operation of the overspeed trip mechanism and the mechanical trip valve can be tested during normal operation.

3. The electrical backup overspeed trip will trip the emergency trip fluid system through two (redundant) trip signals upon reaching its set speed (approximately 112 percent of rated speed). The speed signal is obtained from the third magnetic pickup on the toothed wheel at the high pressure turbine shaft.

   The operation of the backup overspeed trip and the electrically operated master trip solenoid valves can be tested during normal operation. Therefore, there are three independent levels of speed sensing normally in operation and two levels as a minimum during the short period used to test either one of the two overspeed trip devices.

B. Steam Flow Controlling Valves

1. For the main and secondary steam inlets, two valves are used in series.

   a. Control valves are normally controlled by the speed control unit and closed rapidly when pressure in the emergency trip fluid system is removed by any of the redundant trip valves.

   b. The main stop valves are held open by pressure in the emergency trip fluid system and tripped closed rapidly upon removal of the pressure in this system.

2. Combined stop and intercept valves - Such valves are required where the energy storage in reheaters or moisture separators is sufficient to accelerate the turbine generator to excessive overspeed on loss of load. Two independently operated valves are arranged in series in one valve body.

   a. The intercept valves are normally wide open but are closed by the speed control unit upon a moderate speed increase and are tripped closed rapidly upon removal of the pressure in the emergency trip fluid system.

   b. Reheat (or intermediate) stop valves are normally open but are closed rapidly upon removal of the pressure in the emergency trip fluid system.

3. Uncontrolled extraction lines to feedwater heaters - If the energy stored in an uncontrolled extraction line is sufficient to cause a dangerous overspeed, two positive closing non-return valves are required in series. These valves are actuated upon low hydraulic trip fluid pressure caused by operation of either the mechanical or electrical backup overspeed trip. These valves are designed for remote manual periodic tests to ensure proper operation. The extraction lines to the feedwater heaters and check valve systems were reviewed during the design stages to verify that the entrained steam between the turbine, feedwater heaters, and the non-return valves cannot overspeed the unit beyond safe limits.

Both the number and type of non-return valves were reviewed to confirm that the turbine designer's recommendations have been followed. Reviews are also made of proper techniques of inspection and maintenance of governor and protective valves with the purchaser prior to initial startup and at subsequent inspections.

Special tests are made of new components to confirm proper operation. Such special tests include the capability of controls to prevent excessive speed.

All steam control valves are periodically exercised to insure that they are free to operate in the event of a turbine trip.

10.2.2.4 Turbine Generator Trips

In order to protect the turbine generator, various supervisory instruments and the following protective trips independent of the speed control subsystem are provided. Any of the following trips will cause tripping of all turbine steam admission valves:

A. overspeed trip (mechanical)
B. backup overspeed trip (electrical)
C. low vacuum trip
D. excessive thrust bearing wear trip
E. reactor trip
F. generator electrical trips (see Chapter 8)
G. manual trip from control room
H. excessive vibration trip
I. manual located at the turbine
J. moisture separator drain system high level trip
K. prolonged loss of stator coolant
L. low hydraulic fluid pressure trip
M. loss of both speed signals
N. loss of bearing oil pressure
O. shaft pump discharge low pressure
P. loss of 125-volt DC to EH controller
Q. 500 kV breaker 5130/5134 failure.

In addition to the devices listed above, the turbine and steam systems are equipped with the following protective devices:

A. automatic load runback to less than 27 (approximately 25) percent of full load in the event of loss of cooling water to generator stator or high stator coolant outlet temperature;

B. safety valves on the shell side of the moisture separator-reheater to protect the high pressure turbine cylinder from overpressure in the event of a turbine trip;

C. extraction line non-return valves to protect the turbine from overspeed due to reverse flow in the event of a turbine trip and,

D. exhaust casing rupture diaphragms to protect the low pressure turbine cylinders from overpressure in the event of loss of condenser vacuum.

Various parameters for the turbine generator auxiliary systems are recorded and alarmed in the control room and logged on the plant computer. A full compliment of controls and instruments are provided in order that the turbine generator may be started, operated, tested, and shut down from the control room.

10.2.3 TURBINE MISSILES

Because of the redundancy and reliability of the turbine control and protection system, the close control of oil purity, the periodic check of steam admission valve freedom, and the high value of the bursting overspeed, any missile resulting from a turbine generator overspeed incident is hypothetical only and not considered credible.

An analysis of the probability of a hypothetical turbine failure missile is provided in Section 3.5. Previous analyses concentrating on the consequences of a hypothetical turbine missile are provided in Reference 75 of that section, and particularly the references listed in the General Electric Company Memo Report dated March 14, 1973, "Hypothetical Turbine Missiles - Probability of Occurrence," by J. E. Downs (Reference 53 of Section 3). As the discussion in Section 3.5 shows, damage to critical plant components is so improbable as not to require specific protective shielding against hypothetical turbine failure missiles. The discussion below summarizes the major point provided in the references of Section 3.5.

A study of all turbine generator rotating elements' failures known to the Turbine Division of General Electric has indicated that the failures are of two general types:

A. failure of rotating components operating at or near normal speed; and,

B. failure of components that control steam admission to the turbine resulting in excessive shaft rotation speed.

The present advanced state-of-the-art of rotor forgings and inspection techniques, plus the experience gained from past documented incidents guarantees, for all practical purposes, defect free turbine rotors. Therefore, the generation of missiles as a result of turbine failure at or near normal speed is not considered credible.

The turbine generator speed control and overspeed protection system is discussed in Section 10.2.2 above. As the discussion shows, it takes the simultaneous failure of three independent control systems which operate two steam admission valves in series before the turbine generator can exceed the design speed (120 percent of rated speed). Therefore, overspeed beyond 120 percent of rated speed is highly improbable. Also significant is that above 150 percent of rated speed turbine component failures which do not produce missiles would cause braking of the turbine. However, the low pressure turbine last stage bucket vanes, which constitute the most severe hypothetical turbine missile, are not postulated to fail until overspeed reaches 177 percent of rated speed. Therefore, turbine failure missiles of the second type, as a result of excessive overspeed, are even less probable than failure of the three independent overspeed trip systems.

10.2.4 EVALUATION

The steam generated in the two steam generators is not normally radioactive. Only in the event of primary-to-secondary system leakage (due to a steam generator tube leak) is it possible for the SPCS to become radioactively contaminated. In this event, monitoring of condenser air discharge will detect any contamination. A full discussion of the radiological aspects of primary-to-secondary leakage, including anticipated operating concentrations of radioactive contaminants, means of detection of radioactive contamination, anticipated releases to the environment, and limiting conditions for operation, is included in Chapter 11.

A description of the protection provided by bypassing and dumping main steam to the condenser and atmosphere in case of sudden load rejection by the turbine generator is included in Section 10.4.4. A description of the protection provided by exhausting steam to the atmosphere through the safety valves in the event of a turbine generator trip and coincident failure of the SDBS is given in Section 10.3.

The protection of the plant against hypothetical missiles generated due to failure of turbine generator rotating parts is discussed in Sections 3.5 and 10.2.3.

10.3 MAIN STEAM SUPPLY SYSTEM

The Main Steam System (MS) carries the steam generated in the two steam generators through the containment wall to the following major components:

A. turbine generator
B. moisture separator reheaters
C. turbine shaft gland seals
D. main feedwater pump turbines
E. turbine-driven emergency feedwater pump
F. Steam Dump and Bypass System (SDBS) valves.
G. Boric acid concentrator and waste concentrator

10.3.1 DESIGN BASES

The MS is designed to convey steam generated by the steam generators to the turbine generator and to other auxiliary equipment for power generation. It supplies steam to the high pressure turbine and to the moisture separator reheaters during normal plant operation, to the turbine gland seals during low load, and to the main feedwater pumps steam turbine drivers during low loads or whenever low pressure steam is not sufficient. It may also supply steam to ANO Unit 1 via the boric acid concentrator (2M39) and waste concentrator (2M41) supply header.

The MS is designed to remove the heat generated in the Nuclear Steam Supply System (NSSS) during normal load, plant startup, hot standby, hot shutdown and normal cooldown, and to permit load reductions of up to full load. This function is accomplished by means of the SDBS in conjunction with the main condenser, Emergency Feedwater (EFW) System and/or main steam safety valves. The SDBS is discussed in Section 10.4.4 and the EFW System in Section 10.4.9.

The MS is designed to provide isolation of the steam generators from other components of the system by means of the main steam isolation valves following a hypothetical main steam line break.

The MS is designed to provide an assured source of steam to operate the emergency feedwater pump turbine driver.

10.3.2 SYSTEM DESCRIPTION

10.3.2.1 General Description

The MS is shown schematically in Figure 10.2-3. The major components are: two 38-inch main steam lines, one coming from each of the two steam generators and each provided with a venturi flow element; main steam safety valves (five in each line); main steam isolation valves (MSIVs); steam supply lines to the EFW pump steam turbine driver and to the atmospheric dump valves. The main steam piping up to and including the main steam isolation valves outside of the containment is safety-related and designed to meet Seismic Category 1 and ASME Code, Section III, Class 2 requirements. Certain sections of main steam piping are classified as Critical Pipe. Critical Pipe lines are designed to meet the requirements of ANSI B31.1.0, and additionally, to meet the requirements of ASME Code Section III Class III

requirements with respect to repair of defect, material traceability, and nondestructive tests." The quality group classifications for the main steam piping and Seismic Category 1 components of the MS are listed in Section 3.2.2. The MS piping inside containment is environmental Category 1-B (see Section 3.11). All other components of the system are located outside containment and are environmental Category 1-E (see Section 3.11).

The main steam lines carry the total steam flow from the steam generators. The main steam penetration design is discussed in Section 3.8.1.4.2 and is shown in Figure 3.8-9. Each line is anchored to the containment wall and is routed to provide sufficient flexibility for movement of the steam generators and piping due to thermal expansion.

Each main steam line is furnished with a venturi flow element installed at the steam generator outlet inside the containment. The venturi flow element is used to measure steam flow derived from differential pressure measurement during normal plant operation. The venturi flow element can also function to limit the blowdown rate following a postulated pipe rupture in the main steam line; however, the main steam flow restrictors installed in the steam generator outlet nozzles are credited with performing this function (see Section 5.5.4).

Each main steam line has a radiation monitor attached between the containment penetration and the main steam safety valves. The purpose of these monitors is to provide indications of primary-to-secondary reactor coolant leakage as early as possible.

Each main steam line has an unattached radiation monitor between the main steam stop valves and the turbine stop valves. The purpose of these monitors is to detect N-16 gamma radiation, which will provide very rapid indication of the affected steam generator and the rate of primary-to-secondary reactor coolant leakage.

The main steam safety valves are provided to limit steam generator pressure to 1,210 psia as allowed by the ASME Code.

The main steam safety valves provided in the MS are designed in accordance with ASME Code, Section III, Class 2. The design capacities of the safety valves are as shown in Table 10.3-1. The total capacity of the safety valves is sufficient to pass greater than 100 percent of the steam flow generated at rated load. The setpoint of one safety valve on the main steam line from each steam generator is equal to or less than the steam line design pressure. The other valves are set to open at higher pressures, as shown in Table 10.3-1. Pressure will not exceed 1,210 psia which is 110 percent of steam generator line pressure, in accordance with ASME Code, Section III, Class 2.

The spring loaded, dual outlet main steam safety valves are installed on the main steam lines upstream of the main steam isolation valves. The arrangement is such that the valves with lower setpoints are installed ahead of the higher setpoint valves, in numerical order, in the direction of flow.

The main steam isolation valves are provided to isolate the steam generators from the rest of the secondary system in the event of a postulated MS failure as discussed in Section 15.1.14. The valves are designed in accordance with ASME Code, Section III, Class 2. Each valve is a spring loaded, Y-pattern globe designed to function both as an isolation valve and a non-return valve. As an isolation valve, it is designed for tight shut off and fast closing. The MSIV closure time is controlled by a hydraulic speed control, regardless of pressure differential across the valve which may be caused by varying loads on the disk. As a result, the seating velocity is not sufficient to cause significant impact loading of the disk. As a non-return valve, downstream

pressure is internally ported to the top side of the main valve disk, maintaining the valve in the closed position. The valve is designed such that in the closed position, steam leakage in either direction past the valve seats shall not exceed 5 cfs. The valves can not be tested during normal operation without causing severe system transients. Therefore, they are provided with an exercise mode which allows the valves to be cycled from full open to 90 percent open and back to full open during power operation. This ensures that the valve stems are free to move in the event a rapid closure is required.

Full stroke testing of the actuation system can be accomplished during scheduled plant shutdown periods and is performed in accordance with Technical Specification requirements. The valves are furnished with a common accumulator which provides backup motive air to the valves. These are the only valves of this type in any safety-related system. In case of a line break in the non-Seismic Category 1 portion of the air supply line, the accumulator delivers required air to replenish leakage and prevent an undesired fast closing of the valves. This feature is intended to prevent interruption of power generation and is not required for plant safety. During normal plant operation the main steam isolation valves are open and may be controlled (closed) either remote manually or automatically. Redundant Main Steam Isolation System (MSIS) signals are provided to the solenoid air supply valves of each MSIV (see Figure 10.3-1) from independent ESF power supplies. Either signal is adequate to cause a rapid closure of the MSIV.

The branch piping leading to the emergency feedwater turbine and to the upstream atmospheric dump valves is installed upstream of the main steam isolation valves. This arrangement insures that steam to these systems is available with the main steam isolation valves closed.

10.3.2.2 <u>System Operation</u>

Plant startup is effected by means of the Auxiliary Feedwater Pump operating in conjunction with the SDBS. When sufficient heat is generated in the NSSS, feedwater supply operation is shifted over to the Condensate and Feedwater System (CFWS). At low power levels, main steam is supplied to the main feedwater pump turbine drivers and the turbine gland sealing system. At higher power levels, the steam supply to the feed pump drivers is transferred from main steam to the output of the moisture separator reheaters.

If a large, rapid reduction in power demand occurs, the SDBS exhausts steam to the condenser and/or atmosphere to prevent tripping of the reactor. In case the condenser is not available as a heat sink, e.g., high condenser back pressure caused by loss of circulating water, the turbine bypass valves are blocked closed. Steam is then exhausted to the atmosphere through the atmospheric dump valves or main steam safety valves for decay heat removal.

10.3.3 SAFETY EVALUATION

Heat dissipation requirements during plant startup, hot shutdown, and cooldown are normally met by bypassing steam to the condenser via the turbine bypass system described in Section 10.4.4. If the bypass system is not available, the atmospheric dump valves are adequately sized to remove decay heat in the event of plant shutdowns. In the current configuration which has the atmospheric dump valves (ADVs) located upstream of the main steam isolation valves (MSIVs) blocked closed, automatic operation of the SDBS can accept a turbine generator load rejection of up to 49% without a reactor trip and without lifting any main steam safety valves. Failure of the SDBS to function during turbine reactor power mismatch will result in a reactor trip and main steam pressure will rise. However, the main steam safety valves, which are adequately sized to permit load rejection from full power, will open and prevent pressure rise above 110 percent of the maximum allowable pressure for the steam generators.

In the unlikely event of a main steam line rupture, a Main Steam Isolation Signal (MSIS) or Containment Spray Actuation Signal (CSAS) terminates feedwater flow to the affected steam generator and provides for timely isolation of the intact steam generator (see Section 7.3.1.1.11.4).

The main steam isolation valves (MSIVs) will receive a CSAS or an MSIS close signal and the valves will close in 3.0 ± 0.3 seconds. The air operators for these valves are furnished with redundant solenoid supply and vent valves to insure that no single electrical failure will prevent MSIV closure. If the break occurs upstream of the valve, the valve will be maintained in the closed position due to downstream line pressure being internally ported to the topside of the main valve disk. The leakage through the valve in the direction towards the break (reverse flow) will not exceed 5 cfs. This is less than the maximum allowable leak inward to the containment (15 cfs). If the failure occurs downstream of the MSIV, the pressure acting on the disc will maintain the valve tightly closed and will show no discernable leakage. CSAS and MSIS are provided to close the main feedwater isolation valves, the backup isolation valves, and the main feedwater pump turbine steam supply valves. The condensate pumps in both condensate/feedwater trains and the heater drain pumps are also tripped by CSAS and MSIS. This prevents the addition of feedwater to the affected steam generator. A MSIS is also provided to each motor operated atmospheric dump isolation valve as additional conservatism and to ensure closure. Table 10.3-4 contains a single failure analysis which demonstrates the adequacy of CSAS or MSIS to perform the above described design function. Either train of CSAS or MSIS will actuate isolation of main feedwater and main steam. The flow restrictors in the main steam lines limit the rate of blowdown of steam from the steam generators following a postulated steam line break.

Following a main steam line break, the water level in the intact steam generator is maintained by the emergency feedwater (EFW) system, which is described in Section 10.4.9. Emergency feedwater system actuation and control are described in Section 7.3.1.1.11.8. The main steam system is arranged such that steam is always available to the emergency feedwater pump turbine driver from either or both steam generators, even when the MSIVs are closed. The steam line to the turbine driver is routed from a header which connects to the two main steam lines upstream of the MSIVs. The motor operated isolation valves installed in the header are normally open. Although the inlet block valve to the turbine is normally closed, during turbine startup a small bypass line is used to pre-heat the turbine before the inlet block valve opens. This arrangement prevents thermal and steam shock to the turbine and the EFW system steam piping system. Flow between the steam generators is prevented by check valves in the lines from each main steam header.

Two sets of SDBS atmospheric dump and isolation valves are provided in the main steam lines upstream of the MSIVs, one set in each main steam line. This arrangement permits controlled release of steam for Reactor Coolant System (RCS) cooling when the MSIVs are closed. This can be accomplished by manual operation either from the control room or MCC handswitches or by using local handwheels.

All safety-related components in the main steam system are designed to perform their intended function in the normal and accident temperature, pressure, humidity, chemical, and radiation environment to which they will be subjected. Environmental design bases and qualifications are discussed in Section 3.11, Environmental Design of Mechanical and Electrical Equipment.

The MS is Seismic Category 1 up to and including the main steam isolation valves, the emergency feedwater pump turbine driver, and the main steam safety valve outlets. Main steam isolation valve air actuation piping is Seismic Category 1 from upstream of the solenoid isolation valves to and including the MSIV actuator. The control and power circuits for the

redundant equipment have been designed in accordance with the separation criteria as described in Section 8.3.1.4, "Independence of Redundant Systems." The MSIS is a part of the Engineered Safety Features Actuation System (ESFAS) and is described in Section 7.3.1.1. The ESFAS/MSIS conformance to safety criteria is described in Section 7.1.2 and the design bases in Section 7.3.1.2. Note the safety related main feedwater valves are not designed to close against the maximum possible header pressure. The valves function to isolate feedwater after forced flow has been terminated. Termination of forced flow is accomplished by stopping of the non-Q main feedwater pumps, condensate pumps, and heater drain pumps.

The analysis of the effects of main steam line breaks and the criteria employed in postulating the break locations are provided in Section 3.6. Isometrics and cutaway views of the main steam headers necessary for the study of pipe break consequences are also provided in Section 3.6.

10.3.4 TESTS AND INSPECTIONS

Historical data removed, to review the exact wording, please refer to Section 10.3.4 of the FSAR.

The MS is hydrostatically tested in accordance with applicable codes. The components are given preoperational and functional tests to insure that they will perform in accordance with design. The closure times of the main steam isolation valves are determined during the preoperational tests of the main steam system. This is accomplished by measuring the elapsed time from the generation of a main steam isolation signal until the valve is closed, as summarized in Section 14.1. The test is repeated during the life of the unit as required by the Technical Specifications.

The MS piping from the steam generators up to and including the main steam isolation valves is equipped with removable insulation for inservice inspection of welds. Likewise, the steam supply piping to the turbine driver is furnished with removable insulation to allow inspection of the welds.

10.3.4.1 Shop Tests

Historical data removed; see Section 10.3.4.1 of the FSAR.

10.3.5 WATER CHEMISTRY

Secondary system chemistry control is accomplished through the implementation of "Steam Generator Water Chemistry Monitoring Unit II" Procedure No. 1000.043 and by:

A. Close control of feedwater, steam generator water and steam quality by sampling and analyzing to limit the amount of impurities which can be introduced into the secondary system.

B. Chemical injection to neutralize the effect of the trace impurities which do enter the condensate and feedwater system, and maintain a pH level to protect the system from corrosion.

C. Blowdown is employed to reduce the total concentration of impurities and additives which accumulate due to the concentrating effect within the recirculating type steam generators. When blowdown recovery is undesirable, blowdown may be diverted to holdup tanks for treatment or discharged directly to the circulating water flume if water chemistry and radioactivity levels permit.

During normal plant operations, a continuous blowdown from each steam generator is maintained. Under abnormal operating conditions this rate may be increased. The actual blowdown rate is determined by steam generator operating water chemistry requirements. The blowdown is normally processed in the startup and blowdown demineralizer system and returned to the condenser.

In general, the feedwater and steam generator water chemistry is based on the volatile chemistry control method. This is accomplished by the use of volatile chemicals for pH control which do not concentrate in the steam generator, by careful control of feedwater impurities, and by maintaining a proper pH and hydrazine residual. The basis of volatile pH control is the exclusion of solids, both insoluble and soluble, from the steam generator. This method employs the injection of a volatile additive for pH control into the secondary water to maintain alkalinity within the feedwater and the steam generator. This reduces the release of corrosion products from metal surfaces. Exclusion of solids limits the accumulation of scale and deposits on steam generator heat transfer surfaces and internals. Scale and deposit formation can alter the thermal hydraulic performance in local regions and, if allowed to concentrate to high levels, may cause corrosion. Ammonium hydroxide, an amine, and/or hydrazine is added to establish the desired pH range (See Procedure 1000.043, "Steam Generator Water Chemistry Monitoring Unit II), but will not concentrate in the steam generator due to their volatility.

The removal of oxygen (O_2) from the feedwater and steam generator water is essential to prevent corrosion of wet steel surfaces. If oxygen corrosion is allowed to proceed without correction, then this can significantly affect the operating lifetime of the secondary system. Oxygen is removed from the feedwater by the use of the deaerating section of the main condensers and by the addition of hydrazine to the feedwater.

Hydrazine is added to the feedwater at the outlet of the condensate pumps to scavenge traces of oxygen. Hydrazine reacts with oxygen to form nitrogen and water, which are volatile and do not add to the steam generator solids concentration.

Additives to the secondary side water, ammonia and/or an amine and hydrazine, are monitored continually by indicating controllers. Quantities and rates of addition of chemicals are controlled by adjusting the hydrazine and ammonia or amine pump strokes as the system requires chemical addition.

The specific conductivity, cation conductivity, pH, and sodium (Na) concentration of the steam generator water are continually monitored by conductivity sensing elements, pH sensing elements, and sodium sensing elements on each steam generator sample cooler discharge line. On the feedwater system, the cation and specific conductivity and pH as well as hydrazine and oxygen monitoring is done by the sensing elements in the sample lines from the last stage feedwater heater outlets (see Figure 9.3-3).

Free hydroxide concentration in the steam generator water is not measured. At power operation (> 5% reactor power), certain impurities (e.g., chloride) in the steam generator water are measured daily when the feedwater sample analysis is done. Ammonia, hydrazine, and amine in the feedwater sample are also analyzed at this time and recorded by the chemistry lab.

The electrical conductivity as well as Na and O_2 content are monitored continually by the use of sensing elements in the sample lines from the discharge of the condensate pumps. Na is also monitored in the sample lines from condenser water boxes to detect condenser leaks (see Figure 9.3-2).

The chemistry limits for steam generator water and feedwater during normal and action level conditions are presented in Procedure 1000.043, "Steam Generator Water Chemistry Monitoring Unit II".

10.4 OTHER FEATURES OF STEAM AND POWER CONVERSION SYSTEM

10.4.1 MAIN CONDENSER

The two-shell, three-pressure main condenser provides a continuous heat sink for the exhaust from the two tandem low pressure turbines and for miscellaneous flows, drains and vents during normal plant operation.

The main condenser also provides a heat sink for steam bypassed directly to the condenser by the steam dump and bypass system (SDBS) during other operating configurations.

10.4.1.1 Design Bases

The main condenser is designed to function as the steam cycle heat sink and collection point for the following flows:

A. main low pressure turbines exhaust
B. main low pressure turbines last-stage moisture removal drains
C. feedwater heaters drain and vent
D. steam seal regulator leakoff
E. steam packing exhauster drain
F. main feedwater pumps turbine exhaust
G. turbine bypass
H. main feedwater pumps recirculation
I. condensate pumps recirculation
J. demineralized water makeup
K. steam generator blowdown tank vent
L. startup and blowdown demineralizer returns
M. miscellaneous equipment dumps, drains and vents.

Design data of the main condenser at normal full load operation of the plant is shown in Table 10.4-1.

The main condenser is also designed to:

A. Condense main steam bypassed directly to the condenser by the turbine bypass system. This condition could occur in case of a sudden load rejection by the turbine generator, a turbine trip, or during startup and shutdown, as described in Section 10.4.4.

B. Provide for removal of noncondensible gases from the condensing steam through the condenser evacuation system, as described in Section 10.4.2.

C. Deaerate the condensate before it leaves the condenser hotwell.

The main condenser is constructed in accordance with the Heat Exchanger Institute Standards for steam surface condensers and is designed to provide for a seismic load of 0.05 g.

10.4.1.2 System Description

The main condenser is a two-pass, two-shell, three-pressure type with divided waterboxes. Each shell is located below its respective low pressure turbine. The tubes in both the low pressure shell and the high pressure shell are oriented transverse to the turbine generator longitudinal axis. The hotwell storage, which is the third pressure zone, is located under both shells.

The condensate flows by gravity from the low pressure shell to the high pressure shell, where it is heated to the saturation pressure of the high pressure shell. The condensate is then heated by the incoming feed pump turbine exhaust steam as it flows by gravity from the high pressure shell to the 75,000 gallon hotwell live storage section. The live storage is the available condensate volume to meet the condensate and feedwater system requirements. One condensate outlet per shell is provided.

An automatic makeup and reject system was originally provided for the condenser to maintain a normal level in the hotwell. On low water level in the hotwell, a control valve opened to admit condensate from the condensate storage tank (CST) into the hotwell through a gravity (vacuum drag) line. On high water level in the hotwell, another control valve opened to reject condensate from the condensate pump discharge to the condensate storage tank. This system is currently not in use; the hotwell level is controlled manually.

During startup, condensate is recirculated from the condensate pumps discharge to the hotwell. To provide cooling, additional high level recirculation lines may be used which enter the hotwell at levels above the tube bundles. This contact with the tube bundles provides sufficient cooling to prevent damage to the startup and blowdown demineralizer resin. It also limits locally high temperatures at the hotwell recirculation penetrations.

Each condenser shell has two tube bundles, each of which is connected to a separate circulation water line through a waterbox. The waterboxes of the two shells are connected in series so that the circulating water passes through the low pressure shell and then through the high pressure shell as shown on Figure 10.4-1.

The condenser tubes are Titanium, B338 GR2. This material was chosen for its excellent resistance to corrosion.

The removal of noncondensible gases from the main condenser is described in Section 10.4.2.

A number of design modifications have been added to the main condenser and condensate and feedwater system to reduce the time required to locate, isolate and repair a condenser leak. These modifications are as follows:

- A 4-point condenser hotwell quadrant sampling system for the purpose of locating a leak is installed.

- A pumping system is installed to allow for quicker draining of the condenser circulating water boxes.

- Climbing rungs are added inside the condenser circulating water boxes for the purpose of reducing the time required to plug a leaking tube.

- A sample cooler is included to improve the quality of the oxygen analysis.

- Two sodium analyzers are installed in the secondary sample system which can sample both feedwater trains. Multiple sample points allow detection of contaminants from the heater drain pumps and detection of leakage between circulating water and secondary side coolant.

- Permanent connections are provided to slug feed the condenser with hydrazine.

10.4.1.3 Safety Evaluation

The main condenser is used to remove residual heat from the Reactor Coolant System (RCS) during the initial cooling period after plant shutdown when the main steam is bypassed to the condenser by the turbine bypass system. The condenser is also used to condense the main steam bypassed to the condenser in the event of sudden load rejection by the turbine generator or a turbine trip.

In the event of a load rejection, the condenser will condense the steam bypassed to it by the SDBS, which is up to 27 percent of full load main steam flow, as well as any steam used by the turbine to maintain house loads. The atmospheric steam dump valves or spring-loaded safety valves will discharge the remaining main steam flow to atmosphere to permit continued reactor operation or to effect safe reactor shutdown and to protect the MS from overpressure.

If the main condenser becomes unavailable during normal plant shutdown, sudden load rejection or turbine generator trip, the atmospheric steam dump valves and the spring-loaded safety valves can discharge full main steam flow to the atmosphere and effect a safe shutdown condition. Non-availability of the main condenser considered here includes failure of circulating water pumps to supply cooling water, failure of condenser evacuation system to remove noncondensible gases, excessive leakage of air through turbine gland packings due to failure of the turbine gland seal system, or failure of the condenser due to any other reason.

Section 10.4.5 discusses the prevention of flooding of the Engineered Safety Features (ESF) equipment located in the auxiliary building due to failure of waterboxes or circulating water piping.

During normal operation and shutdown, the main condenser will have no significant radioactive contaminants inventory. Radioactive contaminants can only be obtained through primary-to-secondary system leakage due to a steam generator tube leak. A full discussion of the radiological aspects of primary-to-secondary leakage, including anticipated operating concentrations of radioactive contaminants, is included in Chapter 11. No hydrogen buildup in the main condenser is anticipated.

10.4.1.4 Tests and Inspections

The main condenser waterboxes were hydrostatically tested in accordance with Section S-27 of the HEI standards for steam surface condensers.

Condenser shells were completely filled with water and tested in accordance with the ASME Power Test Code before being placed in initial operation.

10.4.1.5 Instrumentation Applications

The main condenser hotwell is equipped with level control devices which were originally designed for automatic control of system water makeup and reject, as described in Section 10.4.1.2 (currently the level is controlled manually). A low-low hotwell water level alarm is provided in the control room. The sampling system takes suction from troughs in condenser shells and measures the sodium content of the condensate to provide an indication of a condenser tube leak. The sampling system can indicate the sodium content of the condensate before it rises to a level where excessive blowdown and, potentially, steam generator shutdown would be required. Local and remote indicating devices are provided for monitoring pressures and water levels in the condenser shells.

10.4.2 MAIN CONDENSER EVACUATION SYSTEMS

The Main Condenser Evacuation System (MCES), shown in Figure 10.4-1, removes noncondensible gases and air from the main condenser during plant startup, cooldown, and normal operation. The system has no safety-related function.

10.4.2.1 Design Bases

The MCES is designed to remove noncondensible gases and inleaking air from the steam space of the two condenser shells. Each exhauster assembly is designed to continuously remove 25 scfm of free dry air at 71.5 °F and 1-inch Hga. The MCES is also designed to rapidly remove air from the two shells to create a vacuum in the condenser during plant startup. Each exhauster assemble has a "hogging" capacity rating of 750 scfm of free dry air at 70 °F and 10 inches Hga.

The system is designed and constructed in accordance with standards of the Heat Exchange Institute's "Standards of Surface Condensers" and to provide for a seismic load of 0.05g.

Each exhauster assembly is designed to draw air from the two condenser shells operating at two different pressures.

10.4.2.2 System Description

The system consists of two 100 percent capacity exhauster assemblies. Each assembly consists of one motor driven rotary type vacuum pump with one seal system including one centrifugal circulating pump and one heat exchanger, two atmospheric air ejectors, two integral jet heaters, one separator and all necessary piping, valves, instruments and electric devices for automatic operation of the system.

In normal operation one exhauster assembly is in use with the second assembly in standby. The noncondensible gases are released to the atmosphere through the auxiliary building ventilation system.

Energizing the exhauster starter for system startup opens the exhauster inlet valves and allows the air to flow directly to the vacuum pump outlet. This operation, called hogging, allows full use of vacuum pump capacity by bypassing the air jets. When the pressure in the condenser reaches approximately 5 inches Hga, the bypass valves close and the motive air valves open, allowing atmospheric air to flow to the jet nozzles. The system air leakage is then drawn through the jets to the vacuum pump. This operation is called holding. Should condenser vacuum decay, the standby exhauster will automatically start, and will remain running to hold condenser vacuum at normal operating level. Should vacuum continue to decay to approximately 5 inches Hga, both exhausters will automatically go into hogging operation.

Energizing the exhauster starter also automatically starts the seal water system associated with the exhauster assembly. Seal water is used as the liquid compressant with the vacuum pump, serves as cooling water for the vacuum pump, and seals clearances within the vacuum pump. The seal water pump takes suction from the bottom of the separator tank and delivers the flow through the seal water to the vacuum pump casing. The seal water return line from each end of the vacuum pump is routed back to the discharge of the vacuum pump. From there, the seal water is returned to the separator tank along with the air and gases drawn from the condenser.

10.4.2.3 Safety Evaluation

The MCES is used during reactor cooldown following a turbine generator or reactor trip when steam is bypassed to the condenser.

If the MCES is not operable, it is possible that the bypassed steam is not condensed after accumulation of noncondensible gases and inleaking air in the condenser. This is considered a main condenser failure and safe shutdown of the reactor in such an event is discussed in Section 10.4.1.

The noncondensible gases and vapor mixture discharged to atmosphere from the MCES is not normally radioactive. However, in the event of primary to secondary system leakage due to a steam generator tube leak, it is possible for the mixture discharged to become radioactively contaminated. A discussion of radiological aspects of primary to secondary leakage and limiting conditions for operation is included in Chapter 11. The anticipated radioactive releases to the environment during normal operation of the system are shown in Table 11.3-5.

A radiation detector is located in the common discharge header which runs from the two MCES moisture separators' discharge to the auxiliary building vent discharge system. The radioactivity level is continuously recorded in the control room. The high radiation switch actuates an alarm in the control room.

10.4.2.4 Tests and Inspections

Testing of the MCES during normal operation is minimal since the system is in use. Pre-startup testing ensures proper operation of valves and verifies pressure switch setpoints. The system can be shut down for short periods of time during plant operation, for inspection, without adversely affecting condenser performance.

10.4.2.5 Instrumentation Applications

A radiation detector is provided in the MCES with the remote indicating switch and alarm located in the control room. To prevent moisture buildup and consequent erroneous readings, radiation detector 2RE-0645 is located in the common discharge header which runs from the two MCES moisture separators' discharge to the auxiliary building vent discharge system.

Radioactivity is monitored by a chart recorder in the control room and can also be monitored on the Safety Parameter Display System (SPDS) or the plant computer. Local indicating devices such as pressure, temperature, and flow indicators are provided as required for monitoring the system operation. There are no control functions of the system which could influence operation of the RCS.

10.4.3 TURBINE GLAND SEALING SYSTEM

The Turbine Gland Sealing System (TGSS) provides sealing of the turbine generator shaft and the main feedwater pump turbine shafts against leakage of air into the turbine casings and escape of steam into the turbine building. The system is shown in Figure 10.2-3. The system has no safety-related function.

10.4.3.1 Design Bases

The TGSS is designed to prevent atmospheric air leakage into the turbine casing and main condenser and steam leakage out of the casings of the turbine generator and main feedwater pump turbines. This system performs these functions from startup to full load.

During normal operation both steam and air are transported along the turbine shafts to the steam packing exhauster. Net excess steam is bypassed to the main condenser. The system is designed to handle greater flows resulting from startup and no load operation, low auxiliary steam source pressure, and twice the normal packing clearances. The Unit 1 startup boiler and the Unit 2 main steam system are the only sources of gland steam that have the capacity to provide the flow required for twice the normal packing clearances. The system is classified Seismic Category 2.

10.4.3.2 System Description

Steam flow to the shaft seals is controlled by the TGSS steam feed control valves and unloading valves. A small quantity of steam leaks into the turbines while the remainder is exhausted through an exhauster system. The packing low pressure side vent annuli are maintained at a slight vacuum by the steam packing exhauster condenser. The exhauster condenser is a shell and tube heat exchanger with two blowers, either of which maintains the necessary vacuum. The Auxiliary Cooling Water System supplies cooling water to the tube side of the exhauster condenser. Drains from the shell side of the exhauster condenser are returned to the main condenser, while non-condensibles and some vapor are discharged to atmosphere above the turbine building roof by the blowers. Excess steam from the steam seal feed header is bypassed to the main condenser by the unloading valves. Condensate is removed from the steam seal header through a floating type steam trap.

At startup, the sealing steam source may be either main steam or auxiliary steam (both from Unit 1). When sufficient pressure has been established in the steam generator, the auxiliary steam source valve is closed and Unit 2 main steam provides sealing. As the turbine is brought up to load, steam leakage past the high pressure turbine high pressure seals enters the steam seal header. When this leakage is sufficient to maintain required steam seal header pressure, the main steam feed control valve is closed, and all sealing steam is supplied from the high pressure turbine.

During normal operation of the turbine generator, the steam from the high pressure turbine casing passes along the turbine shaft through the clearances of the labyrinth-type gland seals. The gland leakage from the high pressure casing is then passed to the gland seals on the low pressure turbine and the main feedwater pump turbines. The exhaust from the turbine seals and the main feedwater pump turbine seals is routed to the steam packing exhauster condenser where the steam is condensed and returned to the main condenser. The air and noncondensible gases from the exhauster condenser are discharged to the atmosphere above the turbine building roof by one of the blowers.

10.4.3.3 Safety Evaluation

The TGSS has the capacity to handle steam and air flows resulting from twice the normal packing clearances.

During the normal operation of the turbine generator, the sealing steam pressure is automatically maintained by opening the steam packing unloading valves which pass excess steam to the main condenser. In the event of a malfunction of one or both of the automatic unloading valves, a motor operated unloading valve bypass valve may be operated to manually control steam seal header pressure. In addition, three relief valves are provided to prevent excessive steam seal header pressure. The relief valves discharge to the main condenser.

The system can be used during reactor cooldown following a turbine generator and reactor trip when steam is bypassed to the condenser. The turbine gland seals can be supplied with the low pressure steam generated in the steam generators during reactor cooldown.

Exhauster vacuum on the low pressure side of the seals can be maintained with either blower, or both, in operation. Failure of one blower (low vacuum) automatically starts the second blower. Loss of both blowers can cause steam leakage into the turbine building and is alarmed. However, a failed steam packing exhauster condenser tube can be plugged during turbine operation by isolating the exhauster condenser tube side. The blowers will continue to operate during this time. In addition, provisions have been made to supply condensate to the shell side to promote direct contact condensation of exhaust steam during maintenance.

The non-condensible gases and vapor mixture discharged to the atmosphere by the steam packing exhauster blower is not normally radioactive. Only in the event of primary-to-secondary system leakage (due to a steam generator tube leak) is it possible for the mixture discharged to be radioactively contaminated. Radiation monitoring of steam generator blowdown and main condenser vacuum pump discharge will detect this condition. A discussion of the radiological aspects of primary-to-secondary system leakage including anticipated releases from the TGSS is included in Chapter 11. The anticipated contamination discharge rates listed in Chapter 11 are based on twice the normal steam and air leakage through the seals to cover wear of labyrinth seals and malfunction of any component of the system. Failure of the TGSS is discussed in Section 15.1.35.

10.4.3.4 Tests and Inspections

The system was tested in accordance with written procedures during the initial testing and operation program, and is readily available for inspection. The system is normally in operation when the plant is operating and thus special tests are not required to ensure operability.

10.4.3.5 Instrumentation Applications

A pressure controller is provided to automatically maintain the gland seal steam supply pressure. In case of high pressure, the steam packing unloading valves bypass excess steam to the main condenser.

During startup or in case of low gland seal steam pressure, the pressure controller signal opens a pressure reducing valve to supply steam from the main steam line. Motor operated valves are provided to permit manual operation of the TGSS in the event the automatic pressure controlled valves malfunction.

Local and remote indicating and alarm devices are provided, as required, for monitoring the system, including the following:

A. steam seal supply header pressure indication
B. steam seal supply header pressure high/low alarm
C. steam packing exhauster vacuum indication
D. steam packing exhauster vacuum low alarm and automatic starting of second exhauster blower
E. loss of both exhauster blowers alarm

10.4.4 STEAM DUMP AND BYPASS SYSTEM

The Steam Dump and Bypass System (SDBS) and the Steam Dump and Bypass Control System (SDBCS) (Section 7.7.1.1.5) are non-safety related systems. The principle operational objectives of these two systems are to maintain plant availability, prevent unnecessary opening of the Main Steam Safety Valves (MSSVs) during power operation, and to provide a means of removing excess Nuclear Steam Supply System (NSSS) energy during start-up, hot zero power and cooldown evolutions. These objectives are achieved by the controlled release of steam. Other systems such as the Feed Water Control System (FWCS), Pressurizer Level Control System (PLCS), and the Pressurizer Pressure Control System (PPCS) also contribute to achieving the objectives.

During load reduction transients and other conditions causing an increase in steady-state steam pressure, the SDBS valves are modulated to maintain steam pressure below a programmed value. The modulation speed of the valves is relatively slow (15 to 20 seconds full stroke time) which limits the maximum load changes that can be accommodated by modulation control only. For load reductions of large magnitude or rate, the energy accumulated in the NSSS while the valves are opening may be large enough to cause a reactor trip or the MSSVs to open. To increase system capability, a quick open design feature fully opens the SDBS valves at a faster speed (less than 1 second stroke time) based on the magnitude and rate of change of system load.

Protection against spurious valve opening is provided by incorporating redundant channels for each valve control mode and requiring a demand from both channels for the valves to open. The SDBS has seven valves: 4 atmospheric dump valves (ADVs) and 3 turbine bypass valves (TBVs) that dump to the condenser. The system was originally designed for a capacity of 85 percent. Six valves consisting of the ADVs and two TBVs were originally designed to have a capacity of 13.3% each. As a result of initial startup testing, these valves were determined to have a capacity of 11.5% each. The remaining TBV is described as having a 5% capacity. The change from 13.3% to 11.5% reduced system capacity to 74%.

A design change in the late 1980s resulted in the upstream ADV isolation valves being kept normally closed and deenergized (blocked closed). This reduced the SDBS capacity in the normal configuration by an additional 23% to 51%.

Power uprate did not reduce the capacity of the SDBS system in terms of cubic feet per minute. However, uprate reduces system capacity as a percent of full power from 51% to 49% since it increases the number of electrical megawatts generated.

The analysis of record indicates that at power uprate conditions, the capacity of the ADVs and TBVs varies over a reasonably narrow range since each valve capacity is a function of the upstream pressure at its location. However, the total capacity of the downstream ADVs and the TBVs at power uprate conditions is 49%.

10.4.4.1 Design Bases

Other operational objectives of the SDBS include:

A. The principle operational objectives of these two systems are to maintain plant availability, prevent unnecessary opening of the Main Steam Safety Valves (MSSVs) during power operation, and provide a means of removing excess Nuclear Steam Supply System (NSSS) energy during startup, hot zero power, and cooldown evolutions.

B. In the normal configuration with the two upstream ADVs blocked closed (i.e., upstream of the main steam isolation valves), to permit small turbine load rejections of up to 49 percent power without tripping the reactor or opening the MSSVs.

C. To provide a means of manually controlling reactor coolant temperature during plant normal heatup and cooldown when the condenser is available.

D. To provide automatic removal of the RCS energy following a unit trip and effect a smooth transition to hot standby conditions.

E. To automatically control main steam pressure during hot standby. Since the ASME Code main steam safety valves provide the required overpressure protection for the steam generators, that portion of the turbine bypass system located downstream of the main steam isolation valves is designed in accordance with ANSI B31.1.0 Code requirements. Two of the valves in the system are located upstream of the main steam isolation valves and are therefore designed in accordance with the ASME Code, Section III, Class 2.

10.4.4.2 System Description

The SDBS is shown in Figures 10.2-3. The SDBS consists of seven parallel air operated globe valves and associated instruments and controls. Three of these valves bypass directly to the condenser (the turbine bypass valves) and the remaining four dump to the atmosphere. The SDBS control system is described in Section 7.7.1.

Two of the four ADVs are located upstream of the main steam isolation valves. During normal operation, these two ADVs are placed in the "OFF" (closed) position, and the three turbine bypass valves and two downstream atmospheric dump valves are under automatic control of the SDBS. In this configuration, the SDBS has a load rejection capacity of up to 49% power at normal operating steam pressure.

During plant cooldown with off-site power available, one bypass valve is remote manually positioned to remove reactor decay heat, pump heat, and RCS sensible heat to reduce the reactor coolant temperature. Since steam pressure decreases as the system temperature is reduced, bypass valve flow capacity becomes limited at low pressures and additional bypass valves are opened to finish the cooldown at the design rate while shutdown cooling is initiated.

In the absence of off-site power, the two atmospheric dump valves located upstream of the main steam isolation valves may be used to remove reactor decay and sensible heat. The isolation valves for these two upstream ADVs are provided with modulating capability and have motor operators that are controlled from the control room and the MCC. In addition, the valve operators have handwheels that will permit local operation. During normal operations, these ADV isolation valves are administratively kept closed.

The SDBS valves are equipped with handwheels to permit manual operation at the valve location. In addition, the SDBS emergency off/condenser vacuum interlock can be actuated and reset from the remote shutdown panel 2C80. This capability enables the operators to prevent excessive cooldown under certain conditions coincident with control room uninhabitability.

Drains are installed on all 10-inch SDBS valve bodies which are horizontally mounted in the system piping. The remaining 10-inch SDBS valves, which are the two non-safety-grade atmospheric reliefs 2CV-0301 and 2CV-0305, are vertically mounted in the piping system such that they do not require valve body drains.

The valves and piping for the system (except the atmospheric dump valves and their isolation valves) are located in the turbine building to facilitate access to the main condenser.

10.4.4.3 Safety Evaluation

The steam dump and bypass control system is designed so that no single component failure or operator error will result in the opening of more than one valve. The effect of such an event on the RCS has been analyzed; this excess load accident is discussed in Chapter 15. The atmospheric dump valves located upstream of the main steam isolation valves fail open on loss of air and are therefore normally kept isolated. The normally closed isolation valves receive Class 1E power and a back-up MSIS to prevent spurious opening following a main steam line break.

The turbine bypass valves in the SDBS are designed to fail closed to prevent uncontrolled bypass of steam to the condenser. Should the bypass valves fail to open on command, the main steam safety valves provide overpressure protection, and the atmospheric dump valves can provide a means for controlled cooldown of the reactor. The main steam safety valves are described in Section 10.3.2.

Should the condenser not be available as a heat sink, a condenser high pressure signal will prevent the opening of, or will close, the valves which discharge to the condenser; the remaining valves (and the main steam safety valves, if required) control the load transient.

10.4.4.4 Tests and Inspections

Preoperational testing was performed to demonstrate that the system operates to control reactor coolant temperature during turbine load transients.

10.4.5 CIRCULATING WATER SYSTEM

The Circulating Water System (CWS) provides cooling water for removal of heat from the main condenser. The system is schematically shown in Figure 10.4-1. In addition, the system serves as the preferred heat sink for normal reactor cooldown until shutdown cooling is available. However, the system has no safety function.

10.4.5.1 Design Bases

The CWS is designed to supply the cooling water required to remove the heat loads developed in the main condenser and the main circulating water pump motor coolers when the plant is operated at maximum rated load.

The CWS design includes the following subsystems:

A. cooling tower makeup
B. cooling tower blowdown
C. cooling tower de-icing
D. cooling tower bypass
E. cooling tower chemical addition
F. circulating water biocide addition
G. condenser tube cleaning
H. circulating water drainage

The CWS components are designed and built in accordance with the following applicable regulations and codes:

A. The State of Arkansas
B. American Concrete Institute (ACI)
C. American Institute of Steel Construction (AISC)
D. American National Standards Institute (ANSI)
E. American Society for Testing and Materials (ASTM)
F. American Society of Civil Engineers (ASCE)
G. American Society of Mechanical Engineers (ASME)
H. American Water Works Association (AWWA)
I. American Welding Society (AWS)
J. Anti-Friction Bearings Manufacturers Association (AFBMA)
K. Cooling Tower Institute (CTI)
L. Expansion Joints Manufacturers Association (EJMA)
M. Federal Aviation Administration (FAA) Regulations
N. Department of Labor, Occupational Safety and Health Administration (OSHA)
O. Hydraulic Institute (HI)
P. Institute of Electrical & Electronics Engineers (IEEE)
Q. International Electro-Chemical Commission (IEC)
R. Manufacturers Standardization Society of Valves & Fittings Industry
S. National Electrical Manufacturers Association (NEMA)
T. National Fire Protection Association (NFPA)
U. Nuclear Energy Property Insurance Association (NEPIA)
V. Underwriters Laboratories "Master Labeled" Lightning Protection System.

All CWS components are designed to withstand transient conditions and to prevent excessive corrosion due to the concentrated brackish type circulating water.

The structural design of all CWS components allows seismic load of 0.05g.

10.4.5.2 System Description

The CWS consists of the following:

A. two 50 percent capacity, vertical mixed flow type, circulating pumps (2P3A & B)
B. one hyperbolic, natural draft cooling tower (2M30)
C. two 100 percent capacity cooling tower acid pumps (2P54A & B)
D. one cooling tower acid tank (2T-24)
E. one condenser tube cleaning system including strainer with motor operated screens, recirculation and reinjection pumps, collectors, and distributors (2M-50)
F. piping, valves, expansion joints, and instrumentation.

The CWS is a closed loop system with provisions for continuous makeup for water losses and continuous blowdown for chemistry control.

The circulating water pumps are installed in a wet pit type pump structure as part of the closed loop CWS which utilizes a cooling tower installation for heat dissipation. Cooled water from the cooling tower collecting basin is conveyed to the adjacent wet pit of the circulating water pumps through stationary screens. The pumps discharge the circulating water through individual 96-inch pressure pipes. The two 96-inch discharge lines join into one 132-inch line leading to the turbine building. Just before entering the main condenser water boxes, the 132-inch line splits into two 96-inch lines. Warm water discharge through two 96-inch lines from the condenser is conveyed through a single 132-inch pipeline to the natural draft cooling tower and recirculated by the pumps.

In addition, the circulating water pumps supply cooling water to the circulating water motors and dilution water to the sulfuric acid addition mixing tee. The data for the circulating water pumps are given in Table 10.4-2.

The Domestic Water System supplies lubricating water to the circulating water pump bearings and packing glands. On loss of domestic water, a solenoid valve at each pump will open automatically and allow the pump discharge lubricating water to provide the required flow. Renewal of domestic water flow will automatically close the solenoid valves. Each circulating water pump is provided with dual cyclone separators to clean the water injected into the packing gland. Dual sump pumps remove shaft packing gland leakoff water from the circulating water pump casing.

The counterflow type, hyperbolic natural draft cooling tower cools the heated circulating water returning from the main condenser. Design data for the cooling tower are given in Table 10.4-3. Performance data showing the cooling water outlet temperature at various dry bulb air temperatures and relative humidities are also shown in Table 10.4-3.

The cooling tower makeup system provides the water necessary to replace losses due to evaporation, drift and blowdown. The cooling tower makeup is supplied from the Service Water System discharge as described in Section 9.2.1.

The cooling tower blowdown system that discharges to the discharge canal through the existing Unit 1 discharge flume maintains the concentration of the circulating water below the solubility limit of calcium sulfate, thus preventing scale precipitation on the condenser tubes. The cooling tower de-icing system shuts off the water flow to the center portion of the tower during freezing weather operation. The isolation of this portion of the tower reduces the working fill surface

while the normal water flow to the tower is maintained. The increased specific water flow over the remaining portion of the tower raises the water temperature, reduces the total air flow and, consequently, prevents ice accumulation over the peripheral sections.

The cooling tower bypass system, which is used during startup and low heat load to the tower in winter, prevents ice formation in the fill by increasing the circulating water temperature.

The cooling tower sulfuric acid addition system maintains an acceptable circulating water pH to prevent formation of calcium carbonate and magnesium hydroxide scales on the condenser tubes. The concentrated acid can be pumped from the acid tank to a mixing tee where it is diluted by water supplied directly from the circulating water pumps discharge or it can be gravity fed to the circulating water pump suction bays.

To assist in system corrosion protection and prevention of calcium carbonate scale, a Calgon additive system may be used. This system consists of bulk tanks, day tanks, electric pumps, and interconnecting piping. The Calgon additive is a mixture which inhibits calcium carbonate deposition by keeping these solids in suspension. The additive mixture is injected as needed to maintain a set concentration. A metal coupons testing program is in progress to monitor effectiveness and to determine the optimal additive concentration in the CWS.

The circulating water biocide addition system controls algae and slime in the CWS. Biocide is supplied by chemical addition equipment at the cooling tower.

The condenser tube cleaning system is a closed loop system. Elastic sponge or abrasive rubber balls are injected into the circulating water flow upstream of the condenser and are forced through the condenser tubes by the natural differential pressure existing between the inlet and the outlet of the condenser. A strainer section with motor operated screens installed in the circulating water pipe downstream of the condenser routes the balls together with a small quantity of water through the recirculation unit back to the condenser inlet pipe.

The circulating water drainage system dewaters the condenser boxes and part of the circulating water pipe through an inline type centrifugal pump.

Isolation valves are provided upstream and downstream of specific equipment to enable maintenance. Metallic bellows type expansion joints are provided upstream and downstream of each condenser waterbox. The 96- and 132-inch diameter steel piping is epoxy lined. Diluted sulfuric acid piping is constructed of carbon steel lined with a suitable polymer. Concentrated sulfuric acid piping is for the most part, constructed of carbon steel; however, some carbon steel plastic-lined pipe or acid resistant metal alloy pipe is also used.

During all modes of power generation, the cooling tower blowdown, makeup, and acid addition systems are operated continuously. The cooling tower blowdown flushing, condenser tube cleaning, and biocide addition systems are operated intermittently as necessary.

10.4.5.3 Safety Evaluation

The CWS is used to supply cooling water to the main condenser to remove residual heat from the reactor coolant during the initial cooling period of plant shutdown when the main steam is bypassed to the condenser. However, if the CWS fails to supply cooling water due to failure of the circulating water pumps, the cooling tower or the circulating water piping, the bypassed main steam cannot be condensed in the main condenser. This is considered a condenser failure and safe shutdown of the reactor in such an event is discussed in Section 10.4.1.

All CWS components including the steel expansion joints are designed for a pressure of 85 psig, the shutoff head of the CWS pumps, and are hydrotested to 128 psig.

The CWS pump discharge valves are motor operated butterfly valves and are programmed to open and close to preclude the possibility of exceeding the CWS design pressure. An abnormal event which will cause a CWS pressure transient is a simultaneous trip of both CWS pumps and a failure of the discharge valve interlock such that both valves are inadvertently closed. In such an event the initial momentum of the circulating water in the forward direction will cause a vacuum to be drawn in the CWS pipe downstream of the discharge valves. The vacuum will be broken by the air vacuum release valves installed in the CWS piping. As the circulating water slows down, stops and starts flowing backwards, the air drawn in when the circulating water was moving forward will be released through the air vacuum release valve, and the controlled release of air will act as a shock absorber to prevent large pressure transients.

In the event a failure occurs to a CWS component inside the turbine building, there is a potential of discharging circulating water into the turbine building basement at a maximum rate of 498,000 gpm (both CWS pumps at runout). At this flow rate, the entire 7.3 million gallon CWS inventory would be pumped into the turbine building in approximately 14.7 minutes. This volume of water has the potential of flooding the turbine building and portions of the non-safety-related part of the auxiliary building to approximately (Elevation) 358 feet, 3 inches, which is 2 feet, 9 inches below the external flood protection level. There are no paths by which this water could enter any safety-related structure. The turbine building sump level indicator and the condenser tubes cleaning system pit level controller have high level alarms which, in conjunction with the circulating water pumps low discharge pressure alarm, will alert the operators to possible CWS leakage.

To prevent degradation of the ESF due to a break in the circulating water pipe, condenser expansion joints or condenser water boxes, all ESF equipment is located in watertight portions of the auxiliary building.

The potential for damage to other plant structures in the event of collapse of the cooling tower is evaluated in Section 2.2.2.

10.4.5.4 Tests and Inspection

Historical data removed, to review the exact wording, please refer to Section 10.4.5.4 of the FSAR.

Operational testing included testing of acid feed components, blowdown system instrumentation and tube cleaning system instrumentation. Operation of the circulating pump lube water and sump level system was tested.

10.4.5.5 Instrumentation Application

The CWS is provided with all necessary instruments and controls to operate the plant safely.

Motor operated butterfly valves are provided at the discharge of each circulating water pump. Each circulating water pump motor starter is interlocked with its respective discharge valve to prevent overloading of the pump motor during startup. Opening and closing of the discharge valves are programmed to protect all CWS components during all modes of operation and hydraulic transients. The circulating water pump discharge valves and condenser inlet and outlet valves are provided with position switches. Indicating lights showing open and closed position of these valves are provided on a control panel.

Circulating water pump sump pumps are operated on level switches. An alarm sounds on high water level.

The bearings and stator of each circulating water pump motor are provided with thermocouple and resistance thermal detectors. Temperature is recorded at each point and an alarm sounds on high temperature.

The discharge pressure of each circulating water pump is logged periodically. An alarm sounds on low and high pressure signals from the pressure switch.

Local pressure and temperature indicators are provided on the discharge of each circulating water pump and the inlet and outlet of each condenser waterbox.

Circulating water temperature is recorded at the inlet and outlet of the condenser waterboxes. Circulating water differential pressure between inlet and outlet condenser waterboxes is recorded.

A level indicating controller is provided in the cooling tower basin. An alarm sounds on high and low level signals from the level switch.

The differential pressure across the stationary screens is measured by a differential level sensor. An alarm sounds on a high pressure signal from a differential pressure switch.

The cooling tower blowdown is controlled by the conductivity level in the circulating water. The control valve opens as conductivity rises. An alarm sounds on a high or low conductivity level signal from the conductivity switch.

Sulfuric acid addition is controlled by the pH of the circulating water. The pH is recorded at either the common discharge of the circulating water pumps or the circulating water return to the cooling tower. The sulfuric acid pumps are interlocked with the acid storage tank level control and dilution water flow. An alarm sounds on a high or low pH from either pH controller and on high and low level signals from the acid tank level switch.

The biocide addition system is either timer actuated or manually controlled.

The cooling tower bypass valve and de-icing gates are manually controlled. Each valve and gate is provided with a position switch. Open and closed indicating lights for these valves and gates are provided in the control room.

The condenser tubes cleaning system is manually operated.

10.4.6 CONDENSATE CLEANUP SYSTEM

Condensate cleanup is accomplished by operation of the Steam Generator Blowdown System (SGBS) in conjunction with the Process Sampling System (PSS) to keep water chemistry within the limits specified in Section 10.3.5. The PSS, described in Section 9.3.2, injects hydrazine, ammonia, and/or an amine for oxygen and pH control via the condensate and feedwater chemical feed system. These chemicals are injected in both condensate streams downstream of the condensate pumps. The SGBS operates as described in Section 10.4.8 to maintain low concentrations of silica (SiO_2), sodium (Na), sulfates (SO_4), and chlorides (Cl^-) and to minimize the corrosion products of iron and copper. The startup and blowdown demineralizer system, described in Section 10.4.10, processes the blowdown and assists in establishing condensate chemistry values prior to plant startup.

10.4.7 CONDENSATE AND FEEDWATER SYSTEMS

The Condensate and Feedwater System (CFWS), shown in Figures 10.4-2and 10.4-3, draws water from the condenser hotwells and high pressure feedwater heater drains and pumps it to the steam generators.

10.4.7.1 Design Bases

The CFWS is designed to provide continuous feedwater supply to the two steam generators at the required pressures and temperatures under all anticipated steady state and transient conditions. It has also been designed with the capability to maintain unit operation when the system has to operate under abnormal conditions due to a feed pump, a condensate pump, a heater drain pump, or a heater or string of heaters, being out of service. It can continuously operate at a reduced output with just one train of pumps and low pressure feedwater heaters.

The Emergency Feedwater System (EFWS) supplies feedwater to the steam generators during plant startup, shutdown, hot standby and emergency conditions as described in Section 10.4.9.

The CFWS design includes provisions for automatic isolation of the system from the steam generators when required to mitigate the consequences of a steam line break or certain malfunctions in the CFWS as described in Section 10.4.7.2.

The portion of the feedwater piping from the condenser hotwell suction up to the main feedwater pumps suction is designed and fabricated in accordance with ANSI B31.1.0, and all components are classified Seismic Category 2. The main header piping from the high pressure feed pump discharge nozzles up to the outboard containment isolation valves (main isolation valves) is designed to meet ANSI B31.1.0 and Critical Pipe requirements.” Critical piping requirements are discussed in Section 10.3.2. The portion from the main isolation valves (including the valves) up to the steam generators is designed and fabricated in accordance with ASME Code, Section III, Class 2, and meets seismic Category 1 requirements. The feed pumps, condensate pumps, and heater drain pumps are all designed and built in accordance with the Standards of the Hydraulics Institute, ASME Code, and ASTM Standards. All the feedwater heaters are designed and built in accordance with the requirements of the Heat Exchanger Institute Standards for Closed Feedwater Heaters, ASME Code Section VIII, and ASTM Standards.

10.4.7.2 System Description

The CFWS is made up of two interconnected trains, Train A and Train B, consisting of condensate pumps, heater drain pumps, main feedwater pumps and feedwater heaters. The two trains are interconnected at the main suction lines from the condenser hotwells, at the condensate pumps discharge, and at the suction and discharge sides of the main feedwater pumps. The CFWS has the following components:

A. Four vertical condensate pumps: 2P2A, B, C, and D.

B. Five stages of low pressure feedwater heaters: 2E7A & B, 2E6A & B, 2E5A & B, 2E4A & B, and 2E3A & B.

C. Two heater drain pumps: 2P8A & B. Each pump takes suction from its own heater drain tank and discharges into its own stream at the feedwater pump suction.

D. Two feedwater pumps: 2P1A & B.

E. Two stages of high pressure feedwater heaters: 2E2A & B, and 2E1A & B.

F. Piping, control and isolation valves, and instrumentation.

The condensate pumps take suction from the condenser hotwells and discharge the condensate into the two strings of low pressure feedwater heaters to supply the feedwater pumps suction. Condensate pump recirculation valves 2CV-0662 and 2CV-0663 are designed to fail closed.

The heater drain pumps take suction from the heater drain tanks, which are supplied by high pressure feedwater heater drains from heaters 2E1A & B through 2E3A & B and drains from the moisture separator reheater units, and discharge to combine with the main condensate streams at the main feedwater pumps suction.

Heater drain pump recirculation valves 2CV-0719 and 2CV-0725 are pneumatically rather than electrically operated to reduce susceptibility to vibration damage.

The drains from the low pressure feedwater heaters from 2E4A & B through 2E7A & B are cascaded down to the condenser hotwell. To accurately measure the vacuum during low power operation, feedwater heaters 2E5, 6 & 7 are equipped with absolute pressure transmitters for the shell and extraction measurements. The feedwater pumps discharge the heated condensate, via a common header and feedwater control valves, into two independent strings of high pressure feedwater heaters before discharging into the steam generators.

The two trains of feedwater and condensate systems have been furnished with several cross connections to have flexibility and to permit the maximum and most efficient combination of operating pumps and feedwater heaters at all times, including the remote case of single train operation.

During full power operation, three condensate pumps are in operation and the fourth condensate pump is available as a standby. Also, there are two heater drain pumps in operation which take suction from their respective heater drain tanks and feed the heater drain flow into the feedwater lines. There are two feedwater pumps, which take suction from the common condensate and heater drain pump discharge header and feed the steam generators. The feedwater control system (FWCS) regulates flow to the steam generators (see Section 7.7.1.1.4).

The condensate pumps and the heater drain pumps are vertical, multistage, can-type, constant speed, motor driven centrifugal pumps. The main feedwater pumps are vertically split, single stage, double suction, steam turbine-driven, horizontal centrifugal pumps. Data for the condensate pumps, heater drain pumps, and the main feedwater pumps are shown in Tables 10.4-4, 10.4-5, and 10.4-6, respectively.

The main feedwater pumps are driven by a dual admission type steam turbine with a connection to both the main steam and crossover steam piping. Under normal conditions the turbine drivers are powered by low pressure crossover steam. High pressure main steam is used during startup, low load, or transient conditions when crossover steam is either not available or of insufficient pressure.

The feedwater heaters are U-tube type with integral drain coolers except the 2E3A and 2E3B feedwater heaters which have no drain cooling sections. The 2E6A, 2E6B, 2E7A and 2E7B feedwater heaters are installed in the condenser necks.

The main feedwater lines just before the containment building penetrations and the crossover piping between the feedwater pumps' suction are furnished with motor operated control valves. Manually operated valves are provided at the suction and discharge side of each pump and at appropriate points in the feedwater trains as required for isolation of a feedwater heater or string of feedwater heaters. Air operated feedwater control valves (2CV-0748 and 2CV-0740) with their corresponding bypass valves (2CV-0753 and 2CV-0744, respectively) are provided downstream of the main feedwater pumps just after the discharge cross-tie piping, and just upstream of the high pressure heaters. At a location outside the containment between the feedwater control valves and the main feedwater isolation valves, a backup main feedwater isolation valve was added in each train. The two motor-operated main feedwater isolation valves, 2CV-1024-1 and 2CV-1074-1, the two motor-operated main feedwater isolation valves, 2CV-1023-2 and 2CV-1073-2, and the two check valves downstream of the containment penetrations are Seismic Category 1 valves. The emergency feedwater line for each steam generator joins the main feedwater lines to the steam generators inside the containment, just downstream of the main feedwater line check valves. The emergency feedwater lines are similarly furnished with Seismic Category 1 motor operated control valves located just outside of the containment and two Seismic Category 1 check valves located inside the containment. The motor operated control valves are further described in Section 10.4.9.2.1.

During normal plant operation, when the plant load output is less than 50 percent of rated load, and with maximum availability of pumps and feedwater heaters, there may be two condensate pumps, two main feedwater pumps, and one heater drain pump running in the two feedwater trains. At over 50 percent load output, two or three condensate pumps, two main feedwater pumps and two heater drain pumps may be running in the two trains. When more than one heater drain pump is out of service, approximately 80 percent feedwater flow can be supplied by the system, but plant power will be less than 80 percent due to reduced feedwater temperature supplied in the steam generators. With one heater drain pump out of service, 100 percent feedwater flow may be supplied by the system, but the heater drain pump in service may be subject to cavitation.

The main feedwater pumps are tripped automatically on any of the following trip signals:

A. Channel One or Two Main Steam Isolation Signal (MSIS)

B. Channel One or Two Containment Spray Actuation Signal (CSAS)

C. high pressure feedwater heaters outlet pressure high and main feedwater pump discharge pressure high

D. low pump suction pressure

E. low pump flow (may be bypassed)

F. low lube oil pressure

G. pump turbine driver overspeed

H. turbine driver exhaust pressure high

I. thrust bearing wear.

The main feedwater pump for which the preferred trip selector switch is positioned will trip when the main turbine trips. The active feedwater pump which remains running after a turbine trip will be accelerated to match the demand of the steam generators to prevent a reactor trip. After a reactor trip without an MSIS or CSAS, the feedwater pump will be run at minimum speed to provide inventory for steam generator level control.

The two steam generators are operated in parallel with each generator's Feedwater Control System (FWCS) maintaining its downcomer water level within acceptable limits. The FWCS for each steam generator consists of a low power mode and a high power mode. In the low power mode, the FWCS operates as a single element control system based on steam generator level. In the high power mode, the FWCS operates as a three-element control system based on steam generator level, feedwater flow, and main steam flow. The FWCS program logic develops a flow demand which controls the main and bypass control valves and feedwater pump speed to maintain steam generator levels at the desired setpoint.

After termination of forced flow, the CFWS is isolated from the steam generators by closing the main feedwater valves, 2CV-1024-1 and 2CV-1074-1, and the redundant main feedwater isolation valves, 2CV-1023-2 and 2CV-1073-2, upon an MSIS or CSAS from either channel. The signal to close the isolation valves will also trip the feedwater pump turbine drivers to prevent shutoff head pressure operation on the high pressure feedwater heaters.

The Feedwater Control System (FWCS) is described in Section 7.7.1.1.4. The Emergency Feedwater Actuation Signal (EFAS) and feedwater isolation by the Main Steam Isolation System (MSIS) are described in Section 7.3. Section 7.7.1.7 contains a description of the Diverse Emergency Feedwater Actuation System (DEFAS).

An automatic system was originally provided to maintain the total water volume in the CFWS through makeup and return of condensate to the condensate storage tank by means of control valves 2CV-0634 (the makeup valve) and 2CV-0633 and 2CV-0632 (the reject valves). This method was unsatisfactory and is no longer used. The hotwell level is now controlled manually.

The system water quality is maintained through the injection of hydrazine and ammonia and/or amine into the condensate. Ammonia and/or amine and hydrazine injection is controlled by pH and dissolved oxygen controllers which continually monitor a sample flow from the system. The condensate and feedwater chemical feed system is shown in Figure 10.2-3.

A condensate system fill connection is provided in the existing cross connect line between condensate storage tanks 2T-41A & B and T-41. The three-inch fill connection line consists of a manual gate valve and a check valve to prevent drainage of the condensate storage tanks in the event of a line break in vendor equipment providing demineralized makeup.

10.4.7.3 Design Evaluation

The CFWS has been designed with ample margin to ensure that the loss of a single component, such as when one feedwater pump is out of service, or when one of the two trains of low pressure feedwater heaters has been isolated, the system can still safely operate at a reduced unit output. The loss of one of the four condensate pumps does not reduce the system capability to maintain feedwater supply for 100 percent load. The loss of one or both heater drain pumps still permits safe and continuous operation at reduced unit output.

The Seismic Category 2 portion of the CFWS, including the condensate pumps, low pressure and high pressure feedwater heaters, the main feedwater pumps and the main feedwater piping up to the motor-operated isolation valves, is not essential for safe shutdown of the plant. In the event of failure of both main feedwater pumps, the emergency feedwater pumps will be started and will supply water for safe shutdown of the plant. If there is a break in the Seismic Category piping of the condensate and feedwater piping, the steam generator level will fall. Low level in the steam generator will trip the reactor which will also trip the main turbine generator unit and cause one main feedwater pump to trip.

Feedwater line isolation limits the blowdown energy release and the magnitude of RCS cooldown in case of a main steam line break. To assure isolation of the steam generators from CFWS after an MSIS or CSAS, two separate control channels are provided. A signal from either channel will cause closure of the isolation or backup valves as described previously.

System transients initiated by or resulting in a reactor trip can cause uncovering of the feedwater feedring in the steam generator or the steam generator feedwater inlet nozzles. This potentially allows steam to enter portions of the feedwater piping and can result in transmission of pressure waves through the piping. Operating experience at similar plants, particularly the water hammer event at Indian Point 2 on November 13, 1973, shows that such pressure waves can damage the feedwater piping. To reduce the possibility of steam bubble formation in the feedring and feedwater piping during normal operating transients, the following design provisions are incorporated in Unit 2:

A. The routing of the main feedwater piping external to the steam generator minimizes the horizontal piping volume at the inlet to the steam generator that could pocket steam, thereby minimizing the potential for water hammer in the feedwater piping and steam generator feedring;

B. The steam generator feedring design incorporates provisions that minimize the potential for water hammer. The steam generator feedring is elevated above the feedwater inlet nozzle to minimize the horizontal volume at the feedwater nozzle. The feedring incorporates top discharge inverted J-nozzles that terminate above the feedring but remain open to the downcomer annulus at that elevation. The feedring design also incorporates a thermal liner that is welded to the feedwater nozzle forging to form a positive seal. If water falls below the feedring due to a system transient, these design features eliminate potential leak paths within the steam generator through which water can drain from the feedring unless it drains back into the feedwater system. They also prevent the formation of a steam pocket in the feedring. Tests performed on steam generators with similar feedring designs have indicated that this feedring design is effective in preventing water hammer.

Samples of the condensate and feedwater are taken from the condenser hotwells, condensate pump discharge, feedwater line to the steam generators and steam generator blowdown lines. The heater drains are also sampled at a point immediately downstream of the pump discharge flanges and upstream of the minimum flow recirculation lines. As described in Section 9.3.2, process sampling system, the samples are analyzed to control the quality of the condensate and feedwater. Samples from the steam generator blowdown lines are also analyzed to detect radioactivity.

During normal operation, condensate and feedwater contain no significant radioactive contaminants. However, in the event of primary-to-secondary system leakage due to a steam generator tube leak, it is possible for the CFWS to become radioactively contaminated. A full

discussion of the radiological aspects of primary-to-secondary leakage, including anticipated operating concentrations of radioactive contaminants, means of detection of radioactive contamination, anticipated releases to the environment and limiting conditions for operation, is included in Section 11.4.

10.4.7.4 Tests and Inspection

Historical data removed, to review the exact wording, please refer to Section 10.4.7.4 of the FSAR.

All of the components of the system will be continually monitored during operation to ensure satisfactory operation.

10.4.7.5 Instrumentation Applications

A flow element with a flow transmitter is installed at the suction of each main feedwater pump. Flow signals are transmitted to 1) a flow switch which sounds an alarm at low flow and trips the feedwater pump turbine driver on low-low flow (this trip may be bypassed), 2) a flow indicating controller which activates and modulates the feedwater recirculation valve to ensure minimum safe flow through the feedwater pump, 3) a condensate recirculation flow controller, which sums feedwater pump suction flow with condensate recirculation flow minus heater drain pump discharge flow (measured to indicate condensate pump flow), and 4) a flow summer which combines both feedwater pump flows. This summer determines the operation of the heater drain pumps and the third running condensate pump. On low-low condensate recirculation flow, the flow controller actuates the condensate pump recirculation valves.

Pressure switches are furnished at the suction and discharge of each feedwater pump. The pressure switch for pump suction pressure starts a standby condensate pump on low suction pressure. Other pressure switches trip the turbine driver on low-low suction pressure to the feedwater pump (2-out-of-3). Pressure switches on the discharge side open the feedwater recirculation valve on high pressure (2-out-of-3). Pressure transmitters, located downstream of the high pressure feedwater heaters 2E1A and 2E1B, provide trip signals to the main feedwater pumps on high pressure to protect the high pressure heater trains from overpressure. These trip signals are combined with signals from the pressure switches that open the feedwater recirculation valves on high discharge pressure to trip the turbine drivers. Control room indication is also provided by signals from these pressure transmitters. Other pressure transmitters are installed at the feedwater pump discharge to provide control room indication. Flow elements, furnished with flow transmitters, provide flow signals to their respective 3-element feedwater control system.

In order to protect the low pressure feedwater heaters, pressure switches are installed at the discharge of each condensate pump to trip the pump on high condensate pump discharge pressure. Also each condensate pump start switch is interlocked with the suction butterfly valve position indicator to avoid starting of a condensate pump with a closed suction valve.

The heater drain pumps can be started only when there is sufficient water in the heater drain tanks. The pumps trip on low suction level or high differential pressure across the pump. In order to ensure sufficient NPSH, the water level in the heater drain tank is maintained at a minimum level by heater drain pump recirculation valves.

The CFWS is furnished with necessary instrumentation at appropriate locations for monitoring flow, pressures and temperatures.

10.4.8 STEAM GENERATOR BLOWDOWN SYSTEM

The Steam Generator Blowdown System (SGBS), shown in Figure 10.2-3, is used in conjunction with the chemical feed system and the process sampling system to control the chemical composition of water in the steam generator shell within the specified limits.

The SGBS, with the exception of the blowdown piping from the steam generators to the containment isolation valves, has no safety-related function.

10.4.8.1 Design Bases

The SGBS is designed to fulfill the following requirements:

A. to maintain the steam generator shell side water chemistry within the conditions shown in Procedure 1000.043, “Steam Generator Water Chemistry Monitoring Unit II”.

B. to provide a continuous blowdown for each steam generator under normal plant operating conditions to maintain steam generator water chemistry.

C. to permit a maximum blowdown rate for each steam generator under abnormal plant operating conditions.

D. to direct the blowdown to the startup and blowdown demineralizers for treatment and/or discharge.

The part of the SGBS from the steam generators to and including the air-operated containment isolation valves comprises an extension of the steam generator boundary. This portion of the system has been designed in accordance with Seismic Category requirements. The remainder of the system is Seismic Category 2, and has been designed in accordance with ANSI B31.1.0.

On the basis of existing data and anticipated operating conditions, an analysis has been performed on the steam generator blowdown activity levels and chemical concentrations for a failed fuel fraction of 0.25 and 1.0 percent and steam generator primary-to-secondary leak rate of 13 and 100 gpd, respectively.

The steam generator blowdown tank has been designed in accordance with ASME Code Section VIII requirements. The steam generator blowdown pumps and motors have been designed and constructed in accordance with the requirements of ASME, ANSI, ASTM, Hydraulic Institute, NEMA and IEEE standards. The SGBS is designed for adequate capacity. The tank is normally vented to the high pressure condenser and the blowdown is directed to the startup and blowdown demineralizer system. When processing and recovery of steam generator blowdown via the startup and blowdown demineralizer system is not desired, blowdown may be diverted directly to the regenerative waste tanks or discharged directly to the circulating water flume if water chemistry and radioactivity levels permit. The components of the SGBS are located outside the containment; the blowdown tank and the tank drain pumps are located in the controlled area of the auxiliary building.

10.4.8.2 System Design

10.4.8.2.1 General Description

The SGBS consists of the following components:

A. one steam generator blowdown tank (2T67)
B. two steam generator blowdown pumps (2P139A, B)
C. two steam generator blowdown control valves 2CV-1017 and 2CV-1067
D. piping, flow elements, control isolation valves, and instrumentation.

Table 10.4-8 shows the physical data for the SGBS tank, Table 10.4-9 shows the data for the pumps.

There are two blowdown lines, one coming from the bottom of the shell side of each steam generator. Each blowdown line has a connection which leads to the sampling systems, one motor operated steam generator isolation valve located inside the containment, one pneumatically operated steam generator isolation valve located just outside the containment, one flow element, and a blowdown control valve. Each blowdown line leaves the containment through its own penetration and discharges into the steam generator blowdown tank. The motor operated and the air operated containment isolation valves are both normally open and can be manually operated from the control room. The air operated valve automatically closes upon receipt of a Main Steam Isolation Signal (MSIS).

The flow element is furnished with a flow transmitter and transmits blowdown flow rate to the control room.

The blowdown control valve, directly installed on the blowdown tank, drops the pressure from steam generator pressure to approximately condenser pressure. It is furnished with a pneumatic operator and can be operated by a hand indicating controller in the control room to regulate blowdown rate.

The steam generator blowdown tank (2T67) is normally vented to the high pressure condenser by means of a 12-inch diameter vent line. This vent causes the blowdown to flash into condenser low pressure, resulting in a low effluent temperature, and permitting continuous processing of the blowdown by the startup and blowdown demineralizer system. Replaceable stainless steel mesh entrainment separators installed inside the tank prevent solid particulates and liquid carry over in the flash steam. Water level sensors monitor the level in the tank and generate signals to automatically start, or stop, operation of the blowdown tank drain pumps and modulate the level control valve.

The two steam generator blowdown tank drain pumps, 2P139A & B, are located in the controlled area and are installed 20 feet below the drain tank to ensure adequate NPSH. These pumps are furnished with mechanical seals to provide zero leakage of the blowdown liquid into the surroundings. The pumps are manually controlled from the control room. In addition, they are furnished with automatic switches, working from preset blowdown tank water levels, to start one pump on high level, and the other pump on high-high level. Both pumps stop on low level. The pumps are set to operate alternately by an alternating controller.

10.4.8.2.2 System Operation

The steam generator blowdown rate is determined by the results of the steam generator shell water sample analyses. During normal plant operation with zero condenser and steam generator primary-to-secondary leakage, the steam generator will require very little blowdown. A nominal blowdown rate is required to maintain steam generator water chemistry.

Should water sample analysis indicate abnormal secondary system chemistry due to condenser and/or primary-to-secondary steam generator tube leakage, the blowdown can be increased as necessary to control the chemistry.

During normal operation, all liquid not flashed to steam in the blowdown tank is pumped to the startup and blowdown demineralizer system regardless of the radioactivity levels in the fluid. If blowdown water quality makes recovery undesirable, blowdown may be diverted to the regenerative waste tanks for holdup and treatment, or discharged directly to the circulating water flume if water chemistry and radioactivity levels permit. To prevent flashing in the blowdown pump suction piping during system operation, condensate is injected into the steam generator blowdown drain line.

The flashed steam effluent that is vented into the condenser is practically clear vapor because of the filtering effect of the entrainment separators in the tank. Any gaseous radioactivity in the tank will be detected by the radiation monitors installed in the discharge lines of the condenser vacuum pumps. The gases carried through the condenser vacuum system to the auxiliary building vent system are processed through HEPA and charcoal filters before being discharged to the atmosphere. Of the total blowdown, at full power, about 35 percent by weight is flash steam.

10.4.8.3 Design Evaluation

Although the SGBS is designed to process potentially radioactive fluids, no release path to the environment for any such radioactivity is available in this system. The monitoring and controlling of radioactive fluids originating in the SGBS is described in Sections 10.4.2.3, 10.4.10 and 11.2.2.3.

The SGBS has no safety-related function, with the exception of the piping from the steam generators to and including the containment isolation valves. These valves and piping constitute an integral part of the steam generator boundary and are discussed in Section 6.2.4. Failure of any component in the system would compromise the system operation but would not affect the safe shutdown of the plant.

The blowdown and sample lines and valves inside the containment are protected from missiles generated by the RCS to avoid any intereffect between a postulated LOCA and blowdown sample line integrity.

The containment isolation valves located outside containment in each blowdown line receive redundant MSIS from separate channels to ensure that the single failure criterion is met.

10.4.8.4 Test and Inspection

Historical data removed; see Section 10.4.8.4 of the FSAR.

10.4.8.5 Instrumentation Applications

Rate of blowdown, steam generator blowdown tank pressure and level are monitored and transmitted to the control room.

10.4.9 EMERGENCY FEEDWATER SYSTEM

10.4.9.1 Design Bases

A. The EFWS is designed to provide means of supplying water to the intact steam generator(s) following a postulated main steam line rupture or loss of main feedwater to remove reactor decay heat and provide for cooldown of the RCS to within the temperature and pressure at which the shutdown cooling (SDC) system can be placed in operation (see Section 9.3.6 for the SDC System description). Redundancy of components is provided to guarantee operation in the event of a single failure of a mechanical or electrical component within the system. The EFW System meets the redundant parallel flow path (piping and valves) requirements of recommendation GL-2 in NUREG-0635, pages X-51. Redundancy of power supplies is also provided to meet the diversity requirement of NRC branch technical position APCSB 10-1. All electrically operated components associated with the turbine driven pump train receive channel 2 DC power except the isolation valves 2CV-1037 and 2CV-1039, which receive channel 1 DC power. Channel 1 AC power is provided to all active components in the motor driven pump train except the isolation valves 2CV-1036 and 2CV-1038, which receive channel 2 AC power.

B. The auxiliary feedwater pump in the EFW System is designed to supply condensate to the steam generators during plant startup, hot standby, hot shutdown, and normal cooldown and operates in conjunction with the main steam system to maintain steam generator level.

C. The EFW System is designed to remain functional after a DBE. The components of the EFW System are designed to meet Seismic Category 1 requirements and ASME Code Section III, Class 3 requirements except for the suction lines from the condensate storage tanks (2T41A and B) and the startup and blowdown demineralizer, the EFW pump turbine exhaust, and the flush and recirculation lines downstream of the first isolation valves, and auxiliary feedwater pump, suction, and discharge piping (up to the first check valve). The isolation valves 2CV-1036, 1037, 1038 and 1039 and piping downstream are designed to meet ASME Section III, Class 2 and Seismic Category 1 requirements. The EFW pump turbine exhaust piping is ANSI B31.1.0 class and has been analyzed to withstand DBE seismic loads.

D. The suction piping of the auxiliary feedwater pump and the discharge piping from the AFW pump discharge nozzle to the main feedwater line and to the first check valve on the two 4" branch lines connected to the EFW pumps' discharge lines are designed and fabricated in accordance with ANSI B31.1.

10.4.9.2 System Description

10.4.9.2.1 General Description

The EFWS is shown in Figure 10.2-4. The system employs two safety related pumps (turbine driven and motor driven) with two independent feedwater trains, each capable of supplying either of the two steam generators, and a non-safety related pump whose discharge line is interconnected to each of the safety-related EFW pump's discharge line and to the main feedwater discharge line. Data for the pumps and their drivers are given in Table 10.4-10 and 10.4-10A.

The EFWS piping and valving arrangement, shown in Figure 10.2-4, is designed to ensure the capability of supplying cooling water to the Steam Generators during emergency conditions, as well as other applicable normal operating modes.

The EFWS is designed so the non-safety auxiliary feedwater pump (2P75) may be used to supply water to the steam generators during non-emergency conditions to avoid challenging the safety related EFW pumps. The auxiliary feedwater pump is capable of supplying sufficient water to the steam generators for heat load of approximately 4% of full NSSS power at maximum steam generator pressure.

During an emergency condition, the safety-related EFW pumps (2P7A and 2P7B) are designed to automatically supply water to the steam generators upon the actuation of an EFAS signal or a DEFAS signal. In addition, in the unlikely failure of both safety related EFW pumps during an emergency condition, the auxiliary feedwater pump can be manually actuated to supply water to the steam generators.

The safety-related EFW pumps are identical. Each pump is capable of providing sufficient water to the steam generators to mitigate the consequences of design bases accident conditions. The pumps are horizontal, multi-stage pumps with horizontally split cases, using double volutes at each stage and impellers arranged in opposed groups for hydraulic balancing.

The steam turbine driver (for 2P7A) is a single stage, solid wheel, non-condensing, horizontal, split case unit. It is designed for variable speed operation and is equipped with an electrohydraulic actuator for speed control, an overspeed trip mechanism, and an integral trip throttle valve. It is designed for rapid starting and will operate with steam generator pressures ranging from 1,100 psia to 60 psia. Steam can be supplied to the turbine driver from either or both steam headers. The turbine exhausts to the atmosphere. Cooling water for the turbine oil cooler is piped from the pump suction line rather than from the pump recirculation line. This is because the pressure available at the suction provides adequate cooling water flow through the cooler.

The electric motor driver for 2P7B is designed to NEMA Class B standards for normal starting torque and low starting current at full voltage. It is capable of accelerating the pump within 4.5 seconds with 80 percent voltage and within 2.4 seconds at full voltage. The motor can be powered from normal, preferred, or emergency power sources.

The electric motor driver for non-safety auxiliary feedwater pump 2P75 is designed to NEMA Class B Standards. It is rated at 1,000HP, 4,000V, and 3,600rpm with a service factor of 1.0. The motor is designed to be powered from the Non-ESF Bus 2A1.

During shutdown and startup with power below ten percent, the AFW pump will be aligned to the startup and blowdown demineralizer effluent for feeding the Steam Generators. Above ten percent power, the AFW suction is shifted to the condensate storage tanks and the startup and blowdown demineralizer source is isolated by closing valve 2EFW-0706, which is then verified to be closed once per shift (2CAN058003), 2CAN078019, 2CAN088506). Valve 2EFW-0706 is normally locked closed under normal conditions at greater than or equal to ten percent power.

The two redundant and independent 6-inch SWS lines provide an assured source of water in the case of failure of the Seismic Category 2 condensate supply line. The condensate supply line is furnished with two motor operated isolation valves, 2CV-0795 and 2CV-0789, and two pressure switches, 2PIS-0795 and 2PIS-0789. The service water lines are each provided with a non-return check valve and motor operated isolation valves, 2CV-0711 and 2CV-0716. The normal pressure in the condensate line is about 20 psig. If the pressure drops to 7 psig, a control room alarm will be actuated. If the pressure drops to 5 psig when an emergency feedwater actuation signal is present, the pressure switches will automatically close the condensate line isolation valves 2CV-0795 and 2CV-0789 and will simultaneously open the SWS valves 2CV-0711 and 2CV-0716.

The preferred method of feeding the steam generators during non-emergency conditions is by means of the auxiliary feedwater pump. The discharge line of the auxiliary feedwater pump is connected to each of the safety-related EFW pump's discharge lines and to the main feedwater discharge line to provide alternate flow paths to the steam generators.

Each branch line to the EFW pump's discharge lines is furnished with a control valve to modulate the pump flow and two series check valves to isolate the safety-related EFW train from the non-safety auxiliary feedwater train.

The branch line to the main feedwater line is provided with a flow control valve for modulation and a check valve to protect the EFW piping from the main feedwater backflow of high operating temperatures.

Each discharge stream of the motor driven EFW pump discharge piping system is furnished with a flushing line which connects to a common header that discharges to the startup and blowdown demineralizer system. Means are also provided by cross-connecting pipe and normally closed block valves for flushing the turbine driven pump discharge piping system. These flushing lines are provided in order to meet feedwater quality requirements. An air operated valve is furnished for each flush line which is automatically closed if emergency operation of the EFWS is initiated.

Manual valves 2EFW-11B and 2EFW-11C are installed between the EFW discharge and 2CV-0798-1. These manual valves are used to provide EFW system isolation from the test/flush line. Although 2CV-0798-1 closes automatically on EFAS, 2EFW-11B and 2EFW-11C are credited with providing isolation for this line.

A pump minimum flow recirculation line is provided from each EFW pump discharge bypassing the air operated flush valves. Each minimum flow line is provided with an orifice and a globe valve for limiting and regulating the flow while providing a normally open flow path to ensure that each pump has a minimum flow of 45 gpm. The auxiliary feedwater pump discharge line includes the automatic recirculation control valve (2EFW-25) that will provide the minimum recirculation flow of approximately 125 gpm during the low load pump operation. This valve (2EFW-25) is essentially a check valve with built in pressure reducing and flow sensing devices that actuate the pilot for the bypass control valves, which permits the passage of limited flows during AFW pump low flow operation. ER 2002-0359-000 adjusted the pilot valve to permit a continuous recirculation flow to prevent water hammer.

The safety related EFW pumps, EFWS discharge piping and valving arrangement is designed to allow either pump to supply water to either or both steam generators. Each supply line to each steam generator is provided with redundant series connected valves, in accordance with the single failure criterion, to ensure isolation of the steam generators and feeding of the remaining intact steam generator(s) as required during an EFAS operation of the emergency feedwater system following a postulated main steam or feedwater line break. The steam supply line feeding the steam turbine driver, shown in Figure 10.2-3, provides an assured source of steam to the turbine, from both or either steam generator, even when the main steam isolation valves are closed. To minimize thermal and steam shock on the turbine and piping, the isolation valves 2CV-1000 and 2CV-1050 are normally open. When an EFAS signal is received, the motor-operated bypass valve and the turbine cooling water solenoid valve will open, and the turbine will reach idle speed allowing the turbine governor hydraulic system to pressurize. Fifteen seconds later, the main steam valve 2CV-0340-2 will open, the motor-operated bypass valve will close, and the turbine will come up to normal speed.

In 1983 a commitment was made in response to 10CFR50.49 which required replacement of the EFWS isolation valves 2CV-1036, 1037, 1038 and 1039. Suitable environmentally qualified ball valves with fail closed actuators similar to the existing valves could not be acquired. Therefore motor operated gate valves were installed with operating times and flow performance specified to be at least as good as the original units. Since the MOVs are fail-as-is components the single failure analysis (Table 10.4-11) was modified. Resulting requirements of the modified analysis were: 1) the turbine driven pump train isolation valves, 2CV-1037 and 2CV-1039, would receive channel 1 DC power and safety initiation circuits, and the motor driven pump train isolation valves, 2CV-1036 and 2CV-1038, would receive channel 2 AC power and safety initiation circuits; and 2) all of the isolation valves would be kept normally open during non-ESF operation when the EFWS is required to be operable. Human factors concerns dictated that the control switches for these valves be kept in their existing locations in ESF control panels 2C16 and 2C17 near the controls and indication for their associated equipment trains. This use of redundant channel power and devices in each panel required special barrier enclosures for these control switches, and the routing of their cables in metal flex conduit from the point of entry into the panel to the switch enclosures, in order to comply with the separation criteria in effect for ANO-2.

A description of Class 1E systems provided for the plant and the criterion with regard to redundancy and separation for these systems are given in Chapter 8. Electrical power to valves 2CV-1025-1 and 2CV-1075-1 is supplied (via transformer) from ESF Bus 2A3, to valves 2CV-1026-2 and 2CV-1076-2 from DC ESF Bus 2D02, to Valves 2CV-1036-2 and 2CV-1038-2 by ESF Bus 2B6, and to Valves 2CV-1037-1 and 2CV-1039-1 by 125V DC ESF Bus 2D01.

The electrical power to control MOVs 2CV-0760, 2CV-0761, and 2CV-0762 for the non-safety auxiliary feedwater pump discharge flow is supplied from non-ESF Bus 2B1.

The EFWS is provided with necessary control for automatic or manual operation of the system. The controls are in the main control room. All controls and control signals for the steam turbine driven pump and the electric motor driven pump are channelized. Physical separation between the electrical components of this system is provided in accordance with IEEE 279-1971, "Standard Criteria for Protection Systems for Nuclear Power Generating Stations."

10.4.9.2.2 System Operation

The EFWS operations discussed below include normal plant operation, emergency operation, and operation of the EFWS during plant startup, hot standby, hot shutdown, and normal plant cooldown.

During normal plant operation, the EFWS is not required to operate. However, the EFWS will automatically start and operate upon an EFAS or a DEFAS. The situations causing automatic operation of the EFWS are indicated in Section 7.3.1.1.11.8; DEFAS is discussed in Section 7.7.1.7.

When an EFAS is received by the EFWS, both pumps 2P7A and 2P7B will start and provide water to the steam generators as required by level control. Simultaneously, all valves in the discharge lines will open. However, if a steam generator isolation is required, as in the case of a postulated main steam line break, the EFAS will open only the valves leading to the intact steam generator and close the valves leading to the isolated steam generator. A combination of measured variables (level and pressure) for each steam generator are used to determine which generator(s) are intact (see Section 7.3.1.1.11.8). The system logic will then open only the emergency feedwater valves to the intact generator(s) with an EFAS. The valves to a generator that is not intact will not receive an EFAS and will therefore be closed. Should one of these valves receive a spurious signal to open to a generator which is not intact, the other valve in series will be closed precluding feeding of the generator.

If condensate supply pressure falls to 7 psig, an alarm will sound. If pressure falls to 5 psig, with an emergency feedwater actuation signal present, the pressure switches in the condensate supply line will close the condensate line isolation valves and will simultaneously open the SWS supply valves.

The above events will occur without any operator action. The operator can subsequently secure one of the EFW pumps since one pump alone has sufficient capacity to provide the required flow.

The preferred water source for emergency feedwater is condensate; therefore, the system is normally aligned to supply condensate from the condensate storage tanks. In the event of a complete loss of AC power, valve 2CV-0711-2 would not be required to open from its normally closed position because: 1) condensate is preferred and available, and 2) service water would not be available even if 2CV-0711-2 were opened as no AC power would be available to the service water pumps.

If emergency feedwater suction were pulled from service water and a loss of AC power occurred, service water would be lost, necessitating a change to condensate feed. If valve 2CV-0711-2 were AC, it could not close to complete the interlock logic with valve 2CV-0795-2 and allow that valve to open. However, since condensate is the preferred emergency feedwater source, the fact that service water was being used would indicate that no condensate was available. Therefore, operation of the valves would not supply a source of emergency feedwater.

The above discussion shows that valve 2CV-0711-2 could be AC powered and still meet the power supply diversity requirement of NRC Branch Technical Position APCSB 10-1. However, to simplify the connection of interlocks between 2CV-0711-2 and 2CV-0795-2, both valves are equipped with DC operators.

During plant startup, hot standby, hot shutdown, and normal plant cooldown, the auxiliary feedwater pump is the preferred source of feedwater. The AFW pump is manually started and is under operator control. The operator maintains the proper flow to the steam generators by means of control valves 2CV-0760, 2CV-0761, 2CV-1075-1 and 2CV-1025-1 when the flow path is through the interconnected safety related EFW pumps discharge lines or the feedwater control valves 2CV-0744 and 2CV-0753 when the flow path is through the interconnected main feedwater lines. When the AFW system is automatically controlled by the FWCS, the proper flow for steam generator level control is by way of 2CV-0744 and 2CV-0753 through the feedwater lines.

During plant startup, the auxiliary feedwater pump is normally used until sufficient steam is available to run the main feedwater pump turbine drivers and the condensate and feedwater system is placed in operation.

During hot standby and hot shutdown, the auxiliary feedwater pump is normally used to maintain steam generator level. The average feedwater flow requirement in this case is about 320 gpm, which is within the rated capacity of the auxiliary feedwater pump (1000 gpm).

During cooldown, the auxiliary feedwater pump is normally used to maintain steam generator level during decay heat removal operation until the RCS temperature is brought down to about < 275°F, at which point decay heat removal is switched over to the Shutdown Cooling (SDC) System. The operation of the EFWS in this mode lasts about 3.4 hours at an average flow of 510 gpm.

10.4.9.3 Safety Evaluation

The EFWS provides a means of supplying emergency makeup to the steam generators for reactor decay heat removal. Redundancy of components is provided to ensure proper functioning, even in the event of a single component failure within the system. Fail-as-is motor operated gate valves with appropriately diverse power sources and redundant safety channelization are provided to ensure positive isolation when required. Each component is designed to provide 100 percent feedwater capacity for safe cooldown of the RCS.

The design basis minimum flow requirement for the emergency feedwater pumps is that each pump must be capable of delivering sufficient emergency feedwater to the steam generators to preserve their function as a secondary heat sink for normal shutdowns. The pump must also provide sufficient feedwater in combination with pressurizer sprays or the RCS safety valves to preclude over pressurization of the RCS for feedwater line break accidents. For normal operating conditions, the emergency feedwater pump capacity will ensure adequate flow to maintain steam generator water level and primary to secondary heat transfer. For normal operating conditions the evaluation of pump capacity is based on the pump rated flow data rather than the design basis minimum flow used in the accident analyses. Based on the manufacturer's head curves, and assuming nominal hot standby steam generator pressure control at 985 psig, and an allowance of 100 psi for line losses, each pump will provide about 615 gpm to the steam generators. This is sufficient flow to remove decay heat equivalent to 2.74% full power, and the heat from four reactor coolant pumps. Based on the ANS/ANSI 5.1-1979 decay heat curve, the decay energy generation rate falls below 2.74% within approximately 320 seconds and is approximately 2.4% 10 minutes following a reactor trip from full power. While this evaluation does not consider uncertainties such as pump degradation, it does demonstrate that for normal operations, the design capacity of the EFW pumps will easily maintain secondary cooling.

For the main feedwater line break, the cases presented in Section 15.1.14 demonstrate that the emergency feedwater pump capacity in combination with either the pressurizer sprays, if AC power is available, or the RCS safety valves, if AC power is lost, is sufficient to prevent overpressurization of the RCS. The assumptions for EFW capacity used in the main feedwater line break analyses are the design basis minimum flow requirements. The assumptions for EFW flow to the steam generators as a function of steam generator pressure, used in both the loss of feedwater and the main feedwater line break analyses, establish the design basis minimum flow requirements for the EFW pumps.

The MSLB event also requires EFW flow. The EFW system is configured to supply feedwater to the intact steam generator which allows long term secondary cooling following the event. However, the MSLB is an overcooling event that does not challenge the minimum capacity of the EFW pumps. Given that a significant amount of energy will be extracted from the primary during the event, the post event demand on the EFW system will be less than that from either the loss of feedwater or the main feedwater line break.

In a main steam line break from full power with a concurrent loss of AC electrical power and no return to power, there is an immediate trip and the decay heat generation rate is the same as for a loss of AC electrical power transient. Isolation of the intact steam generator on a MSIS due to low steam generator pressure ensures that the steam generator heat removal capacity is initially unaffected. Automatic startup of emergency feedwater to the steam generator connected to the intact steam line is subsequently initiated on a low steam generator water level or can be actuated by operator action. The combination of the steam generator water inventory and emergency feedwater pump capacity is adequate to maintain the secondary heat sink.

For the steam line break cases with a return to power, the intact steam generator water inventory and emergency feedwater pump capacity are also adequate to maintain a level in the steam generator during the transient, thus preserving the secondary heat sink.

The pumps take suction from either of two sources: one of the condensate storage tanks or the redundant and independent SWS lines. The supply lines are designed to ensure isolation of the Seismic Category II condensate water supply line and permit transfer of suction to the Seismic Category I SWS if condensate water from the condensate storage tanks is unavailable. Check valves in the SWS lines prevent loss of suction pressure in the event a SWS line fails or is not pressurized. This suction piping arrangement ensures a positive supply of water to the pumps. The safety-grade condensate storage tank, T41B, is connected to the Unit 2 EFW system as an available source of EFW. This tank is a shared source of EFW with Unit 1.

The uses of an electric motor driver for one Emergency Feedwater pump and a steam turbine driver for the other pump provides maximum pumping availability. The electric motor driver can draw power from normal, preferred, or emergency power sources. The automatic transfer of power supply is discussed in Section 8.3. In the remote case of simultaneous failure of normal, preferred, and emergency electrical power, steam is available from either or both steam generators to drive the turbine driven pump.

The EFWS is required to mitigate the consequences of a rupture in the main steam line or a loss of main feedwater accident as discussed in Sections 10.3.3 and 10.4.7.3, respectively. Table 10.4-11 demonstrates the adequacy of the EFWS to perform its design function in the event of a single active failure within the system. In addition, a single failure of the non-safety related portion of the EFWS has no effects on the safety function of the EFWS. Analyses of the effects of the main steam line and main feedwater line ruptures have been performed, in accordance with the criteria set forth in Section 3.6, to ensure that none of these postulated ruptures would result in a loss of redundancy within the system. The results of these analyses are contained in Chapter 3.

The EFWS supply from one of the condensate storage tanks provides a means of pumping condensate quality water to the steam generators during all modes of operation. The condensate storage tank has sufficient volume to sustain the operation of the EFWS during these conditions. Water level is transmitted to the control room and is alarmed at low level in the selected tank.

The EFWS is designed to remain functional after a DBE. The pumps, valves, SWS supply lines, and the discharge piping are all designed, fabricated, and hydrostatically tested to meet the applicable requirements for ASME Code Section III, Class 3 and Seismic Category 1 components with the exception of the isolation valves (2CV-1036, 1037, 1038 and 1039) and downstream piping, which are designed, fabricated and tested to meet the applicable requirements for ASME Section III, Class 2 and Seismic Category 1 components. The condensate water supply line and the flush and recirculation lines downstream of the first isolation valves are designed to ANSI B31.1.0 requirements. The pumps and the components of the EFWS are all Seismic Category 1 and are installed within the Seismic Category 1 auxiliary building.

The auxiliary feedwater pump is non-seismic and is installed within the Turbine Building. The discharge piping for the auxiliary feedwater pump is designed in accordance with ASME Code, Section III, Class 3 criteria from the first isolation check valve (2EFW-28, 2EFW-30) to its tie-in with the EFW pump discharge piping.

In the event of a break in the common steam supply line to the turbine driven emergency feedwater pump, the steam flow through the break will not exceed 4.7 percent of the main steam flow. Should a pump discharge valve, e.g., 2CV-1075, stick open in the line to the low pressure generator, i.e., 2E24B, the other valve in series, i.e., 2CV-1036, will remain closed as it is actuated by a different EFWS bus. This redundancy will protect both feedwater pumps from a runout flow condition under the postulated single failure (valve sticks open).

The common suction piping for the safety related emergency feedwater pumps 2P7A and 2P7B includes the pressure safety relief valve 2PSV-0706 with a set pressure of 150 psig to prevent the overpressurization of the piping due to the possible leakage of the EFW pumps discharge stop check valves during the auxiliary feedwater pump operation.

10.4.9.4 Tests and Inspections

Historical data removed Section 10.4.9.4 of the FSAR.

Each EFWS pump is designed, fabricated and hydrostatically tested to the requirements of ASME Code Section III, Class 3. The piping and valves are designed, fabricated, and hydrostatically tested to ASME Code Section III, Class 3 requirements.

The portion of the EFWS piping inside the containment is furnished with removable insulation for inservice inspection.

The EFWS is normally in use during plant startup and shutdown and proper operation of all components will be observed at these times. The emergency start capability will be functionally tested as required by the Technical Specifications.

10.4.9.5 Instrumentation Applications

DISPLAY INFORMATION - Display instrumentation related to the EFWS is discussed in Section 7.5. Information indicative of the readiness of the EFWS prior to operation and the status of active components during system operation is displayed for the operator in the control room.

Indicating lights are provided to monitor equipment status. Each motor-driven component has "on" and "off" indicating lights; each remotely controlled open-shut service valve has corresponding open-shut light indication; and each breaker control switch has an associated open-shut indicating light. A red light is used to indicate an operating status, i.e., motor running, valve not fully closed, or breaker closed. A green light indicates that the equipment is not in an operating status, i.e., motor off, valve not fully open, or breaker open.

Equipment availability and bypass status indication/annunciation are provided as described in Section 8.3 and Chapter 7.

Sensing and indicating instruments are provided for emergency feedwater pump discharge pressure, feedwater flow rate, feedwater pump turbine speed, and turbine supply steam pressure. Condensate water supply pressure and SWS supply pressure are indicated and low pressure is alarmed. Indication and alarm are also provided for condensate storage tank level.

EFWS component inoperable alarm circuits monitor the status of associated electrical equipment and the EFWS suction and discharge valves. The EFWS component alarm circuits alarm in the control room. In addition, an EFWS turbine pump train inoperable alarm will annunciate in the control room whenever steam supply valves 2CV-1000-1 and 2CV-1050-2 are not fully open.

SYSTEM INITIATION - Initiating circuits and logic are discussed in Chapter 7.

10.4.10 STARTUP AND BLOWDOWN DEMINERALIZER SYSTEM

10.4.10.1 Design Bases

The startup and blowdown demineralizer system, shown in Figure 10..2-4, is designed to fulfill the following requirements:

A. to achieve and maintain the chemistry requirements of the water inventory in the condensate and feedwater system prior to introduction of feedwater into the steam generators during plant startup operations; and,

B. to process the liquid discharged by the steam generator blowdown system.

This system is designed to demineralize quantities of water originating in the secondary systems during plant startup operations and during normal plant operations. The bases for sizing the system were the temperatures, pressures, quantities and chemistry of fluids to be processed.

The pressure vessels in the system have been designed in accordance with ASME Code, Section VIII requirements. The appropriate requirements of ANSI, ASTM, ASME, Hydraulics Institute, IEEE, and NEMA have been included in the design and fabrication standards for components in the system. The components of the system are located outside the containment.

10.4.10.2 System Design and Operation

The startup and blowdown demineralizer system consists of the following components:

A. steam generator blowdown heat exchangers (2E68A, B)

B. one startup and blowdown demineralizer (2T94A) and one steam generator blowdown demineralizer (2T94B)

C. three resin regeneration system pressure vessels (2T95, 96, 97)

D. one regeneration heater (2E69)

E. one demineralizer regeneration pump (2P138)

F. two resin traps (2F212A,B)

G. piping, valves, and instrumentation

H. one startup blowdown condensate filter (2F-807)

I. one steam generator blowdown filter (2F-808)

Demineralizer Regeneration Equipment - The active Demineralizer Regeneration Equipment consists of a 17,000 gallon acid storage tank, a 17,000 gallon caustic storage tank, and a caustic heating system. The acid tank and caustic tank (as well as the adjacent ammonia storage tank) are surrounded by a concrete wall to protect nearby equipment in the event of a tank rupture. In addition, the caustic tank vents are heat traced to prevent the vent pipes from freezing during cold weather.

Following the initial stages of cleaning the condensate and feedwater system prior to the plant startup, a recirculation flow from the discharge of feedwater heaters 2E1A & B back to the condenser passes through the startup and blowdown demineralizer. The recirculation cleanup flow rate is 3,200 gpm and will be maintained below 140°F to prevent damage to the mixed bed resin.

During normal plant operation, the effluent from the steam generator blowdown tank is processed in this system. The startup and blowdown demineralizer (2T94A) must process a minimum flow of 624 gpm to prevent resin bed channeling. The blowdown flow is supplemented by flow from the condensate pumps to meet the 624 gpm requirement during normal plant operation. The steam generator blowdown demineralizer (2T94B) is designed to operate at flows from 60 to 500 gpm. The steam generator blowdown heat exchanger is used to cool the blowdown, if required, before it passes through the demineralizer or is discharged to the circulating water flume via the regenerative waste transfer system. Auxiliary cooling water is the cooling fluid in the heat exchanger. The demineralizer blowdown is returned to the condenser for water conservation.

Adequate instrumentation and sampling of fluids is provided to ensure that proper operation of the system and to indicate when cleaning and/or regeneration of the demineralizer mixed bed resin is required.

When regeneration or cleaning of the resin is needed, the resin is transferred to the regeneration vessels. All waste water from the cleaning regeneration sequences including backwashes, regenerant chemicals, sluice water, etc. is discharged to the regenerative waste processing system shown in Figure 11.1-1. The startup and blowdown demineralizer system is designed to process radioactive steam generator blowdown. During the regeneration sequence, the radioactive constituents are removed from the resin and discharged with the regenerant waste water to the regenerative waste processing system. The regenerant waste water volumes generated are summarized in Table 11.2-24.

10.4.10.3 Design Evaluation

The startup and blowdown demineralizer system has no potential radioactivity release path to the environment except to the circulating water flume via the Emergency Feedwater System. In the event that the fluid being processed in the system is radioactive, the system has the effect of concentrating the activity on the resin which is then discharged to the regenerative waste processing system during a regeneration. The system has no safety-related function. Failure of any component in the system would compromise the system operation but would not affect safe shutdown of the plant.

10.4.10.4 Testing and Instrumentation Applications

The startup and blowdown demineralizer system is functionally tested to ensure satisfactory operation for all operating modes.

A local control panel is provided for system monitoring and control. Chemistry monitoring instrumentation is provided on the process lines to ensure efficient demineralizer operation. Trouble alarms are provided in the control room to indicate "train exhausted" and "service trouble".

TABLE 10.3-4

**MAIN STEAM ISOLATION SYSTEM
SINGLE FAILURE ANALYSIS**

COMPONENT	FAILURE	COMMENTS AND CONSEQUENCES
Main Steam Isolation Valves (MSIV) (2CV-1060-2, 2CV-1010-1)	Electrical failure of MSIS or CSAS actuation circuitry to MSIV.	Redundant solenoid valves are provided on the air supply and exhaust lines to the air cylinders on each of the MSIVs. Redundant power supplies, CSAS, and MSIS signals to these solenoid valves preclude the possibility of a single electrical failure resulting in the failure of the MSIV to close.
	Mechanical failure resulting in failure of MSIV of either steam generator to close on MSIS.	The MSIVs are designed such that they will close upon loss of air with the springs only. A mechanical failure resulting in the failure of the MSIV to close is not considered credible.
Main Feedwater Isolation Valves (2CV-1024-1, 2CV-1074-1, 2CV-1023-2, 2CV-1073-2)	Affected steam generator feedwater isolation valve fails to close on MSIS or CSAS.	MSIS or CSAS trips the main feedwater pump turbine drivers, trips the condensate pumps and the heater drain pumps. Redundant MFWIV closes. See Note 1.
	Unaffected steam generator feedwater isolation valve fails to close on MSIS or CSAS.	MSIS or CSAS trips the main feedwater pump turbine drivers, trips the condensate pumps and the heater drain pumps. See Note 1.
Main Feedwater Pumps (2P1A,B)	MSIS or CSAS fails to trip a main feedwater pump turbine driver.	MSIS or CSAS closes main feedwater isolation valves. Closure of MSIV's results in loss of steam supply to main feedwater pump turbine driver. All other CFWS pumps trip on MSIS or CSAS. Note 2.
Condensate Pumps (2P2A,B,C,D)	MSIS or CSAS fails to trip one condensate pump.	MSIS or CSAS closes main feedwater isolation valves and trips other CFWS pumps. Both channels of MSIS and CSAS are applied to each pump. Note 2.

Table 10.3-4 (continued)

COMPONENT	FAILURE	COMMENTS AND CONSEQUENCES
Heater Drain Pumps (2P8A,B)	MSIS or CSAS fails to trip one heater drain pump.	MSIS or CSAS closes main feedwater isolation valves and trips all other CFWS pumps. Both channels of MSIS and CSAS are applied to each pump. Note 2.
Atmospheric Steam Dump Isolation Valves (2CV-1002, 2CV-1052)	Spurious "OPEN" signal.	Valves are normally closed. MSIS provides backup "CLOSE" command and prevent spurious "OPEN" signal.
Steam Generator Blowdown Tank Isolation Valves (2CV-1016-1, 2CV-1066-1)	Spurious "OPEN" signal or failure of one MSIS to provide "CLOSE" signal.	Valves fail closed on loss of air. Redundant and independent MSIS signals are provided to separate air supply solenoid valves to ensure that the blowdown tank isolation valves close even if one solenoid valve fails.

NOTES:

(1) The main feedwater turbine driver steam supply valves and the condensate pumps are non-Class 1E equipment and are powered from non-vital power supplies. Both channels of MSIS and CSAS will trip the heater drain, condensate, and main feedwater pumps. During a loss of off-site power, these are de-energized which is the safe condition. Section 6.2.1 presents an analysis of the most limiting single failure and its effect on containment pressure.

(2) The main feedwater isolation and backup valves are redundant only for retention of upstream condensate. The valves are not credited for closing with more than one condensate, heater drain, or feedwater pump running.

Design flow rate, gpm	15,700
Size of Connections	
Suction	24-inch flanged
Discharge	24-inch buttweld
Design head, ft.	1,240 @ 3,775 RPM
NPSH required at design flow rate, ft.	130
Maximum operating flow rate, gpm	24,000 @ 5,050 RPM
Head at maximum operating flow rate, ft.	1,900 @ 5,050 RPM
NPSH required at maximum operating flow rate, ft.	250
Minimum available NPSH, ft.	901
Shut off head, ft.	2,775 @ 5,050 RPM
Materials of construction	
Casing	ASTM A217 C5
Impeller	17-4 PH
Shaft	Type 410 SS
Driver	
Type	Variable speed steam turbine
bhp	11,250 @ max. flow rate

TANK DATA**

Characteristics	Data
Equipment number	2T67
Quantity	1
Type	Horizontal
Stored material	Condensate
Design pressure, psig	200
Normal operating temperature, °F	200
Tank dimensions: ft.	
Outside diameter	6
Overall length	10
Capacity, gal.	---
Material of construction:	ASTM SA-515-70
Tank internals separator	4" thick SS entrainment

Table 10.4-9

STEAM GENERATOR BLOWDOWN PUMP DATA

Characteristics	Data
Equipment numbers	2P139A,B
Quantity	2
Type	Horizontal, end-suction, 1-stage
Pumped liquid	Blowdown condensate
Design pressure, psig	180
Design temperature, °F	250
Design flow rate, gpm	180
Design head, ft.	180
NPSH required at design flow rate, ft.	7.5
Maximum operating flow rate, gpm	270
Head at maximum operating flow rate, ft.	120
NPSH required at maximum operating flow rate, ft.	11.0
Minimum available NPSH, ft.	17
Materials of construction	
Casing	A 395
Impeller	A 48 C1.25
Shaft	A 322 Gr. 4140
Driver	
Type	Induction motor
Service factor	1.15
Nameplate horsepower rating	20
Voltage	460
RPM	3450

EMERGENCY FEEDWATER PUMP DATA

Characteristics	Data
Equipment	2P7A,B
Quantity	2
Type	Centrifugal-horizontal-multistage
Pumped fluid	Water
Design pressure, psig	1600
Design temperature, °F	100
Design flow rate, gpm	575
Design head, ft.	2800
NPSH required at design flow rate, ft.	16
Minimum available NPSH, ft.	32
Discharge pressure at shutoff, psig	1390
Rated speed, rpm	3575[1]
Materials of construction:	
Casing	ASME SA 216 Gr. WCB
Impeller	ASME SA 351 Gr. CA-15
Shaft	ASME SA 479 Type 410 H.T.
Turbine driver:	
Type	Solid wheel, variable speed, horizontal
Steam inlet pressure: psia	
Operating	Function of steam generator pressure
Minimum	60
Maximum	1100
Steam condition, 0/0 moisture	1/2
Back pressure, psig	10
Rated bhp	575
Rated speed	3575[1]
Electric motor driver:	
Voltage	4000
Rated rpm	3600
Rated bhp	600

[1] 2K-3 turbine and 2P-7A pump speed of 3790 rpm is authorized by Byron Jackson and Terry Turbine. 2K-3 turbine and 2P-7A pump speed of 3790 rpm has been accepted by Operations in accordance with PER 2-83-06 dated July 7, 1983.

Table 10.4-10A

AUXILIARY FEEDWATER PUMP DATA

Characteristics	Data
Equipment	2P75
Quantity	1
Type	Centrifugal-Horizontal-Multistage
Pumped fluid	Water
Design pressure, psig	1600
Design temperature, °F	160
Design flow rate, gpm	1000
Design head, ft.	2694
NPSH required at design flow rate, ft.	17
Minimum available NPSH, ft.	23
Discharge pressure at shutoff, psig	1460
Rated speed, rpm	3550
Materials of construction:	
Casing	Carbon Steel
Impeller	13-4 Chrome/Nickel
Shaft	410 HT-Steel
Electric motor driver:	
Voltage	4000
Nameplate rpm	3600
Rated bhp	1000

Table 10.4-11

EMERGENCY FEEDWATER SYSTEM
SINGLE FAILURE ANALYSIS

Component	Failure	Comments & Consquences
Condensate Water Supply	Failure of normal supply from condensate storage tank.	Condensate wate supply line will be isolated and SWS isolation valves will automatically open
Service Water Line	Failure of a line supplying service water to pumps.	Service water will be supplied by other line.
EFW Pumps	Failure of electric motor driven pump to operate.	Steam driven pump will operate and supply 100% required flow.
	Failure of steam driven pump to operate.	Motor driven pump will operate and supply 100% required flow.
EFW Discharge Piping System	One of two series valves in the supply lines fails to close during steam generator isolation (EFAS).	Other valve will close. (Valve uses a power supply from a redundant power supply to the first series valve.)
	One of two series valves fails to open (EFAS).	Affected steam generator will be supplied by the other supply line.
Turbine driver	Loss of steam supply from one steam generator due to low steam generator pressure.	100% required steam will be supplied by intact steam generator.
	EFAS and Failure of ESF bus 2D01	2P7B cannot start. However since 2CV-1037 and 2CV-1039 are normally open, turbine train can supply either generator.

11 RADIOACTIVE WASTE MANAGEMENT

The purpose of this section is to provide assurance that the plant has sufficient installed capacity and treatment equipment in the radioactive waste (radwaste) systems to reduce the radioactivity to levels which will not be in excess of the appropriate limits for the general public or plant personnel and are as low as practicable.

Actual operating experience may differ from the assumptions used in this chapter.

Note: In descriptions of detectors, monitors, and samplers, ″in-line″ or ″on-line″ means that the instrument is in the process flow. ″Off-line″ instruments require a venturi or sample pump to provide a representative sample.

11.1 SOURCE TERMS

This section defines the sources of radioactivity which serve as input into the various radwaste systems. These are original design basis assumptions and analyses which were used to verify the adequacy of the radwaste systems as designed.

11.1.1 FISSION PRODUCTS

[This section consists of historical information.]

The mathematical model used for determining the specific concentration of nuclides in the reactor coolant involves a group of time dependent simultaneous equations. The fuel pellet region and the reactor coolant region are analyzed by applying a mass balance of production and removal for each nuclide thereby establishing a set of first order, differential equations. In the fuel pellet region, the mass balance includes the fission product production by direct fission yield, by parent fission product decay and by neutron activation, and removal by decay, by neutron activation, and by escape to the reactor coolant. In the coolant region, the analysis includes the fission product production by escape from the fuel through defective fuel rod cladding, parent decay in the coolant, and neutron activation of coolant fission products. Removal is by decay, by coolant purification by feed (makeup) and bleed (letdown to Boron Management System (BMS), and by leakage or other feed and bleed due to such operations as cold or hot startups and shutdowns or load follow operations.

The expression derived to determine the fission product inventory in the fuel pellet region is:

$$\frac{dN_{pi}}{dt} = FY_iP + \left(f_{i-1}\lambda_{i-1} + \sigma_{i-1}\phi\right)N_{pi-1} - \left(\lambda_i + \upsilon_i + \sigma_i\phi\right)N_{pi} \qquad \text{Eq. 11.1.1}$$

and in the reactor coolant region is:

$$\frac{dN_{ci}}{dt} = D\upsilon_iN_{pi} + \left(f_{i-1}\lambda_{i-1} + \sigma_{i-1}\phi\ FCS\right)N_{ci-1} - \left[\lambda_i + \frac{R_p}{W_c}\eta_i + \frac{\left(1-\eta_i\right)}{C_o - \dot{C}t_i}\dot{C} + \lambda_c\right]N_{ci} \qquad \text{Eq. 11.1.2}$$

where

N = Population (atoms)

F = Average fission rate (fission/MWt-sec)

Y = U-235 fission yield of nuclide (fraction) (Reference 31)

P = Core power (MWt)

λ = Decay constant (sec^{-1}) - Half lives taken from the "Chart of Nuclides" (Reference 3)

σ = Microscopic capture cross section (cm^2) (Reference 11)

ø = Thermal neutron flux (neutrons/cm^2-sec)

υ = Escape rate coefficient (sec^{-1})

f = Branching fraction

t = Time (sec)

D = Defective fuel rod cladding (fraction)

FCS = Core coolant volume-to-reactor coolant volume ratio

R = Purification flow rate during power cycle (lbm/sec)

W = Reactor coolant mass during power cycle (lbm)

η = Resin efficiency of Chemical and Volume Control System (CVCS) ion exchanger for a given nuclide

C_o = Beginning of Cycle (BOC) boron concentration (ppm)

$\dot{C}$ = Boron reduction rate by feed and bleed (ppm/sec) compensating for fuel burnup

Subscripts

P = pellet region

C = coolant region

I = Designates the nuclide parameters (i.e., XE^{133})

i-1 = Designates the parent nuclide parameters (i.e., I^{133})

This model does not involve the fuel plenum and gap region. Instead escape rate coefficients are used to represent the overall release for the fuel pellets to the reactor coolant. Plenum and gap region activities are presented in Section 15.1.23.

The primary factor in determining the fission product inventories is the escape rate coefficient. This is an empirical coefficient which was derived from experiments initiated by Bettis and run in the NRX and MTR reactors (Reference 27). The present escape rate coefficient derived from these data are shown in Table 11.1-1. The escape rate coefficients were obtained from test rods which were operated at high linear heat rates. The linear heat rates were uniform over the test sections which were only 1.25 inches in length. The exact linear heat rates were not precisely known but post-irradiation inspection showed that some test rods had experienced centerline melting. Later tests were done in Canada to determine the effect of rod length on the release of fission gases and iodines from defective fuel (Reference 18). A byproduct of these experiments was the effect of linear heat rate on the escape rate coefficient. Escape rate coefficients for several nuclides as a function of the linear heat rate are shown in Figure 11.1-1. Also shown in Figure 11.1-1 are the escape rate coefficients used for noble gases and halogens. Since the average heat rate for a fuel rod (approximately 7 kilowatts per foot) is well below the crossover point in Figure 11.1-1 which is above 17 kilowatts power foot in each case, the presently used escape rate coefficients are conservative.

The fission product activity concentration used as basic source terms are given in Tables 11.1-2 through 11.1-4. The data used for these calculations are given in Table 11.1-1.

11.1.2 CORROSION PRODUCTS

[This section consists of historical information.]

The activity of radioactive crud and its thickness on primary system surfaces have been evaluated using measured data from various operating Pressurized Water Reactors (PWR's). (References 4, 5, 8, 9, 10, 15, 16, 17, 37 and 38).

Even though these reactors have different water chemistries and different materials in contact with the primary coolant, their crud activity (dpm/mg-crud), crud film thicknesses and dose rates due to this crud are markedly similar. The half-lives, reactions and gamma weighted average decay energy for each of the long-lived isotopes in the radioactive crud are as shown in Table 11.1-5. The long-lived isotopes are those significant isotopes remaining after a 48-hour delay.

The radioactive crud originates on in-core and out-of-core surfaces. The crud plates out on the in-core surfaces and re-erodes after a short irradiation period. This irradiation period or core residence time is determined by the following expressions.

Circulating Crud:

$$t_{res} = \frac{1}{\lambda} \ln\left[1 - \frac{A \;\; S \;\; (16.67)}{\Sigma_c \, \phi \;\; C}\right] \text{sec} \qquad \text{Eq. 11.1.3}$$

where

A is the crud activity (dpm/mg-crud)

S is the total primary system area (cm^2)

$\Sigma_c\phi$ is the activation rate (d/g-sec)

C s the core surface area (cm^2)

λ is the decay constant (sec^{-5}).

See Section 11.1.8 for the derivation of Equation 11.1.3.

Deposited Crud:

$$t_{res} = -\frac{1}{\lambda}\ln\left(1 - \frac{A(16.67)}{\Sigma_c \phi}\right), \quad \text{secs.}$$

The average and maximum crud activities (dpm/mg-crud) for those reactors considered in the determination of the core residence times are as shown in Table 11.1-6. The average and maximum core residence times as determined by the above expressions and the activities in Table 11.1-6 are as shown in Table 11.1-7. As all the Fe-59 residence times are long, its activity is assumed saturated. The average values of the maximum residence times for each isotope are also given.

Utilizing these average values of the maximum core residence times, the calculated crud activities (dpm/mg-crud) are determined by the following expression:

$$A = \Sigma_c \phi\left(1 - e^{-\lambda t_{res}}\right)0.06\frac{C}{S} \quad , \ \text{dpm/mg} \qquad \text{Eq. 11.1.4}$$

As the average values of the maximum residence times are used, the calculated crud activities will be conservative. The resulting calculated crud activities of the long-lived isotopes considered are as shown in Table 11.1-8.

Using the average crud level in the primary coolant (75 ppb) of those operating reactors shown in Table 11.1-6 and the calculated crud activities (dpm/mg crud), the average isotopic activities in the primary coolant are determined by the following expression:

$$\overline{A} = \frac{A}{60} (75 \times 10^{-6}) \rho (2.7 \times 10^{-5}), \ \mu\text{ci/cm}^3 \qquad \text{Eq. 11.1.5}$$

where

ρ is crud density (g/cm^3)

The average calculated activities of the primary coolant using the above expression are also shown in Table 11.1-8. The maximum coolant activities can be higher due to "crud bursts" during shutdowns or changes in power. However, these "bursts" occur over a short period of time; therefore, the average values are more reasonable to use for long-term operation.

The equilibrium thickness of radioactive crud film (mg crud/cm^2) has been determined by two methods:

A. The direct measurement of the film during maintenance and or tests in operating reactors.

B. Calculating crud film thickness from measured dose rates and specific activities (dpm/mg crud) of deposited crud.

The equilibrium crud film thicknesses for various primary system areas are as shown in Table 11.1-9.

11.1.3 TRITIUM PRODUCTION

[This section consists of historical information.]

Tritium may be produced in the coolant or enter the coolant from a number of sources. One source is from fissioning of uranium within the fuel yielding tritium as a ternary fission product. Since zircaloy fuel cladding reacts with tritium to form zirconium hydride, no tritium diffuses through the cladding (References 33 and 36). Therefore, the tritium released to the coolant from the fuel is only from defective fuel rod cladding.

Tritium is also produced by the reaction of neutrons with boron in the Control Element Assemblies (CEA's). Data from operating plants using B_4C control rods indicates that no tritium is released from the control rods. The tritium may combine with carbon to form hydrocarbons and or with lithium to form lithium hydride thereby preventing diffusion through the NiCrFe cladding. Another possibility is the low internal temperature of the B_4C control rods (relative to stainless clad fuel rods from which about 45 percent escape can be expected) may prohibit tritium diffusion. To account for possible control rod cladding defects it is assumed that one percent of the tritium produced in the CEA is released to the coolant.

Other sources of tritium are the activation of boron, lithium, deuterium, and nitrogen within the reactor coolant. Boron in the form of boric acid is used in the coolant for reactivity control. Lithium is produced in the coolant as a result of neutron-boron reaction and may also be added as a pH control agent. Deuterium is a naturally occurring constituent of water. Nitrogen may be present due to aeration of the coolant during shutdown and due to aerated makeup water.

The expression used to determine the Reactor Coolant System (RCS) tritium inventory is:

$$\frac{dN}{dt} = A(t) - B(t)N$$

where N is the tritium population in atoms, A(t) is the generalized production rate in atoms/sec and B(t) is the removal rate in sec^{-1}. The expressions for A(t) and B(t) are:

$$A(t) = PFYD(C_o - \dot{C}_t)(L_o - \dot{L}t)(FCS)E$$

$$B(t) = \lambda + \left(\frac{\dot{C}}{C_o \dot{C}t}\right) + \lambda_c$$

where

P = Core power (MWt)

F = Average fission rate (fissions/MWt-sec)

Y = Yield (see Table 11.1-10)

D = Defective fuel rod cladding (fraction)

C_o = nitial boron concentration (ppm Boron)

$\dot{C}$ = Boron concentration reduction rate (ppm B/sec)

L_o = Initial lithium concentration (ppm Lithium)

$\dot{L}$ = Core coolant volume to reactor coolant volume ratio

FCS = Core coolant volume to reactor coolant volume ratio

E = Equivalent full power CEAs in the core

λ = Tritium decay constant (sec^{-1})

λ_c = Leakage constant (sec^{-1})

As indicated in Table 11.1-10, when one or more factors of A(t) do not apply to a given source, they reduce to unity, leaving A(t) unaffected. Hence, only one expression is needed to calculate tritium production from all sources.

Tables 11.1-2, 11.1-3 and 11.1-4 list the appropriate tritium concentrations obtained using this model.

11.1.4 NITROGEN-16 ACTIVITY

[This section consists of historical information.]

Nitrogen-16 is produced by the $^{16}0(n,p)^{16}N$ reaction when beta decays, emitting high energy gammas 82 percent of the time. The gamma energies are 6.13 and 7.10 mev in a ratio of 12.5 to 1.0. The N-16 half-life is 7.13 seconds. The threshold for the reaction is 10.2 mev.

The N-16 activity at the reactor vessel outlet nozzle is 4.08×10^6 disintegrations/cm^3-sec. This activity is based on the following expression and reactor parameters:

$$\text{Activity (d/cm}^3\text{-sec)} = \frac{\Sigma\phi\left(1-e^{-\lambda t_c}\right)e^{-\lambda t_R}}{\left(1-e^{-\lambda t_T}\right)}$$

where

$\Sigma ø$ = reaction rate (4.23×10^7 d/cm^3-sec),

t_c = core transit time (0.80 sec),

t_T = total primary loop transit time (11.59 sec),

t_R = time from the core outlet to the point of interest (1.42 sec. to outlet nozzle).

λ = N-16 decay constant (0.0943 sec^{-1})

11.1.5 FUEL EXPERIENCE

[This section consists of historical information.]

Zircaloy-clad UO_2 fuel in the Obrighem reactor in Germany sustained a fuel failure rate just over 0.1 percent in its first cycle; this has fallen in the second cycle to essentially zero (< 0.00 percent). The fuel failure rate in the Dresden 1 reactor over a 9-year period has averaged < 0.1 percent with the rate more recently being even lower. Fuel in the Mihama reactor in Japan and the Point Beach reactor has exceeded the burnup at which failures in fuel of similar design were observed in Ginna, without exhibiting increases in coolant activity (indicative of fuel defects).

The fact that widespread defects in some reactors, associated with fuel clad contamination, have now been recognized, and corrective measures taken, provides further assurance that failures at this frequency from this cause will not occur in the future. Nevertheless, there is always the possibility, despite careful testing and manufacture, that other defects will become apparent in new fuel designs in the future which, because of statistical considerations or unrecognized or uncontrollable environmental differences, could not be foreseen. The design refinements continually introduced to nuclear power reactors and their fuel as a natural outcome of a dynamic industry will, on rare occasions, introduce such defects. Existing licensing regulations limit coolant activity to that associated with one percent failed fuel, even during those transitory and infrequent periods. Over the lifetime of an operating reactor, it is expected that reactor coolant activity levels corresponding to 0.1 percent failed fuel will predominate.

11.1.6 REACTOR COOLANT LEAKAGE

[This section consists of historical information.]

Systems containing radioactive coolant are potential sources of leakage that can contribute to the total release to the environment. If leakage occurs from systems containing reactor coolant, gaseous radioactivity could be released via several pathways.

Leakage from the RCS exposed to the containment atmosphere is expected to be 40 gallons per day or less. Concentrations of the nuclides up to those defined in Table 11.1-2 with one percent failed fuel could enter the containment. Under equilibrium conditions, 10 percent or less of the iodine and particulates leaking into the containment remains in the atmosphere and is available for release. The other 90 percent of the iodine and particulates is either plated out in the containment or remains in the liquid and is collected in the containment sump. The annual average exposed leakage into the auxiliary building is expected to be 20 gallons per day or less. The maximum specific activity of the leakage with one percent failed fuel is indicated in Table 11.1-2.

Means of detecting leakage are discussed in Section 5.2.7.

11.1.7 STEAM GENERATOR ACTIVITY

[This section consists of historical information.]

Radionuclides will be released in effluents from the secondary system during periods of primary-to-secondary leakage through defective steam generator tubes. Annual releases in liquid and gaseous effluents are given in Sections 11.2 and 11.3, respectively. These releases have been derived from equilibrium radionuclide concentrations in steam generator water during assumed conditions of reactor coolant activity, primary-to-secondary leak rate and steam generator blowdown rate.

Assuming that radionuclides are removed from the secondary system only by exhausting through the main condenser vacuum pumps, by steam generator blowdown, or by radioactive decay during steam generator residency, the activities of radionuclides in steam generator water are described by the equation:

$$\frac{dN_{Si}}{dt} = \frac{R_L\ N_{Ci}}{V_s} - \left[\frac{R_s\,\eta_{Si}\ (1 - \eta_{Ci})}{V_S} + \lambda_i + \frac{R_B}{V_S}\right] N_{Si}$$

where

N_s	=	nuclide concentration in steam generator water (µCi/cc)
N_C	=	nuclide concentration in reactor coolant (µCi/cc)
R_L	=	primary to secondary leakage rate (cc/sec)
R_S	=	main steam flow rate (cc/sec)
R_B	=	steam generator blowdown flow rate (cc/sec)
V_S	=	steam generator liquid volume (cc)
λ	=	radioactive decay constant (sec^{-1})
η_S	=	nuclide concentration in steam/nuclide concentration in steam generator water
η_C	=	1 - 1/main condenser partition factor
i	=	nuclide index.

Under the assumption of constant reactor coolant activities, the concentrations of nuclides in steam generator water at equilibrium are given by:

$$N_{Si} = \frac{R_L N_{Ci}}{R_S \eta_{Si}(1 - \eta_{Ci}) + \lambda_i V_S + R_B}$$

An additional source term is employed in the above equations to determine activities of daughter nuclides in steam generator water resulting from decay of precursor nuclides within the secondary system.

The parameters appearing in the above formulation which have been used to calculate equilibrium steam generator water activities are given in Table 11.1-11. Equilibrium steam generator steam and water activities upon which normal and anticipated operational occurrence secondary system effluents have been determined are given in Tables 11.1-12 and 11.1-13.

11.1.8 DERIVATION OF CORE RESIDENCE TIME (EQUATION 11.1.3)

[This section consists of historical information.]

For Circulating Crud

A. The number of radioactive atoms in the film on in-core surface is:

$$\frac{dN_f}{dt} = \Sigma_c\phi - \lambda N_f$$

where

N_f = Number of radioactive atoms in film

λ = Decay constant

$\Sigma_c\phi$ = Reaction rate

Integrating the above equation:

$$N_f e^{\lambda t} = \frac{\Sigma_c \phi e^{\lambda t}}{\dot{\lambda}} + C$$

where

C = Constant of Integration

Evaluating C:

At t=0, N_F=0

Therefore:

$$C = \frac{-\Sigma c\phi}{\lambda}$$

Substituting C into the Equation for N_f

$$N_f = \frac{-\Sigma c\phi}{\lambda}(1 - e^{-\lambda t}) \text{ atoms/gm}$$

Since t is the in-core residence time, the above equation becomes:

$$N_f = \frac{-\Sigma c\phi}{\lambda}(1 - e^{-\lambda t\ res})$$

B. Now determining an expression for the net number of radioactive atoms released to the coolant:

$$\frac{dN_R}{dt} = N_F RC - (\propto + \beta + \lambda) N_R$$

where

N_R = Number of atoms released

R = Erosion rate

C = Core surface area

$\propto$ = Plateout rate

β = Purification cleanup rate

Integrating the above equation:

$$N_R e^{(\propto+\beta+\lambda)t} = \frac{N_f RCe^{(\propto+\beta+\lambda)t}}{\propto+\beta+\lambda} + D$$

where

D = Constant of Integration

Evaluating D:

At t=0, N=0

Therefore:

$$D = \frac{-N_f RC}{\propto+\beta+\lambda}$$

Substituting D into the equation for N_R:

$$N_R = \frac{N_f RC}{\propto+\beta+\lambda}\left[1-e^{-(\propto+\beta+\lambda)t}\right] \text{atoms}$$

C. Determining the total net amount of crud released to the coolant from all primary system surfaces assuming that the contribution of radioactive crud is negligible,

$$\frac{dM_R}{dt} = RS - (\propto+\beta)M_R$$

where

M_R = Total crud released from system surfaces

S = Total RCS surface area

Now integrating and solving for the constant of integration similar to the method used for determining N_R:

$$M_R = \frac{RS}{\propto+\beta}\left(1-e^{-(\propto+\beta)t}\right) \text{ gm - crud}$$

D. Then the activity of crud released to the system is:

$$A = \lambda \frac{N_R}{M_R} \quad \text{dps / gm - crud}$$

Substituting for N_R and M_R, and since λ is small as compared to $\propto$ and β, the activity becomes:

$$A = \frac{\Sigma_c \phi C}{S}\left(1 - e^{-\lambda t_{res}}\right)$$

Rearranging and solving for t_{res}

$$t_{res} = \frac{-1}{\lambda} \ln\left(1 - \frac{AS}{C\Sigma_c \phi}\right)$$

With the units of A in dpm/mg-crud and the units of $\sum_c \phi$ in dps/gm the above equation becomes:

$$t_{res} = \frac{-1}{\lambda} \ln\left(1 - \frac{16.67AS}{C\Sigma_c \phi}\right)$$

<u>For Deposited Crud</u>:

A. The activity deposited on in-core surfaces is:

$$A = \lambda N_f \qquad \text{dps/gm}$$

Substituting for N_f:

$$A = \Sigma_c \phi\left(1 - e^{-\lambda t_{res}}\right)$$

or

$$t_{res} = \frac{-1}{\lambda} \ln\left(1 - \frac{A}{\Sigma_c \phi}\right)$$

With the units of A in dpm/mg-crud and the units of $\sum_c \phi$ in dps/gm the above equation becomes:

$$t_{res} = \frac{-1}{\lambda}\left(1 - \frac{16.67A}{\Sigma_c \phi}\right)$$

11.2 LIQUID WASTE SYSTEMS

11.2.1 DESIGN OBJECTIVES

The Boron Management System (BMS), the Waste Management System (WMS), and the Regenerative Waste Processing System (RWPS) are designed to provide controlled collection, handling, treatment, and disposal of radioactive wastes from plant operation. Due to technological changes in waste monitoring and processing, alternative, vendor-supplied, specifically authorized methods may be used. The principle original design criteria to ensure protection of the general public from hazardous radiation exposure by maintaining activity release levels as low as practicable and to provide a reliable, functional, processing system were as follows:

A. Process the various potentially radioactive liquid wastes such that the radioactivity release to the environment during normal plant operation will be in accordance with the Appendix I limits to 10 CFR 50. The numerical design objectives for releases during normal operation were to limit the average annual liquid activity release quantity to five Ci and the average annual liquid activity release concentration to 2×10^{-8} uCi/cc (excluding tritium and dissolved fission product gases).

B. Limit the annual average tritium discharge concentration to 5×10^{-6} uCi/cc in accordance with the Appendix I limits to 10 CFR 50.

C. Limit releases due to anticipated operational occurrences with 10 CFR 20 limits.

D. Provide sufficient flexibility to allow the plant operator to select the desired balance between holdup and radioactive decay, evaporation, ion exchange, filtration, and dilution. This capability permits removal of radioactivity as soon as feasible in the process in order to concentrate activities into areas where adequate shielding can be provided, thus preventing the buildup of excessive activity in the remainder of the system.

E. Provide the capability to process wastes with activities resulting from continuous operations within the criterion of one percent fuel rod cladding failures. In addition, the system shall have the capacity to accommodate all liquid wastes generated during the following operations:

   1. Base loaded operation at warranted output up to approximately 97 percent of equilibrium cycle core life.

   2. Back-to-back cold shutdowns to five percent subcritical and startups to approximately 82 percent of equilibrium cycle core life assuming that the boric acid concentrator is available for use during the shutdown period.

Table 11.2-1 gives the source and expected volume of liquid waste based on estimates made before Unit 2 began operating. This information is historical. Normal operation is defined as operating with 0.25 percent failed fuel and anticipated operational occurrences are evaluated assuming operation with 1.0 percent failed fuel.

11.2.2 SYSTEM DESCRIPTION

Liquid waste influents to the liquid waste treatment systems are segregated by chemistry and/or probable source activity for more efficient processing. Tritiated, hydrogenated, borated reactor coolant quality wastes of potentially high activity are mainly processed in the BMS. Aerated, chemically contaminated, and low activity liquid wastes are received and processed separately in the WMS. Low activity waste resulting from startup and blowdown ion exchanger regeneration is processed in the RWPS. If necessary, similar waste from Unit 1 condensate demineralizer regeneration could be transferred to the Unit 2 RWPS for processing.

11.2.2.1 Boron Management System

The major influent to the BMS is reactor coolant from the Chemical and Volume Control System (CVCS) letdown due to feed and bleed operations for shutdown, startups, and boron dilution over core life. Reactor coolant quality water from valve and equipment leakoffs, drains, and relief valves within the containment are collected in the reactor drain tank and subsequently processed by this system. During plant heatup and cooldown, controlled bleed-off flow from the reactor coolant pump seals may also be collected by the reactor drain tank. Reactor coolant from leakoffs and drains in the reactor auxiliary building are collected in a waste tank of the WMS.

The BMS simplified diagram is shown on Figure 11.2-1. The borated and hydrogenated water discharged by the reactor drain pumps or diverted by the CVCS volume control tank diversion valve is sent to the vacuum degasifier for dissolved gas removal or transferred directly to one of the holdup tanks for further processing or holdup if dissolved gas levels are sufficiently low. If necessary, hydrogen is stripped from the water so that an explosive gas mixture does not occur in subsequent process equipment. Borated and hydrogenated water that has been transferred to the holdup tanks may be recirculated back to the degasifier if sample results indicate further gas stripping is necessary. The degassed liquid is pumped from the degasifier to the holdup tanks or back to the CVCS when preparing for a plant shutdown. The holdup tanks provide sufficient storage capacity to accumulate discharges until a sufficient volume is available for further processing on a batch basis. The radioactivity of the liquid is significantly reduced during storage by natural decay of the short half-lived radionuclides. During this period, any degasification and radioactive decay can be monitored by liquid sample analysis or periodic grab samples of the tank gas space. The holdup tanks have high and low pressure alarms that annunciate locally on the Boron Management System Control Panel and high level alarms that annunciate on the control panel and input to a common system trouble alarm in the Control Room. The holdup recirculation pump was originally intended to supply flushing water to the preconcentrator ion exchangers and spent resin tank during resin sluice operations. ANO-2 resin is transferred using one of the Reactor Makeup Water Pumps (2P-109A/B) and the holdup recirculation pump has not been used for this purpose.

The contents of the holdup tanks are normally processed through either the vendor processing skid or the installed preconcentrator filter and preconcentrator ion exchanger to the waste condensate tanks or the boric acid condensate tank. If necessary, a holdup tank may be recirculated for processing prior to transfer. The holdup pumps (or holdup recirculation pump, if being used to transfer) are (is) stopped manually when the desired holdup tank level is reached. The water may be recirculated for further processing or discharged to the circulating water flume. The BMS was originally designed with a boric acid concentrator that is currently not in use. Fluid from the holdup tanks could be transferred to the boric acid concentrator through the preconcentrator filter and preconcentrator ion exchanger. If necessary, the contents of one holdup tank could be recirculated through a preconcentrator filter and ion exchanger prior to

discharge to the boric acid concentrator. The holdup pumps and holdup recirculation pump can be stopped manually on low holdup tank level. The boric acid concentrator has local grab sample provisions that can ensure control of the effluent chemistry. The boric acid concentrator provides a level signal that, after the initial manual pump start, can automatically start and stop the holdup or holdup recirculation pump aligned to the boric acid concentrator. Concentrate (recoverage boric acid) from the boric acid concentrator can pass through a discharge strainer and be collected in the boric acid makeup tanks. These bottoms could also be pumped to the Solid Radioactive Waste System (SRWS) for ultimate off-site disposal. The solidification portion of the SRWS has been abandoned. The distillate from the boric acid concentrator, after flowing through one of the boric acid concentrate ion exchangers, could be collected in the boric acid condensate tanks. The water could then be recirculated to the holdup tanks or the boric acid concentrator condensate ion exchanger for further processing or discharged to the circulating water discharge.

Prior to a controlled discharge of the treated liquid waste, the fluid must be analyzed and its activity verified as acceptably low. Controlled discharge is accomplished through an effluent radiation monitor which records the release activity level and automatically terminates discharge on high radiation.

Design data for the major components are given in Table 11.2-2. Flow, temperature, and pressure are given in Table 11.2-3. In addition, process flow Mode 1 indicates the system parameters during processing of the reactor drain tank contents through the vacuum degasifier. Modes 2, 3, and 4 indicate the system parameters during three possible conditions of processing the CVCS letdown flow which has been diverted from the volume control tank. Mode 5 was based on processing a full holdup tank through the boric acid concentrator (currently not in use) after nine days of decay. In the event that the holdup tank contents require additional processing, recirculation Mode 6 can be employed to cycle the tanks' contents through the preconcentrator filter and ion exchanger.

The nuclide concentrations for normal operation and for anticipated operational occurrences have been determined using the component design data shown in Table 11.2-2 and the process flow data shown in Table 11.2-3. The resulting concentrations, adjusted to 70 °F, are indicated for selected system locations in Tables 11.2-4 and 11.2-5, respectively. Normal operation is defined as operating with 0.25 percent failed fuel and anticipated operational occurrences are evaluated assuming operation with 1.0 percent failed fuel.

Analysis is made assuming that the activities in Tables 11.1-3 and 11.1-4 exist in the coolant upstream of the purification equipment in conjunction with the expected equipment performance given in Tables 11.2-6 and 11.2-7.

Systems similar in function and design to the BMS described herein have been used successfully at plants such as Connecticut Yankee and Ginna. Even with significant coolant radioactivity at Ginna, releases have been controlled well within the 10 CFR 20 limits.

All process components have been used extensively in the nuclear industry to remove radioactive contaminants from liquids. The performance of process units used in the analysis is in agreement with general industry experience.

11.2.2.2 <u>Waste Management System</u>

The WMS is shown in Figure 11.2-1. Liquid waste influents to this system include those from chemical laboratory drains, decontamination area drains, sampling drains, equipment drains, and building sumps.

Low activity equipment drains are collected by the drain collection and LRW drain headers and directed to either of two Waste Collection Tanks (2T-20A/B). If contamination levels in steam generator blowdown preclude processing in the RWPS, the blowdown can be aligned to the LRW drain collection header if necessary. Low activity, aerated and potentially dirty liquid drains, building sumps, chemical drains from the sampling system, decontamination drains, and contaminated shower drains are collected in the Auxiliary Building Sump. The contents of the Auxiliary Building Sump are then automatically pumped to either of the two Waste Collection Tanks when an established level setpoint is reached, or are manually pumped to one of the tanks when desired. When sufficient volume in the on-line waste tank is collected, the contents are transferred to a BMS Holdup Tank (2T-12A/B/C/D) for subsequent processing with collected BMS waste or processed directly via the Vendor Processing Skid to a Waste Condensate Tank (2T-20A/B) or a Boric Acid Condensate Tank (2T-69A/B). If desired, the waste collection tank can be recirculated for sampling prior to transfer or processing.

The WMS was originally designed with a waste concentrator that is currently not in use. Currently, the LRW system effluent collected in a BMS Holdup tank is then processed via the Vendor Processing Skid (or the BMS filters/demineralizers if desired) to a Boric Acid Condensate Tank (2T-69A/B). A BMS Holdup Tank may also be processed via the VPS to a Waste Condensate Tank (2T-21A/B). LRW system effluent that has been processed directly to a Boric Acid Condensate Tank or a Waste Condensate Tank is then sampled for release purposes. If activity and pH levels permit, the Boric Acid or Waste Condensate Tank contents are pumped out at a controlled rate to the Circulating water discharge. If discharge limitations can not be met, tank contents are recirculated through the VPS for further treatment. The activity of the discharge line effluent is monitored and recorded. Should the activity exceed the high setpoint value, the discharge is automatically terminated.

All tanks are equipped with water level instrumentation alarms and their respective pumps are tripped on low level signals.

There is no field run piping in this system.

Design data for the major components is given in Table 11.2-8. Flow, temperature, and pressure are given in Table 11.2-9.

In addition, process flow Mode 1 indicates the system parameters during the purification of waste tank 2T20A contents via the waste concentrator (currently not in use) and waste condensate tanks. Mode 2 indicates a similar procedure for the processing of waste tank 2T20B.

The nuclide concentrations adjusted to 70 °F for the original design normal operation and anticipated operational occurrences are given in Tables 11.2-11 and 11.2-12, respectively. The selected locations are indicated by the process data points described on Table 11.2-9. The original design equipment performance characteristics utilized by these tables are defined in Table 11.2-10.

The activity of the aerated liquid wastes collected in the waste tanks is approximately one percent of the reactor coolant activity, owing to dilution from washdown and decontamination procedures.

As the system was originally designed, major radioactivity removal, if necessary, could have been accomplished by the concentrators. Experience indicated that a concentrator DF (bottoms to distillate) of 10^4 could have been obtained. The concentrators were specified at this rating and testing by the vendor confirmed the performance.

Section 11.2.6 defines the leakage sources and the assumptions used in calculating estimated normal and anticipated operational occurrence releases due to leakage sources. This information is historical.

11.2.2.3 Regenerative Waste Processing System

Aqueous waste from chemical regeneration of spent startup/blowdown demineralizer resins in Unit 2 (or spent condensate demineralizer resins in Unit 1, if necessary) is drained into regenerative waste holdup tanks. Normally, a block flange is installed to prevent inadvertent cross contamination between units. Unprocessed steam generator blowdown water may be directed into the regenerative waste tanks after being cooled in the blowdown heat exchangers. The system is shown in Figure 11.2-1. Waste samples are taken prior to release of each batch to verify monitor accuracy and isotopic composition peculiar to regenerative waste. If holdup tank activity is below a calculated release activity limit, the waste batch is neutralized to a 6.0 - 9.0 pH and discharged to the circulating water flume. While the release is in progress, pH and radioactivity levels are monitored either by installed instrumentation or by grab sample analyzed by chemists. If at any time during the release the pH level is found to be outside the 6.0 to 9.0 band or activity is found to be above the predetermined limit, the release is terminated. Additionally, a discharge isolation valve can automatically terminate the waste discharge if pH and/or radioactivity limits are exceeded.

As the RWPS was originally designed, a radioactive circulating batch could be processed through the Regenerative Waste Evaporator System. The evaporator is currently not in use. This system could concentrate the total solids and radioactivity from the wastes into a bottoms slurry which could be immobilized in drums or shielded casks for transport to off-site radwaste burial. Over 95 percent of the water in the regenerative waste could be removed as very low activity level distillate. The distillate could then be recycled to the Condensate System through the startup/blowdown demineralizers. It could also be monitored for radiation and, if sufficiently nonradioactive, discharged to the circulating water flume. Flow and radioactivity of the distillate discharge could be monitored and recorded.

Design data for the major components of this system are given in Table 11.2-23. A tabulation of flows to be processed by the RWPS is given in Table 11.2-24.

11.2.3 SYSTEM DESIGN

The liquid waste systems are designed on batch mode basis for flexibility of operation. These batching operations proceed intermittently at faster flow rates than the annual average process rates and therefore, the system components are sized per this criterion. Tables 11.2-2 and 11.2-8 list the design parameters for the major components of the liquid waste systems. The designation as "non-nuclear safety" of components listed in Tables 11.2-2 and 11.2-8, and Section 3.2.2 is based on the hypothetical failure of the component not resulting in calculated potential exposures in excess of 170 mRem (whole body). For example, failure of the holdup tanks filled with letdown concentrations of radionuclides from the vacuum degasifier would release 784 equivalent curies of Xe-133 and results in a dose $\leq$ 170 mRem. Noble gases would be the limiting criteria for whole body dose, and the largest inventory of noble gases in all the non-nuclear safety components would be in the holdup tanks.

Similarly, the Seismic Category (described in Section 3.2.1) was determined from the total site boundary dose received after a simultaneous failure of all nonseismic components. The two major nonseismic components containing noble gases, the holdup and waste condensate tanks, could only release 833 equivalent curies of Xe-133 and would result in a whole body dose $\leq$ 2.5 rem.

Process and radiation instrumentation are depicted in Figure 11.2-1 and are described in Table 11.2-14.

On all tanks containing radioactive liquid, provisions have been made to contain and collect overflow in the event that any of these tanks are inadvertently overfilled. In addition, high level alarms are provided on the majority of these tanks to minimize the possibility of inadvertent overfilling. Level indication and alarm instrumentation for the tanks are located inside the auxiliary building. The four boron management holdup tanks (2T12A-D) are interconnected via the common gas vent/gas analyzer header and the common vent relief header so that the overflow from any one of these tanks will be collected in the other three. The waste tanks (2T20A, B) and the boric acid condensate tanks (2T69A, B) overflow to the auxiliary building sump. The spent resin storage tank (2T13) and the waste condensate tanks (2T21A, B) overflow to the waste tanks via the drain collection header. The concentrator bottoms tank (2T78) was originally designed to overflow via the drain collection header, but it has been abandoned in place and isolated.

In addition to the above, the following tanks were originally designed to contain potentially radioactive liquid:

A. Refueling Water Tank (RWT) (2T3);

B. Reactor Makeup Water Tank (RMWT) (2T73);

C. Regenerative Waste Tanks (2T-92A, B, C);

D. Boric Acid Makeup Tanks (2T6A, B); and,

E. Volume Control Tank (VCT) (2T4)

The operating modes of the WMS and BMS processes have resulted in 2T73, 2T6A, and 2T6B not having contained radioactive liquid.

With the exception of the RWT and the RMWT, all of the above tanks are located inside the auxiliary building. The RWT is located just southwest of the containment, on the top slab of Area 26 of the auxiliary building. The inherent system design for the enclosure of this tank and the associated piping makes it highly improbable that the radioactive liquid will spill to the ground. If the tank were inadvertently overfilled, a 4-inch overflow line would route the liquid to the holdup tank vault which drains to the auxiliary building sump. This line will adequately accommodate the maximum makeup rate to the tank. There are no obstructions to flow in this line. System valves and components associated with the RWT are located inside the Seismic Category 1 auxiliary building. This tank is shown on the Containment Spray System Diagram (Figure 6.2-17).

The RMWT is located on the ground northwest of the containment. Makeup to the RMWT is normally from the vendor's Mobile Water Treatment Facility. Tank level indication is provided in the control room with a high level alarm to preclude inadvertent tank overfill.

Level indication and level alarms for the regenerative waste tanks are provided on the Regenerative Waste System control panel. Overflow from each of these tanks is directed to a sump located in one corner of the tank room. Sump level is maintained automatically by pumping the liquid to the off-service tank.

Level indication and level alarms for the boric acid makeup tanks and the volume control tank are provided in the control room. Overflow from the boric acid makeup tanks is routed to the waste tanks via the tank room floor drain. The volume control tank is not a vented tank. In the event of increasing tank level beyond the alarm set point, the reactor coolant letdown flow to this tank is automatically diverted to the BMS.

11.2.4 OPERATING PROCEDURES

Procedures are available and used when their associated equipment or process is used. All of the equipment and processes listed below are available, but not necessarily used.

11.2.4.1 Boron Management System

Liquid waste enters the BMS for processing by the method described in Section 11.2.2.1. The operating procedures necessary to process this fluid are identified below to logically reflect the various monitoring and operating functions required of plant operators.

11.2.4.1.1 Chemical Volume Control Letdown to Holdup Tank (Automatic Operation)

CVCS letdown that is diverted to the BMS normally bypasses the vacuum degasifier as specified by procedure. Monitoring requirements of the vacuum degasifier controls and vacuum degasifier pumps are also specified and procedures for valve lineup to the holdup tanks are specified.

11.2.4.1.2 Chemical and Volume Control System Letdown Degassing in Preparation for Plant Shutdown

Procedures and valve lineups for degassing the reactor coolant in the vacuum degasifier and returning it to the CVCS prior to plant shutdown are specified.

11.2.4.1.3 Reactor Drain Tank Operations

Monitoring requirements of reactor drain conditions are specified and procedures for processing the tank contents via the vacuum degasifier to a holdup tank are specified.

11.2.4.1.4 Vacuum Degasifier Bypass

Monitoring and possible actions to be taken to limit hydrogen and air mixtures in the holdup tanks are specified for normal operation when the vacuum degasifier is bypassed.

11.2.4.1.5 Holdup Tank Operations

Monitoring requirements for the conditions of the four holdup tanks are specified. Further processing requirements are based on the chemical and radioactivity sample analysis.

11.2.4.1.6 Holdup Tank Processing Recirculation

Procedures and valve lineups for processing the contents of a holdup tank through the vendor processing skid or through a preconcentrator filter and ion exchanger back to the same or different tanks are specified. Process sampling requirements are specified.

11.2.4.1.7 Holdup Tank Processing to Boric Acid Concentrator

The Boric Acid Concentrator is currently not in use. If placed in service, the procedure and valve lineups for processing the contents of a holdup tank through a preconcentrator filter and ion exchanger to the boric acid concentrator will be developed. Operation of pump and concentrator interlocks will be specified. Process sampling requirements will be specified.

11.2.4.1.8 Boric Acid Concentrator Operating Procedure

The Boric Acid Concentrator is currently not in use. If placed in service, the procedures for startup, steady state, shutdown and layup operations will be developed. Sampling requirements to confirm low carryover and proper operation of boron concentration controls will be specified. Automatic and manual batch bottoms discharge control procedures and heat tracing system operating procedures will be specified.

11.2.4.1.9 Boric Acid Condensate Tank Operations

Monitoring requirements for the condensate tanks conditions and procedures for valve lineups are specified. Sampling and reprocessing procedures are specified.

11.2.4.1.10 Environmental Discharge Procedures

Operating procedures for the discharge instrumentation and valves are specified. The method for determining whether to process or reprocess the liquid or discharge is specified. The method for determining the discharge flow rate in terms of radioactivity discharge limits is specified.

11.2.4.2 Waste Management System

Liquid waste enters the liquid waste system for processing by the methods described in Section 11.2.2.2. The operating procedures necessary to process this fluid are briefly described below to logically reflect the various monitoring and operating functions required of plant operators.

11.2.4.2.1 Waste Tank Operation

Procedures for waste tank influent valve lineups, monitoring tank conditions, sampling, and valve line-up are specified.

11.2.4.2.2 Waste Concentrator Operation

The Waste Concentrator is currently not in use. If placed in service, the procedures for waste concentrator startup, steady state, shutdown and lay-up operations will be developed. Sampling procedures to assure low carryover and to monitor bottoms concentration will be provided. Heat tracing system operating procedures will also be specified.

11.2.4.2.3 Waste Condensate Tank Operation

Monitoring requirements for waste condensate tank conditions, valve lineups, sampling and reprocessing are specified. Discharge is done under the same procedure used for the BMS.

11.2.5 PERFORMANCE TESTS

The BMS and WMS were tested prior to initial power plant startup to verify satisfactory flow characteristics through the equipment, to demonstrate satisfactory performance of pumps and instruments, to check the integrity of piping and equipment, and to verify proper operation controls. All piping and components were checked to ensure that they are properly installed. All manual and automatic valves were operated and checked for ability to function. All alarms were checked for operability and verification of locations. The concentrators were tested for operation before installation at the site and after installation to assure proper integration with the system. The boric acid and waste concentrators were shop tested prior to shipment to demonstrate compliance with performance objectives. During hot functional testing, the BMS operation was integrated with the CVCS. The purpose of this test was to check the procedures and system components used for receiving and processing waste water. Boric acid transfer operations and liquid waste disposal procedures were tested.

During normal plant operation, periodic testing verifies that the system components are operating as designed. Filter performance is determined by the observation of filter differential pressure. Filters are monitored for differential pressure and radiation level on a regular basis. Ion exchanger performance is determined by comparing the level of radioactivity from inlet and outlet samples. Ion exchangers are monitored for differential pressure and radiation level on a regular basis. To ensure that the vacuum degasifier is performing adequately, a liquid sample from the influent and effluent can be obtained to verify the hydrogen stripping function of the unit. Although the boric acid concentrator is currently not in use, if it were placed in service its performance could be determined by comparing the concentration of boric acid from inlet, bottoms and condensate samples. All liquid discharges to the environment are sampled for radioactivity before discharge. The discharge radiation monitor is calibrated on a regular basis to assure accuracy.

11.2.6 ESTIMATED RELEASES

[Information on expected releases is historical as are some of the system descriptions. Because releases were estimated before the unit began operating, actual operating experience may differ from the assumptions used in this section.]

The release of radioactive liquid from the plant discharge header will vary with plant operating conditions. The quantities of liquids generated by the systems discharging to the plant discharge header during various operating conditions and the radioactive content of these waste effluents are discussed below. Section 11.2.6.4 describes liquid releases from Unit 1.

11.2.6.1 Liquid Waste Systems

[This section contains historical information.]

The expected liquid releases from the plant are summarized by nuclide in Table 11.2-15A. The reactor coolant concentrations utilized for this evaluation are indicated in Tables 11.1-3 and 11.1-4. The curies released from the BMS and WMS are determined by multiplying the nuclide concentrations in the boric acid and waste condensate tanks as shown in Tables 11.2-4,

11.2-5, 11.2-11 and 11.2-12 by the waste processed through each system. The assumptions used in calculating the estimated normal and anticipated operational occurrence releases are summarized in Table 11.2-13. Expected performance data for the filters and ion exchangers is given in Table 11.2-6 and component performance data for the BMS is given in Table 11.2-7. The waste schedule is shown in Table 11.2-1.

Tables 11.2-16A and B provide a comparison of the liquid releases to 10CFR20 limits. As indicated by the data presented in this table the activity released to the circulating water discharge canal is within the design objectives stated in Section 11.2.1.

11.2.6.2 Steam Generator Blowdown Releases

[This section contains historical information.]

Although Unit 2 steam generator blowdown is normally recycled via the Startup and Blowdown Demineralizer System described in Section 10.4.10, it may be released to the circulating water flume if it meets the applicable chemistry limits (i.e., pH, radioactivity, suspended solids).

The following assumptions were made in determining the activity released as steam generator blowdown during normal operation:

A. Reactor coolant activity is based on fuel cladding defects in 0.25 percent of the fuel rods.

B. Primary-to-secondary leakage amounts to 13 gal/day.

C. A continuous blowdown of 15 gpm is discharged to the WMS for 313 days a year. The liquid released is at equilibrium steam generator activity levels for the assumed conditions as listed in Table 11.1-12.

The following assumptions were made in determining the activity released by the Steam Generator Blowdown System for anticipated operational occurrences:

A. Reactor coolant activity is based on fuel cladding defects in 1.0 percent of the fuel rods.

B. Primary-to-secondary leakage amounts of 100 gal/day.

C. A continous blowdown of 15 gpm is discharged to the WMS for 313 days a year. The liquid released is at equilibrium steam generator activity levels for the assumed conditions as listed in Table 11.1-12.

A detailed description of the analysis of secondary system activities is presented in Section 11.1.7. The estimated annual activity released by the Steam Generator Blowdown System is summarized in Table 11.2-15 for normal and anticipated operational occurrences.

11.2.6.3 Tritium Releases

[This section contains historical information.]

Tritium, in the form of tritiated water, is treated separately because, at this time, there is no feasible way of removing it from the waste through processing. It is assumed that all tritium leaking into or produced in, the reactor coolant is released to the environment. For an equilibrium fuel cycle with 0.25 percent failed fuel, this will amount to about 204 Ci per year (see Section 11.1.3). For a one percent failed fuel condition, estimated tritium releases increase to 290 Ci per year.

11.2.6.4 Unit 1 Liquid Releases

[This section contains historical information.]

In order to meet the plant design objectives outlined in Section 11.2.1, Unit 1 liquid releases can be processed through Unit 2 liquid waste systems. Discharges from the Clean Liquid Radioactive Waste System (CZ) and Dirty Liquid Radioactive Waste System (DZ) can be processed by the Unit 2 BMS and WMS, respectively. Condensate demineralizer regenerative wastes can be processed through the RWPS. Operation of the Laundry Radioactive Waste System has been discontinued. The Unit 1 SAR presents a complete description of the Unit 1 radioactive waste systems.

Table 11.2-15 summarizes the releases from the Clean and Dirty Liquid Radwaste Systems.

11.2.6.4.1 Clean Liquid Radioactive Waste System Releases

[This section contains historical information.]

The Unit 1 CZ processes the same type of waste as the Unit 2 BMS, i.e. hydrogenated, borated reactor coolant quality wastes of potentially high activity.

After processing by the CZ, effluent from the treated waste monitor tanks can be routed through the Unit 2 boric acid concentrator (currently not in use), boric acid condensate ion exchanger and collected in the boric condensate tanks. As with Unit 2 wastes, sampling prior to discharge and continuous monitoring during discharge is required.

The following assumptions were made in determining the activity released by the CZ during expected (normal) operation.

A. 513,000 gallons of clean wastes were generated in the cycle as a result of bleed wastes from base loaded operation at 2,568 MWt for 310 days, two cold startups and refueling concentration, and one drain for refueling.

B. Reactor coolant concentration based on 0.25 percent failed fuel.

C. DF = 100 in Purification Demineralizer for all isotopes in bleed wastes except the noble gases (DF = 1), Cs, Mo, and Y (DF = 1).

D. DF = 400 for degasification of bleed wastes in the vacuum degasifier.

E. 20-day decay of all isotopes in the clean waste receiver tanks.

F. DF = 10,000 for corrosion activity in the purification filter, clean wastes filter and ion exchangers for bleed wastes.

G. DF = 1000 for all soluble activity in the bleed wastes for two radwaste demineralizers in series (except Mo and Y DF = 10).

H. DF = 200 for Unit 2 boric concentrator.

I. All wastes discharged into a circulating water flow of 383,000 gpm. The ANO-1 Condenser Replacement (ER 951018D101) resulted in a 2.4% increase in circulating water flow rate. This increase in flow rate provides more dilution water for radiological releases. Therefore, the flow rate stated above is bounding and conservative.

Maximum expected release activity levels (anticipated operational occurrence) are based on one percent failed fuel and the above assumptions.

11.2.6.4.2 Dirty Liquid Radioactive Waste System Releases

[This section contains historical information.]

The Unit 1 DZ processes the same type of waste as the Unit 2 WMS, i.e., low activity aerated and potential dirty chemical drains, decontamination drains and building sumps.

After processing by the DZ, effluent can be routed to the Unit 2 waste concentrator, the Unit 2 waste condensate ion exchanger, and collected in the Unit 2 waste condensate tanks. The resulting effluent is sampled prior to discharge and continuously monitored during discharge.

The following assumptions were made in determining the activity released by the DZ during normal operation.

A. 142,000 gallons of miscellaneous or dirty wastes generated from equipment drains, decontamination operations, contaminated showers, etc. at average concentrations equal to one percent of the average reactor coolant concentrations with a 0.25 percent failed fuel.

B. DF = 100 for corrosion activity in the dirty waste filters for miscellaneous wastes.

C. One-day decay of all miscellaneous wastes.

D. DF = 500 for Unit 2 waste concentrator

E. All wastes discharged into circulating water flow of 383,000 gpm. The ANO-1 Condenser Replacement (ER 951018D101) resulted in a 2.4% increase in circulating water flow rate. This increase in flow rate provides more dilution water for radiological releases. Therefore, the flow rate stated above is bounding and conservative.

Maximum expected (anticipated operational occurrence) releases are based on the above assumptions and time averaged reactor coolant concentrations with one percent failed fuel.

11.2.6.4.3 Condensate Demineralizer Regenerative Waste Releases

[This section contains historical information.]

Unit 1 has once-through steam generators. Water chemistry is maintained by treating 70 percent of the feedwater flow with deep-bed demineralizers. The demineralizers are regenerated periodically and the regenerant solutions can be processed through the Regenerative Waste Processing System described in Section 11.2.2.3, if necessary. Currently a blank flange is installed to prevent the transfer of water from Unit 1.

Expected releases from the condensate demineralizer regenerative waste evaporator are based on the following assumptions:

A. Reactor coolant activity is due to 0.25 percent failed fuel;

B. Steam generator tube leak amounts to 20 gpd for 310 days;

C. All soluble activity leaking into the secondary system is removed by the demineralizers;

D. Demineralizers normally operate on a hydrogen cycle. Each of the five demineralizers will be regenerated as necessary;

E. In regeneration all activity accumulated will be removed from the resin and pumped via the neutralizing tank to holdup tanks where a five day holdup is assumed; and,

F. The regenerative waste is processed through the Regenerative Waste Evaporative System (currently not in use). DF = 10 (+3) for iodine and 10 (+4) for all other isotopes.

Maximum expected releases are based on one percent failed fuel, steam generator tube leakage of 100 gpd, and the remainder of the above assumptions. Table 11.2-15 summarizes the estimated releases.

11.2.6.4.4 <u>Laundry Radioactive Waste Releases</u>

Operation of the Laundry Radioactive Waste System has been discontinued and replaced by use of an off-site vendor's service at an approved facility. The Unit 1 FSAR presents a description of this process which was designed to accommodate Unit 1 and Unit 2.

11.2.7 RELEASE POINTS

The planned release of liquid radioactivity effluents to unrestricted areas at Unit 2 occurs through the Unit 1 circulating water discharge canal. The canal receives liquid waste from Unit 1 and Unit 2 systems that may contain radioactive nuclides and discharges them to the Dardanelle Reservoir by way of a discharge embayment. Unit 2 systems discharging wastes to the canal include the BMS, the WMS and the RWPS discharge. Water from steam generators may also be discharged to the canal via the Startup and Blowdown System and Emergency Feedwater System (see Figure 10.2-4). A site plot plan for liquid and gaseous releases is shown in Figure 11.3-2.

All flow of radioactive effluents is regulated by valves which may be throttled as necessary to establish a desired release rate of radioactive liquids. These valves may be positioned, dependent upon the actual levels of activity to be released and available dilution, such that the radioactive concentration after dilution in the discharge canal will not exceed Unit 2 Technical Specification limits for effluents to unrestricted areas. The flow of effluents is monitored by an in-line radiation monitor that will stop discharge flow if unacceptable activity levels are detected, by automatically shutting an air-operated isolation valve. The system response and the isolation valve location in the discharge piping are such that high activity liquid will not be released before the valve closes.

Section 11.4.2 discusses the monitoring system and the basis for the detector setpoints.

The turbine building sump may be considered a release point in the event of tube leakage in one or both of the steam generators. Primary to secondary leakage is monitored by both the Steam Generator Monitoring System (see Section 11.4.2.1.4) and the Condenser Air Discharge Monitoring System (see Section 11.4.2.2.1). Should a valid alarm on either monitor occur, the Turbine Building Sump pumps will be secured and subsequent discharges will be sampled in accordance with radioactive release procedures prior to release.

11.2.8 DILUTION FACTORS

The waste systems direct system effluents to the Unit 1 discharge canal where they are diluted by discharge flow to the reservoir from the Unit 1 Circulating Water System.

The amount of flow available for diluting the waste is a function of the number of Unit 1 circulating water pumps in operation.

During normal operations, the maximum dilution flow rate will be approximately 766,000 gpm with four circulating water pumps in operation and the minimum dilution flow will be approximately 383,000 gpm with two circulating water pumps in operation. On limited occasions when less than two circulating water pumps are in operation, release of radioactive liquid is allowed under strict administrative controls. The ANO-1 Condenser Replacement (ER 951018D101) resulted in a 2.4% increase in circulating water flow rate. This increase in flow rate provides more dilution water for radiological releases. Therefore, the flow rate stated above is bounding and conservative.

Tables 11.2-15A and B give the annual average concentration in the circulating water canal prior to dilution in the reservoir.

11.2.9 ESTIMATED DOSES

Three principal pathways exist through the environment for exposure due to the release of liquid effluents. An internal dose can result from the ingestion of water and foods that contain radioactive material. An external dose can result either from swimming in the river or by being exposed to sediment that has accumulated radioactive material.

Radionuclide concentrations in the circulating water discharge canal have been estimated using the dilution factors discussed in Section 11.2.8 and the release rates of Tables 11.2-15A and B. Table 11.2-15A and B gives these concentrations for both normal operation and during anticipated operational occurrences.

Radionuclide concentrations in aquatic biota (fish, invertebrates, and vegetation) have been estimated by multiplying the radionuclide concentrations in water by appropriate freshwater biological concentration factor for each nuclide. The concentration factors employed are given in Table 11.2-17 (References 6, 20, 24, 28, 29 and 32). The average freshwater concentration factors given in Reference 29 were employed where available, supplemented by the average freshwater values given in Reference 24. Concentration factors given in References 6, 20, 28 and 32 confirm that the values employed here are conservative values.

The deposition of radionuclides in bottom sediment has been estimated by assuming that the fraction of each nuclide associated with suspended sediment will be completely retained and uniformly distributed over the river bottom and shoreline downstream from Unit 2 with subsequent removal only by radioactive decay.

Nuclides for which suspended fractions were not available were assumed to be completely retained in the downstream bottom sediment. By this method, the deposition of the nuclide per unit area of bottom sediment is given by:

$$S = \frac{1000Rf}{A}\left(1 - e^{-\lambda t}\right)$$

where:

S = cumulative deposition of nuclide in bottom sediment, mCi/km^2

R = rate of discharge of nuclide, Ci/year

F = fraction of nuclide retained in bottom sediment

A = downstream area of the river, km^2

λ = radioactive decay constant, yr^{-1}

t = time after the discharge begins, yr

The annual dose to man from drinking water and from consumption of fish and invertebrates has been determined from recommended Maximum Permissible Concentrations (MPCs) in water and Maximum Permissible Doses (MPDs) of the ICRP (Reference 12) according to the following relationship:

$$D = \left(\frac{C}{MPC}\right)\left(\frac{r}{2200}\right)MPD$$

where:

D = dose to man, mrem/yr

C = concentration of nuclide in water or biota, µCi/cc

MPC = maximum permissible concentration in water, µCi/cc

r = consumption rate of water or biota, cc/day

MPD = maximum permissible dose, mrem/year.

For the radioactive isotopes of iodine and strontium, the recommendations of the Federal Radiation Council (Reference 2) were used to determine the dose to the thyroid and bone.

Two external exposure pathways were considered: swimming in the river downstream of the plant, and exposure to contaminated sediment on the bank of the river. The dose from swimming in the river is given by the relationship:

$$D = 1.87 \times 10^{7} C\left(\frac{T}{8760}\right)^{\left(0\ 5E_{\beta} + E_{\gamma}\right)}$$

where:

D = dose to man, mrem/yr

C = radionuclide concentration in the river water (µCi/cc)

T = time spent swimming (hr/yr)

E_β = average beta energy per disintegration (Reference 30), MeV

E_γ = average gamma energy per disintegration (Reference 30), MeV

The external gamma dose from exposure to contaminated sediments is given by the relationship:

$$D = \frac{K}{G} C \left(\frac{T}{8760}\right)$$

where:

D = dose to man, mrem/yr

C = radionuclide concentration on the surface of the river bank, mCi/km^2

T = time of exposure, hr/yr

G = geometry factor to account for the depth distribution of the radionuclides (Reference 19), 2.5

K = dose conversion constant, $(mrem/yr)/(mCi/km^2)$.

The values of the constant K for each radionuclide are listed in Table 11.2-18 (Reference 25).

Two types of individuals were considered in the dose estimates:

A. The maximum exposed individual - a person whose dietary, recreational, or commercial activities result in higher-than-normal internal or external dose. This individual would be an avid sports fisherman or a commercial fisherman. Doses to this individual are summarized in Table 11.2-21.

B. The average exposed individual - a person whose dietary and recreational habits are representative of the general population from this particular geographic region. The doses to this individual are summarized in Table 11.2 20.

Consumption rates of water and biota, and annual exposure times in water and along the shoreline are given in Table 11.2-19 for both the maximum exposed individual and the average exposed individual (Reference 7).

In addition to the annual dose to individuals, the total dose to various population groups in the vicinity of the plant has been estimated. For this purpose, it has been assumed that:

A. The entire commercial fish catch from the Arkansas River (2.7 million pounds per year) is uniformly contaminated using the concentration factors presented in Table 11.2-17 and is entirely consumed.

B. 3,200,000 man-hr of occupancy on the shoreline is expended annually. This corresponds to 400,000 fisherman per year at an average occupancy time of eight hours (Reference 1).

C. 36,000 boaters and 42,000 swimmers are assumed to use the river each year at an average duration of eight hour per boater and eight hours per swimmer (Reference 1).

Population exposures resulting from radionuclides in liquid effluents are summarized in Table 11.2-22 for normal operation and for operation during anticipated operational occurrences.

11.3 GASEOUS WASTE SYSTEM

11.3.1 DESIGN OBJECTIVES

The Gaseous Waste System (GWS) processes the vent gases from equipment located in the Chemical and Volume Control System (CVCS), Waste Management System (WMS), Boron Management System (BMS) and Fuel Pool System such that the radioactive gaseous release to the environment will be as low as practicable in accordance with Appendix I to 10 CFR 50. The numerical design objective for releases during normal operation is to limit the site boundary noble gas dose to less than 10 mrem/year and Iodine-131 and particulate concentrations at the nearest pasture to 10^{-5} times 10 CFR 20 limits. Releases due to anticipated operational occurrences will be within 10 CFR 20 limits.

11.3.2 SYSTEM DESCRIPTION

The principal flow paths of the GWS are shown on Figure 11.3-1. Process flow and activity data for the original system design are given in Tables 11.3-1 and 11.3-2. Component data is provided in Table 11.3-3.

Plant gaseous releases come from the steam generator blowdown, reactor auxiliary building ventilation, turbine system leakage, containment purges, waste gas decay tank discharges, and the gas collection header.

Waste gas is collected from the various source components by two headers: containment vent header and the gas collection header. The containment vent header receives hydrogenated, potentially radioactive gas mixtures vented from the reactor drain tank, quench tank, and the regenerative heat exchanger and directs the gases to the suction of the waste gas compressors. Hydrogenated and potentially radioactive gases are also collected directly from the volume control tank and vacuum degasifier tank gas spaces to the suction of the waste gas compressors. The waste gas surge tank and the gas surge header are not used to collect waste gases for processing with the waste gas compressors. The waste gas surge tank is available as a relief volume in the event of a waste gas decay tank or compressor suction, interstage, or discharge relief valve lifting. The gas surge header is isolated and unused.

Waste gases flow from the containment vent header, volume control tank, and the vacuum degasifier tank at positive pressures to a waste gas compressor where they are compressed to 350 psig and cooled by an aftercooler prior to entering the waste gas decay tanks where the gases are held up for radioactive decay. Two compressors are available for transferring the gas to the gas decay tanks.

Aftercoolers supplied with each gas compressor cool the compressed gas prior to entering the gas decay tanks. There are three gas decay tanks (each provided with a pressure indicator including local alarm and temperature indicator) which receive the compressed gas from the waste gas compressors. The decay tanks have sufficient storage capacity for an average 30-day holdup. After radioactivity has decayed to an acceptable level which is consistent with the design objective and has been verified by laboratory sample analysis, the gas is released to the environment via the plant vent at a controlled rate.

The fill procedure for the decay tanks is to have only one tank lined up to the compressor discharge. When the pressure in the tank increases to about 250 psig, the tank is isolated and the compressor discharge is manually switched over to an empty tank. The gaseous radioactivity in the filled tank is allowed to decay for approximately 30 days. During this decay period the gas is periodically sampled and activity level determined. The Process Sampling System is described in Section 9.3.2.

Prior to release, the required flow rate is determined, and the setpoint on the radiation monitor is established. Initially, the discharge valve from the gas decay tank, needle valve and pneumatic operated valve are closed. The on-off pneumatic operated valve is opened and placed in automatic, and the discharge valve on the desired gas decay tank is opened. The needle valve is then opened as required to establish the desired flow rate to the plant vent, and the pressure reducing valve will maintain constant downstream pressure of 30 psig. The on-off pneumatic operated valve automatically closes on high radioactivity level thus terminating discharge flow. An alarm will annunciate this event in the control room. When discharge flow decreases and the decay tank pressure decreases to approximately 30 psig, as noted by observing the gas flow meter and pressure indicator on the gas decay tank, the pressure reducing valve setpoint must be reduced to vent the tank down to atmospheric pressure.

The system flow paths and release points of the gases from the gas decay tanks and gas collection header are indicated on Figure 11.3-1.

The gas collection header collects the gases from primarily aerated vents of process equipment in the CCW System, BMS, SRS, WMS, CVCS, and FPS. Also the high point pipe vents and concentrator vents will be aerated during initial plant startup, when nitrogen is purged from the process equipment or during maintenance and released through the gas collection header. During these periods essentially no activity will be present in the gas.

Table 11.3-4 identifies each of the inputs to the gas collection header. Because of the large volume of gas and the low activity level from the sources, the gases are routed directly to the plant vent. The gases and expected activities to the plant vent from the gas collection header based on the original system design are given in Tables 11.3-1 and 11.3-2 at process data point No. 12. As a further check on activity from this source, the plant vent contains radioactivity monitors with alarms to indicate unexpected activity release.

There is no field run piping in the GWS.

11.3.3 SYSTEM DESIGN

Each piece of equipment in the GWS is described in Table 11.3-3. Within the GWS the waste gas surge tank and waste gas decay tanks are Seismic Category 1, and the waste gas compressors are Quality Class D components. The GWS is housed within the auxiliary building which is also Seismic Category 1.

The process instrumentation (including hydrogen analyzers) and radiation instrumentation are shown on Figure 11.3-1 and are described specifically in Table 11.2-14.

The Waste Gas Analyzer System (WGAS) provides the capability to monitor hydrogen and oxygen concentrations in the tanks and equipment listed in Table 9.3-3 and indicated in the Sample P&ID (M-2237). The gas sample is analyzed for free oxygen and hydrogen. When concentrations exceed a predetermined set point, an alarm is annunciated. Ranges are identified in Section 9.3.2.2.3.

If the analyzer panel is out of service, grab samples are taken.

The gas analyzer represents an appropriate safeguard against an explosion hazard in the GWS when compared with the risks involved. An explosion in the GWS would have to involve the simultaneous occurrence of three unlikely events:

A. There would have to be an operator error or equipment failure to admit oxygen to the GWS such as not purging a tank after maintenance.

B. The gas analyzer would have to malfunction at the time oxygen was present in the system so as not to cause an alarm.

C. There would have to be a spark to initiate detonation. The low probability of occurrence of each of these events is examined below.

Potential sources of oxygen to the waste gas system are the degasifier, volume control tank, quench tank, reactor drain tank, and regenerative heat exchanger. Hydrogen, nitrogen and fission gases stripped from letdown are sent to the waste gas tanks for storage and decay. The volume control, quench and reactor drain tanks are operated at a positive pressure with either hydrogen or nitrogen as the cover gas so O_2 will not enter. The only feasible time for O_2 to be in these tanks would be during maintenance periods. There are procedures for purging tanks, piping and components with nitrogen after maintenance to reduce the possibility of O_2 entering GWS.

Assuming that O_2 does inadvertently enter the GWS, the gas analyzer will automatically alarm to warn operators of a potentially dangerous situation. Since the only feasible time of O_2 entering the system is during shutdown, many of the components will not have to be analyzed. The gas analyzer would have to malfunction during this time for the O_2 to go undetected.

All active components in the GWS are explosion-proof; they will not create a spark within the piping.

If in the worst conditions air was added to a gas decay tank by two compressors, it would take 1.5 to seven hours to reach an explosive mixture, depending on the initial hydrogen content and gas volume in the tank. Under the more probable and realistic circumstances of trace oxygen, the time to reach an explosive mixture would be substantially greater.

In view of the low probability of significant oxygen being present in the GWS and the substantial time periods required for explosive mixture buildup, manual sampling with portable or laboratory analysis provides adequate backup for the gas analyzer.

11.3.4 OPERATING PROCEDURE

Operating procedures are available within the GWS to perform each of the following functions.

11.3.4.1 Tank Purging

Tank purging and venting procedures for all tanks venting to the WGS and for the tanks in the GWS are specified.

11.3.4.2 Compressor Lineup

Gas decay tank valve and compressor lineup procedures, requirements for monitoring proper operation of the gas compressors, procedures for servicing the compressors, filters, and after coolers are all specified.

11.3.4.3 Gas Decay Tank Isolation

Procedures for isolating a gas decay tank after filling and for monitoring the contents during the decay period are specified.

11.3.4.4 Discharge Monitoring

Procedures have been established for setting the high trip setpoint on the discharge radiation monitor, for lining up the valves for discharge, and for determining the discharge flow rate and establishing it. Monitoring requirements during the discharge period and procedures to reduce gas decay tank pressure to atmospheric at the end of the discharge period are also specified.

11.3.4.5 Water Draining From Gas Surge Tank

Procedures for draining water from the gas surge tank and the gas decay tanks are specified.

11.3.4.6 Gas Analyzer Control and Gas Sampling

Procedures for gas analyzer control of sample point selection, procedures for obtaining a gas sample in a sampling cylinder for laboratory analysis and procedures for calibrating the gas analyzers to assure representative automatic sampling are specified.

11.3.5 PERFORMANCE TESTS

The gas compressors were shop tested to assure proper operation. The gas analyzer system was shop tested.

The GWS preoperational tests are described in Table 14.1-1.

During plant operation, periodic testing is done as follows:

A. The discharge radiation monitor is periodically calibrated with standard radiation source;

B. The hydrogen and oxygen gas analyzer is periodically calibrated with zero and upscale gas concentrations; and,

C. Process instrumentation is periodically calibrated.

11.3.6 ESTIMATED RELEASES

[Information on expected releases is historical as are some of the system descriptions. Because releases were estimated before the unit began operating, actual operating experience may differ from the assumptions used in this section.]

The release of radioactive noble gases, airborne halogens, and air particulates from Unit 1 and Unit 2 GWSs and other potential release points will vary with plant operating conditions. The basis for estimating the annual release of gaseous activity, by isotope, includes assumptions about each of the systems involved. In each case, analysis is made of the normal activity levels of wastes expected during plant operations as well as the maximum levels of activity for anticipated operational occurrences during the life of the plant. The number of curies of each isotope estimated to be released annually from each of these systems and potential release points for normal and anticipated operational occurrences are summarized in Tables 11.3-5A and 11.3-5B.

The general assumptions made in estimating the annual release of gaseous wastes are:

A. Normal operational reactor coolant activity levels are determined on the basis of fission product diffusion through cladding defects in 0.25 percent of the fuel rods. Reactor coolant activity levels for this condition are listed in Table 11.1-4;

B. The reactor coolant activity levels for anticipated operational occurrences are based on fission product diffusion through cladding defects in 1.0 percent of the fuel rods. Reactor coolant activity levels for this condition are listed in Table 11.1-3;

C. High Efficiency Particulate Air (HEPA) filters have a particulate removal efficiency of 99.9 percent and do not retain iodine or noble gases. No credit is taken for the particulate retentions by prefilters; and,

D. Charcoal filters have an iodine removal efficiency of 90 percent and do not retain noble gases or particulates.

11.3.6.1 <u>Gaseous Waste System</u>

[This section contains historical information.]

The estimated releases from the GWS in curies per year are listed in Tables 11.3-5A and B. The source terms and assumptions used to determine these releases are given in Section 11.3.2 (see Section 11.3.2 of the FSAR). During normal operation the expected activity releases from the plant are based on 0.25 percent failed fuel, while the anticipated operational occurrences are assumed at 1.0 percent failed fuel. The radioactivity that is released from the failed fuel is reduced in concentration by the process equipment in the CVCS, WMS and BMS. For iodine, the purification and preconcentrator ion exchanger Decontamination Factor (DF) is 1,000, and a liquid to gas partition factor of 10,000 is used for the reactor drain tank, vacuum degasifier, holdup tank, waste tanks, and boric acid concentrator. Noble gases are stripped by a factor of approximately 120 in the vacuum degasifier and five in the boric acid concentrator. (The boric acid concentrator is currently not in use.) Activity will be reduced by natural decay due to residence time in the reactor drain tank, and gas decay tanks. The noble gas releases from the gas collection header and gas surge header are based on diffusion estimates from all the components.

Table 11.3-5 shows the calculated releases of radioactive material in the gaseous effluents. As indicated by the data presented in this table, the activity released to the site boundary falls within the design objectives stated in Section 11.3.1.

11.3.6.2 <u>Containment Purge Exhaust</u>

[This section contains historical information.]

The gaseous wastes released annually from containment purging under normal operating conditions are based on the following assumptions:

A. Containment air activity is based on RCS leakage of 20 gpd with reactor coolant at equilibrium fission product activity levels for diffusion through cladding defects in 0.25 percent of the fuel rods;

B. A partition coefficient of 10 is assumed for halogens and particulates at the leakage point. A partition coefficient of one is assumed for noble gases;

C. Ninety days of activity accumulation is assumed. There is no particulate plateout, containment leakage, or other activity removal except natural decay; and,

D. Containment purge rate is 40,000 cfm, and the purge is filtered through HEPA and charcoal filters.

The gaseous wastes released annually from containment purging under anticipated operational occurrences are based on the following assumptions:

A. Containment air activity is based on RCS leakage of 40 gpd, with reactor coolant at equilbrium fission product activity levels for diffusion through cladding defects in 1.0 percent of the fuel rods;

B. A partition coefficient of 10 is assumed for halogens and particulates at the leakage point. A partition coefficient of one is assumed for noble gases;

C. Ninety days of activity accumulation is assumed. There is no particulate plateout, containment leakage, or other activity removal except natural decay; and,

D. Containment purge rate is 40,000 cfm, and the purge is filtered through HEPA and charcoal filters.

11.3.6.3 <u>Auxiliary Building Ventilation System</u>

[This section contains historical information.]

The estimated annual release of gaseous activity from the auxiliary building ventilation exhaust will result from two general input sources.

A. The fuel handling floor area is exhausted by two 40,000 cfm fans, one of which is normally in operation. The exhaust flow passes through a HEPA filter and a charcoal filter and is discharged to the exhaust duct. The spent fuel pool contains reactor coolant grade water that is normally maintained at low activity levels by the Spent Fuel Pool Purification System described in Section 9.1.3. The pool will contain activity levels due to partial mixing with the Reactor Coolant System (RCS) once each year during refueling. Coolant degassing and pool purification reduce gaseous, air particulate, and iodine releases. The release of gaseous waste from the spent fuel pool area is based on evaporation and diffusion from the spent fuel pool.

B. The remainder of the auxiliary building and the radwaste area is exhausted by two 53,250 cfm exhaust fans, one of which is normally in operation. This exhaust path will carry with it any gaseous activity generated by valve stem leakage, equipment vents, and other radioactive sources not served by the vent collection or gas collection headers. The air flow passes through one HEPA filter and one charcoal filter before being exhausted to the main ventilation exhaust path. Proper equipment operation, adequate preventative and corrective maintenance practices, and other good engineering practices will minimize gaseous activity in this exhaust path.

The gaseous waste release from this source is assumed to generate from reactor coolant leakage of 20 gpd downstream of the letdown heat exchanger. The partition coefficient for halogens and particulates is assumed to be 1,000 at the 20 gpd leakage point. The partition coefficient for noble gases is uniformly assumed to be one. The coolant activity during normal operation is assumed to be at equilibrium levels for fission product diffusion through cladding defects in 0.25 percent of the fuel rods. Anticipated operational occurrence coolant activity is assumed to be at equilibrium levels for fission product diffusion through cladding defects in 1.0 percent of the fuel rods.

11.3.6.4 Steam Generator Blowdown Tank Vent

[This section contains historical information.]

The estimated annual release of gaseous waste from the steam generator blowdown tank vent under normal operating conditions is based on the following assumptions.

A. Steam generator activity is at equilibrium levels for 13-gpd primary-to-secondary leakage and 15-gpm continuous blowdown flow. Reactor coolant activity is assumed to result from fission product diffusion through cladding defects in 0.25 percent of the fuel rods. Primary coolant activity reduction due to leakage into the secondary system is negligible;

B. Steam flashing in the blowdown tank is assumed to account for a partition coefficient of 1,000 for particulates, 20 for iodine, and one for noble gases;

C. The blowdown tank vent exhausts to the main condenser which provides a partition coefficient of 2,000 for particulates and halogens; and,

D. All noble gas in the blowdown flow is assumed to be released through the tank vent to the main condenser and ultimately to the environment via the condenser vacuum pumps and Auxiliary Building Ventilation System (ABVS).

The estimated release of gaseous waste from the steam generator blowdown tank vent during anticipated operational occurrences is based on the following assumptions:

A. Steam generator activity is at equilibrium levels for 100-gpd primary-to-secondary leakage and 15-gpm continuous blowdown flow. Reactor coolant activity is assumed to result from fission product diffusion through cladding defects in 1.0 percent of the fuel rods. Coolant activity reduction due to leakage into the secondary system is negligible; and,

B. The assumed partition coefficients are the same as for normal operation.

A description of the analysis of steam generator activity levels for normal and anticipated operational occurrences is presented in Section 11.1.7, and Tables 11.1-12 and 11.1-13 summarize the resulting concentrations by isotope.

11.3.6.5 Condenser Vacuum Pump Exhaust

[This section contains historical information.]

The estimated annual release of gaseous waste from the condenser vacuum pump exhaust during normal operation is based on the following assumptions.

A. Steam generator activity is at equilibrium levels for 13-gpm primary-to-secondary leakage and 15-gpm continuous blowdown flow. Reactor coolant activity is assumed to result from fission product diffusion through cladding defects in 0.25 percent of the fuel rods. Primary coolant activity reduction due to leakage into the secondary system is negligible.

B. Activity carryover in the steam flow is assumed to be 0.25 percent for halogens, 0.1 percent for particulates, and 100 percent for noble gases. Steam flow is assumed to be 12,660,000 lb/hr.

C. The main condenser is assumed to provide a partition coefficient of 2,000 for particulates and halogens and one for noble gases.

D. The vacuum pump exhaust is assumed to release all gaseous waste partitioned in the condenser from a total steam flow of 12,660,000 lb/hr for 313 days a year. Exhaust is filtered through a HEPA and charcoal filters in the ABVS.

The estimated release of gaseous waste from the condenser vacuum pump exhaust for anticipated operational occurrences is based on the following assumptions.

A. Steam generator activity is at equilibrium levels for 100-gpd primary-to-secondary leakage and 15-gpm continuous blowdown flow. Reactor coolant activity is assumed to result from fission product diffusion through cladding defects in 1.0 percent of the fuel rods.

B. The assumed carryover fractions, partition coefficients, and total steam flow values are the same as for normal operation.

A description of the analysis of steam generator activity levels for normal and anticipated operational occurrences is presented in Section 11.1.7, and Tables 11.1-12 and 11.1-13 summarize the resulting concentrations by isotope.

11.3.6.6 <u>Turbine Gland Seal Exhaust</u>

[This section contains historical information.]

The estimated annual release of gaseous waste from the Turbine Gland Sealing System (TGSS) during normal operation is based on the following assumptions.

A. The activity of the steam system is as defined by the assumptions in Section 11.3.6.5 for normal operation.

B. Total turbine gland exhaust flow amounts to 6,040 lb/hr of steam for 313 days a year.

C. The turbine gland seal condenser exhaust is assumed to provide a partition coefficient of 100 for halogens and particulates, and one for noble gases.

D. The turbine gland seal condenser exhaust releases all gaseous waste partitioned in the exhauster.

The estimated release of gaseous waste from the TGSS for anticipated operational occurrences is based on the following assumptions.

A. The activity of the steam system is as defined by the assumptions in Section 11.3.6.5 for anticipated operational occurrences.

B. Total turbine gland seal exhaust flow, based on twice normal packing clearances, will be 12,080 lb/hr of steam for 313 days a year.

C. The assumed partition coefficients are the same as for normal operation.

11.3.6.7 Steam Dump Valve and Relief Valve Discharge

[This section contains historical information.]

The estimated annual release of gaseous and air particulate activity from the steam dump valves and relief valves are normally expected to be nil.

The estimated release for anticipated operational occurrences is based on action of one valve for 300 seconds, assuming an average valve discharge rate of 720,000 lb/hr saturated steam. This amounts to 60,000 lb of steam which is assumed to be at equilibrium activity levels determined on the basis of the assumptions in Section 11.3.6.5 for anticipated operational occurrences.

11.3.6.8 Turbine Building Vent Exhaust

[This section contains historical information.]

The estimated annual release of gaseous waste from the turbine building vent exhaust during normal operation is based on the following assumptions.

A. The activity released is assumed to generate from steam leaks in the turbine building totaling 1,700 lb/hr for 313 days a year.

B. The activity of the steam system is as defined by the assumptions in Section 11.3.6.5 for normal operation.

C. No partitioning of activity is assumed to occur at the leakage point.

The estimated annual release of gaseous waste from the turbine building vent exhaust during anticipated operational occurrences is based on the following assumptions.

A. The activity released is assumed to generate from steam leaks in the turbine building totaling 1,700 lb/hr for 313 days a year.

B. The activity of the steam system is as defined by the assumptions in Section 11.3.6.5 for anticipated operational occurrences.

C. No partitioning of activity is assumed to occur at the leakage point.

11.3.6.9 LLRWSB Vent Exhaust

The only activity releases from this path are assumed to be those from high specific activity waste prepared for shipment, and those associated with compaction and storage of dry active waste. The LLRWSB is equipped with a HVAC system which maintains a negative pressure within the building when in service. HEPA filters are installed to reduce the release of airborne particulates to the atmosphere. Storage capacities are presented in Section 11.5, Solid Radioactive Waste Program. These insignificant releases are not included in the tables dealing with effluent releases.

11.3.6.10 PASS Discharges

During normal operation these discharges are through other systems for both Unit 1 and Unit 2 and the discharges pass through HEPA and charcoal filters. During accident conditions all discharges are returned to the containment building.

Normal operation discharges are due to testing, emergency procedure training, and possible use during emergency drills. These releases are not included in the Tables dealing with effluent releases because these releases are insignificant.

11.3.6.11 Unit 1 Gaseous Releases

[This section contains historical information.]

As with Unit 2, the releases of noble gases, airborne halogens, and air particulates vary with plant operations.

Unit 1 release points and potential release points are as follows:

A. Gaseous Radioactive Waste System (GRWS);
B. Reactor Building Purge Exhaust;
C. Auxiliary Building Ventilation;
D. Condenser Vacuum Pump Exhaust;
E. Turbine Gland Seal Exhaust;
F. Steam Dump and Relief Valves;
G. Turbine Building Exhaust; and,
H. Penetration Room Vents.

The general assumptions made in estimating the annual release of gaseous wastes are:

A. Expected reactor coolant activity levels are determined on the basis of fission product diffusion through cladding defects in 0.25 percent of the fuel rods. Reactor coolant concentrations for 0.1 percent failed fuel are presented in the ANO-1 Unit 1 SAR. These values have been linearly extrapolated to obtain 0.25 percent failed fuel;

B. The reactor coolant activity levels for maximum expected occurrences are based on fission product diffusion through cladding defects in 1.0 percent of the fuel rods. Reactor coolant activity levels for these conditions are also presented in the ANO-1 Unit 1 SAR;

C. HEPA filters have a particulate removal efficiency of 99.9 percent and do not retain iodine or noble gases. No credit is taken for the particulate retentions by prefilters; and,

D. Charcoal filters have an iodine removal efficiency of 90 percent and do not retain noble gases or particulates.

11.3.6.11.1 Gaseous Radioactive Waste System

[This section contains historical information.]

The purpose of this Unit 1 system is to collect and discharge, under monitored conditions, radioactive gases vented from auxiliary system equipment and tanks and collect, compress, store, and discharge under controlled conditions radioactive gases released from RCS equipment and other primary systems. The Unit 1 SAR gives a complete description of the GRWS.

Aerated low activity gases are collected in the gas collection header, and are vented directly to the station vent plenum through HEPA and charcoal filters. The sources of these gases are the various equipment vents in the auxiliary building which may contain air. These gases are therefore separated from all the gases associated with primary system water (which contains hydrogen gas) to prevent the formation of an explosive mixture anywhere in the GRWS.

Primary system vents and the discharge of the vacuum degasifier contribute the largest quantity of gaseous radwaste of all the components processed through the system. These gases are normally filtered, monitored, and discharged to the environment. Should the activity in the discharge header be too high, the gaseous waste discharge valve will close and the gas flow will be diverted to an empty waste gas tank. The gas is compressed and stored in the waste gas decay tanks until the radioactivity level drops sufficiently to be discharged through the discharge header to the environment. The decay tanks are conservatively sized to provide a 30-day holdup time for decay. Compressors are alternately started by a mechanical sequencer.

The following assumptions were used in determining gases expected to be released during normal operations.

A. All radioactive gases in bleed wastes that were generated in the core and leaked into the coolant during the base loaded cycle were removed in the vacuum degasifier. Reactor coolant concentration due to 0.25 percent failed fuel.

B. All gases held up 30 days (45 equivalent days) for decay.

C. Annual average exclusion distance X/Q = 2.8E-6 sec/m^3 used for evaluating exclusion distance concentrations.

Tables 11.3-5A and B summarize the releases from the GRWS during expected (normal) and maximum expected (anticipated operational occurrences).

11.3.6.11.2 Reactor Building Purge Exhaust

[This section contains historical information.]

Expected and maximum expected releases due to Unit 1 reactor building purge are based on the same assumptions used for Unit 2 containment purge during normal and anticipated operational occurrence (see Section 11.3.6.2).

11.3.6.11.3 Auxiliary Building Ventilation

[This section contains historical information.]

Expected releases from the Unit 1 Auxiliary Building Ventilation System are based on the following assumptions:

A. A 20-gpd reactor coolant leak occurs downstream of the letdown heat exchanger and releases activity for 313 days;

B. A partition coefficient of 1,000 is assumed for halogens and particulates at the leak point;

C. A partition coefficient of one is assumed for noble gases; and,

D. Ventilation exhaust is through HEPA and charcoal filters.

Maximum expected releases are based on the above assumptions with fission product activities based on 1.0 percent failed fuel.

11.3.6.11.4 Condenser Vacuum Pump Exhaust

[This section contains historical information.]

Expected releases from the Unit 1 condenser vacuum pump are based on the following assumptions:

A. Steam generator activity is at equilibrium levels for 13-gpd primary-to-secondary leakage. Reactor coolant activity is assumed to result from fission product diffusion through cladding defects in 0.25 percent of the fuel rods. Primary coolant activity reduction due to leakage into the secondary system is negligible;

B. Activity carryover in the steam flow is assumed to be 100 percent for halogens, particulates, and noble gases. Steam flow is assumed to be 10,600,000 lb/hr;

C. The main condenser is assumed to provide a partition coefficient of 2,000 for particulates and halogens and one for noble gases;

D. Condensate demineralizers are uniformly assumed to provide a DF of 10 for halogens and particulates;

E. The vacuum pump exhaust is assumed to release all gaseous waste partitioned in the condenser for a total steam flow of 10,600,000 lb/hr for 310 days a year. Exhaust is filtered through HEPA and charcoal filters.

Maximum expected releases are based on a 100 gpd primary to secondary leak with reactor coolant activity due to 1.0 percent failed fuel.

11.3.6.11.5 Turbine Gland Seal Exhaust

[This section contains historical information.]

Expected and maximum expected releases due to Unit 1 turbine gland seal exhaust are based on the same assumptions used for Unit 2 normal and anticipated operations except expected gland seal flow is 5,870 lb/hr for 310 days a year and maximum expected flow is 11,740 lb/hr for 310 days a year.

11.3.6.11.6 Steam Dump Valve and Relief Valve Discharges

[This section contains historical information.]

The estimated annual release of gaseous and air particulate activity from the Unit 1 steam dump valves and relief valves are normally expected to be nil.

The estimated release for maximum expected occurrences is based on actuation of one valve for 300 seconds assuming an average valve discharge rate of 335,000 lb/hr saturated steam. This amounts to 28,000 pounds of steam which is assumed to be at equilibrium activity levels determined on the basis of the assumptions in Section 11.3.6.11.4 for anticipated operational occurrences.

11.3.6.11.7 Turbine Building Vent Exhaust

[This section contains historical information.]

Expected and maximum expected releases from Unit 1 turbine building ventilation exhaust are based on the same assumptions used for Unit 2 turbine building vent exhaust for normal and anticipated operational occurrences.

11.3.7 RELEASE POINTS

Releases from the Unit 2 gas collection header, Gaseous Waste System, containment purge, fuel handling floor, auxiliary building extension, and the auxiliary building ventilation exhaust all discharge from release points at the top of the containment at Elevation 533 feet (180 feet above grade). Figure 11.2-2, an elevation view of the containment, shows the rectangular duct which directs the effluents from these systems along one of the buttresses of the containment to the release point.

The turbine gland seal exhaust is located between the turbine building and auxiliary building. Releases are directed to the atmosphere through a line that exhausts at Elevation 461 feet (108 feet above grade).

The main steam dump and relief valves are located between the containment and the auxiliary building. Releases from the valve discharges are directed through individual pipes extending upwards to release points at Elevation 455 feet (102 feet above grade).

Releases from the Penetration Room Ventilation System discharge through a 12 inch line (see Figure 11.2-2) that exhausts at the top of the containment at Elevation 536.5 feet (183.5 feet above grade).

Discharges from potential release points within the turbine building are directed through penetrations in the turbine building roof. The turbine building ventilation exhaust is released through roof vents at Elevation 448 feet (95 feet above grade). Grade elevation is 353 feet.

Discharges from the PASS Building and Low Level Radwaste Storage Building are released through exhaust lines at each location (see Figure 11.2-2).

11.3.8 DILUTION FACTORS

The discharge of gaseous wastes to plant effluent paths will account for some inplant dilution prior to exhausting to the environment. Table 11.3-6 summarizes the total air flow from each gaseous waste discharge point which will provide this dilution.

Once the discharge is released from the plant, dispersion of the plume occurs. The annual average X/Q value used in calculating the radionuclide concentrations at the site boundary is 2.8(-6) sec/m^3. Its derivation is discussed in Section 2.3. The annual average meteorological data used to determine the total radiation exposure to the population was that observed for the period from February 7, 1972 to February 7, 1973 using wind speeds recorded at the 40-foot elevation.

The models used in the analyses of relative concentrations, plume depletion, radioactive decay and deposition are described as follows:

<u>Straight Line Trajectory Air Flow Model Relative Concentrations</u>

The computer program used for this analysis is based on the specifications in Regulatory Guide 1.111 (Reference 14).

For calculations, the plume is assumed to be a ground release because the stack vents fail, by a small margin, to exceed the height of closest solid adjacent structures. For ground level releases, the relative dispersion factor is determined from:

$$X/Q\ (i,D) = \frac{2.032}{nD} \sum_{j=1}^{n} \sum_{i=1} \frac{K}{\bar{u}(j)\left[\sigma_z(j,D)^2 + \frac{CV^2}{\pi}\right]^{1/2}} \qquad (1)$$

where

X/Q (i,D) = relative ground level dispersion factor (seconds/meter^3) in sector i at distance D.

σ_z (j,D) = vertical dispersion coefficient for hour j (dependent on Pasquill stability class), at distance D (meters)

$\bar{u}$(j) = average wind speed (meters/second) for hour j at the 10 meter height

D = distance from reactor containment structure to point of interest (meters)

V = height of reactor containment structure (meters)

C = building wake shape factor

n = number of valid observations during the period of interest

K = wind direction dependent variable (1 if wind blowing to sector i, 0 if wind not blowing to sector i)

The effect on X/Q of the wake factor is limited to a factor $\frac{CV^2}{\pi}$ of 3 or less, i.e., (X/Q) wake ≥ ⅓ (X/Q) no wake. Calm wind conditions are included in the calculation by assigning a wind speed of one-half threshold of the anomometer and distributing them around the 16 direction sectors in proportion to the directional frequencies of the lowest speed class interval for the appropriate Pasquill stability class. The above equation reflects the annual average (longer averaging periods) dilution factor which are applicable to routine venting or other routine gaseous effluent release. This equation uses the sector spread technique which accounts for variations of wind direction from the sector center lines during each hour's release.

Radioactive Decay

Relative concentrations of radionuclides were adjusted to account for radioactive decay in accordance with procedures given in Meteorology and Atomic Energy (Reference 35) using the following equation:

$$X / Q_{(\mathrm{decay})} = X / Q \exp\left[-\frac{0.693}{T_{1/2}} t\right] \qquad (2)$$

where

$X/Q_{(decay)}$ = the relative concentration decreased by the decay of the radionuclides

X/Q = undecayed relative concentration

t = transit times for radionuclides; distance to receptor divided by wind speed

$T_{1/2}$ = half life of radionuclide

A half life of 2.26 days was used for all noble gases and of eight days for iodines.

Deposition

Deposition was calculated in accordance with the procedures recommended in Regulatory Guide 1.111. The values of relative deposition rate from Figure 7 of this guide are a function of distance only for ground level releases. The values are determined from the distance of the sources to the receptor divided by the arc length of the 22.50 wind sector at that distance:

$$D = \frac{\Gamma_D}{\mathrm{WDTH}}$$

where

D = relative deposition

Γ_D = relative deposition rate of distance d from the source (obtained from curve in Figure 7 of Regulatory Guide 1.111)

WDTH = width of 22.5° sector at distance d (2 d sin (11.25))

The above are determined for each observation of a given wind direction and distance.

Plume Depletion

Plume depletion effects were accounted for in accordance with procedures recommended in Regulatory Guide 1.111. Proportion of plume remaining after travel to distance, D, was taken from Figure 3 of this Guide. Annual relative concentrations, decayed and depleted, are derived by multiplying all values of decayed plumes, at distance D, by the depletion value at Distance D.

11.3.9 ESTIMATED DOSES

The dose to man resulting from radionuclides in gaseous effluents has been evaluated for the following principal exposure pathways.

A. Immersion in a semi-infinite cloud containing radioactive material.

B. Inhalation of radioactive halogens and airborn particulate material.

C. Exposure to direct radiation from radionuclides that have deposited on ground around the site.

D. Ingestion of food containing radionuclides deposited from gaseous effluents in the atmosphere.

Maximum radionuclide concentrations in air at the site boundary have been estimated using an annual average X/Q value of 2.8(-6) sec/m^3 and the annual radionuclide releases given in Section 11.3.6.

Tables 11.3-7A and B give the maximum site boundary radionuclide concentrations under normal operation and operation during anticipated operational occurrences.

Radionuclide concentrations on the ground were found by assuming a deposition velocity of 0.5 cm/sec for halogens and particulates (1). The equation describing the radionuclide concentrations on the ground is:

$$C_G = \frac{1 \times 10^7 C_A V}{\lambda}\left(1 - e^{-\lambda t}\right)$$

where

C_G = radionuclide concentration on ground, (mCi/km^2)

C_A = radionuclide concentration in air, (μCi/cc)

V = deposition velocity, (cm/sec)

λ = radioactive decay constant, (sec^{-1})

t = reactor lifetime, (sec) assumed to be 40 yr

The whole body dose to man from gamma radiation emitted by radionuclides deposited on the ground is given by:

$$D_g = \frac{KC_G}{g}$$

where

D_g = annual whole body dose, mrem/yr

K = dose conversion constant, mrem/yr/mCi/km² (Reference 25)

g = self-absorption factor.

The dose conversion constants, K, apply to the dose from both uncollided and collided photons three feet above an infinite plane source containing uniform radionuclide deposition. A value of 2.5 was employed for the self-absorption factor, g, to account for radionuclide penetration into the soil. This value can be arrived from measurements by Beck (Reference 19). It has also been assumed that an individual spends eight hr/day and 365 days/yr exposed to radionuclides deposited on the ground.

The external dose to the surface of the body from immersion in a semi-infinite cloud of radioactive material is given by:

$$D_C = 250\ (E_\beta + E_\gamma)\ R\ X/Q$$

where

E_β = average beta energy per disintegration, Mev

E_γ = average gamma energy per disintegration, Mev

R = radionuclide release rate, Ci/yr

D_C = annual dose, mrem/yr

The decay energies employed in the immersion dose calculation are given in Table 11.3-8.

Estimated site boundary whole body doses are summarized in Tables 11.3-10A and B for normal operation and anticipated operational occurrences.

In evaluating the dose from inhaled radioactive materials, continuous exposure to maximum site boundary airborne concentrations is assumed.

The dose from inhalation is given by:

$$D = \frac{C_A}{MPC}\ MPD$$

where

D = annual dose to a given organ, mrem/yr

C_A = airborne radionuclide concentration at the site boundary, µCi/cc

MPC = maximum permissible radionuclide concentration in air, µCi/cc (References 2 and 13)

MPD = maximum permissible organ dose resulting from continuous exposure at MPC, mrem/yr (References 2 and 13).

For purposes of estimating the lung dose, it was assumed that the insoluble form of the radionuclide was present.

Estimated site boundary inhalation doses are summarized in Tables 11.3-10A and B for normal operation and for anticipated operational occurrences.

The dose from the consumption of food was evaluated for the following pathways.

A. Adult consumption of green and tuberous vegetables containing deposited radionuclides.

B. Adult consumption of meat from animals that have grazed continuously on pasture land containing deposited radionuclides.

C. Infant and adult consumption of milk from cows at the nearest dairy herd 4.8 mi to the northwest of the plant.

The principal isotopes of significance in food chains leading to man are Sr-89, Sr-90, Cs-134, Cs-137 and I-131. Only these nuclides have therefore been included in the estimated doses from food consumption.

Two mechanisms for transfer into vegetation have been considered. These are uptaken from the soil via the roots of the plant, and foliar deposition. For Sr-89 and I-131, only foliar deposition was considered. In general, radionuclide concentrations in food material are given by an empirical equation of the form (see References 22 and 34):

$$C_F = P_r F_r + P_d F_d$$

where

C_F = radionuclide concentration in food, μCi/g

P_r = ate proportionality constant, μCi/g/mCi/km^2

F_r = annual rate of radionuclide deposition, mCi/km^2

P_d = soil proportionality constant, μCi/g/mCi/km^2

F_d = cumulative radionuclide deposit, mCi/km^2

The empirical constants, P_r and P_d, employed in the analysis for strontium and

cesium isotopes are given in Table 11.3-9.

Concentrations of radioiodine isotopes in milk were determined assuming a deposition velocity of 1 cm/sec, a pasture half-life of 14 days, and an empirical rate constant of 9(-8) (μCi/cc) milk/(mCi/km^2) pasture. This set of assumptions corresponds to the factor of 700 reduction in the MPC_a for I-131 which is commonly employed to account for the milk-infant exposure pathway (Reference 23).

The annual average concentration of radioiodine isotopes in milk has been based on the assumption that cows are grazed for nine months each year.

The doses from food consumption were computed using the equation:

$$D = \frac{C_F}{MPC} \frac{R}{2200} MPD$$

where

D	=	organ or whole body dose, mrem/yr
R	=	rate of food intake, g/day
C_F	=	radionuclide concentration in food, µCi/g
MPD	=	maximum permissible organ dose, mrem/yr (References 2 and 13)
MPC	=	the maximum permissible radionuclide concentration corresponding to the MPD, µCi/cc (References 2 and 13)

The dose to adults and infants from food ingestion are summarized in Table 11.3-10A and B.

The dose to individuals and populations within a 50-mile radius of ANO have been evaluated as a function of distance and direction from the containment. For simplification, only the immersion dose was included in the evaluation. The exposure per person in each 22.5 degree sector as a function of distance is given by:

$$D_S = D_B \frac{(X/Q)_S}{(X/Q)_B}$$

where

D_S	=	immersion dose in a given sector at a given distance, mrem/yr
D_B	=	immersion dose at the north site boundary, mrem/yr
X/Q_B	=	annual average X/Q value at the north site boundary, sec/m^3
X/Q_S	=	annual average X/Q value in a given sector at a given distance, sec/m^3.

The x/Q values employed in the analysis are given in Section 2.3, and are annual average values based on 40-foot level wind data.

Population immersion doses, i.e. man-rem, were determined by multiplying the dosed determined above by the number of people in each sector and distance interval. The population distribution data given in Section 2.1 were employed.

The resulting doses to individuals and population groups are presented in Tables 11.3-11 and 11.3-12 for normal operational gaseous release, and in Tables 11.3-13 and 11.3-14 for releases during anticipated operational occurrences.

For information on site characteristics, including population distribution, agricultural usage, and fish and wildlife usage, see Chapter 2.

11.4 PROCESS AND EFFLUENT RADIOLOGICAL MONITORING SYSTEMS

The process and effluent radiological monitoring systems provide the means for monitoring the containment atmosphere and the ventilation exhaust from spaces containing components used for the recirculation of hypothetical Loss of Coolant Accident (LOCA) fluids. These systems also monitor all other gaseous and liquid effluent paths by which radionuclides may be released to the environment except the turbine building sumps. The turbine building sumps are monitored as described in 11.6.3.3. The system consists of permanently installed continuous monitoring devices together with a program of and provisions for specific sample collections and laboratory analyses. The overall system is designed to function and provide information of use in evaluating the radiological consequences of normal plant operation, anticipated operational occurrences, and hypothetical accidents.

This section describes the instrumentation and the program of sample collection and analysis at Unit 2. The design of the overall system is evaluated for radioactivity releases during normal plant operation, as described in Sections 11.2 and 11.3, and for release during hypothetical accidents, as described in Chapter 15.

11.4.1 DESIGN OBJECTIVES

The principal objectives of the monitoring systems are:

A. To provide for evaluation of the performance of all plant systems that function to minimize the release of radioactivity to accessible areas of the plant and to the environment;

B. to estimate quantities of radioactivity in effluents or potential effluents before and/or during their release to unrestricted areas; and,

C. to quantify releases of individual nuclides and radionuclides in effluents to unrestricted areas during and after release.

The accomplishment of these general objectives will provide assurance that doses to individuals in restricted and unrestricted areas are as low as practicable during normal plant operation and during anticipated operational occurrences as defined in 10 CFR 20, Appendix I of 10 CFR 50, and the Technical Specification limits for releases. In addition, these monitoring systems will allow plant personnel to evaluate the radiological consequences of hypothetical accidents.

Specific design objectives include the following:

A. To collect representative samples of planned air and water effluents prior to discharge to unrestricted areas during normal reactor operation and during anticipated operational occurrences in order to allow measuring and recording of the quantity of each of the principal radionuclides present in these discharges as required by Section 50.36A of 10 CFR 50 and Regulatory Guide 1.21 (12/29/71).

B. To collect representative samples of air and water effluents that are discharged continuously to unrestricted areas during normal reactor operation and during anticipated operational occurrences in order to allow measuring and recording of the quantity of each of the principal radionuclides present in the discharges as specified in 10 CFR 50 and Regulatory Guide 1.21.

C. To provide sample facilities that allow monitoring of the containment atmosphere, spaces containing components for recirculation of LOCA fluids, effluent discharge paths, and the plant environment for radioactivity that may be released from postulated accidents.

D. To continuously monitor radioactivity in both intermittent and continuous discharges of potentially radioactive plant air and water effluents to unrestricted areas during normal plant operations, including anticipated operational occurrences. The turbine building sumps monitoring is discussed in Section 11.6.3.3. This pathway is not continuously monitored. The monitors verify that such releases are at concentrations and radiation levels that are within the limits specified in Table II of Appendix B to 10 CFR 20, as well as the guidelines of Sections I, IIc, III, and IV, of Appendix I to 10 CFR 50.

E. To provide alarm and automatic termination of the release of effluents when radionuclide concentrations and/or radiation levels exceed the limits specified in "D" above. Where the termination of releases is not feasible, the monitors provide continuous indication of the magnitude of the activity releases.

F. To provide an indication of the existence of and, to the extent possible, the magnitude of Reactor Coolant System (RCS) and Reactor Auxiliary System leakage to the containment atmosphere, the CCW, the Service Water system, or the secondary plant side of the steam generators.

11.4.2 CONTINUOUS MONITORING

The continuous Liquid and Gas Radiation Monitoring Systems are presented and described in the following sections. For each location subject to continuous monitoring, the basis for location selection, the expected concentrations or radiation levels, and the parameters to be measured are presented. The detectors used are described by type, sensitivity and range. The recording and indicating devices and annunciators and alarms are also discussed. The bases for the selection of monitor setpoints and the actions initiated upon exceeding the setpoints are discussed. Indicators and controls for continuous Liquid and Gas Process and Effluent Monitoring Systems are provided in the control room at the radiation monitoring panels.

The radiation monitoring control panel is a Seismic Category 1 enclosure and houses the remote readouts and associated controls for the monitoring systems. They are the liquid radiation monitoring system control panel, the gaseous waste monitoring system control panel and the area radiation monitoring control panel. The monitor outputs are recorded on multi-point recorders. Monitor detector outputs provide indication at the monitoring panels on a logarithmic ratemeter having two ranges (wide range-five decades and expanded range-three decades) or on a ratemeter with an auto ranging digital display).

The liquid monitoring and gaseous monitoring system control panels are provided with dual level alarms. Selected channels are provided with triple level alarms. The low level alarm is set below the background counting rate to act as a circuit failure alarm. The high level alarm is set at a high level trip point corresponding to the maximum permissible radiation level for the particular system. The third setpoint is adjustable over the full range between circuit failure and maximum permissible level.

The alarm circuits are operative when the ratemeters are in the power-on condition. When ratemeters are in a voltage checking mode, the alarm circuits are not bypassed. In a calibration mode the alarm circuits are used to set and check bistable trip points. Failure of power causes an alarm of all circuits. The low alarm circuits are automatically reset when the cause of the alarm condition is corrected and the high alarm is manually reset.

Most monitors in thecontinuous gaseous and liquid monitoring system are provided with a solenoid or motor operated check source that will simulate a radioactive sample in the detector sample chamber and is used for operational and gross calibration checks of the detector and readout equipment. All check sources have half-lives greater than 10 years. The control room inlet air monitor system is provided with a pulsed LED which provides an identical detector response as an isotopic check source and is used for the functional check of the detector, preamplifier, and readout equipment.

Most monitors in the continuous gaseous and liquid monitor systems are provided with an in-line or off-line sample chamber, a radiation detector, a check source, associated process filters and other applicable equipment. The sample chamber is sized and shielded as required to achieve the specified minimum system sensitivities. Each sampler is constructed of 304 stainless steel in accordance with the fabrication codes of the associated system and is located as close as practical to the process stream, such that sample line interference or losses will be insignificant. Table 11.4-1 lists the process radiation monitors. The control room inlet air monitor system is provided with a radiation detector (which incorporates a pulsed LED for functional verification), preamplifier, and ratemeter.

Figure 9.2-7 (Sheet 4) shows the turbine building sump and associated pumps and piping. The system collects turbine building liquid waste, normal (nonradioactive) and oily waste from the auxiliary building, component leakage, and chemical waste from the chemistry laboratory and battery rooms. Chemical wastes are neutralized prior to processing in an oil/water separator. Waste oil is collected in 55-gallon drums for off-site disposal. Water from the oil/water separators is routed to the turbine building sump. The turbine building sump level is controlled automatically by pumps which are started on high sump level. Effluent from the sump is pumped to the outside oil/water separator where the water is discharged to the intake canal.

The volume and activity of potentially contaminated liquid waste discharged from the turbine building drains is expected to be negligible. During periods of primary to secondary leakage, this could be slightly radioactive. Provisions have been made to allow local sampling for laboratory analysis to ensure that Technical Specifications are not exceeded.

11.4.2.1 Process Liquid Monitors

The process liquid monitors are provided to detect failed fuel and leakage between process systems, and to continuously monitor the activity of liquids discharged to the environment. The isotopic concentrations that are expected for each of the liquid streams are presented in Section 11.2 for normal plant operations including anticipated operational occurrences. The concentrations of releases resulting from postulated accidents are presented in Chapter 15.

11.4.2.1.1 Chemical and Volume Control System Process Radiation Monitor (Failed Fuel Detector)

The primary purpose of the Chemical and Volume Control System (CVCS) process radiation monitor is to alert plant operators to an increase in coolant radioactivity as quickly as possible. Such an increase in radioactivity would usually be caused by crud released in the RCS or CVCS letdown line. However, an increase in specific fission product nuclide activity along with an increase in gross gamma activity would indicate failed fuel cladding.

The monitor is located in the CVCS letdown line in parallel with the purification filter but upstream of the ion exchangers. This location was selected because a continuous sample at relatively low temperature and pressure can be conveniently obtained and the sample effluent can be returned to the purification system without difficulty. This location also provides an optimum compromise between a minimum sample lag time and the required delay time for sample background radioactivity decay. The time lag from the RCS to the monitor is sufficient to permit N-16 to decay to a low level that will not interfere with monitor readings for all operating conditions.

Gross gamma activity concentration and the activity concentration of a specific nuclide are monitored simultaneously. Iodine-131 is the specific nuclide chosen for activity monitoring for several reasons.

First, Iodine-131 is a fission product that is found in relative abundance in the reactor coolant in the event of fuel cladding failure. Second, it is released from defective fuel with relative ease and does not plate out on the system surfaces. Finally, Iodine-131 is chosen because its 0.364 Mev gamma can be readily monitored using discrimination techniques, and its 8.04 day half-life is long relative to sample lag time but short enough to provide indication of current fission product escape from the fuel. Some fission products that would contribute to gross gamma level plate out on the walls of the piping. The gross gamma activity after minimum lag time is dominated by gaseous fission product and is representative of coolant activity.

The reactor coolant specific activity sensitivity as measured at a coolant temperature of 70 °F by the CVCS process radiation monitor is listed in Table 11.4-1. Design data for the process monitor is listed in Table 9.3-19.

The monitor consists of shielding, sampler, detector holder, gamma scintillation detector preamplifier, logarithmic ratemeter, and single-channel linear ratemeter/analyzer. The gamma scintillation detector is a sodium iodide crystal, one and one-half inches diameter by one inch long, with photomultiplier tube and integral preamplifier which monitors gamma radiation in the energy range of 100 Kev to 3 Mev. The minimum and maximum detectable coolant activities are 1(-4) and 1(-2) in μCi/cc of I-131, respectively. A remotely operated Cs-137 check source is used to test the overall operation of the system.

The sampler is of the in-line type with a sample volume two and one-half inches in diameter and 1-3/4 inches deep. The sampler and tubing are fabricated from stainless steel designed for 200 psig at 250 °F. The detector assembly is completely shielded in 4π geometry by approximately four and one-half inches of lead to reduce the background signal contribution. The shielding assembly also includes a removable collimating plug that must be placed between the detector and sample cell to increase the operating range of the monitor above 1 (-1) μCi/cc of I-131.

After amplification, the detector output signal is fed to a linear ratemeter/analyzer and a logarithmic ratemeter located in the control room. The linear ratemeter/analyzer can monitor a specific fission product gamma activity (I-131) with a total range of 0 to 1.0 (+6) cpm. The logarithmic rate meter measures gross gamma activity with a range of 10 to 1.0 (+6) cpm. Alarms are provided on both the linear ratemeter/analyzer and the logarithmic ratemeter with adjustable set points over the complete range.

The CVCS process radiation monitor is a trend monitor and its primary purpose is to indicate the possibility of fuel clad failure. See Table 11.4-1 for information concerning alarm setpoints. It is expected that gross activity and perhaps Iodine-131 activity will periodically increase above the

alarm setpoints due to normal plant transients. Consequently, the alarm will periodically activate and the operator must determine the cause of the alarm. If an alarm is received and the Iodine-131 activity has increased and remains significantly above the prior steady state level, additional fuel failure can be assumed to have occurred. However, if an alarm is received due to an increase in gross activity and a plant load increase, crud burst release can be suspected. In time, the coolant activity should return to the prior, lower, steady state value.

11.4.2.1.2 Component Cooling Water Monitoring System

The Component Cooling Water Monitoring System is provided to continuously monitor the activity level of components that may contain radioactivity. Each of the two component cooling water loops is provided with an off-line sampler that takes a continuous sample and returns it to the component cooling water heat exchanger inlet. Section 9.2.2 presents a detailed discussion of the Component Cooling Water System and Figure 9.2-6 shows the monitor locations in the process stream.

The normal monitor readings will result from the detector background radiation levels, since contaminated leakage to the system is not expected. The monitor provides a high alarm when concentration levels reach a preset limit, which constitutes positive indication of contaminated leakage to the system. The receipt of this alarm will alert the operator to the presence of leakage so that additional radiation surveys, sampling, and equipment isolation can be effected in order to locate and repair the leakage source.

The detector is a one and one-half inches in diameter by one inch thick NaI (TI) crystal optically coupled to a photomultiplier tube which is housed in a mu-metal shield. The detector has a fixed position with respect to the waste liquid monitor, and is shielded by 7.5 inches of lead in all directions. An electronic matching network applies a DC voltage to the photomultiplier tube, and couples the radiation response signal into the interconnecting cable. Only passive components are located at the detector.

The system is capable of detecting 5(-6) μCi/cc of Cs-137 in a 2.5 mr/hr background. Readout is provided in the control room by two log count ratemeters.

11.4.2.1.3 Service Water Monitoring System

The Service Water Monitoring System is provided to continuously monitor the Service Water System (SWS) to detect leakage in any of the heat exchangers. The SWS continuously circulates water through the plant for cooling purposes and leakage in any of the heat exchangers handling a radioactive liquid could potentially release radioactive material to the Dardanelle Reservoir.

The Service Water Monitoring System consists of one channel downstream of each pair of containment cooling coils, one channel downstream of each shutdown heat exchanger and one channel downstream of the fuel pool heat exchanger. Section 9.2.1 presents a detailed discussion of the SWS and Figure 9.2-1 shows the monitor locations in the process stream.

The normal monitor readings will result from the detector background radiation levels and any associated electronics since contaminated leakage to the system is not expected. A high alarm from the monitor downstream of each pair of containment cooling coils initiates a signal which annunciates an alarm in the control room. The operator will then activate the service water isolation valves as required.

Each channel consists of a continuous off-line sampler and scintillation detector as described in Section 11.4.2.1.2. The two channels downstream of the containment cooling coils are designed to detect 5(-6) uCi/cc of Cs-137 in a 2.5 mr/hr background and readout is provided in the control room by two log count ratemeters. The channel downstream of each shutdown heat exchanger is sensitive enough to detect 5(-6) µCi/cc of Cs-137 in a 2.5 mr/hr background and readout is provided in the control room by two log count ratemeters. The channel downstream of the fuel pool heat exchanger is sensitive to 5(-6) µCi/cc of Cs-137 in a 2.5 mr/hr background and readout is provided by a log count ratemeter in the control room.

11.4.2.1.4 Steam Generator Monitoring System

The Steam Generator Monitoring System is provided to continuously monitor the activity level of the secondary side of the steam generators during normal plant operations. These monitors provide positive indication of primary-to-secondary leakage and a means of determining which steam generator is leaking.

The Steam Generator Monitoring System consists of three separate monitoring systems described below:

A. The Process Sampling System monitors consist of one channel downstream of each steam generator sample cooler.

   Section 9.3.2 presents a detailed description of the Process Sampling System.

   Each monitor channel consists of a sampler and scintillation detector as described in Section 11.4.2.1.2. The monitors downstream of each steam generator sample cooler have a sensitivity of 5(-6) µCi/cc of Cs-137 in a 2.5 mr/hr background. Readout is provided in the control room by three log count ratemeters and by a chart recorder in the control room on panel 2C14. Normal monitor readings will result from detector background radiation.

B. The Main Steam Line Area Monitors consist of one detector attached to each main steam line located in the upper elevation of the Main Steam Isolation Valve Room in the Auxiliary Extension Building.

   Each monitor channel consists of a Geiger-Mueller type detector with a range of 0.1 mR/h to 10,000 mR/h. Readout is provided in the control room on the control modules, chart recorder on 2C14, and the SPDS and PMS computers.

C. The Steam Generator N-16 Monitoring System consists of one detector in close proximity to each main steam line located on elevation 354 of the Turbine Building in the southwest corner of the CCW room.

   Each monitor channel consists of a scintillation type detector and computer control system located in the Startup and Blowdown Demineralizer Control Room on the 374 elevation of the Auxiliary Extension Building.

   The N-16 gamma is a result of the neutron activation of oxygen and subsequent unique seven second half life gamma decay. The energy range of the N-16 gamma is above the energy range of gammas produced by other reactor interactions or naturally produced gammas. The N-16 gamma concentration is directly proportional to power level. These factors make the N-16 gamma an ideal isotope to detect and quantify primary-to-secondary leakage.

The computer control system has been programmed to provide indication of primary-to-secondary leakage in gallons per day whenever plant power is above 20%. The designed minimum detectable leakage is 5.25 GPD. The calculated leakrate is provided to the Plant Monitoring System where it is displayed in Leak Rate (GPD), Leak Rate (GPM), and Leak Rate Rate of Change. The Plant Monitoring System also provides three system related alarms on 2K11.

11.4.2.1.5 Liquid Radioactive Waste Discharge Monitoring System

The Liquid Radioactive Waste Discharge Monitoring System continuously monitors the activity of liquids discharged to the plant discharge header. The header receives liquid wastes from plant systems that potentially contain radioactive nuclides and constitutes a path by which planned releases of radioactive liquid effluents can be discharged to the environment from the Waste Management System (WMS) and Boron Management System (BMS). The monitor is located in the WMS discharge line to the circulating water canal. Monitoring before dilution with circulating water allows greater accuracy of measurement. Section 11.2 presents a detailed discussion of the WMS and BMS and Figure 11.2-1 show the monitor locations in the effluent streams.

The Liquid Waste Monitoring System consists of a single channel, in-line sampler and a scintillation detector as described in Section 11.4.2.1.2 with a sensitivity of 5(-6) µCi/cc of Cs-137 in a 2.5 mr/hr background. If the activity reaches the alarm setpoint, an alarm is activated in the control room, and valves 2CV-2330A and 2CV-2330B, shown on Figure 11.2-2, are tripped closed to stop the discharge flow. The operator must then determine the cause of the alarm. Operator actions would be the same as those described for the gaseous discharge monitor.

The Regenerative Waste Processing Monitoring System consists of two monitors. The monitor of the RWP discharge from the neutralizing tank, 2RE-4425, is currently not in use. The monitor located in the line from the regenerative waste transfer pump to the discharge flume, 2RE-4423, consists of a sampler and a scintillation detector as described in Section 11.4.2.1.2. The sensitivity of this detector is 5(-6) µCi/cc of Cs-137 in a 2.5 mr/hr field. If the activity reaches the alarm setpoint, an alarm is activated on the local control panel and in the Control Room and the discharge valve, 2CV-4424, is automatically closed.

11.4.2.2 Gas Monitoring Systems

The Continuous Gas Monitoring Systems are provided to monitor and quantitatively analyze discharges from plant gaseous effluent paths which potentially contain radioactive noble gases, halogens and particulates. The isotopic concentrations expected for each of the gaseous discharge paths monitored are presented in Section 11.3 for normal plant operation, including anticipated operational occurrences. The concentrations of releases resulting from postulated accidents are presented in Chapter 15.

Each of the Gas Monitoring Systems consists of one or more of the following, depending upon the intended service of the monitoring system:

A. Airborne particulate and iodine channel-removable filter; or

B. low level gas channel.

The airborne particulate channels are removable paper filters for particulate collection and activated charcoal for iodine collection with a 99.9 percent collection efficiency for 0.3 micron particles. These filters are removed and counted by laboratory analysis.

11.4.2.2.1 Main Condenser Air Discharge Radiation Monitoring System

The Condenser Air Discharge Monitoring System is provided to continuously monitor the gaseous activity levels released to the plant vent by the condenser vacuum pump. In the event of a steam generator tube leak, the vacuum pump exhaust will contain airborne activity entrained in the air evacuated from the condenser during normal plant operations. The Condenser Air Discharge Monitoring System is provided to detect the presence and, to the extent possible, the magnitude of primary-to-secondary system leakage as well as to quantitatively analyze the resulting discharge of radioactivity to the plant vent. Section 10.4.2 presents a detailed discussion of the condenser evacuation system, and Figure 10.4-1 shows the location of the monitor in the effluent stream.

The monitor consists of an off-line sampler and a G-M tube for gross beta-gamma analysis and the system has a sensitivity of 1(-5) µCi/cc of Xe-133 in a 2.5 mr/hr background. The readout is provided in the control room by the secondary system trend recorder on panel 2C14 and by a log count ratemeter.

11.4.2.2.2 Waste Gas Monitoring System

The Gaseous Radioactive Waste Monitoring System is provided to continuously monitor the gaseous activity levels released to the vent from the waste gas decay tanks. The tanks potentially contain high levels of radioactive noble gases which are periodically released to the plant vent on a controlled basis. Section 11.3 presents a detailed description of the GWS and Figure 11.3-1 shows the location of the monitor.

The monitor consists of an in-line sampler and the detector is a gross beta-gamma G-M tube. The system is capable of detecting 1(-5) µCi/cc of Xe-133 in a 2.5 mr/hr background. The monitor has an alarm and trip system that is operated by a logarithmic ratemeter. The setpoint of the alarm and trip is adjustable over the full range of the ratemeter. Prior to the release of gaseous activity, a sample is taken for radioactive analysis. The Process Sampling System is described in Section 9.3.2. Both gross and isotopic radioactivity analyses are performed to verify that the activity in the tank can be released to the environment without exceeding the applicable limits. The alarm setpoint of the monitor is set slightly greater than the level determined by the gross gamma radioactivity analysis but below the applicable release limits.

If the activity should increase above the set point, an alarm is activated in the control room and valve 2CV-2428 (see Figure 11.3-1) is tripped closed to stop discharge flow. The operator must then determine the cause of the alarm. Another sample would be taken for radioactivity analysis to determine if the alarm and trip were due to high activity or instrument miscalibration or malfunction. If high activity is the source of alarm, discharging from that particular gas decay tank must either be justified at a higher activity level or the contents must be allowed to decay for an additional time period.

11.4.2.2.3 Containment Atmosphere Monitoring System

The Containment Atmosphere Monitoring System is a redundant system provided to continuously monitor the gaseous and particulate activity levels in the containment in order to determine if there is leakage from the reactor coolant pressure boundary. The Containment

Atmosphere Monitoring System (CAMS) also provides a means of controlling reactor building pressure and maintaining the oxygen concentrations at levels acceptable for human occupancy. Section 5.2.7 gives a complete system description and Figure 9.4-4 shows the monitor locations in the process stream.

11.4.2.2.4 Vent Radiation Monitoring System

The original Westinghouse Vent Radiation Monitoring System provides the capability of continuously monitoring the gaseous activity released to the environment and provides the capability of determining the particulate and iodine releases by laboratory analysis. With the addition of the Eberline SPING (Super Particulate Iodine Noble Gas) monitors, the capability of directly reading the particulate and iodine releases was provided. The SPING Monitor has on-line monitoring of particulates, iodines, and noble gases in the effluent.

The readings taken by the SPING Monitor are corrected for background radiation levels by the use of an area monitor which is integral to the SPING Monitor. Removable filters are provided along with sample ports upstream of the filters permitting plant personnel to obtain representative grab samples of the effluent being released. Sample stream concentrations of up to 10^{-4} μCi/cc of gaseous radioiodine and particulate can be monitored by use of filters and grab samples.

The SPING Monitor has the capability to remotely purge the monitor assembly as well as remotely actuating a check source. Readouts of each detector channel and the status of each monitor are available in both control rooms.

Radiological releases or potential releases occur through three plant vents which handle the ventilation exhaust from the fuel handling area, radwaste area, and containment purge. The SPING monitors provide backup monitoring for the three areas listed above and additional monitoring for the Penetration Room Exhaust and the Auxiliary Building Extension Ventilation that input into these vents.

SPING Monitors are provided for the PASS Building and the Low Level Radwaste Building ventilation exhaust.

A. The fuel handling area ventilation monitor is provided to continuously monitor the gaseous activity levels released to the environment by the ventilation fans exhausting the new fuel area and the spent fuel pool area of the auxiliary building. The spent fuel pool will contain gaseous activity levels due to partial mixing with the RCS during each refueling. Diffusion of this activity from the pool will generate airborne activity which the fuel handling area vent monitoring system quantitatively analyzes prior to release to the environment. The monitor will also provide an indication of gaseous activity released incident to a fuel handling accident. Section 9.4.3 presents a detailed description of the fuel handling area ventilation system. The system consists of an off-line sampler incorporating a sliding vane pump which draws a gas stream through particulate and charcoal filters where radioiodines and solid isotopes are extracted for laboratory analysis. The gas is then monitored for radioactivity by the gas monitor. Sample flow is continuously drawn from and returned to the vent exhaust duct by an isokinetic sampling probe.

   The detector consists of a gross beta-gamma G-M tube and the system is capable of measuring 1(-5) µCi/cc of Xe-133 in a 2.5 mr/hr background. Readout is provided in the control room by a log count ratemeter.

The expected monitor readings for the detector channel during normal plant operation will result from the combined activity levels contributed by the various releases directed into the fuel handling area ventilation exhaust. These expected activities are described in Tables 11.3-5A and B.

Information concerning process radiation monitor alarms is contained in Table 11.4-1.

Additional monitoring of this area is provided by a SPING Monitor.

B. The radwaste area ventilation monitor continuously monitors the gaseous activity levels released to the environment in the combined ventilation exhaust flow from the auxiliary buildings and provides the capability of determining particulate and iodine releases by lab analysis of the fixed particulate and charcoal filters. This flow path provides ventilation exhaust for all building structures housing reactor coolant and reactor auxiliary system components outside the containment. These components represent potential sources for release of gaseous and air particulate activities in addition to the drainage sumps, tanks, and equipment purged by the vent collection and gas collection headers. The system will additionally monitor releases from the vacuum pump exhaust, the gas collection header, and the waste gas decay tanks after they are diluted in the radwaste area ventilation exhaust flow. Section 9.4.3 presents a detailed description of the radwaste area ventilation system. The monitoring equipment and its function is identical to that used in the fuel handling area ventilation monitoring system.

Additional monitoring of this area is provided by a SPING Monitor.

C. The containment purge monitor is provided to continuously monitor the gaseous activity levels released to the environment during normal purge operations and provides the capability of determining particulate and iodine releases by analysis of the fixed particulate and charcoal filters. Section 9.4.5 describes the containment purge system and the location of the monitor is shown in Figure 9.4-4.

The monitoring equipment is identical to that used in the fuel handling ventilation monitoring system. On high radiation alarm, containment purge is automatically terminated.

Additional monitoring of this area is provided by a SPING Monitor.

11.4.2.2.5 Control Room Inlet Air Monitoring System

The Control Room inlet air monitor continuously monitors the activity level in the inlet air. Section 9.4.1.2.2 presents a detailed description of the Control Room Ventilation System and the location of the detector in the inlet air duct is shown in Fig. 9.4-1.

The detector is a beta-gamma scintillation type detector and is capable of measuring 1(-5) μCi/cc of Cs-137. Readout is provided in the control room by an auto ranging digital display rate meter. A high radiation level in the inlet air to Unit 2 will automatically isolate both Units 1 and 2 from unfiltered outside air.

11.4.3 SAMPLING

The Process Sampling System is described in Section 9.3.2.

11.4.4 INSPECTION, CALIBRATION, AND MAINTENANCE

11.4.4.1 Continuous Monitoring Systems

The continuous radiation monitors have been calibrated by the manufacturer for at least the principal radionuclides listed in Table 11.4-1. The manufacturer's calibration is traceable to certified NIST or commercial radionuclide standards, and is accurate to at least five percent. The source-detector geometry during this primary calibration was identical to the sample-detector geometry in actual use. Secondary standards which were counted in reproducible geometry during the primary calibration are supplied with each continuous monitor for calibration after installation. Each continuous monitor is calibrated during plant operation using the secondary radionuclide standard or dedicated sources traceable to the certified NIST or commercial radionuclide standard.

The count rate response of each continuous monitor to remotely positionable check sources supplied with each monitor was recorded by the manufacturer after the primary calibration, and again after installation.

Following repairs or modifications the monitors will be recalibrated at the plant with the secondary radionuclide standards or dedicated sources traceable to the certified NIST or commercial radionuclide standard.

All detectors monitoring the activity of WMS, BMS and Gaseous Waste System (GWS) waste being discharged to the environment, i.e. to the circulating water flume or the atmosphere, are in-line detectors. Valves are provided to isolate the process flow stream from the detector and the environment in the event detector replacement is necessary. To ensure that all radioactive discharge to the environment is monitored, no bypass lines have been provided around these detectors. If it becomes necessary to replace the associated detector or place the associated monitor out of service, grab samples must be obtained and analyzed per appropriate procedures prior to discharging any given process system to the environment.

11.4.4.2 Laboratory Radiation Detectors

Counting efficiencies of all laboratory radiation detectors have been determined with certified radionuclide standards having accuracy better than five percent. Gross beta analyses are standardized against a selected beta source and gross alpha analyses are standardized against a selected alpha source. The high purity germanium gamma spectrometers have been calibrated in terms of photopeak efficiency versus gamma energy, and counting efficiencies for individual gamma emitters are based on nuclear decay schemes as given in the Table of Isotopes.

The response of each laboratory detector to alpha, beta or gamma check sources was recorded during the primary calibration with the certified radionuclide standards. These check sources are ruggedized to maintain their integrity during repeated handling. The response of each beta and gamma counter to the appropriate check source and the background count rate of each detector is determined at least weekly, and in most cases daily. The response of each alpha counter to the appropriate check source and the background count rate of each detector is determined at least monthly and/or prior to use. A control chart showing check source response and counter background is maintained for each laboratory counter. Instrument responses falling outside of statistical limits imposed by counting statistics are investigated and the instrument serviced as required.

11.5 SOLID RADIOACTIVE WASTE PROGRAM

The installed Radioactive Waste Concentration and Solidification Systems which were designed to process boric acid and other highly radioactive liquid wastes are obsolete due to technological advances. Therefore use of these systems has been suspended. Any system used to process radioactive wastes is controlled by the Process Control Program and appropriate operating procedures. Boric acid and other highly radioactive liquid wastes are presently processed similarly to lower level liquid radioactive wastes. The description of the previous program has been replaced with a description of the current Solid Radioactive Waste Program.

11.5.1 PROGRAM OBJECTIVES

The purpose of the Solid Radioactive Waste Program is to solidify, stabilize, or encapsulate solid radioactive waste materials for storage, off-site shipment and disposal in accordance with applicable regulations. Solid radioactive waste processing is controlled under a single program at ANO which serves Units 1 and 2. Processed wastes typically include spent ion exchanger resins, used filter elements, and miscellaneous refuse classified as radioactive waste.

Considerations for keeping personnel dose As Low As Reasonably Achievable (ALARA) are factored into the management of solid radioactive wastes at ANO. These considerations include items such as shielding of waste packages to reduce dose rates, remote operations, use of quick connect fittings, and use of temporary shielding when required.

Another objective of the Solid Radioactive Waste Program is to reduce the volume of radioactive waste generated at ANO. This objective is met by incorporating practices which:

A. Recommend, review and evaluate radioactive waste operations and volume reduction techniques to minimize further radioactive waste volumes,

B. Implement policies and procedures which eliminate or minimize the number of contaminated areas within the ANO facility and which also control the amount of material and equipment introduced into contaminated areas,

C. Implement waste segregation and sorting procedures,

D. Incorporate volume reduction requirements, techniques and practices into the ANO General Employee Training Program.

11.5.2 RADIOACTIVE WASTE INPUTS

11.5.2.1 Spent Resins

Spent ion exchanger resins are disposed of after being collected and held for decay in spent resin storage tanks. Disposal is normally accomplished by shipping the resins to an authorized off-site processing facility or disposal facility in approved containers. Typically shipment occurs after the resins have been solidified or dewatered. The capability to solidify spent resins is available as an alternate method of disposal processing. Vendor services may be employed either to dewater or solidify spent resins. All vendor services are performed in accordance with the Radioactive Waste Process Control Program, as specified in the Offsite Dose Calculation Manual.

11.5.2.2 Expended Filter Cartridges

Spent radioactive filters may be removed and transported to the work area by means of a remotely operated shielded cask or by other approved means. The filters are placed in approved shipping containers and shipped to an off-site processing facility or disposal facility in accordance with the Radioactive Waste Process Control Program.

11.5.2.3 Dry Active Waste

Low level, or potentially contaminated, wastes are processed in a low level waste work area. Solid wastes such as anti-contamination clothing, rags, paper, gloves, shoe coverings, glove bags and other items are packaged in approved containers. Filled containers are monitored for radiation and may be temporarily stored prior to shipment to an off-site processing facility or disposal facility.

11.5.3 EQUIPMENT DESCRIPTION

Solid radioactive waste processing is not vital to plant protection and has no accident prevention functions. The drumming station, waste storage tanks, and permanent waste handling equipment are all located in Seismic Category 1 structures.

11.5.4 EXPECTED SOLID WASTE QUANTITIES

The quantity of solid waste generated and processed at ANO will vary with plant conditions. Operating conditions, maintenance activities, outages, repairs, and installation of new equipment influence the volume of waste generated.

11.5.5 PACKAGING AND SHIPPING

Radioactive wastes shipped from the ANO site are packaged and transported in accordance with applicable regulations.

11.5.6 STORAGE FACILITIES

11.5.6.1 Low Level Radioactive Waste Storage Building

A Low Level Radioactive Waste Storage Building (LLRWSB) is provided consistent with the guidance of Generic Letter (GL) 81-38, "Storage of Low-Level Radioactive Wastes at Reactor Power Sites" and is located northeast of Unit 2, adjacent to the switchyard. The facility is designed to provide a controlled environment for receiving and shipping, inspection, equipment sorting, compaction, and decontamination activities associated with on-site storage and off-site shipment of LLRW (see Figure 11.5-2). In addition to the GL 81-38 recommendations, area gamma detectors are provided as an additional personnel protective feature. The LLRWSB is a reinforced concrete structure containing separate storage areas for Dry Active Waste (DAW) and other low activity waste, and High Specific Activity Waste (HSAW). Reusable radioactive material may also be stored in the LLRWSB. A truck bay, a waste segregation and compaction area, and an office area are also included in the building design. The LLRWSB is used to temporarily store packaged waste prior to shipment to an off-site processing facility or disposal facility and other (non-waste) low level radioactive material. The building design includes storage capacity for five years of waste generation.

The DAW and other waste are generally characterized by relatively low activities and the ability to handle by direct contact using appropriate radiological controls. Typically, DAW consists of general contaminated trash items such as protective clothing, laboratory equipment, small tools, mops, brooms, rags, HEPA filters, and other miscellaneous items including various wood, metal, plastic, and rubber objects. Other waste typically consists of absorbed or solidified oil and sludge, damp trash and scintillation vials. HSAW, consisting primarily of filters and resins, is considered LLRW, but is characterized by higher activities than DAW and the necessity of remote handling and are maintained in a locked high radiation area within the LLRWSB, which is surrounded on all sides by concrete shield walls. The HSAW containers are transported to the LLRWSB in shielded transportation casks and remotely moved to a dedicated storage area. The total annual generation of LLRW for ANO is estimated to be approximately 24,000 ft^3.

The overall building design incorporates systems for remote handling of HSAW containers via overhead crane and camera system, handling of DAW and other waste, drainage collection and sampling, fire detection/protection, HVAC, electrical power supply and lighting, radiation detection and decontamination, and building utilities such as water and sewer. A remotely operated overhead crane, equipped with closed circuit television cameras, is used to handle HSAW containers within the LLRWSB. DAW containers are typically handled by use of an electric forklift.

The LLRWSB is designed to permit unrestricted access to the outside of the building at any time (except near the truck bay entrances during handling of resin or filter liners). Dose rates around the LLRWSB should not exceed 2.0 mrem/hr (reference 10 CFR 20.1302(b)(2)(ii)) at the vertical plane of the inner security fence forming the protected area boundary. Dose rates beyond the site boundary should not exceed 0.9 mrem/year. The LLRWSB office area is designed to keep dose rates less than 0.5 mrem/hr. Administrative controls associated with the stacking of waste containers near the office area boundary wall may be required to maintain this design objective.

Calculated dose rates and radioactive energies conservatively assumed the HSAW full of resin containers. The Curie content was calculated using the isotopic content (reference Calc 83-0-2228-01) in order to determine expected dose rates. An estimation of facility dose rates is provided in Figure 12.1-13 for informational purposes. The total estimated Curie content in the facility is 1.96E3 Ci. The dose rate at the Exclusion Area Boundary (EAB) per Curie of stored material is estimated at 8.8E-10 mR/hr per Curie. See Table 11.5-1 for radioactive isotope inventory.

The only potential release of radioactivity would occur during compacting operations; however, this process is not currently used. The LLRWSB is equipped with an HVAC system which maintains a negative pressure within the building. HEPA filters are installed to reduce the release of airborne particulates to the atmosphere. The HVAC system is normally in operation. Radiation Protection personnel perform air sampling based on work activities and the potential for the generation of airborne radioactive contamination.

The radiation monitoring system in the LLRWSB consists of area radiation detectors with local and control room monitors and alarms. The effluent release path is monitored by 2RX-9850 (SPING-11), which is an Eberline SPING-4 type monitor. The SPING has on-line monitoring of particulates, iodines and noble gases in the effluent.

The readings taken by the SPING are corrected for background radiation levels by the use of an area monitor which is integral to the SPING. Removable filters are provided along with sample ports upstream of the filters permitting plant personnel to obtain representative grab samples of the effluent being released. Sample stream concentrations of up to 10^{-4} μCi/cc of gaseous radioiodine and particulate can be monitored by use of filters and grab samples.

The SPING has the capability to remotely purge the monitor assembly as well as remotely actuating a check source. Readouts of each detector channel and the status of each monitor are available in both control rooms.

Fire protection systems within the LLRWSB include an automatic deluge system for the HSAW area and a portion of the DAW storage area, automatic wet pipe sprinkler systems for the office area, truck bay and remaining DAW storage areas. Other fire protection equipment includes portable fire extinguishers, smoke/heat detectors and alarms, a fire hose station and a nearby fire hydrant.

11.5.6.2 Original Steam Generator Storage Facilities

The Original Steam Generator Storage Facilities (OSGSFs) are located north of Unit 2 within the Security Owner Controlled Area (SOCA), outside the protected area, and adjacent to the north access road. They are reinforced concrete structures designed for long-term storage of contaminated equipment. The Unit 2 OSGSF contains both original steam generators (OSGs). The Unit 1 OSGSF contains the two Unit 1 OSGs, the Unit 1 RCS hot leg elbows, and the original Unit 1 reactor vessel closure head (RVCH) with service structure and Control Rod Drive Mechanisms (CRDMs). Based on a response to a Commissioner's comment in SECY-80-511 and NRC memorandum from L. Cunningham/Po Lohaus to directors of the regional headquarters, these components are not treated as radwaste, but contaminated equipment to be retained on site until the plant is decommissioned (reference EC 4372). The facilities are not intended for onsite storage of radwaste materials such as resins, solid radwaste shipping casks, contaminated clothing, or other waste products. Further detail of the Unit 2 OSGSF is included below. For further information related to the Unit 1 OSGSF, refer to Section 11.1.3.3.8.2 of the ANO-1 SAR.

The Unit 2 OSGSF is a permanent reinforced concrete and steel structure of approximately 4000 ft^2 with 30-inch thick walls and an 18-inch thick roof slab, designed to the Uniform Building Code (UBC). No ventilation is provided. The south side of the building originally contained a construction opening to allow access for placement of the OSGs. After the OSGs were placed inside the OSGSF, the opening was closed by a wall composed of 30-inch thick, pre-cast, tongue-and-groove configuration, reinforced concrete blocks. With the opening sealed, the OSGSF has no normally open penetrations. The two OSGs were placed end-to-end with the channel head ends of the OSGs facing the northern side of the OSGSF.

A labyrinth-type vestibule is provided at the personnel entrance to the OSGSF. A water collection sump is provided in the OSGSF floor slab. The sump access/monitoring port is located within the vestibule and designed to accommodate checking the collection sump without entry into the facility (only entry into the vestibule is required) and to allow access for radiological survey of the facility sump. As the OSGs were drained and the nozzle openings sealed prior to storage in the OSGSF, the normal source of water collected in the sumps, if any, will be condensation. In the unlikely event the sump fills with water and requires draining, the sump can be pumped by inserting a hose through the access port from the vestibule. The OSGSF walls are sealed to a minimum of 361 ft (probably maximum flood). In addition, the entrance into the OSGSF from the vestibule is sealed to a minimum of 361 ft by a removable vertical steel plate.

The OSGSF is a non-safety-related structure. The facility is designed for dead, live, wind, seismic, and flood loads which meet or exceed the Unit 2 SAR requirements for Seismic Category II structures. The applicable recommendations of RG 1.69, Concrete Radiation Shields for Nuclear Power Plants, were used in the design and construction of the OSGSF. The OSGSF is a stand-alone facility, having no interface with other permanent plant SSCs, onsite or offsite power supplies, and is not equipped with lighting or electrical convenience outlets. The OSGSF design is illustrated in Figure 11.5-1 and location illustrated in Figure 2.5-39.

The shielding provided by the concrete walls and roofs is sufficient to keep cumulative external doses external to both the Unit 1 and Unit 2 OSGSFs below the requirements of 10 CFR 20 and 40 CFR 190. The exterior dose rate of the OSGSF has been shown to be less than the design dose rate of 1.0 mR/hr. Cumulative dose has been calculated based on an occupancy factor of 5% at the EAB and a 100% occupancy factor at the nearest occupied building and nearest permanent residence. The shielding (building) was designed to ensure ≤ 1 mR/year at the EAB. The calculated dose rate for the OSGSF exterior classifies it as a radiation Zone I area, although the roof is designated as a Zone II area, since the roof will not be accessed by non-plant personnel or visitors to the site and will be accessed infrequently by plant personnel. For radiological considerations, the OSGSF is assumed to fail during a seismic event. A design basis event (fire, tornado, seismic event, flood) which causes the simultaneous collapse of the Unit 1 and Unit 2 OSGSF and the subsequent release of contamination from each OSGSF will not result in doses that exceed a small fraction of 10 CFR 100 dose limits for accidental releases, or the maximum predicted dose that a member of the public at the EAB could receive as the result of a waste gas tank rupture as evaluated in the SAR.

Total estimated Curie content for both Unit 2 OSGs in the mausoleum at the time of internment (October, 2000) is (2680 Ci)(2) = 5360 Ci. The dose rate at EAB per Curie of stored material is estimated at 1.65 E-11 mR/hr per Curie. Table 11.5-3 contains the total Curie content with respect to each nuclide for the OSGs. Note that Curie concentrations decrease over time as a result of radioisotope decay. Radiation zoning is illustrated in Figure 12.1-15.

11.5.6.3 Old Radwaste Storage Building

A second storage facility is located east of the Unit 1 turbine building and will be used for storage of reusable, contaminated tools. The standard storage container used is a B-25 box. The building is a metal and concrete structure with 6' high 0.64' thick concrete shield walls provided along the inside of the north and south walls as necessary to comply with applicable regulations. Building drains are collected in a trench that is directed to a sump located in its north-west region. Based on dimensions, the facility could house up to 1799 B-25 boxes (reference CR-ANO-C-2014-1356 and SAR Figure 12.1-12). The total estimated Curie content in the facility is 150 Ci. The dose rate at EAB per Curie of stored material is estimated at 1.0E-6 mR/hr per Curie. See Table 11.5-2 for radioactive isotope inventory.

11.5.6.4 Pole Barn

The pole barn is a metal building with approximate dimensions of 100' x 200' x 50' which contains a posted radioactive material storage area. The area contains low activity level material that is logistically challenging (size, origin, plan for storage and disposal) to the site. Based on dimensions, the facility could house material such that the total estimated Curie content would be 0.218 Ci (reference CR-ANO-C-2014-1356 and SAR Figure 12.1-11). The dose rate at EAB per Curie of stored material is estimated at 1.2E-6 mR/hr per Curie. See Table 11.5-5 for radioactive isotope inventory.

11.5.6.5 Cask Transfer Facility

A Cask Transfer Facility (CTF) commercial building has been constructed to enclose the CTF structure (where dry fuel storage activities will transfer canister of spent fuel assemblies from a metal transfer storage cask to a concrete storage cask) located on the northeastern part of the plant protected area just northeast of the Low Level Radwaste Storage facility. Radioactive / contaminated dry fuel transfer equipment and tools will be kept and stored in the CTF building. No radwaste will be permanently stored in the CTF building. Storage of the radioactive / contaminated dry fuel equipment and tools will be controlled per ANO site and Entergy Radiological Protection (RP) procedures and ANO dry fuel procedures.

11.6 OFF-SITE RADIOLOGICAL MONITORING PROGRAM

The radiological monitoring program consists of the measurements of environmental radionuclide concentrations and radioactivity levels of important pathway media at off-site and onsite locations of the ANO plant. The objectives of this program are:

A. To provide an estimate of the dose to man and biota from direct radiation and releases of radionuclides from ANO.

B. To verify conformance with governmental regulations pertaining to radionuclide release rates and resultant environmental concentrations and doses.

C. To document radiological conditions and report this information for examination by the NRC, local health agencies, and the general public.

The preoperational monitoring program for Unit 2 was a smooth continuation of the current off-site radiological monitoring program established for Unit 1.

11.6.1 EXPECTED BACKGROUND

Whole body dose to individuals living in the site region from existing natural radiation sources is expected to average about 135 mrem/year. The major portion of this radiation dose (approximately 100 mrem/year) is due to external exposure from cosmic-induced radiation and radiation from naturally occurring radionuclides in the soil and air. An additional average dose of approximately 7 mrem/year is from buildings where people live and work. A dose of approximately 25 mrem/year is due to internal exposure from naturally occurring radionuclides such as K^{40} that become incorporated in body tissues. A dose associated with tritium and radioactive fallout by all pathways to man should be less than 4 mrem/year.

The average dose to members of the population within 50 miles of the station resulting from gaseous effluents will be less that 0.01 mrem/year. All liquid effluents leaving ANO enter the Arkansas River. The Arkansas River is used by the city of Russellville as a supplementary source of drinking water during periods of extremely low flow of the Illinois Bayou. An estimated average dose of 0.01 mrem/year would be obtained from drinking two liters per day of the river water three miles downstream of the plant. An average dose of less than 0.01 mrem/year will result from all other uses of the water.

Analytical data on background levels of radioactivity in air, water, and terrestrial media are given in Tables 11.6-1, 11.6-2 and 11.6-3.

11.6.2 CRITICAL PATHWAYS

The possible pathways of human exposure from plant operation are shown in Figure 11.6-1. These pathways are dependent upon the type of release (gaseous or liquid) and the nature of the dispersing media. The estimated doses resulting from the various pathways and the models and assumptions used are presented in Sections 11.2.9 and 11.3.9.

The critical pathways are those pathways which contribute the maximum dose to man. Consideration must be given to those pathways in which individual doses as well as population dose is possible. The critical pathways from gaseous releases will be whole body dose from noble gases and the passage of radioiodine from the air to grass to cow to milk to infant. The critical pathways for liquid releases will be exposure to shoreline sediments containing long-term accumulations of Cs-134 and Cs-137, and the consumption of fish that have accumulated released radionuclides.

11.6.3 SAMPLING MEDIA, LOCATIONS AND FREQUENCY

To ensure that Arkansas Nuclear One presents no real hazard to man or his environment, an environmental monitoring program has been implemented. Part of this program includes radiological surveillance. The surveillance network is designed to document levels of direct radiation and concentrations of radionuclides that exist in the environment both before and during the operation of the plant. The parameters being measured are direct radiation and radionuclide concentrations in airborne particulate and radioiodine, water, milk, vegetation, fish, and bottom sediment.

The type, location, and frequency of sampling of each of the above media were determined by studying the most probable pathway to man for all important radiological emissions from the plant. For sample locations and schedules see Table 4.1 of the ODCM.

11.6.3.1 Atmospheric Discharges

Airborne releases from the plant may contain low level radionuclide concentrations. This type of discharge can affect man in the following ways: (1) whole body external exposure, (2) inhalation exposure, (3) deposition on grass → cattle → milk → man, (4) deposition on grass → cattle → beef → man, (5) deposition of leafy vegetables → man, and (6) deposition on soil → plants → man.

Environmental contamination due to atmospheric discharge of radionuclides is monitored per guideline listed in Table 11.6-4 for airborne and ingestion exposure pathways.

11.6.3.2 Liquid Discharges

Aqueous discharges containing radioactive materials are released into the Arkansas River. This type of discharge has the following possible pathways to man: (1) waterway → external exposure, (2) waterway → sediment → external exposure, (3) waterway → drinking water supply → man, (4) waterway → fish → man, and (5) waterway → aquatic plants → animals → man.

Environmental contamination due to the release of radionuclides in liquid discharges is monitored per guidelines listed in Table 11.6-4 for surveillance of waterborne and ingestion exposure pathway.

11.6.3.3 Sampling Frequency

In developing the frequency of sampling for the various media of the radiological monitoring program, the major consideration was the acquisition of the maximum amount of relevant and practical data of the critical pathways to meet the requirements of the NRC.

All effluents containing radionuclides, except the turbine building sumps, at ANO are monitored by continuous instrumentation which record, alarm, and terminate discharge. Frequent sampling is also performed with subsequent and immediate in-plant laboratory analysis; therefore, it is highly improbable that a significant release of radioactivity at ANO would occur. Periodic samples are taken of the contents of the Turbine Building Sump. If the contents are identified as contaminated, the liquid is accounted for in the offsite liquid release totals. If a valid high alarm exists on any Secondary System radiation monitor, the Turbine Building Sump

pumps will be secured. A sample of the sump contents will be obtained prior to release and, if contaminated, will be accounted for in the offsite liquid release totals. Section 11.2.7 provides additional information on the turbine building sump. For this reason, the off-site radiological monitoring program is not specifically designed to give an instantaneous alert of increased levels of environmental radioactivity. The frequency of sampling reflects the expected variability in environmental radioactivity levels, the radioactive half-lives of the nuclides expected in ANO effluent that contribute most significantly to dose, and the reporting requirements of the NRC and is consistent with guidelines promulgated by NUREG 0472, "Radiological Effluent Technical Specifications."

11.6.4 ANALYTICAL SENSITIVITY

Analytical lower limits of detection (LLD) and reportable levels for radionuclide in the various sample matrices addressed by the radiological environmental program are in accordance with guidelines promulgated by the ODCM. The accuracy of the analytical data is ascertained through the Interlaboratory Comparison Program specified in the ODCM.

11.6.5 DATA ANALYSIS AND PRESENTATION

The analytical data generated in the radiological environmental monitoring program is reported each year in accordance with the ODCM.

11.6.6 IN-PLANT EFFLUENT MONITORING

During operation, off-site radiation doses can also be evaluated from in-plant measurements of nuclides in gaseous and liquid effluents in the same fashion as done earlier in Sections 11.2 and 11.3. While these doses may be less accurate and less realistic than doses that are calculated from actual measurements of environmental media, they provide a more detailed definition of the dose increment due to plant effluents than will the environmental measurements. An indication of the sensitivity of the in-plant effluent monitoring systems for the assessment of off-site dose is given here by determining the annual average concentrations of the most important nuclides in the effluent stream of highest flow which would result in off-site doses of 5 mrem/year.

For radioiodine in gaseous effluents, the effluent stream of highest average flow, and thus, lowest average radionuclide concentration for a given release rate of a nuclide (Ci/year) is the turbine building vent exhaust having an air flow of approximately 1(+6) cfm. The release rate of I-131 resulting in a 5 mrem/year infant thyroid dose at the nearest dairy farm is 2.3 Ci per year. Assuming continuous release at a constant rate, the corresponding concentration in the turbine building vent exhaust is 1.5 (-4) pCi/cc. The turbine building air will be periodically monitored for radioactive material with portable sampling instruments. In reality, releases of radioiodine are expected to be of a more periodic nature in addition to being monitored in other effluent streams of lower flow. Releases of radioiodine resulting in conservatively calculated thyroid doses of several orders of magnitude less than 5 mrem/year are therefore readily determined by the in-plant monitoring system.

The principal effluent streams through which noble gas nuclides may be released are the auxiliary building vent exhaust, the containment purge exhaust, the condenser vacuum pump exhaust. Of these, the auxiliary building vent exhaust has the highest flow, 110(+6) cfm and hence, the lowest average radionuclide concentration for a given release rate. The annual average concentrations of Kr-85 and Xe-133 in the auxiliary building vent exhaust which would result in 5 mrem/year submersion doses at the site boundary are 3.0(-6) and 3.4(-6) μCi/cc,

respectively. In reality releases such as from the venting of waste gas decay tanks and the purging of containment will be intermittent in nature, rather than continuous, resulting in higher concentrations in effluents over short periods of time. The detection limit of the off-line noble gas detectors on each of the three effluent streams above is 1(-7) μCi/cc for Kr-85 and Xe-133. The inplant measurements of noble gases will, therefore, provide sufficient sensitivity for determining site boundary doses of less than 5 mrem/year.

The critical nuclides in liquid releases will probably be Cs-134 and Cs-137, and the critical pathway will probably prove to be the consumption of fish. From the analysis in Section 11.2.8 and 11.2.9, the annual release of Cs-137, which would result in a 5 mrem/year dose (GI tract) by the fish consumption pathway, is found to be 60 Ci/yr. Assuming that the entire release occurs through the liquid radioactive waste monitor tanks, the in-plant concentrations of Cs-137 prior to dilution are 1(+5) pCi/ml for liquid radwaste. These concentrations are many orders of magnitude higher than the laboratory detection limits of 0.01 to 0.1 pCi/ml. The diluted concentration of Cs-137 in the discharge would be 4 pCi/ml.

In summary, the in-plant process and effluent monitoring system and the off-site radiological monitoring program provide adequate sensitivity, independently, to enable estimation of the dose to man at present NRC guidelines of 5 mrem/year (10 mrem/year for noble gas).

Table 11.1-1

BASIS FOR REACTOR COOLANT FISSION PRODUCT ACTIVITIES
[This table consists of historical information]

Duration of Reactor Operation at 2900 MWt		5 core cycles	
Equilibrium Fuel Cycle, Full Power Days		313	
Average Thermal Fission Rate (fissions/MW-sec)		3.12×10^{16}	
Thermal Neutron Flux - Average (n/cm²-sec)		4.62×10^{13}	
Reactor Coolant Mass, 1bm		4.619×10^{5}	
Core Coolant Volume to Reactor Coolant Volume Ratio		0.0713	
Purification Flow, gpm		40	
Beginning of Cycle Coolant Boron Concentration, ppm		1140	
Boron Concentration Reduction Rate, ppm/sec		4.215×10^{-5}	
Ion Exchanger Removal Effectiveness		DF*	%EFF
All Nuclides Except Xe, Kr, Y, Mo, Cs, H-3		10	90
Xe, Kr and H-3		1	0
Y, Mo and Cs		10**	90
Fission Product Escape Rate Coefficients, sec^{-1}			
Noble Gases		6.5×10^{-8}	
Cs		2.3×10^{-8}	
Halogens		1.3×10^{-8}	
Te, Mo		1.4×10^{-9}	
All others		1.4×10^{-11}	
	Normal	Abnormal	
Percent Failed Fuel	0.25	1.0	
Cold Shutdowns***	50% Core Life	30%, 60%, 90% Core Life	
Hot Shutdowns	None	55%, 65% Core Life	

* Ion Exchanger decontamination factors (DF) were estimated from the following: Simon, Abrams and Lindsey, "The Performance of Base Form Ion Exchangers For pH Control and Removal of Radioisotopes From a Pressurized Water Reactor," Reactor," WAPD-TM-215, 1960.

** These nuclides are removed from the process fluid via the purification ion exchanger used to control the lithium concentration within the reactor coolant. This ion exchanger is used approximately 20 percent of a core cycle.

*** For shutdown waste volumes see Table 9.3-6.

Table 11.1-2

MAXIMUM FISSION PRODUCT ACTIVITY IN THE REACTOR COOLANT DUE TO CONTINUOUS OPERATION AT 2900 MWt WITH ONE PERCENT FAILED FUEL

Nuclide	Activity at 70 °F (µCi/cc)	Nuclide	Activity at 70 °F (µCi/cc)
H-3	6.10 (-1)	I-131	3.73

Ammonia	1.79(-9)	5.34E-9	1.0	1.0	0.0	1.0	0.0	.06	1.0

* Denotes actual value (i.e. input value)

** Based on 150 ppm naturally present in water

Table 11.1-11

PARAMETERS USED IN THE CALCULATION OF STEAM GENERATOR WATER ACTIVITIES[a]

[The information in this table is historical]

Parameters	Value
Reactor coolant activities, percent failed fuel[b]	
Normal operation	0.25
Anticipated operational occurrence	1.0
Primary to secondary leak rate, gal/day	
Normal operation	13
Anticipated operational occurrence	100
Main steam temperature, °F	532
Main steam flow rate, lb/hr	1.27(+7)
Steam generator water volume, ft^3	4976
Steam generator average water temperature, °F	492
Steam generator blowdown temperature, °F	452
Steam generator blowdown rate, gal/min, Annual average	15
Steam generator partition factors	
Noble gases	1
Halogens	400
All other nuclides	1000
Main condenser partition factors	
Noble gases	1
Halogens	2000
All other nuclides	2000

[a] Flow rates and volumes are totals for both steam generators at a reactor power of 2900 MWt.

[b] Average reactor coolant activities corresponding to one percent and 0.25 percent failed fuel are given in Table 11.1-3 and 11.1-4.

Table 11.2-1

SOURCE AND VOLUME OF LIQUID WASTE
[The information in this table is historical]

1. Boron Management System

Source	Amount (Gal.) Anticipated Operations	Amount (Gal.) Normal Operations
Refueling Shutdown	12,500	
Refueling Startup	59,000	
Total Refueling Waste	71,500	71,500
Leakage to Reactor Drain Tank @ 220gpd	68,860	68,860
Cold Shutdowns & Startups		
30% Core Life	54,600	
50% Core Life		66,200
60% Core Life	74,600	
90% Core Life	138,800	
Total	268,000	66,200
Hot Shutdowns & Startups		
55% Core Life	37,000	
65% Core Life	47,600	
Total	84,600	0
Boron Dilution (Fuel Burnup Waste)	201,600	201,600
Total Liquid Waste Volume	694,560	408,160

2. Waste Management System

Source	Amount (Gal.)
Equipment drains and leakage	28,000
Sample and laboratory sink drains	7,000
Equipment Decontamination	73,000
Floor Drains	18,000
Fuel Cask Washdown	30,000
Total Estimated Normal Operation or Anticipated Occurrence	156,000

Table 11.2-2

DESIGN DATA FOR BORON MANAGEMENT SYSTEM COMPONENTS

1. Ion Exchangers

Ion Exchangers	Preconcentrator	Boric Acid Condensate
Quantity	2	2
Type	H-OH Mixed-Bed	OH
Design Pressure, psig	150	150
Design Temperature, °F,	240	240
Normal Operating Pressure, psig	60	60
Normal Operating Temperature, °F	120	140
Normal Operating Flow, gpm	20	20
Resin Volume, ft^3, useful	32	32
Materials	ss	ss

2. Tanks

Tanks	Reactor Drain	Holdup	Boric Acid Condensate
Quantity	1	4	2
Internal Volume, gal	1600 min.	51,270	30,267
Design Pressure, psig	25 Int.; 15 Ext.	10 Int.; 2 Ext.	Atmosphere
Design Temperature, °F	250	240	250
Normal Operating Pressure, psig	0.5	1.0	Atmosphere
Normal Operating Temperature, °F	120	120	120
Blanket Gas	Nitrogen	Atmosphere	
Material	s.s.	s.s.	s.s.
ASME Code	VIII		

3. Pumps

Pumps	Reactor Drain	Holdup Drain Holdup Recir.	Boric Acid Condensate	Degasifier Effluent
Quantity-Full Capacity	2	3	2	2
Type	Centrifugal	Centrifugal	Centrifugal	Centrifugal
Design Pressure, psig	150	150	150	75
Design Temperature, °F	200	200	200	140
Design Conditions				
Flow, gpm	50	50	50	140
Head, ft	145	145	145	107
Wetted Materials	s.s.	s.s.	s.s.	s.s.
Seal type	Mechanical	Mechanical	Mechanical	Mechanical
Motor Horsepower	7.5	7.5	7.5	10
Motor Voltage, volt	460	460	460	460
ASME Code	III	None	None	None

Table 11.2-2 (Continued)

4. Preconcentrator Filters

Quantity	2
Type of Elements	Surface
Design Pressure, psig	150
Design Temperature, °F	240
Design Flow, gpm	100
Material	s.s.
ASME Code	VIII

5. Boric Acid Concentrators (currently not in use)

Quantity	1
Design Pressure, psig	60
Design Temperature, °F	200
Design Flow, gpm	20
Cooling Water Flow Rate, gpm	1104
Steam required at 15 psig, lb/hr	13,000
ASME Code	VIII

6. Vacuum Degasifier

Quantity	1
Design Pressure, psig	75 Int; 15 Ext.
Design Temperature, °F	250
DF	120
ASME Code (Class)	VIII

Table 11.2-3
BORON MANAGEMENT SYSTEM PROCESS FLOW DATA

Mode #1: Processing RDT Contents

Location:*	1	2	3	4	5	6	7	8
Flow, gpm	200 gpd	50	50	50	50	60	50	50
Pressure, psig	1	4	12	7.5	6.5	4	45	2
Temperature, °F	120	120	120	120	120	120	120	120

Mode #2: CVCS Normal Purification VCT Diversion Processing

Location:*	1	2	3	4	5	6	7	8
Flow, gpm	200 gpd	-	-	40	40	50	40	40
Pressure, psig	1	-	-	5	4.5	4	44	2
Temperature, °F	120	-	-	120	120	120	120	120

Mode #3: CVCS Intermediate Purification VCT Diversion Processing

Location:*	1	2	3	4	5	6	7	8
Flow, gpm	200 gpd	-	-	84	84	94	84	84
Pressure, psig	1	-	-	21	18.5	4	34	2
Temperature, °F	120	-	-	120	120	120	120	120

Mode #4: CVCS Maximum Purification VCT Diversion Processing

Location:*	1	2	3	4	5	6	7	8
Flow, gpm	200 gpd	-	-	128	128	138	128	128
Pressure, psig	1	-	-	51	45.5	4	18	2
Temperature, °F	120	-	-	120	120	120	120	120

Mode #5: Processing Holdup Tank Contents Via the Boric Acid Concentrator (Note 3)

Location:*	12	13	14	15	16	17	18	19	20	21
Flow, gpm	20	20	20	20	20	16-19	16-19	75	75	75
Pressure, psig	3	65	62	60	59	2	4	4	60	10
Temperature, °F	120	120	120	120	120	120	120	120	120	120

Mode #6: Holdup Tank Contents Recirculation Through Preconcentrator Filter and Preconcentrator Ion Exchanger

Location:*	9	10	11
Flow, gpm	50	50	50
Pressure, psig	4	32	27
Temperature, °F	120	120	120

Table 11.2-3(continued)

***Locations**

1.	Reactor Drain Tank inlet	12.	Holdup Tank Drain Pumps suction
2.	Reactor Drain Pumps suction	13.	2F15B inlet
3.	Reactor Drain Pumps discharge	14.	2F15B outlet
4.	Letdown inlet to Vacuum Degasifier	15.	2T15s to U-1/U-2 Liquid RW/BMS manifold
5.	Vacuum Degasifier inlet	16.	Waste influent from manifold
6.	Vacuum Degasifier outlet	17.	Concentrator outlet to ion exchanger
7.	Degasifier Effluent Pumps discharge	17a.	Concentrator outlet to Boric Acid Makeup Tank
8.	Downstream of 2CV2222	18.	Boric Acid Condensate Tanks inlet
9.	Holdup Tank Recirc Pump suction	19.	Boric Acid Condensate Tanks outlet
10.	2F15A inlet	20.	Boric Acid Condensate Pumps discharge
11.	2F15A outlet	21.	Discharge to the flume

Notes:
1. Values given are nominal; actual operating flows, pressures, and temperatures may vary.
2. Location 17a is referenced in other SAR tables.
3. Boric Acid Concentrator is currently not in use.

3. Pumps	Waste; Waste Condensate
Quantity	4
Type	Centrifugal
Design Pressure, psig	150
Design Temperature, °F	200
Design Conditions	
Flow, gpm	50
Head, ft	135
Wetted Materials	ss
Seal Type	Mechanical
Motor Horsepower	7.5
Motor Voltage	460
4. Filters	Waste
Quantity	1
Type of Elements	Replaceable cartridge
Design Pressure, psig	150
Design Pressure, °F	200
Design Flow, gpm	50
Material	ss
5. Concentrator (currently not in use)	Waste
Quantity	1
Design Pressure, psig	80
Design Temperature, °F	250
Design Flow, gpm	20
Cooling Water Flow Rate, gpm	1184
Steam required at 100 psig, lb/hr	13,150

Table 11.2-9

WASTE MANAGEMENT SYSTEM FLOW DATA

Mode #1: Processing Waste Tank 2T20A Contents Via The Waste Concentrator (Note 3); Discharging a Waste Condensate Tank

Location*	1	1a	2	2a	3	4	5	6

Table 11.2-13

ASSUMPTIONS USED IN CALCULATING ESTIMATED NORMAL AND ANTICIPATED OPERATIONAL OCCURRENCE RELEASES
[The information in this table is historical]

		Estimated Normal Releases	Anticipated Operational Occurrence
1.	Steam Generator (SG) Blowdown Releases		
	Main Stream Flow Rate, lb/hr	12,660,000	12,660,000
	SG Liquid Inventory Per SG, lb.	131,000	131,000
	Blowdown Rate Gal/Min @ 70 °F	15	15
2.	Failed Fuel Percent	0.25	1.0
3.	Miscellaneous Liquid Waste from the BMS gal/yr	156,000	156,000

		Time (days)
4.	Holdup Time	
	Reactor Drain Tank (Average fill and drain time)	3
	Holdup Tank (Average decay time in BMS)	9
	WMS	0
5.	Fuel Power Days or Cycle	313

Table 11.2-14

BORON AND RADIOACTIVE WASTE MANAGEMENT SYSTEM INSTRUMENTATION APPLICATION

System Parameter & Location	Indication Local	Indication Control Room	Alarm[1] High	Alarm[1] Low	Rec	Control Function	Inst. Range	Normal Operating Range
Gas Decay Tanks Temperature	x						0 - 250 °F	70 - 150 °F
Gas Surge Tank Temperature	x						0 - 200 °F	70 - 150 °F
Reactor Drain Tank Pressure	x		x				0 - 25 psig	2 - 4 psig
Vacuum Degasifier Pressure	x		x				0 - 100 psig	20 - 30 psig
Holdup Tanks 2T12A, 2T12B, 2T12C, & 2T12D Pressure	x		(2)	(2)			0 - 10 psig	2 - 3 psig
Spent Resin Tank Pressure	x		(2)				0 - 50 psig	0 - 15 psig
Gas Decay Tanks Pressure	x		(2)				0 - 400 psig	0 - 250 psig
Gas Surge Tank Pressure	x		(2)				0 - 30 psig	1 - 5 psig
Reactor Drain Pump Discharge Pressure	x						0 - 100 psig	1 - 4 psig
Holdup Drain Pumps Discharge Pressure	x						0 - 100 psig	0 - 60 psig
Boric Acid Condensate Pumps Discharge Press.	x						0 - 100 psig	0 - 60 psig
Waste Tank 2T20A & 2T20B Pump Discharge Pressure	x						0 - 100 psig	0 - 60 psig

Table 11.2-14 (continued)

System Parameter & Location	Indication Local	Control Room	Alarm[1] High	Alarm[1] Low	Rec	Control Function	Inst. Range	Normal Operating Range
Waste Condensate Pumps Discharge Pressure	x						0 - 100 psig	0 - 60 psig

** Discharge from BMS and WMS.
*** In μCi/cc, based on flow rate of 383,000 gpm for 1 year.

The ANO-1 Condenser Replacement (ER 951018D101) resulted in a 2.4% increase in circulating water flow rate. This increase in flow rate provides more dilution water for radiological releases. Therefore, the flow rate stated above is bounding and conservative.

Table 11.2-19

CONSUMPTION RATES OF WATER AND BIOTA BY MAN

	Maximum Individual	Average Individual
Consumption of water*, gm/day	~2200	~1000
Consumption of fish, gm/day	100	25
Consumption of aquatic plants, gm/day	0	0
Consumption of invertebrates, gm/day	0	0
Exposure time on shore, hr/yr	500	50
Exposure time swimming, hr/yr	240	30

* Only for dose calculations. No water is consumed from the Arkansas River between and including the Dardanelle Reservoir down to the Mississippi River.

COMPONENT DATA FOR GASEOUS WASTE SYSTEM

1. <u>Waste Gas Compressor</u>

Type	Positive Displacement
Quantity	2
Capacity, scfm	10
Discharge pressure, psig	350
Codes	Manufacturer Standard
Materials	Ductile Iron
Design Temperature, °F	175 - Inlet; 350 – Outlet
Design Pressure, psig	400

2. <u>Compressor Aftercooler</u>

Type	Shell and Tube
Quantity	2
Codes: gas side	ASME VIII
shell side	ASME VIII
Materials	Stainless Steel
Discharge Temperature, °F	120 maximum

3. <u>Gas Surge Tank</u>

Type	Vertical
Quantity	1
Volume, ft^3	10
Design Pressure, psig	40
Design Temperature, °F	200
Codes	ASME VII, Div. 1
Material	Carbon Steel

4. <u>Gas Decay Tank</u>

Type	Vertical
Quantity	3
Volume, each, ft^3	300
Design Pressure, psig	380
Design Temperature, °F	250
Codes	ASME VIII, Div. 1
Materials	Carbon Steel

Table 11.3-9

PARAMETERS USED IN INGESTION DOSE ANALYSIS

Consumption rate of milk by adults and infants	1000 cc/day
Consumption rate of green vegetables	1500 g/day
Consumption rate of tuberous or root vegetables	1000 g/day
Consumption rate of meat	200 g/day
Calcium content in vegetables	200 mg Ca/100 g
Calcium content in milk	1.40 g/l

Rate Factors for Milk

Sr-90	P_r = 0.8 pCi/gram Ca per mCi/km^2 per year
	P_d = 0.3 pCi/gram Ca per mCi/km^2 cumulative deposit
Cs-134, Cs-137	P_r = 3.6 pCi/1 per mCi/km^2 per year
	P_d = 0.65 pCi/1 per mCi/km^2 for the previous 2 yr

Rate Factors for Tuberous or Root Vegetables

Sr-90	P_r = 0
	P_d = 1.0 pCi/gram Ca per mCi/km^2 cumulative deposit

Rate Factors for Green Vegetables

Sr-90	P_r = 1.0 pCi/gram Ca per mCi/km^2 per year
	P_d = 1.0 pCi/gram Ca per mCi/km^2 cumulative deposit

Rate Factors for Meat

Cs-137	P_r = 15 pCi/kg meat per mCi/km^2 per year
	P_d = 2.5 pCi/kg meat per mCi/km^2 deposited in the previous 2 yr

2RE-8845 2RE-8846	Penetration rooms monitoring system	"	Log Count ratemeters	1(-5) µCi/cc of Xe-133 in 2.5 mr/hr background		Alarm on high radiation and circuit failure
2RE-8271-2 2RE-8231-1	Containment atmosphere monitor	Particulate: Gamma Scintillation crystal, Gas: Beta-Gamma sensitive GM tube	Log Count ratemeters	Particulate: 1.5 (-10) µCi/cc of Cs-137, Gas: 1(-5) µCi/cc of Xe-133 in 2.5 mr/hr background		Alarm on high radiation and circuit failure
			Ventilation Monitoring System			
2RE-8540	Fuel Handling area ventilation monitor	Beta-Gamma sensitive GM tube	Log Count ratemeters	1(-5) µCi/cc of Xe-133, 2.5 mr/hr background		Alarm on high radiation and circuit failure
2RE-8542	Radwaste area ventilation monitor	"	"	"		"
2RE-8233	Containment purge monitor	"	Log Count ratemeter	1(-5) µCi/cc of Xe-133, 2.5 mr/hr background		Alarm on high radiation and circuit failure terminates containment purge

Table 11.4-1 (continued)

Channel	Monitor	Type-Detector	Readout	MDL*	Setpoint[1]	Alarm & Control
2RE-7828	Aux. Bldg. extension ventilation monitor	"	"	"		Alarm on high radiation and circuit failure
2RE-8750-1A 2RE-8750-1B	Control Room inlet air monitor	Beta-Gamma sensitive scintillation	Auto Ranging digital ratemeter	1(-5) μCi/cc of Cs-137 with no lead shield		Alarm on high radiation and circuit failure High alarm isolates control room.
2RE-4301	Turbine Bldg. drain line monitor	Off-line liquid sampler assembly with NaI (TI) detector	Logarithmic ratemeter	3.7(-7)μCi/cc of Cs-137 with .02 mr/hr Co-60 background		Alarm on high radiation and rad monitor flow trouble.

* MDL = Minimum Detectable Level
** Currently not in use.

Note 1: Low alarm setpoints are set below the normal background level to act as a circuit failure alarm. The Control Room ventilation inlet setpoint is determined in accordance with Technical Specifications Table 3.3-6. Other setpoints are approximately two times normal background. See ANO Procedure 2105.016 for specific requirements.

- Modeling of the SG to assess curie content utilized WMG Megashield, Version 3.0.
- Isotopic proportions based on previous samples.
- The composite curie content mixture was derived from gamma spectrum analyses performed at the general time of SG removal, and from waste stream analyses performed by Duke Engineering and Services Environmental Laboratory (DE&S) in support of 10 CFR 61 waste characterization requirements.
- The estimate is conservative to arrive at a value that bounds component storage. Reference ANO-2014-0034.

12 RADIATION PROTECTION

12.1 SHIELDING

This section describes the bases for the radiation shielding design, discusses the shielding configurations, identifies source terms, and gives estimates of exposure to personnel involved in plant operation and to persons proximate to the site boundary. Design methods for maintaining personnel doses as low as practicable are discussed.

12.1.1 DESIGN OBJECTIVES

The primary objective of the plant radiation shielding is to reduce external doses to plant personnel, in conjunction with a program of controlled personnel access and occupancy in radiation areas, to levels which are both as low as practicable, and which are within the dose regulations of 10 CFR 20 and 10 CFR 50. Regulatory Guide 8.8 will be employed as a shielding and equipment design guide document to ensure that doses are maintained as low as reasonably achievable during all anticipated personnel activities in all areas of the plant containing radioactive materials.

The radiation shielding design considers three plant conditions:

A. Normal full power operation;

B. Plant shutdown; and

C. Design basis events.

12.1.1.1 Shielding for Normal Full Power Operation

Design objectives of plant radiation shielding during normal operation, including anticipated operational occurrences are:

A. To protect plant personnel, administrators, construction workers, visitors, and proximate site boundary occupants from potential direct radiation and maintain whole body doses within the requirements of 10 CFR 20 and 10 CFR 50 and in conformance with the guidelines of Regulatory Guide 8.8.

B. To ensure, in the unlikely event of an operational occurrence, adequate protection for plant personnel to permit the safe termination of accident conditions within the guidelines of 10 CFR 20 and 10 CFR 50. (Section 13.3)

C. To assure sufficient access and occupancy time to allow normal maintenance or safety-related operations required for each plant equipment area and instrumentation area.

D. To reduce potential equipment activation and mitigate the possibility of radiation damage to materials.

The shielding design is based on assumed plant operating parameters which produce conservative, yet reasonable, radiation activities for each piece of piping and plant equipment (Section 12.1.3). It is expected that the average doses will be much lower than the upper dose levels for each of the accessible zone plant areas.

12.1.1.2 Shielding for Plant Shutdown

The shielding design for the shutdown plant condition considers mainly radiation from the subcritical reactor core, radiation from spent fuel assemblies during onsite transfer, residual activity in the reactor coolant, radiation from neutron-activated materials, and radiation from deposited crud on system internal surfaces.

12.1.1.3 Shielding for Design Basis Events

For the design basis events, the shielding design considered the waste gas decay tank rupture, the fuel handling accident, and the Loss of Coolant Accident (LOCA). For all accident cases, sufficient shielding is provided such that the safety of the personnel remaining on the premises and the general populace is maintained. Doses remain within limits delineated in 10 CFR 50.

12.1.2 DESIGN DESCRIPTION

This section outlines the criteria used in the shielding design and describes the major shielding structures.

12.1.2.1 General Shielding Design Description

Shielding is designed to attenuate radiation through walls and penetrations to less than the upper limit of the radiation zone for each plant area.

Sufficient shielding is provided to reduce the dose rate in each indicated area to the rate for which the area is zoned. In the shielding calculations, the highest anticipated content of radioactive materials in the equipment contributing to the dose is assumed and the dose rate is evaluated at the point in the areas having the highest dose from the aggregate of all contributing sources. Specifically, doses are evaluated for anticipated operational occurrence equipment activity levels corresponding to one percent defective fuel, with conservative credit being taken for decay, dilution and purification losses upstream of the equipment being shielded. Normally, the point within each area at which the dose is evaluated is at the surface of either the shield wall or the surface of the equipment within the area. During normal reactor operation, less than 0.2 percent of the fuel is expected to be defective. In addition, the normal fluid activity contained in each piece of equipment will be substantially lower than assumed in the shielding evaluation due to decay and purification processes for which reduced credit has been taken during shielding design.

Because shielding design is based on conservative plant operating source terms which are much larger than any potential crud source terms, the dose contribution from crud during full power operation is negligible.

A site plot plan is shown in Figure 2.1-3 and a site boundary plan with locations for estimated exposure is given in Figure 2.5-17. A scaled isometric view and a layout drawing of the control room are presented in Figure 12.1-14.

Most plant shielding material is ordinary concrete with an average bulk density of 147 pounds per cubic foot. Variation of concrete density does not exceed minus four percent. Wherever poured-in-place concrete has been replaced by concrete blocks, design assures protection on an equivalent shielding basis. Water and concrete are used for shielding during spent fuel handling and storage. Steel and lead are occasionally used for shielding where space is limited.

12.1.2.2 Radiation Zoning and Access Control

The amount of shielding required was dictated by radiation source strengths and radiation zone dose limits of adjacent areas. Access to areas inside the plant structures and plant yards is regulated by radiation zoning and access control (Sections 12.3.2 and 13.7). Each radiation zone defines the radiation level to which the aggregate of all contributing radiation sources must be attenuated by shielding.

Zoning was determined by required access and occupancy periods in conformance with 10 CFR 20 and 10 CFR 50. Each room, corridor, and pipeway of every plant building was evaluated for potential radiation sources during normal operation, shutdown, and emergency operations; for maintenance occupancy requirements; for general access requirements; and for material exposure limits to determine appropriate zoning. Radiation zones employed and their descriptions are given in Table 12.1-1. All frequently accessed areas such as corridors are shielded for Zone II or Zone I access. The Zone II maximum of 2.5 mrem/hr is based on a restricted occupancy of 40 hours per week. An individual receiving the maximum Zone I dose rate (1.0 mrem/hr) could spend up to 100 hours/wk in Zone I areas and remain within the 10 CFR 20 limits.

It would be of marginal benefit to lower the Zone II maximum allowable dose rate since plant radiation workers generally receive most of their dose from maintenance work in higher zoned areas. The cost of additional shielding, of structural design and engineering, and of architectural rearrangement would outweigh the possible slight benefits from reduced radiation levels.

Zoning and acceptable radiation levels at valve stations were determined by a weighted combination of anticipated radiation level at the valves resulting from crud buildup and/or process fluid in lines and valves, radiation from adjacent shielded or unshielded equipment, and the anticipated frequency of required valve operations.

In areas where the product of the dose rate times the access time required for valve operation yields an expected dose of 100 mrem/wk or greater to plant personnel, the valves are equipped with reach rods which pass through or over the shield wall, or with remote manual operators, or with motor operators. All valves located in Zone V areas which must be operated manually will be provided with reach rods or remote manual operators or motor operators.

When equipment located in Zone V is operated intermittently, only those valves associated with safe operation, shutdown, and draining of the equipment have remote-manual operators, or reach rods. All other operations may be performed with the equipment in the shutdown mode.

Instrumentation which required periodic visual inspection is located in corridors or on local or central control boards. Most pieces of equipment are located in individually shielded compartments for maintenance or repair to limit radiation exposure from adjacent sources.

Removable shadow shields of concrete, steel, or lead will be utilized to facilitate maintenance and repair operations which must be performed in the presence of radiation fields.

Pipes carrying radioactive materials have been routed through controlled access areas properly zoned for that level of activity. Each piping run has been individually analyzed to determine potential radioactivity level and surface dose rate. Where it is necessary that radioactive piping be routed through corridors or other low zoned areas, shielded pipeways are provided. Care

was exercised to separate radioactive piping from non-radioactive piping to minimize personnel dose. Should maintenance be required, provision is made to drain piping and associated equipment. Potentially radioactive pipes are always located in appropriately zoned and restricted areas. Health physicists will monitor process piping to ensure that access is controlled to limit personnel dose (see Section 12.3.1).

Plant personnel ingress and egress to controlled areas are supervised from the access control station at Elevation 386 feet of the auxiliary building. Access will be permitted only after an area has been adequately surveyed to establish that dose rates and allowable working time are within 10 CFR 20 limits.

Any area, accessible to personnel, having a radiation level which could produce a whole body dose in excess of 5.0 mrem in any hour, will be posted as a "Radiation Area." Any area having a radiation level which could produce, in any one hour, a dose equal to or greater than 100 mrem will be posted as a "High Radiation Area."

Restrictions are enforced by locked doors and other barriers, removable concrete shielding, and administrative control. Radiation areas are provided with barriers and postings.

Personnel have been given instruction in the use of escape routes which involve the minimum exit time in case of emergencies. Wherever practical, the measured radiation level and location of the source will be posted at the entrance into any radiation areas.

12.1.2.3 Penetrations

Penetrations or other discontinuities in shield walls required for piping, ventilation, electrical cables, or access to any equipment are arranged carefully to avoid a direct line of sight with the radiation source to prevent streaming into a lower zoned area. Grouting material is used to fill the voids between the penetration and the wall where necessary. Bends and offsets are also used where necessary to reduce streaming through the penetrations.

Shield discontinuities include concrete hatch covers, shielding doors and access labyrinths. To reduce radiation streaming through the gap between the main shield and the removable section, offsets were used. Access labyrinths into rooms containing radiation sources were designed to eliminate direct shine through the offset passage to the accessible areas.

12.1.2.4 Justification for Shield Design Thickness

The shielding thicknesses provided to ensure compliance with plant radiation zoning and to minimize plant personnel exposure were based upon maximum equipment activities under the plant operating conditions as described in Section 12.1.3. The thickness of each shield wall surrounding radioactive equipment was determined by approximating as closely as possible the actual geometry and physical condition of the source or sources. In general, the volumetric sources were assumed to be homogeneous and static. The isotopic concentrations were converted to energy group sources using data from Reference 13.

The geometric model assumed for shielding evaluation of tanks, heat exchangers, filters, demineralizers, evaporators, and the containment was a finite cylindrical volume source. For shielding evaluation of piping, the geometric model was an infinite shielded cylinder. In cases where corrosion products are deposited on surfaces such as a pipe, the latter was treated as a cylindrical surface source. The shielding thicknesses were selected to maintain the aggregate

computed dose rate from all sources of radiation at less than the maximum allowable dose rate for each particular radiation zone. Dose rates were evaluated at the point of maximum radiation dose through any wall. Therefore, the actual anticipated radiation levels in the greater area of each radiation zone are less than the upper radiation zone limit.

The computer programs that were used in shielding calculations are briefly described in Table 12.1-2. A bibliography of shielding references and data references is given in Section 12.5.

12.1.2.5 Containment Shielding Design Description

The containment is a reinforced, prestressed, post-tensioned, steel-lined concrete structure. During operation the containment and containment internal structures protect personnel in adjacent plant structures and yard areas from radiation emanating from the reactor vessel and primary loop components. The reactor vessel shield and steam generator shield walls, together with the 3-foot, 9-inch thick concrete containment wall, reduce radiation levels outside the containment to less than 1 mrem/hr (see Section 12.1.2.7).

For the design basis accident, the containment shell would reduce the plant and off-site radiation intensities from fission products inside the containment to acceptable emergency levels as defined by 10 CFR 50, Appendix A, Criterion 19 for the control room (see Section 12.1.2.7) and 10 CFR 50.67 for off-site and exclusion locations (see Section 15.1.13).

Where personnel and equipment hatches or other penetrations pass through the containment wall, additional shielding is provided to attenuate radiation to the required level defined by the outside radiation zone.

12.1.2.6 Containment Interior Shielding Design Description

During reactor operation, access to most areas inside the containment will be prohibited due to high radiation levels. However, shielding is provided to reduce dose rates to as low as practicable to allow access into areas of the containment during reactor operation. These areas are designated Zone IV or lower.

The main radiation sources are the reactor vessel and primary loop components consisting of the steam generators, pressurizer, reactor coolant pumps, and associated piping. The reactor vessel is shielded by the primary shield wall (5 feet, 6 inches of reinforced concrete) and the reactor cavity neutron shield. The reactor cavity neutron shield consists of a 1-foot thick ring of a silicone elastomer between the reactor vessel and primary shield wall, with the top of the shield just below the reactor vessel nozzles. (See Figure 12.1-16.) Table 12.1-6 lists the chemical and physical data of the shield material. One inch of insulation is provided between the reactor vessel and the reactor cavity neutron shield and its supports to prevent direct contact of the shield material with the reactor vessel. Ventilation flow paths are provided through the shield by the use of double-elbow ventilation ducts distributed throughout the shield. These ducts prevent overheating, dehydration, and degradation of the shielding and structural properties of the primary shield. The primary shield and reactor cavity neutron shield, in conjunction with the secondary shield, attenuate radiation from the vessel and reduce neutron activation of components and structures over the life of the plant.

The secondary shield consists of four feet of reinforced concrete. It surrounds the steam generators, reactor coolant pumps, pressurizer and all associated piping. The secondary shield supplements the primary shield by further attenuating neutrons escaping the primary shield. It also attenuates high energy gamma radiation from the Reactor Coolant System (RCS) allowing limited local access in containment during full power operation.

After shutdown, most of the containment is accessible for limited time periods; all access is controlled. Areas are surveyed to establish allowable working periods. Dose rates are expected to range from one to 1,000 mrem/hr depending on the location inside the containment (excluding the reactor cavity). These dose rates result from residual fission products, neutron-activiated materials, and corrosion products in the RCS.

Spent fuel is the primary source of radiation during refueling operations (see Section 9.1.2). Because of the extremely high activity of the fission products contained in the spent fuel elements, massive shielding has been provided for areas surrounding the fuel pool and the fuel transfer canal. All removal and transfer operations of spent fuel assemblies are performed under borated water. During fuel handling, a dose rate of 2.5 mrem/hr or less in working areas is maintained.

12.1.2.7 Control Room Shielding

Layout and isometric drawings of the control room, given in Figure 12.1-14, show its relationship to the containment.

The design basis LOCA dictates the shielding requirements for the control room. Shielding is provided to permit access and occupancy of the control room under LOCA conditions with radiation exposures limited to 5 rem TEDE for the duration of the accident in accordance with 10 CFR 50.67.

The design basis LOCA is described in Section 15.1.13 and is based on Regulatory Guide 1.183. Protection of the control room personnel from the fission product release in the containment is provided by the concrete walls between the control room and the containment. Direct radiation from the airborne fission products inside the containment would contribute less than 0.1 rem TEDE to personnel inside the control room for the 30-day period following the LOCA (see Section 15.1.13).

The parameters used in the demonstration of the control room habitability, in addition to Regulatory Guide 1.183, are listed below.

A. No credit is taken for shielding by the internal structures in the containment. Credit is taken for the 3-foot, 9-inch containment wall.

B. Credit is taken for the 1-foot, 6-inch thick control room walls.

C. Credit is taken for radiological decay.

D. Credit is taken for iodine species distribution as listed in Section 15.1.13.

E. Credit is taken for spray removal of iodine as listed in Section 15.1.13.

Emergency air conditioning and filtration systems are provided for post-LOCA conditions (see Section 9.4.1). Ventilation system parameters are listed in Section 12.2.

12.1.2.8 Spent Fuel Handling Area Shielding

Fuel handling area shielding is designed to protect personnel during spent fuel removal, spent fuel transfer to the spent fuel pool, spent fuel pool storage, and subsequent handling and loading into shipping casks. All spent fuel storage and handling operations take place under borated water until placed into a dry fuel storage system cask.

In the fuel handling area, massive shielding is provided around the transfer tube, the tilt pit, spent fuel storage pool, and the cask pit. Other equipment in the fuel handling area that requires shielding includes the fuel pool heat exchangers, fuel pool cooling pumps and associated piping.

12.1.2.9 Auxiliary Building Shielding

Each piece of equipment in the auxiliary building is shielded in accordance with its postulated maximum activity and with the specified zoning and access requirements of adjacent areas.

During normal operation the main equipment in the auxiliary building with potentially high radioactivity is that in the Chemical and Volume Control System (CVCS), described in Section 9.3.4. The auxiliary building shielding includes all concrete walls, floors, ceilings, covers, and removable blocks that protect personnel working near various system components of the CVCS, primary sampling system, and Shutdown Cooling (SDC) System. This includes the letdown lines, letdown heat exchanger, purification filters and demineralizers, volume control tank, and charging pumps. Sufficient transit time exists in fluid lines from the reactor pressure vessel exit to the outside of containment to decay virtually all the Nitrogen-16 activity (see Section 12.1.3). The design of the letdown line ensures a delay of at least 52 seconds.

Specific activities of the reactor coolant in each of these components are given in Section 12.1.3.

The filters and demineralizers could accumulate large amounts of radioactivity during letdown system operation and are located in individually shielded compartments accessible through removable hatches. Contaminated filter elements may be remotely removed and raised into a shielded filter handling device depending on radiation levels. After being transported to the low level radwaste building, the elements are transferred to a shielded shipping cask for off-site disposal or processing.

Spent resins are flushed from the demineralizers to the spent resin storage tank. This operation does not involve dose to the operators. The entire route of the backwashed resins is provided with extensive shielding in conformance with area zoning and access requirements.

Components of the Gaseous Waste System (GWS) are shielded for the maximum accumulated activity discussed in Section 12.1.3 and given in Table 11.3-2.

12.1.2.10 Radwaste and Source Area Shielding

The shielding of the radwaste area includes exterior and interior shield walls. The radwaste area exterior shield walls surround all equipment in the area. The interior shield walls provide shielding for each piece of equipment consistent with its postulated maximum radiation level and with the access requirements of the area and adjacent areas. The sources of radiation in the radwaste area are gases and liquids from the RCS, leakages from other systems, and solids from the spent resins, filters, liquid waste solidification, and shipping container storage area. See Chapter 11 for a discussion of the radwaste systems.

The ANO-2 Auxiliary Building Extension Elev. 335' (east and west concrete racket ball courts) are locked by a chain-link gate and are used for dosimeter irradiations and historically contain a 3 Ci (original activity) Cs-137 source and a 1.2 Ci (original activity) Cs-137 source, respectively. In addition, the ANO-1 Turbine Building Elev. 335' (Pu-Be storage room) is accessed via a locked door and is used to response check neutron instrumentation. This area historically contains a 4.71 Ci (original activity) PuBe source, a 0.72 Ci (original activity) AmBe source, and a 0.120 Ci (original activity) Cs-137 source. The aforementioned areas are posted and controlled in accordance with procedure at all times.

12.1.2.11 Miscellaneous Plant and Plant Yard Areas

The radiation fields at all areas outside the auxiliary building and the containment are much the same during both operation and shutdown. For each of these cases, the dose rate at the building outside surface is normally less than 1 mrem/hr. One exception is the Old Radwaste Storage Building if assumed to be loaded to full capacity; however, normal radioactive material stored is of less curie content than that assumed in calculations and area loading is minimal in comparison to that which the facility is capable of storing. Refer to SAR Section 11.5.6.3 for further radiological information.

The turbine building and plant yard areas are fully accessible during normal operation and shutdown. Shielded solid waste shipping casks and low level solid wastes such as used gloves, anti-C clothing and plastic bags are typically stored in the Low Level Radioactive Waste Storage Building at the east end of the complex. Radwaste storage is further discussed in SAR Section 11.5.6.3. Figure 2.5-17 shows the site plan with locations for estimated exposure.

12.1.2.12 OSGSF Shielding

The shielding for the Original Steam Generator Storage Facilities (OSGSFs) is designed to keep the dose rate outside the OSGSFs less than 1 mrem/hr. The OSGSFs are further discussed in SAR Section 11.5.6.2 and Section 11.1.3.3.8.2 of the ANO-1 SAR. Radiation zoning is illustrated in SAR Figure 12.1-15 (ANO-1 SAR Figure 11-5).

12.1.2.13 LLRWSB

A Low Level Radioactive Waste Storage Building (LLRWSB) provides a controlled environment for receiving and shipping, inspection, equipment sorting, compaction, and decontamination activities associated with on-site storage and off-site shipment of LLRW (see Figures 11.5-2 and 12.1-13). HSAW, consisting primarily of filters and resins, is considered LLRW, but is characterized by higher activities than DAW and the necessity of remote handling and are maintained in a locked high radiation area within the LLRWSB, which is surrounded on all sides by concrete shield walls. The LLRWSB is further discussed in SAR Section 11.5.6.1.

12.1.2.14 ORWSB

The Old Radwaste Storage Building is primarily used to store reusable radioactive material. The standard storage container used is a B-25 box. The building is a metal and concrete structure with 6’ high 0.64’ thick concrete shield walls extending along north and south sides (see Figure 12.1-12). The ORWSB is further discussed in SAR Section 11.5.6.3.

12.1.2.15 Pole Barn

The pole barn is a metal building with approximate dimensions of 100' x 200' x 50' which contains a posted radioactive material storage area. The area contains low activity level material that is logistically challenging (size, origin, plan for storage and disposal) to the site (see Figure 12.1-11). The Pole Barn is further discussed in SAR Section 11.5.6.4.

12.1.3 SOURCE TERMS

[Information on estimated activities is historical. Because activities were estimated before the unit began operating, actual operating experience may differ from the assumptions used in this section.]

Shielding design source terms are based upon the three general plant conditions: normal full power operation, shutdown, and design basis accidents.

12.1.3.1 Sources for Normal Power Operation

At normal full power operation the core produces 2,815 MWt. For conservatism, the shielding design is based on a reactor power of 2,900 MWt. The main sources of activity are Nitrogen-16 from coolant activation processes, fission products from fuel leaks, and corrosion and activation products. The estimated activity level of Nitrogen-16 at various locations in the RCS is shown in Table 12.1-3. The isotopic inventory of fission, corrosion, and activation products in the reactor coolant is given in Tables 11.1-2 and 11.1-8 for operation at one percent failed fuel. Most shielding was based on the maximum case of one percent failed fuel. It is expected that no greater than 0.2 percent failed fuel will be experienced.

Each plant system was shielded according to the amount of activity present and adjacent zoning and access criteria. These systems include the following:

- Reactor Coolant System
- Chemical and Volume Control System
- Waste Management System
- Gaseous Waste System
- Spent Fuel Pool Cooling and Purification System
- Safety Injection System
- Containment Spray System
- Steam Generator Blowdown System
- Shutdown Cooling System

The main source of radiation in the RCS is Nitrogen-16. Sources of radiation in the Safety Injection System (SIS) and Containment Spray System (CSS) arise from operation with coolant flow from the Refueling Water Tank (RWT). The RWT activity was assumed to be the 313-day concentration of the maximum fission and corrosion product activity in the reactor coolant at 70 °F, excluding tritium, xenon, and krypton, decayed for 30 days and diluted by the volume of the RWT. An ion exchanger purification factor was applied to all isotopes. The assumed maximum RWT activity is given in Table 12.1-4.

In most cases shielding for each component of the radioactive waste systems was based on operation under the maximum activity conditions as outlined in Sections 11.2 and 11.3 for the liquid and gaseous Radioactive Waste Systems (RWS). Tabulation of maximum activities is shown in Tables 12.1-4 and 12.1-4A.

The steam generator blowdown system sources result from carryover of reactor coolant activity through possible steam generator tube leaks into the secondary system. The shielding of the blowdown system was designed for a 1,500 gal/day steam generator tube leak.

The spent fuel pool cooling and purification system has two major sources of activity, reactor coolant activity dispersed to the pool following reactor vessel head removal after shutdown and possible leakage of fission products from spent fuel elements. The maximum spent fuel pool water activity is given in Table 12.1-5.

The CVCS (see Section 9.3.4) source activity is the reactor coolant inventory assuming one percent failed fuel, Table 11.1-2. The Nitrogen-16 coolant activity decays to a very low level before the letdown line exits the containment. It is, therefore, not significant in determining shielding of the CVCS equipment outside the containment. The design activities of the CVCS demineralizer, filters and piping are given in Tables 11.5-1 and 11.1-2.

12.1.3.2 Sources for Shutdown Conditions

In the reactor shutdown condition, the only sources of radiation requiring shielding are the SDC equipment and the spent fuel elements during transfer and storage operation.

The maximum specific activity in the SDC System and the design basis source for SDC shielding is the reactor coolant activity assuming one percent failed fuel decayed three and one-half hours (Table 11.1-2).

For all shielding associated with spent fuel handling, the gamma spectra data are taken from Figures 8-1 and 8-2 of "Reactor Physics Constants," ANL-5800.

12.1.3.3 Sources for Design Basis Events

The accidents evaluated for shielding design are the fuel handling accident and LOCA. Accident parameters for these design basis events are discussed and evaluated in Chapter 15.

12.1.3.4 Stored Radioactivity

Shielded solid waste storage casks are typically stored in a special area of the plant yard as discussed in Section 11.5. Design source terms for outside plant water storage tanks and shielded solid waste shipping casks contribute approximately 0.327 mrem/yr at the site boundary.

The case of two liners (containers) filled with CVCS ion exchanger resins with a holdup time of one year was assumed. The surface dose rate of the 2-inch thick lead casks containing the liners was assumed to be 200 mrem/hr, and the casks were positioned as closely as possible to the radwaste storage building wall. It was assumed that the two casks were placed in the building such that they were closest to the dose point chosen on the site boundary. The building wall thickness was 1/8-inch steel. Source geometry was a right circular cylinder of height 127 cm and radius 60.96 cm. Concentric shielding was assumed. The computer code GRACE II, described in Table 12.1-2, was used to compute the dose rate.

The Original Steam Generator Storage Facilities (OSGSFs) are located north of Unit 2, outside the protected area and adjacent to the north access road. They are reinforced concrete structures designed for long-term storage of contaminated equipment (i.e., the steam generators originally stored in Units 1 and 2, the Unit 1 RCS hot leg elbows, and the reactor vessel closure head originally installed in Unit 1). The shielding provided by the concrete walls and roofs is sufficient to keep doses external to the OSGSFs below the requirements of 10 CFR 20 and 40 CFR 190.

12.1.3.5 Field Run Process Piping

There is no field run process piping which contains radioactive material.

12.1.4 AREA RADIATION MONITORING SYSTEM

12.1.4.1 Design Bases

The Area Radiation Monitoring System (ARMS) is provided to supplement the personnel and area radiation monitoring provisions of the plant health physics program described in Section 12.3. Included in this system are 23 permanently located radiation detectors which provide continuous local and remote indication and alarm of direct radiation dose rate. Also included are the two containment high range monitors for post-accident monitoring and two of the area radiation monitors installed in the Post Accident Sampling System (PASS) building. (A third area radiation monitor In the PASS building is designated as a Unit 1 instrument).

The primary objectives of the ARMS are:

A. To immediately alert plant personnel prior to entering or working in areas of increasing or abnormally high radiation levels, which, if unnoticed, might possibly result in inadvertent overexposures;

B. To inform the control room operators of the occurrence and approximate location of abnormal events resulting in the release of radioactive materials or the degradation of shielding structures;

C. To provide, in the event of many types of hypothetical accidents leading to the contamination of the plant, a means of remotely determining external dose rates in those areas most likely to be contaminated, prior to entry by personnel; and,

D. To provide a continuous record of external dose rates at selected locations, thereby ensuring detection of transient increases in dose which are attributable to rapid changes in the radioactivity content of equipment and process streams.

The ARMS has no function related to the safe shutdown of the plant, or to the quantitative monitoring of releases of radioactive material to the environment. Only in unusual circumstances where spurious personnel dosimeter readings are suspected would the area monitor readings be utilized to estimate radiation exposures of plant personnel.

12.1.4.2 System Description

The ARMS consists of 20 low range area monitors, three containment area monitors for normal operations, two high-range containment monitors for post-accident monitoring, and two PASS building monitors. Each monitor channel consists of a detector, remote and local alarms, remote and local indicators and a remote power supply.

The low range detectors are wall mounted gamma sensitive Geiger-Mueller tubes with a dynamic range of 1.0E-4 R/hr to 10 R/hr. Their energy dependence is typically flat within ± 20 percent from 80 KeV to three MeV and each detector is provided with an integral 1.0 μCi Sr-90 check source operated from the ratemeter processing electronics in the control room.

The three containment radiation detectors are gamma sensitive Geiger-Muller tubes with a dynamic range of 1.0(E-2) R/hr to 1.0(E+3) R/hr and a typically flat response within ± 20 percent from 80 KeV to three MeV. An integral check source is not provided with the three containment radiation detectors.

Periodic checks are performed on the containment radiation detectors. An electronically simulated signal is used during normal plant operating conditions. Portable calibration sources are used for radiation monitor checks during plant shutdown. Handling of check sources is described in Section 12.4, Radioactive Materials Safety.

Each monitor channel is provided with a dual alarm that does not impair indicator movement. One level is set below the background radiation level to act as a circuit failure alarm. The second alarm level is set high enough above the normal measured radiation levels in the area to prevent spurious alarms yet low enough to indicate transient radiation level increases. On occasion other alarm points may be selected depending upon work in progress in the area or operations that will vary the normal measured radiation levels in the area. Some monitors are expected to have different alarm points when the reactor is critical than they will have when the reactor is shut down. Setpoints for high and low alarms are established in accordance with a plant procedure. Both alarms initiate continuous audible and visual alarms at the detector. The local visual alarm is a 75-W incandescent light with a red protective glass cover mounted on a NEMA III enclosure and protected by a cage. The control room annunciator provides a single window which alarms for any channel detecting high radiation levels. Visual verification of the channel that has alarmed is done at the area radiation monitoring control panel in the control room.

Each radiation monitor channel is recorded on a multi-point recorder to provide the operator with a continuous indication and a permanent record of radiation levels in each area.

The two containment high-range radiation monitors are gamma sensitive ion chamber with a range of 1 R/hr to 10E8 R/hr. The monitors are qualified for post-accident use and the detector for each monitor is encased in stainless steel to protect it from harsh post accident conditions. The maximum design temperature for these detectors is 350 °F. Both detectors have an internal Uranium-234 source that is used as an instrument check. The U-234 source should provide a reading of 1 R/hr during normal conditions. The monitors have indication in the control room and one channel is also recorded. They have control room alarms separate from the other area radiation monitors. Ambient temperatures greater than 150 °F in the containment can cause indication errors due to thermally induced "noise" in the detector cabling. The error is greatest at low detector current and will become negligible during post-accident conditions. When the temperature falls below 150 °F, the indication will again be accurate.

The PASS Building monitors are gamma sensitive Geiger-Mueller tubes with a range of 1E-4 R/hr to 10 R/hr. These monitors are similar to the low range area monitors in range. The PASS monitors provide indication in the control room, but no remote indication or alarm. The control modules have a green NORMAL light that is normally illuminated. Upon loss of input pulses from the detector, the NORMAL light will extinguish indicating a failure. The ALERT and HIGH alarm lights on the control module are not used. The monitor has a check source that is activated by depressing the NORMAL light. The check source will cause an upscale reading on the control module meter.

In the auxiliary building, the criterion for selecting these particular locations is to provide a minimum of one radiation monitor on each elevation where equipment handling normally radioactive material is located. On each such building elevation, the monitors are placed in those areas having 40-hr/week occupancy (Radiation Zone II) so as to be seen and/or heard, upon alarming, from both ingress points and points of highest expected occupancy. Readings from the monitors inside containment will permit estimation of personnel occupancy times prior to entry. Three monitors located at elevation 404 feet in the spent fuel area of the auxiliary building are available to indicate abnormal gamma radiation levels in the new fuel and spent fuel handling and storage areas. The three monitors do not meet (and are not required to meet) the criteria specified in Regulatory Guide 8.12 and ANSI/ANS-8.3-1979 for the Criticality Monitoring Instruments described in 10 CFR 70.24.

12.1.4.3 <u>Design Evaluation</u>

The original 23 units of the ARMS are designed to operate unattended for extended periods of time, measuring and recording ambient gamma radiation. Ambient radiation dose rate at the detector is indicated locally at the detector and remotely in the control room. Audible and visual alarms are given at both locations if radiation levels exceed preset limits. The components are solid-state and the system is designed for maximum reliability. The Containment High Range monitors provide alarms in the control room only, and only Channel 1 is recorded. The PASS monitors provide indication only in the control room.

The original 23 units of the ARMS are not essential for safe shutdown and serves no active emergency function during operation. The system warns of increasing radiation levels in various plant areas. All monitor channels are independent and failure of one channel will have no effect on the others. The locally mounted detector and alarm units are housed in NEMA III enclosures. The remote readout modules in the control room are general purpose for panel mounting. All monitors and alarms are fabricated to Seismic Category 2 requirements. The control panel is fabricated to Seismic Category 1 requirements. The Containment High Range monitors are class 1E, and Seismic Category 1 detectors. They provide indication to the operators during accident conditions and are classified as EOP significant. The PASS monitors are not safety related. The indicators are mounted in Control Room Seismic Category 1 cabinets.

12.1.4.4 <u>Inspection and Tests</u>

Each of the monitors was calibrated by the instrument manufacturer prior to shipment using secondary long half-life isotope standards traceable to the National Bureau of Standards. Subsequent monitor calibrations use either on-site calibration standards supplied by the manufacturer or known adjustable radiation fields provided by fixed sources, similar to the Shepherd Source, located on-site. Each of the low range area radiation detectors, including the

PASS building detectors, is supplied with a solenoid operated check source. The low range containment monitors have no check source at all while the containment high range monitors have an internal U-234 source. This source is continually exposed to the detector and provides approximately 1R/hr indication to show that the monitoring circuit has not failed. All monitors are calibrated at the frequency and with the calibration source(s) specified in station procedures.

12.1.5 OPERATING PROCEDURES

Radiological health and safety procedures (see Section 13.5) provide for the protection of plant personnel and visitors against exposure to radiation and radioactive materials during all phases of plant operation and maintenance, as well as during any abnormal plant occurrence. The health physics program is described in Section 12.3.

Visual inspections of plant shielding were made during construction. Due to the massive structure of the shielding, these inspections are limited to inspecting for major defects. Once the reactor is operating, radiation surveys are made to ensure that:

A. There are no defects or inadequacies in the shielding that might affect personnel doses during normal operation and maintenance of the plant; and,

B. Areas of the plant are correctly posted and barricaded as radiation and high radiation areas.

These surveys will consist of both gamma and neutron monitoring where appropriate. Continued routine radiation surveys of all plant areas will assure integrity of the shielding (see Section 12.3).

While it is impossible to completely eliminate the production of crud and its subsequent activation, transport, and redeposition throughout the RCS, various means are available to reduce their formation rate and to minimize their concentration in areas of low flow ("crud traps"). These means include system design, material selection, and chemistry control.

<u>System Design</u>

The coolant system is designed to minimize crud buildup problems by the elimination of "crud traps" to the maximum extent possible. Piping runs are kept as short and as unrestrictive as possible to reduce the possibility of low flow areas which could become crud traps and, unless necessary for their operation, all penetrations of the reactor coolant piping originate at the side or top of the pipe to prevent the formation of areas where crud could easily settle.

<u>Material Selection</u>

To avoid the formation of excessive amounts of corrosion products, all piping and components in contact with reactor coolant are constructed of corrosion resistant material. Zircaloy, stainless steel, and Inconel are the major alloys used and all three exhibit superior corrosion resistance at the temperatures and pressures of the RCS. The use of alloys high in Cobalt is minimized in the system unless their superior hardness and wear properties necessitate their use.

Chemistry Control

Effective control over long-term corrosion (the primary source of crud) starts with careful chemistry control during the commissioning period. Chemistry control during the early stage of plant operation is aimed at:

A. Protection from corrosion due to the presence of construction residues or inadvertent chemical contamination.

B. Development of a passive oxide film on the system surfaces prior to critical operation.

C. Protection of the system from localized corrosion induced by oxygen.

Excluding the core, which is not installed initially, the major surfaces are either Inconel-600 or 300 series stainless steel. These materials, although extremely resistant to general corrosion are susceptible to localized attack by contaminants, primarily halide ions, especially before a protective film has been built up. By minimizing the presence of the contaminants by high velocity flushing, by avoiding sensitized materials through close quality control during manufacture, by controlling the concentration of impurities in flush and layup water, and by the use of inhibitors (hydrazine/carbohyrazide), the possibility of attack is substantially reduced. Hydrazine/carbohyrazide also serves the purpose of removing oxygen.

The development of a passive oxide film on primary system surfaces (preconditioning) is extremely important in minimizing corrosion and corrosion product release following critical operation. As the general corrosion of Inconel and stainless steels proceeds, part of the metal oxide forms an adherent layer on the metal surface. As the layer develops, it becomes increasingly passive and slows the corrosion rate to the low, steady state values. To ensure adequate formation of this layer, a special preconditioning period is specified during which reactor coolant chemistry is adjusted to assist in the rapid development of the passive film.

During operation, reactor coolant chemistry is controlled to minimize general corrosion and protect the passive layer developed during pre-core operation. This is accomplished by limiting the impurities present in makeup water and limiting the impurities in the reactor coolant water itself.

Makeup water can contain only limited amounts of dissolved impurities if it is to be used in the RCS. Certain ions known to be harmful (chloride and fluoride) are specifically limited in the makeup water and the presence of other impurities is determined by monitoring and trending conductivity. Thus, the introduction of potential corrodents into the RCS is minimized.

Reactor coolant is maintained in a chemistry condition which is conducive to protecting the passive layer and minimizing corrosion. Oxygen is limited through the use of hydrogen normally, or hydrazine/carbohydrazide when the coolant temperature is below 150 °F. pH is maintained in a band consistent with low corrosion rates by the combined action of lithium (which is produced in the coolant by the neutron activation of B10) and boric acid. Chloride and fluoride, already limited in the makeup water, are also limited in the RCS. By this limitation of corrodents, the corrosion rate is maintained at a low level.

12.1.6 ESTIMATES OF EXPOSURE

Doses to individuals in the plant and at locations in the vicinity of the plant are estimated for normal plant operating conditions, including anticipated operational occurrences. Doses in the plant proper are determined by the occupancy times in the specific radiation zones.

Plant vicinity doses consider direct and scatter radiation associated with equipment inside plant structures as well as radiation source contributions from all outside plant water storage tanks and shielded solid waste shipping casks.

Estimated annual doses and peak dose rates under normal operation with anticipated operational occurrences were calculated for the site boundary, administration building, intake structure, control room, health physics office and hot machine shop. Results are given in Table 12.1-5A.

12.1.7 EQUIPMENT AND AREA DECONTAMINATION PROVISIONS

The design of certain equipment, piping and plant area facilitates decontamination to minimize radiation exposure, in compliance with Regulatory Guide 8.8.

Piping is designed to minimize low points with dead legs. Drains are provided on piping where low points cannot be eliminated. In radioactive systems, the use of backing rings in the piping joint is prohibited to avoid faulting the results of ultrasonic tests of joints and to reduce the potential of crud trap formation for radioactive materials.

Those systems which will become highly radioactive, such as the reactor coolant purification and radwaste slurry transport system, are provided with flush and drain connections to facilitate decontamination.

Access control and traffic patterns are considered in the basic plant layout to minimize the spread of contamination. In addition, to minimize the spread of contamination, (a) equipment vents and drains are piped directly to a collection device connected to the collection system instead of allowing any contaminated fluid to flow across the floor to the floor drain; (b) all-welded piping systems are employed on contaminated systems to the maximum extent practicable to reduce system leakage; and, (c) the valves in some systems are provided with leak-off connections piped directly to the collection system. Decontamination of potentially contaminated areas within the plant is facilitated by hose washdown stations and the use of suitable coatings applied to the concrete floors and walls. Floor drains are provided in all areas of the plant which are potentially contaminated.

12.2 VENTILATION

The plant ventilation systems are designed to provide a suitable environment for both personnel and equipment during normal plant operation, including anticipated operational occurrences. Certain parts of the plant ventilation system also perform safety-related functions.

12.2.1 DESIGN OBJECTIVES

The plant ventilation system for normal plant operation, including anticipated operational occurrences, is designed to meet the requirements of 10 CFR 20, "Standards for Protection Against Radiation," 10 CFR 50, "Licensing of Production and Utilization Facilities" and 10 CFR 100, "Reactor Site Criteria."

Design criteria for the plant ventilation systems include the following:

A. During normal operation and anticipated operational occurrences, the maximum airborne radioactive material concentrations in air breathed by personnel in restricted areas of the plant must be as low as reasonably achievable and within the limits specified in Appendix B, Table 1 of 10 CFR 20.

   The maximum airborne radioactive material concentrations in unrestricted areas of the plant must be within the limits specified in Appendix B, Table II of 10 CFR 20.

B. During normal operation and anticipated operational occurrences the dose from concentrations of airborne radioactive material in unrestricted areas beyond the site boundary are As Low As Reasonably Achievable (ALARA) and within the limits specified in 10 CFR 20 and 10 CFR 50.

C. The dose guidelines of 10 CFR 50.67 must be satisfied following hypothetical accidents.

D. The dose of control room personnel shall not exceed the limits specified in General Design Criterion 19 of Appendix A to 10 CFR 50 and 10 CFR 50.67.

E. Airborne radioactivity monitoring is provided in compliance with General Design Criteria 63 and 64 of Appendix A to 10 CFR 50.

In the design of all ventilation systems, the following guidelines are followed wherever practicable:

A. The airflow is directed from areas of lesser potential contamination to areas of greater potential contamination.

B. In building compartments with a potential for contamination, a greater volumetric flow is exhausted from the area than is supplied to the area to minimize the amount of exfiltration from the area.

C. Airborne radioactivity indication is provided by a recorder and alarms in the control room. Local alarms are provided in potentially contaminated areas in which personnel normally have access.

D. Consideration is given to the disruption of normal airflow patterns by maintenance operations. Ventilation systems are provided with backdraft dampers and manually adjustable volume dampers to re-establish airflow patterns.

E. Ventilation fans and filters are provided with adequate space around the units to allow servicing.

F. Generally, ducts which have a potential high radiation source are routed in low access zones. If a duct with a higher radiation level is routed through a low radiation zone, shielding is provided in the form of a ductway.

G. Access control and traffic patterns are considered in the basic plant layout to minimize the spread of contamination. In addition, to minimize the spread of contamination, (a) equipment vents and drains are piped directly to a collection device connected to the collection system instead of allowing any contaminated fluid to flow across the floor to the floor drain; (b) all-welded piping systems are employed on contaminated systems to the maximum extent practicable to reduce system leakage; and (c) the valves in some systems are provided with leak-off connections piped directly to the collection system, Decontamination of potentially contaminated areas within the plant is facilitated by hose washdown stations and the use of suitable coatings applied to the concrete floors and walls. Floor drains are provided in all areas of the plant which are potentially contaminated.

H. In order to minimize the amount of airborne contamination, as a result of valve leakage, a double set of packing with lantern ring is provided for most larger valves (three inches and larger) in lines carrying radioactive fluids. A packing gland is also provided with a leak-off connection which may be piped to a drain header. Metal diaphragm valves are utilized on those systems where essentially zero leakage is required.

I. Contaminated equipment have design features which will minimize the potential for airborne contamination during maintenance operations. These include flushing connections on pump casings for draining and flushing the pump prior to maintenance, smaller pumps have flanged connections, for ease of removal and flush and drain connections on those piping systems which could become highly radioactive.

12.2.2 DESIGN DESCRIPTION

The following sections describe the ventilation systems for each building expected to contain radioactive material. The descriptions include the design criteria, building volumes, expected flow rates and filter characteristics for the containment ventilation systems, the fuel handling floor radwaste area and the auxiliary building radwaste area ventilation systems, the control room ventilation system, and the turbine building ventilation system.

12.2.2.1 Containment Ventilation System

The systems provided for ventilation of the atmosphere inside the containment and their design criteria (Sections 6.2.2, 6.2.3, 9.4.5) include the following:

A. Containment Purge System (CPS);

B. Containment Cooling System (CCS); and

C. Containment Air Recirculation System.

The following data pertain to the containment ventilation systems design.

A. Containment volume, cu.ft. 1,800,000

B. Flow rates, cfm

1. Containment 153,000

a. Containment cooling units (3 of 4) 90,000

b. Control Element Drive Mechanism (CEDM) shroud cooling units 66,000

c. Control Element Drive Mechanism (CEDM) shroud coolings units mimimum required flow 32,450

2. Containment Purge System 40,000

3. Containment Air Recirculation System 10,000

A roughing filter, a HEPA filter, and a charcoal adsorber are provided in the CPS. See Section 9.4.5 for a description of the filters and adsorbers.

The condensate from the unit coolers is drained to the Waste Management System (WMS).

A discussion of the estimated environmental releases from containment purge operations is presented in Section 11.3 for normal and anticipated operational occurrences. Section 5.2.7 presents a discussion of the containment monitoring system provided to allow remote indication and alarm of airborne activity within the containment. A tabulation of equilibrium airborne activity levels for expected reactor coolant leak rates and activity levels is presented in Tables 2.2-1 and 12.2-2 and is based on the source term assumptions presented in Section 11.1.

12.2.2.2 <u>Fuel Handling Floor Radwaste Area and Auxiliary Building Radwaste Area Ventilation Systems</u>

The fuel handling floor radwaste area and the auxiliary building radwaste area ventilation systems are described in detail in Section 9.4.3. The fuel handling floor radwaste area ventilation system consists of a single air handling unit equipped with a centrifugal type supply fan, a heating coil and a roll type filter. The auxiliary building radwaste area ventilation system consists of two air handling units each equipped with a centrifugal type supply fan, a heating coil, a cooling coil, and a roll type filter. The incoming air of both systems is directed to all parts of the radwaste area through two independent ductwork systems.

Two independent exhaust systems serve the fuel handling floor radwaste area and the auxiliary building radwaste area. Each system consists of a roughing filter, a HEPA filter, a charcoal adsorber, and two vaneaxial type exhaust fans (one standby). See Section 6.5.2 for a detailed description of the filters and adsorbers, with the following exceptions. Replacement medium efficiency roughing filters are 80% efficient with initial resistance not to exceed 0.56 inch W. G. clean and a face area of 23-3/8″ x 23-3/8″. Replacement HEPA filters are in compliance with and meet the basic design criteria of ASME AG-1 in lieu of AEC-HSB-306, MIL-F-51079A, and MIL-F-51068D and are not evaluated for dust holding capacity.

The air for each system is exhausted through a containment flute (vent). Automatic continuous radiation monitoring is provided for the exhaust ducts as described in Section 11.4.2.

The following data pertain to the fuel handling floor radwaste area and the auxiliary building radwaste ventilation system.

A.	Fuel handling floor radwaste area volume, cu.ft.	390,000
B.	Auxiliary building radwaste area volume, cu.ft.	438,000
C.	Flow rates, cfm	
1.	Fuel handling floor radwaste area supply system (2VSF-4)	See P&ID M-2262
2.	Fuel handling floor radwaste area exhaust system (2VEF-14A <u>or</u> 2VEF-14B)	See P&ID M-2262
3.	Auxiliary building radwaste area supply system (2VSF-7A <u>and</u> 2VSF-7B)	See P&ID M-2262
4.	Auxiliary building radwaste area exhaust system (2VEF-8A <u>or</u> 2VEF-8B)	See P&ID M-2262

The exhaust systems are designed to maintain the preferred direction of air flow from spaces with low potential radioactivity into spaces of higher potential radioactivity, thus preventing exfiltration of any airborne radioactivity from the radioactive areas.

12.2.2.3 Control Room Ventilation System

The control room is served by both a normal and an emergency air conditioning system. These systems are described in detail in Section 9.4.1.

The following data pertain to the control room air conditioning and filtering systems:

A.	Control room volume, ft^3	28,500
	combined control room volume, ft^3	~ 40,000
B.	Flow rates, cfm	
1.	Normal system (air conditioning and filtering)	21,300
2.	Emergency system	
a.	Air conditioning	9,900
b.	Filtering	2,000

Evaluation of the capability of the control room ventilation system to meet General Design Criterion 19 is discussed in Section 12.1 for shielding and radiation monitoring and in Section 9.5.1 for fire protection. The air conditioning portion is discussed in Section 9.4.1 and in the following paragraph.

The control room is designed to sustain a simultaneous Design Basis Accident (DBA) and Design Basis Earthquake (DBE) without loss of function or habitability. It has been extensively analyzed to ensure that it remains habitable for the 30-day period following a DBA. The results of these analyses are presented in Chapter 15.

The air filter banks are sized for maximum efficiency. See Section 6.5.2 for a detailed description of the filters and adsorbers, except that replacement HEPA filters are not evaluated for dust holding capacity and contain $\leq$ 7% combustible material by weight.

12.2.2.4 Turbine Building Ventilation System

No consideration was given to potential sources of radioactivity during establishment of air flow paths in the turbine building. Upon indication of steam generator tube leakage, the turbine building air will be periodically monitored for radioactive material with portable sampling instruments. Steam generator tube leakage will be detected by the N-16 monitors, the radiation monitor on the condenser air ejector lines, main steam line radiation monitors, or the steam generator sample monitors. Ventilation air for the areas in the turbine building is supplied by 34 supply fans equipped with roll type filters. Air is exhausted through 10 roof mounted and three wall mounted exhaust fans.

The following data pertain to the turbine building ventilation system design:

A. Turbine Building volume, ft^3	1,660,000
B. Flow rates, cfm	
1. Supply	990,000
2. Exhaust	686,000

12.2.3 SOURCE TERMS

The leakage of steam or liquids containing radioactive material can introduce radionuclides into plant building ventilation air. In the case of steam leakage, essentially all of the noble gases as well as most of the entrained halogens and radioactive particulates will become airborne. For leaking liquids all of the noble gases as well as some of the radioiodines and particulates will become airborne. A complete discussion of the source terms in each plant building is given in Section 11.3. A summary of this material is presented in Table 12.2-2.

12.2.4 AIRBORNE RADIOACTIVITY MONITORING

All fixed airborne radioactivity monitoring instruments within the plant are designed for service as process and effluent monitors. Section 11.4, Process and Effluent Radiological Monitoring System, has a complete discussion of these monitors, including criteria used to determine:

A. Necessity for and location of instruments.

B. Sampler and detector operational characteristics;

C. Detector type, sensitivity, and range;

D. Type and location of power sources, indicating and recording devices;

E. Setpoint and their bases;

F. Type and location of annunciators and alarms, and the system or operator actions they initiate; and,

G. The maintenance and calibration programs to be followed.

A discussion of portable airborne monitor instruments used to check the fixed systems is also included.

12.2.5 OPERATING PROCEDURES

Plant operating procedures assure that onsite inhalation exposures will be kept ALARA during plant operation and maintenance. Health physics procedures and methods for controlling radiation exposures are described in Section 12.3.

12.2.6 ESTIMATES OF INHALATION DOSES

The inhalation doses received by plant personnel are dependent on many factors. Some of the more important of those factors are:

A. Fluid leaking into various building compartments.

B. The time spent in each compartment.

C. The activity level of the leaking fluid.

D. The ventilation flow rate in the building compartment.

E. The activity level of the ventilating air.

F. Type of leaking fluid (steam or water).

G. The use of administrative procedures such as masks or supplemental air supply.

In the design of the plant various measures are taken to prevent the spread of airborne contamination to normally accessible areas of the plant. Wherever practicable, the mechanical equipment will be designed to prevent the release of radioactive material to the building atmosphere. During periods of plant maintenance, the inhalation doses are expected to be low due to the design features of the plant that minimize the potential for airborne contaminants.

The thyroid inhalation doses given in Table 12.2-4 were evaluated for radioiodine nuclides using the equation:

$$D = \frac{B}{P} \left(\frac{t}{8760} \right) \Sigma_j \, C_j DCF_j$$

where

D = dose rate, rem/yr

B = breathing rate, cc/yr

t = annual hours of exposure

8760 = total hours per year

C = airborne radionuclide concentration, μCi/cc

DCF = dose conversion factor, rem/μCi inhaled

P = respirator protection factor

j = subscript denoting radioiodine nuclide.

The noble gas and radioiodine concentrations employed in the calculation are given in Table 12.2-2. A conservative upper limit to the inhalation dose that could be received by an operator can be estimated by assuming that an operator breathes the plant ventilation exhaust air for 40 hours per week, 50 weeks per year. The occupancy factor for the radwaste area of the auxiliary building was also assumed to be 40 hours per week, 50 weeks per year.

The noble gas decay energies and radioiodine dose conversion factors which were employed are given in Table 15.1.0-2. The breathing rate of plant personnel during the exposure periods was assumed to be 1.1 (+10) cc/yr (10 m^3/8 hr). Other assumptions are given in Table 12.2-5.

Surveys to determine concentrations of airborne radioactive materials will be performed routinely at fixed frequencies in predetermined plant areas, and immediately prior to and during personnel entry into areas where the potential for airborne contamination exists. The results of these surveys will determine personnel occupancy factors, respirator requirement, or the need for purging of equipment contents constituting the source of airborne radioactivity, which will limit the weekly intake of radioactive materials by inhalation and skin absorption to the intake derived from 10 CFR 20, Table 1, Column 1, concentrations assuming 40 hr/wk exposure. The exposure of personnel above these levels will require prior authorization from the NRC.

12.3 HEALTH PHYSICS PROGRAM

12.3.1 PROGRAM OBJECTIVES

Rules and procedures have been established for protection against radiation and contamination. All personnel assigned to the plant and all visitors are required to follow these rules and procedures.

A program is in place which will ensure the capability to accurately determine the airborne iodine concentration in vital areas under accident conditions. This program includes the following:

1. Training of personnel,

2. Procedures for monitoring, and

3. Provisions for maintenance of sampling and analysis equipment.

The ANO Radiation Protection Manual and Health Physics procedures specify administrative controls designed to provide protection of personnel from exposure to radiation in excess of the limits specified in 10 CFR 20 and further to maintain personnel radiation exposure As Low As Reasonably Achievable (ALARA).

The procedures concerning radiation exposure are subject to the same review and approval process as all other plant procedures. All work in controlled access, or other radiation or contamination areas, requires an appropriate Radiological Work Permit (RWP). An RWP must be approved by Health Physics. The radiological hazards associated with the jobs will typically be determined and evaluated prior to approval of the RWPs. The RWP identifies the precautions to be taken, the protective clothing to be worn, and any other radiological safety precautions that are required. In order to control access to radiological areas, warning signs, audible and visual indicators, barricades, and locked doors are used as appropriate.

It is the policy of Entergy Operations, Inc. to keep personnel radiation exposure within the limits set forth in applicable regulations. In addition, Entergy Operations, Inc. is dedicated to the philosophy of ALARA and has established an ALARA program at the Arkansas Nuclear One Facility. The ALARA program is designed to ensure that each person will keep their radiation exposure as low as is reasonably achievable, consistent with performing assigned work. Each individual is responsible for observing rules adopted for the individual's safety and the safety of others.

Procedures, work plans, Radiological Work Permits, and other documents required for jobs involving substantial radiation hazards are reviewed by the ALARA Committee. Items considered in this review may include the use of remote or special tools, temporary shielding, preliminary job-site decontamination, special ventilation containment areas, respiratory protection, special anti-contamination clothing, continuous air monitoring, or any other procedures or devices that will serve to reduce the dose received during the job performance.

12.3.2 FACILITIES AND EQUIPMENT

12.3.2.1 Controlled Access Facilities

Most of the ANO radiologically controlled areas exist inside the Unit 1 and Unit 2 Reactor and Auxiliary Buildings. (Notable exceptions are the Radioactive Waste Storage Building and the Contaminated Materials Storage Building.) Normal ingress to the Unit 1 and Unit 2 Reactor and Auxiliary Buildings is through a single controlled access portal located on the 386 foot elevation of the Unit 2 side of the plant. Normal egress from these areas is through a similar controlled access portal located on the 386 foot elevation of the Unit 1 side of the plant. The Unit 2 controlled access point contains offices for Health Physics personnel and the ingress control point. The Unit 1 controlled egress point contains a frisking station, personnel decontamination station and the egress control point.

12.3.2.2 Nuclear Chemistry Laboratory Facilities

Nuclear chemistry facilities consist of two conventional chemistry laboratories, a nuclear chemistry laboratory, nuclear chemistry counting room, sample rooms, and sample preparation room.

The nuclear chemistry laboratory has been constructed for ease of decontamination. The lab is designed for the preparation and chemical analysis of reactor coolant. There is a stainless steel lined fume hood in the nuclear chemistry laboratory with a designed exhaust flow of 800 cfm. Two exhaust fans are capable of drawing air from the fume hood, nuclear chemistry laboratory, and other areas in the Auxiliary Building. One fan will start automatically if the other fan stops. If both fans fail, an alarm will sound in the Control Room. Drains from the nuclear chemistry laboratory including the fume hood, floor drains and sinks are connected to the radioactive liquid collection system.

The counting room contains laboratory equipment needed to implement the Nuclear Chemistry Program.

12.3.2.3 Decontamination Facilities

The personnel decontamination station is equipped with a shower, sink, hampers for contaminated clothing, and monitoring equipment for personnel decontamination. Detergents and other cleaning agents along with brushes and towels are also available for this purpose.

Large pieces of equipment can be decontaminated in the cask washdown area on the fuel handling floor, if necessary.

12.3.2.4 Medical Facilities

Medical observation and treatment are available in case of overexposure and contamination. Local physicians and hospital facilities are used in the initial care and treatment of injuries received at ANO.

12.3.2.5 Portable Health Physics Instruments and Equipment

Available portable instruments are of sufficient variety and function to measure all types of radiation of concern and in all ranges expected during normal and emergency operations. Health Physics instrument procedures are available and training is conducted to assist qualified personnel in the proper selection and use of instrumentation.

Typical types of portable health physics survey and monitoring instruments available at ANO include:

A. Battery powered GM count rate meters,
B. High range GM survey meters,
C. AC powered GM count rate meters,
D. Scintillation detectors,
E. High and low range ionization chamber survey meters,
F. Neutron REM Meters.

Calibration and maintenance of portable health physics instrumentation is performed in accordance with applicable procedures, using National Institute of Standards and Technology traceable sources and equipment.

12.3.2.6 Air Monitoring Equipment

Continuous air monitors consist of air samplers capable of continuously sampling and monitoring airborne particulate and iodine radioactivity. The monitors can be set to identify airborne activity levels, alarm locally, and transmit data to a remote station for display and recording. When continuous air monitors indicate airborne activity, portable air samplers equipped with collection media for particulate, radioiodine, and noble gas are used to obtain air samples for analysis.

12.3.2.7 Personnel Protective Equipment

Anti-contamination clothing, such as shoe covers, gloves, coveralls, and head covers, is available for use. The protective clothing, respiratory protective equipment and other equipment required for use in contaminated areas is determined by Health Physics and is typically specified on the required Radiological Work Permit.

Respiratory protection equipment used at Arkansas Nuclear One for radiological protection consists of full face respirators, air-line breathing units, and self contained breathing apparatus. Procedures governing the use and maintenance of this equipment comply with the requirements of 10 CFR 20 and rules of good practice such as those published by the American Industrial Hygiene Association, "Respiratory Protective Devices Manual".

12.3.2.8 Special Equipment and Devices

Temporary shielding, remote and special tools, and mock-ups are used as applicable to reduce personnel radiation exposures. Temporary shielding in various forms, such as bricks, blankets and sheets, is available at ANO. Standard types of remote handling tools are also available. Other remote or special handling tools may be purchased or fabricated as the need arises.

12.3.3 PERSONNEL DOSIMETRY

12.3.3.1 External Dosimetry

Personnel monitoring devices such as electronic alarming dosimeters (EADs) and primary dosimeters of legal record (DLRs) are used for measuring personnel dose equivalent due to beta-gamma and neutron radiation from external sources. External dosimetry measurements, records, and reporting systems comply with the requirements set forth in 10 CFR 19 and 10 CFR 20.

Dose of legal record from external radiation exposure is based upon primary dosimeter results. Primary dosimeters are processed by a laboratory certified by the National Voluntary Laboratory Accreditation Program (NVLAP) as required by NRC regulations. If valid primary dosimeter results are not available, external dose of record will be assigned in accordance with applicable procedures.

12.3.3.2 <u>Internal Dosimetry</u>

Arkansas Nuclear One has the capability to assess the presence of radionuclides and perform in-vivo isotopic analysis. The presence of internally deposited radionuclides is assessed periodically. The reasons for monitoring include initiation of dose monitoring, assessment of the effectiveness of the respiratory protection program, evaluation of suspected intakes of radioactive material, and termination of dose monitoring. This monitoring is performed by personnel monitoring equipment. In-vivo isotopic analyses are normally performed when the assessment indicates internally deposited radionuclides in quantities that exceed the monitor setpoint.

Certain isotopes, such as tritium (H^3), which are difficult to assess in-vivo are assessed by in-vitro analyses. These measurements may be made using Entergy facilities or contracted to vendor services. The need for in-vitro bioassay measurements is evaluated by Health Physics. Any calculated doses, due to internal exposure, are assigned in accordance with the requirements of 10 CFR 20.

12.3.4 PROCEDURES

Procedures are an integral portion of any program. Our Radiological Waste Management and Health Physics Programs are no exception. The procedures which are part of these programs deal with many topics. As a minimum procedures are maintained to address the following areas:

A. Solid Radioactive Waste Program

1. Minimize the number of contaminated areas and reduce the introduction of materials into contaminated areas.

2. Waste segregation methods and procedures.

B. Health Physics Program

1. Protection against radiation and contamination.

2. Use of survey and monitoring instruments.

3. Calibration of survey and monitoring instruments.

4. Use and care of respiratory protective equipment.

5. Assignment of dose received if dosimeter of legal record (DLR) results are not available.

C. Radioactive Material Safety

1. Control, use and storage of Special Nuclear Material.

2. Fuel handling.

3. Sealed source inventory.

12.4 RADIOACTIVE MATERIALS SAFETY

12.4.1 RADIOACTIVE MATERIALS SAFETY PROGRAM

The Radioactive Materials Safety Program is administered at ANO as a single program for both Unit 1 and Unit 2.

12.4.1.1 Special Nuclear Material

Entergy Operations, Inc. has implemented a program to control the Special Nuclear Material under title to or in possession of the company. The use, storage and control of Special Nuclear Material is accomplished as specified in the operating license and as specifically implemented in applicable procedures. These procedures are part of the company's fuel accountability program and are used in receiving, handling and storing all Special Nuclear Material.

Special Nuclear Material contained in unirradiated fuel assemblies is stored in noncritical arrays in either the new fuel pit or spent fuel pool, both of which are Seismic Class I structures as described in Section 9.1, "Fuel Storage and Handling." Fuel assemblies are inserted into and removed from the reactor according to approved fuel handling procedures using fuel handling equipment as described in Section 9.1. Irradiated fuel assemblies are handled and stored underwater, as described in Section 9.1.2, "Spent Fuel Storage." Licensed storage or shipping casks will be used to move spent fuel from the spent fuel pool.

12.4.1.2 Other Sealed Sources

Other sealed sources of radioactive material, including specific quantities of Special Nuclear Material are controlled through the Health Physics Program described in Section 12.3. Sealed sources containing a sufficient quantity of radioactive material to create a High Radiation Area are locked in a shield or stored in the shielded position when not in use. The rooms in which these sources are used are posted and locked when the sources are in an unshielded position and left unattended.

12.4.2 RADIOACTIVE MATERIALS CONTROL

Reactor Engineering is responsible for the physical accountability of special nuclear material at ANO. Reactor Engineering is also responsible for providing the storage, movement and loading sequences to minimize the handling of fuel assemblies. Operations is responsible for the safe movement and handling of fuel assemblies according to written plant procedures. Personnel trained and qualified in the use of fuel handling equipment perform material movement operations. Onsite shift Operations management is responsible for fuel handling operations on the respective shift.

Other sealed sources of radioactive material are controlled through the Health Physics Program. These sealed sources are used primarily for instrument and out-of-core detector calibrations and may typically include materials, such as radiocesium, radiocobalt, or plutonium-beryllium of various activities. Sealed sources are accounted for through inventories performed as specified by procedure. Leak testing of sealed sources is performed in accordance with Plant Technical Specifications.

12.4.3 RADIOACTIVE MATERIALS

A complete inventory of licensable quantities of sealed radioactive sources is maintained. At present there are no plans to have any radioactive materials onsite that exceed the limits specified below:

	Material	Form and Use	Possession Limit
A.	Any Byproduct, Source and Special Nuclear Material	As reactor fuel; as sealed sources for reactor start up; as sealed sources for reactor instrument and radiation monitoring equipment calibration; and as fission detectors	As required for reactor operation
B.	Any Byproduct, Source or Special Nuclear Material Krypton-85	Any form for sample analysis or instrument calibration excluding	100 millicuries each isotope; any by-product material 100 milligrams each isotope; any source or special nuclear material *2 curies Krypton-85 as instrument calibration source

* A maximum of 2 curies of Krypton-85 will be onsite for use as an instrument calibration source for both plant process and area radiation monitors. The isotope is kept in pressurized bottles. The maximum total activity for any single bottle is not expected to exceed 950 millicuries.

Table 12.1-1

RADIATION ZONES

Zone	Dose Rate (mrem/hr)	Description
I	≤ 1.0	Controlled access, unlimited occupancy
II	> 1.0 ≤ 2.5	Controlled access, limited occupancy 40 hr/wk
III	> 2.5 ≤ 15	Controlled access, limited occupancy between 6-40 hr/wk
IV	> 15 ≤ 100	Controlled access, limited occupancy for short periods; 1-6 hr/wk
V	> 100	Normally inaccessible. Controlled access, limited occupancy for short periods during emergencies.

Controlled Access Areas - where higher radiation levels and/or radioactive contamination, which have a greater probability of radiation health hazard to individuals, can be expected. Only individuals directly involved in the operation of the plant will, in general, be allowed to enter these areas. Ingress and egress are under the direct supervision and authorization by the plant health physics staff.

Occupancy - the time spent by an individual in a particular area. For Zones III-V, occupancy is to be determined on an area-by-area basis and individual-by-individual basis by the plant health physics staff.

Table 12.1-2

LIST OF COMPUTER CODES USED IN ORIGINAL SHIELDING DESIGN CALCULATIONS

GRACE I	Multigroup, multiregion, gamma ray attenuation code used to computed gamma heating and gamma dose rates in slab geometry (Reference 7).
GRACE II	Multigroup, multiregion, gamma ray attenuation code used to compute the dose rate or heat generation rate for a spherical or a cylindrical source with slab or concentric shields (Reference 8).
ANISN	Multigroup, multiregion code solving the Boltzman transport equation for neutrons or gamma rays in one dimensional slab, cylindrical, or spherical geometry using discrete ordinate, Sn, techniques (Reference 9).
FAIM	Multigroup, multiregion neutron diffusion code used to compute neutron dose rates and neutron heating in one dimensional slab, cylindrical, or spherical geometry (Reference 5).
2DBS	Multigroup, multiregion neutron diffusion code used to compute neutron dose rates and neutron heating in two-dimensional geometry (Reference 14).

Table 12.1-5A

ESTIMATES OF EXPOSURE

Location	Peak Dose Rate (mrem/hr)	Annual Dose (mrem/yr)
Site Boundary	4.34×10^{-5}	.375 (note 2)
Administration Bldg.	6.75×10^{-4}	5.83 (note 2)
Intake structure	8.15×10^{-4}	7.04 (note 2)
Control room (El.386')	8.6×10^{-4}	7.43 (note 2)
Health physics off. (El. 386')	7.44×10^{-4}	6.42 (note 2)
Hot machine shop (El. 354')	2.37 (note 1)	4.74 (+3) (note 3)

Notes:

1. Worst case with adjacent sources of volume control tank and spent resin tank having maximum radioactivity.
2. Continuous occupacy, 365 days.
3. 40 hr/wk for 50 wk/yr occupancy (2000 hr/yr)

Table 12.1-6

REACTOR CAVITY NEUTRON SHIELD MATERIAL PROPERTIES

Base	Silicone Elastomer
Temp. Range	0 °F to +550 °F (Min)
Specific Gravity	1.08 (67.3 pcf) at 25 °C (77 °F) (Min)
Gamma Radiation Resistance	1×10^{10} rads (Min)
Heat Aging - Weight Loss	Max 4% - 30,000 hrs. at 400 °F in air
Hydrogen Loss	Max 0.2% - 30,000 hrs. at 400 °F in air
Fire Resistance	
Limiting Oxygen Index	Min 40% oxygen atmosphere to sustain combustion
Heat Conductivity	4×10^{-4} to 8×10^{-4} Cal/sec/cm/c^2/c°
Toxicity	No toxic effects
Hydrogen Density	.065 gm/cc

	Auxiliary Building Radwaste Area	Containment*
Inhalation Thyroid		
Normal Operation	1.43(-02)	5.91(-01)
Anticipated Operational Occurrences	7.92(-02)	8.81(-03)

* Assumptions are given in Table 12.2-5.

Table 12.2-5

ASSUMPTIONS FOR INHALATION THYROID DOSE CALCULATION

CONTAINMENT

A. Four purges per year
B. Semi-infinite cloud model for inhalation thyroid dose calculation.
C. DF = 1000 for wearing respirator
D. Assume one two hour containment entry per year at anticipated operational occurrence activity level.
E. Occupancy factor of 40 hrs per week, 50 weeks per year for normal operation.

AUXILIARY BUILDING

A. Building vent exhaust rate of 5.32 x 10^4 CFM
B. Semi-infinite cloud model for inhalation thyroid dose calculation
C. Occupancy factor of 40 hrs per week, 50 week per year.

13 CONDUCT OF OPERATIONS

13.1 ORGANIZATIONAL STRUCTURES OF APPLICANT

13.1.1 MANAGEMENT AND TECHNICAL SUPPORT ORGANIZATIONS

The Entergy organization is described in the Quality Assurance Program Manual (QAPM). The role of the corporate organization is to monitor, assess and provide support to the Entergy Operations' nuclear sites and help minimize the activity of the nuclear sites staffs that are not directly related to day-to-day site management.

The direct plant organizational structure is shown in Figure 13.1-5. Plant specific titles for generic titles in the Technical Specifications are located in Figure 13.1-1.

13.1.2 ORGANIZATIONAL INTERFACES AND RESPONSIBILITIES

Entergy Arkansas, Inc. and Entergy Operations, Inc. are joint licensees under the facility operating license condition, each responsible for specific areas and jointly responsible for regulatory compliance and response. Entergy Arkansas, Inc. is licensed to possess the facility and Entergy Operations, Inc. is licensed to possess, use, and operate the facility.

Each supplier of equipment, material, or services and each maintenance or modification contractor is responsible for administering the applicable quality assurance/quality control functions as required by ANO. The Quality Organization is responsible for assuring by surveillance, inspection, audit, or review of objective evidence that onsite functions are accomplished for systems, structures, and services that affect the safety and integrity of the plant.

13.1.3 QUALIFICATIONS OF NUCLEAR OPERATIONS PERSONNEL

The education and experience of the plant operation, technical, and maintenance support personnel meet the requirements set forth in ANSI/ANS 3.1 (1978).

Qualification requirements for Quality Control Personnel that are not specifically addressed in ANSI/ANS 3.1 (1978) have been adopted from and meet the intent of Regulatory Guide 1.8.

Qualification and educational backgrounds of Arkansas Nuclear One management and supervisory personnel are maintained on file at Arkansas Nuclear One.

13.1.4 TECHNICAL CONSULTANTS

Historical data removed; see Section 13.1 of the FSAR.

13.2 TRAINING PROGRAM

Section 13.2.1 describes the initial training developed and conducted for personnel at ANO-2 during the time up to and including initial licensing. Current training is described in Sections 13.2.2 and 13.2.3.

13.2.1 PLANT STAFF INITIAL TRAINING PROGRAM

Historical data removed - To review the exact wording please refer to Section 13.2.1 of the FSAR.

13.2.2 REPLACEMENT TRAINING

13.2.2.1 Replacement Training – Licensed Personnel

The replacement training program for Licensed personnel is based on a Systems approach to training and is accredited by the National Academy of Nuclear Training. The initial accreditation of the training program took place in January, 1984. The new training program, which incorporated revisions required by changes to 10 CFR 55, was audited by the National Academy of Nuclear Training in January, 1988. The current program supercedes the previously existing NRC approved training program (certified to the Commission in accordance with Generic Letter No. 87-07 and the guidance given in NUREG-1262 in May, 1988).

13.2.2.2 Replacement Training - Non-Licensed Personnel

Training for personnel not requiring NRC licenses is provided based upon the individual's background experience and duties and responsibilities of his or her position.

A. General Employee Training

All employees who enter the protected area at ANO are required to attend the General Employee Training program or be accompanied by someone who has completed the training. The program provides a general plant physical and safety orientation to ensure safe execution of their duties. Refresher training is provided to personnel at least once every two years.

B. Non-Licensed Operator Training

Non-Licensed Operator Training consists of two separate programs. The first program is the auxiliary operator program which includes on-the-job training and classroom instruction in the categories shift administration, plant design and plant auxiliary systems.

The second program is the waste control operator program which includes classroom presentation and on-the-job training in shift administration, plant systems and design, and advanced radiation worker training.

C. Shift Engineer/Shift Technical Advisor Training

The Shift Engineer/Shift Technical Advisor (SE/STA) Training Program is a comprehensive program of study based on NUREG 0737 designed to provide a SE/STA candidate with a Bachelor's Degree or equivalent in a scientific or engineering

discipline with the necessary knowledge and training to perform the duties of an SE/STA. The program is divided into classroom presentations and on-the-job training in the following courses: general employee training, plant systems/instrumentation and controls, plant response and analysis, operating procedures, shift administration, and simulator training.

Continuing training for shift engineers/shift technical advisors consists of attending the licensed operator continuing training program on the unit involved. A minimum of 40 hours of simulator training per year is provided. This 40 hours will include 20 hours of classroom training and 20 hours of training on the simulator.

D. Other Non-Licensed Training

Other areas of training are provided for non-licensed personnel as needed and include such areas as maintenance training (electrical, mechanical and I&C) Health Physics training, Radioactive Waste training, Chemistry training and Radiochemistry training.

13.2.3 RETRAINING PROGRAM

13.2.3.1 Licensed Operator Continuing Training Program

This program was established for the purpose of maintaining Licensed Operators at a level of knowledge and proficiency which is necessary for continued safe operation of the plant.

The Licensed Operator Continuing Training program for Licensed personnel is based on a Systems approach to training and is accredited by the National Academy of Nuclear Training. The initial accreditation of the training program took place in January, 1984. The new training program, which incorporated revisions required by changes to 10 CFR 55, was audited by the National Academy of Nuclear Training in January, 1988. The current program supercedes the previously existing NRC approved training program (certified to the Commission in accordance with Generic Letter No. 87-07 and the guidance given in NUREG-1262 in May, 1988).

13.2.4 RECORDS

Records of qualifications, experience, training, and retraining are maintained at the plant site for each member of the plant organization. These records include grades for individual courses as well as details of experience obtained during observation and on-the-job training periods at operating nuclear power plants. Results of these tests are also maintained in the plant records.

13.3 EMERGENCY PLANNING

The Arkansas Nuclear One Emergency Plan was developed to accommodate emergencies involving Unit 1 and/or Unit 2. For further information, see the Emergency Plan.

This Plan:

A. Establishes an Emergency Organization to cope with emergency conditions of radiological incidents;

B. Identifies personnel and delineates their duties and responsibilities in the Emergency Organization;

C. Establishes criteria for determining the magnitude of the release of radioactive material and the appropriate response;

D. Establishes a system for reporting radiological incidents to local, state and federal agencies in compliance with the criteria for notification;

E. Establishes a system for requesting radiological assistance;

F. Establishes a system of communication for use during emergencies; and,

G. Identifies possible emergency conditions and the equipment and facilities available to combat them.

13.4 REVIEW AND AUDIT

A program for reviews, including in-plant and independent corporate reviews and audits is established to provide for independent and objective evaluation of matters affecting the Safe Operation of ANO.

A complete description of this program is discussed within the Quality Assurance Program Manual.

ANO facility review and audit procedures are consistent with the requirements of Regulatory Guide 1.33.

13.5 PLANT PROCEDURES

13.5.1 ADMINISTRATIVE PROCEDURES

For the administrative control of safety-related activities, the plant staff will adhere to detailed written procedures covering administrative areas listed below:

A. Administrative procedures describing operator authority and responsibilities and definition of "Control Room."

B. Quality Control procedures including, but not limited to, design equipment and material control.

C. Surveillance and testing requirements.

ANO administrative procedures are consistent with the requirements of Regulatory Guide 1.33.

EOI Headquarters administrative and section procedures provide guidance to the site to ensure consistent management direction on programs and processes. They also convey information to the site for specific requirements based on multi-site development of standardized programs and processes. The site maintains alignment with these procedures through direct implementation or implementation through site administrative and section procedures. All procedures issued from corporate headquarters that are implemented directly at the site and provide instructions in the areas of significant safety or management administrative controls are prepared and reviewed as delineated in Section 13.5.3, PROCEDURE CONTROL.

13.5.2 OPERATING AND MAINTENANCE PROCEDURES

For the operation and maintenance of all systems and components involving nuclear safety, the plant staff will adhere to detailed written procedures covering the activities listed below:

13.5.2.1 Operations Procedures

A. Plant Operating Procedures, including, but not limited, to the following activities:

1. Plant Preheat and Precritical Check
2. Plant Startup
3. Power Operation
4. Plant Shutdown and Cooldown
5. Refueling Operations (various procedures)

B. Reactor Coolant System Operating Procedures, including, but not limited to, the following activities:

1. Filling and Venting Reactor Coolant System
2. Soluble Poison Control
3. Pressurizer Operation
4. Reactor Coolant Pump Operation
5. Quench Tank Operation
6. Draining and Blanketing Reactor Coolant System
7. Reactor Coolant Leak Detection
8. Reactivity and Heat Balance Calculation

C. Auxiliary System Operating Procedures, including, but not limited to, the following activities:

1. Chemical and Volume Control System Operation
2. Shutdown Cooling System Operation
3. Safety Injection Tank Operation
4. Containment Spray Operation
5. Spent Fuel Cooling Operation
6. Circulating Water System Operation
7. Waste Control (various procedures)
8. Instrument and Service Air System Operation
9. Cooling Water System Operation (various procedures)
10. Diesel Generator Operations
11. Building Atmosphere Control (various procedures)

D. Instrumentation and Control Systems, including, but not limited to, the following activities:

1. CPC/CEAC Operations
2. Vibration and Loose Parts Monitor Operation
3. ESF Electrical System Operation
4. COLSS Operations
5. Control Element Drive Mechanism Control System
6. Computer Operation

E. Steam System Operating Procedures, including, but not limited to, the following activities:

1. Turbine Startup
2. Condenser and Vacuum System Operation
3. Condensate, Feedwater and Steam System Operation
4. Startup and Blowdown Demineralizer System
5. Main Feedwater Pump and FWCS Operation

F. Abnormal Operating Procedures, including, but not limited to, the following conditions:

1. Loss of Turbine Load
2. Loss of Instrument Air
3. Loss of Service Water
4. Reactor Coolant Pump and Motor Emergencies
5. Remote Shutdown
6. Primary to Secondary Leakage
7. Alternate Shutdown
8. Natural Emergencies
9. CEA Malfunction
10. Loss of Containment Integrity
11. Annunciator Corrective Actions

G. Emergency Operating Procedures, including, but not limited to, the following conditions:

   1. Reactor Trip Recovery
   2. Loss of Reactor Coolant
   3. Loss of Feedwater

13.5.2.2 Other Procedures

A. Radiation Protection Procedures.

B. Plant Instrumentation Calibration and Test Procedures.

C. Plant Maintenance Procedures, including, but not limited to:

   1. Pressurizer Maintenance
   2. Reactor Coolant Pump Maintenance
   3. Steam Generator Maintenance
   4. Reactor, Internals, Head and Control Element Maintenance
   5. Auxiliary Systems Maintenance
   6. Refueling Maintenance Procedures

D. Security Procedures

E. Emergency Plan Implementing Procedures, including, but not limited to:

   1. Offsite Dose Assessments (various procedures)
   2. Evacuation
   3. Communications System Operation

13.5.3 PROCEDURE CONTROL

Procedure 1000.006, “Procedure Control” provides the administrative controls and requirements for 1) all ANO administrative procedures and 2) all ANO implementing procedures.

13.6 INDUSTRIAL SECURITY

The Arkansas Nuclear One Industrial Security Plan was developed to accommodate the security of both Unit 1 and Unit 2. This plan is designed to provide the information described in Regulatory Guide 1.17 and covers basically three objectives:

A. To describe the physical security protection of Arkansas Nuclear One;

B. To define actions taken by individuals to prevent a security hazard; and,

C. To describe the preventive measures beyond physical barriers taken to minimize hazards.

Further details are given in the Arkansas Nuclear One Industrial Security Plan (Docket No. 50-313).

13.7 FIRE PROTECTION PLAN (See Section 9.5.1.5)

13.8 TECHNICAL REQUIREMENTS MANUAL

The NRC's Final Policy Statement on Technical Specification Improvements for nuclear power plants and 10 CFR 50.36 allow certain requirements to be relocated from the Technical Specifications (TS) to other licensee controlled documents such as the SAR, ODCM, or administrative procedures. To provide an alternative central location for the requirements relocated from the TS and ensure that the necessary administrative controls are applied to these requirements, ANO developed a Technical Requirements Manual (TRM).

The TRM is an operator aid that provides a central location for relocated items. In addition to using the TS numbering and format for relocated items, the TRM provides a reference to the TS, when appropriate, to connect the relocated information to the applicable TS.

13.8.1 REGULATORY STATUS/REQUIREMENTS

The requirements contained in the TRM are part of the licensing basis. Failure to comply with a requirement of the TRM will be evaluated in accordance with the ANO corrective action program. This evaluation will consider effects upon equipment operability and applicable reporting requirements.

13.8.2 CHANGES TO THE TRM

The TRM is administered as part of the SAR. Changes to the TRM are subject to the criteria of 10 CFR 50.59. Administrative controls for processing TRM changes are included in the site procedures.

14 INITIAL TESTS AND OPERATION

14.1 TEST PROGRAM

A comprehensive preoperational and operational program was conducted on Unit 2 similar to that performed on Unit 1. The purpose of this program is: (1) to assure that the equipment and systems perform in accordance with design criteria, (2) to effect initial fuel loading in a safe, efficient manner, (3) to determine the nuclear parameters, and (4) to bring the unit to rated capacity.

The test program began as installation of individual components and systems was completed. The individual components and systems were tested and evaluated according to written test procedures. An analysis of the test results verified that each component and system performed satisfactorily.

The startup organization, under the supervision of the Production Startup Supervisor, maintained a technical file of all test records. These records consisted of system release packages, completed component test data sheets, technical procedures, and completed test procedures. At the conclusion of the test program, these records were transmitted to the ANO General Manager for permanent retention in accordance with plant administrative procedures for retention of test records.

The written procedures for the preoperational and operational tests included the purpose, initial conditions, limits and precautions, prerequisites, and acceptance criteria.

Testing of the applicable, individual systems was conducted in accordance with Regulatory Guides 1.41, dated March 16, 1973, and 1.52, dated June 1973, through the test methods described in the Test Abstracts of Table 14.1.1.

The scope of the test program was as defined in Regulatory Guide 1.68, "Preoperational and Initial Startup Test Programs for Water-Cooled Power Reactors," dated November 1973. However, the neutron count rate deviated somewhat from that proposed in Regulatory Guide 1.68, Section C (startup to critical procedures). The test method used for this test is described in Section 14.1.4.2. Additionally, Regulatory Guide 1.80 was followed, with the exception of Sections C.8, C.9 and C.10. These sections suggested a method for acquiring loss of air data. It was planned to conform with the intent of these sections within each individual system test by simulation of a loss of air condition with all combinations of component status.

In general, the Emergency Core Cooling System (ECCS) was tested as suggested by Regulatory Guide 1.79, Revision 1. However, the preoperational test program deviates from Section C.1.b(2). This section suggests that the capability to recirculate coolant from the containment sump into the Reactor Coolant System (RCS) be verified. Because of small sump capacity and inability to test screen pressure drop in the as-built configuration, this test was not conducted.

Containment sump design is discussed in Section 6.2.2.2.1.B.7. Since the design provides for two flow paths into the sump, the probability of excessive screen pressure drop in an accident condition is reduced. Tests were conducted to demonstrate the realignment of valves and pumps for recirculation from the containment sump. In addition, adequate Net Positive Suction Head (NPSH) was verified by pumping from the refueling water storage tank. The measured NPSH was corrected to account for friction losses and the height differences between tank level and sump level and the result compared to the minimum acceptable NPSH.

Figure 14.1-3 shows the interrelationships and sequence for performing the preoperational, fuel load, low power and power escalation tests. The duration and relationship to the fuel load date is also depicted.

Final revision of the draft test procedures was scheduled to begin at least three months prior to the projected test date. The objective was for this revision and subsequent review and approval to be completed in a manner such that the approved test procedure was available for onsite NRC review at least 30 days prior to the scheduled test date.

14.1.1 ADMINISTRATIVE PROCEDURES (TESTING)

14.1.1.1 Organization

The AP&L organization as it existed during preoperational testing is illustrated in Figure 14.1-1. The Production Startup Supervisor had overall responsibility for the test program and administered the preoperational testing program. Two Assistant Production Startup Supervisors assisted the Production Startup Supervisor in administering all aspects of the test program and acted for him in his absence.

Resumes for the Production Startup Supervisor and an Assistant Production Startup Supervisor are presented in Section 13.1.1.2.5.1 of the FSAR.

The Plant Safety Committee's (PSC) function in the preoperational testing program was to review the fuel load and all post-fuel load test procedures to assure the safe operation of all affected equipment. The General Office Safety Review Committee's (SRC) function in the preoperational testing program was to review all Unit 2 test procedures which may constitute an unreviewed safety question as defined by 10 CFR 50.59(a).

Additional information on the ANO organization during startup and on the duties of the PSC and SRC at that time is provided in Chapters 13 and 17 of the FSAR.

A Test Working Group (TWG) was formed and met at regular intervals during the most active phases of the test program. This group was composed of experienced people from the AP&L staff and from startup (S/U) consultants (as required).

The membership of the TWG was as follows:

DUTY	POSITION	ORGANIZATION
Chairman	Assistant Production Project S/U Supervisor (Testing)	AP&L Startup
Member	Combustion Engineering Lead S/U Engineer	Combustion Engineering
Member	Performance Engineer	AP&L ANO Plant Staff
Member	Combustion Engineering Site Manager	Combustion Engineering
Member	Bechtel Project S/U Engineer	Bechtel S/U

A quorum consisted of the chairman, or alternate, and three members, or alternates. Regular members who could not attend a scheduled meeting were to designate a responsible alternate from their own organization.

The TWG evaluated the test program and test procedures periodically and recommended to the Production Startup Supervisor any changes they felt should be made in order to fulfill requirements. The TWG reviewed all test procedures before testing. After testing, the TWG reviewed test results and recommended to the Production Startup Supervisor the action the TWG felt should be taken: (1) in resolving discrepancies or deficiencies that had been found to exist, (2) in determining if acceptance criteria had been met, and (3) when, for any reason, the test was found to be unacceptable.

AP&L engaged the services of special S/U consultants, as required, to supplement the AP&L staff during startup activities.

14.1.1.2 Test Procedure Development

Test procedures were written in advance for all plant systems. All test procedures were submitted initially to the Production Startup Supervisor who, with the aid of the appropriate Assistant Production Startup Supervisor, coordinated the review process in a timely fashion so as to accomplish approved procedures before the test was scheduled to be conducted.

The review and approval process for all test procedures is shown in Figure 14.1-2. During initial procedure development, administrative controls existed which required the procedures writer to utilize all existing approved project documents in the development of a test procedure. These documents included the project FSAR, design specification, design drawings, regulatory guides, vendor manuals, and all applicable codes and regulations.

These test procedures were written by procedures writers within the various organizations (the Architect/Engineer, the Nuclear Steam Supply System (NSSS) vendor or Arkansas Power and Light Company). To ensure a review by the responsible design organization, the procedure writers submitted the test procedures to their respective organization for review prior to transmittal of the procedure to the Production Startup Supervisor. Administrative controls existed to ensure this review.

Prior to review by the TWG, the procedure was updated to the latest revision of all project documents by the Systems Engineer. The Systems Engineer is a member of the startup group who was assigned primary responsibility for testing a specific portion of the total plant. The Systems Engineer was a graduate of a 4-year accredited engineering or science college or university and had two years of experience in startup testing activities on test facilities, nuclear or fossil power plants or equivalent installations, or he was a high school graduate and had four years of experience.

Through TWG participation, the NSSS vendor and the plant staff had an opportunity to provide inputs to the test procedures. Review of all fuel load and post-fuel load test procedures by the PSC and approval by the General Manager assured proper inputs on matters involving safe plant operation. The Safety Review Committee further reviewed those test procedures to which the PSC might refer.

Development of the test procedure was complete upon review by the appropriate committees and the Production Startup Supervisor's approval.

14.1.1.3 Test Execution

A Test Director (TD) was assigned by the Production Startup Supervisor for each test. His responsibility was to coordinate the preparation for and performance of the test, maintain a chronological test log of significant events and unusual conditions occurring during the test, identify discrepancies between test results and acceptance criteria, and have test results analyzed. The minimum qualifications for the Test Director were that he must be a high school graduate and have one year of experience in testing or inspection of construction and installation activities. In most cases, the Systems Engineer also served as the Test Director.

A "clearance to proceed" was required prior to actual testing. This "clearance to proceed" consisted of verification by the Production Startup Supervisor or an Assistant Startup Supervisor that prerequisites were completed, including required inspections, checks, and associated records, that support systems were available, as required, and that the system was ready to be tested.

The test was conducted in accordance with the official copy of the procedure, except as provided in Section 14.1.2 below. Administrative procedures were implemented which will assure that a retest was performed, where applicable, on systems or components which were repaired, replaced, or modified. Modifications proposed as a result of testing were reviewed and approved by the appropriate design organization.

The Systems Engineer reviewed all new and/or revised project documents to determine if a change required retesting. The technical files which contained data sheets and test records were then updated and any affected test procedure was modified and re-executed, as applicable.

After system release from construction, all work performed by construction on a system was authorized by the Production Startup Supervisor's approval of a Startup Work Request. This special form required the Systems Engineer to indicate in writing if a retest was required.

All retesting was reviewed and approved in the same manner as original testing.

14.1.1.4 Test Results

The TWG reviewed all test results and specified any action necessary to meet all acceptance criteria. A successful and completed test was be acknowledged by the TWG when the chairman signed the test endorsement record which was attached to the official copy of the test procedure.

Any discrepancies or deficiencies found to exist during testing or upon review of test data after testing was completed were documented on a special form and attached to the official copy of the test procedure. The TWG reviewed the form and recommended to the Production Startup Supervisor the action they felt should be taken in resolving the deficiency. Retests were performed on systems and components, as necessary, to verify the adequacy of the corrective action.

Final approval of a test was given by the Production Startup Supervisor when he reviewed the test results and signed in the space provided on the test endorsement record.

Administrative controls were established to ensure that safety-related preoperational test results were reviewed and approved prior to fuel loading. In some cases, certain aspects of the test results, while not meeting the acceptance criteria, have met the safety requirements, and an interim endorsement of the test results may have been obtained. During the post-fuel load phase startup test results were reviewed and given at least interim endorsement at each major power test plateau prior to raising power to the next plateau. Any limitation or restriction required as a result of the interim endorsement (if any) was to be clearly denoted within the test procedure by any of the groups or individuals responsible for approving the test results. Final approval was required before the limitation or restriction was excluded, or by the end of the test program, if no limit or restriction exists.

14.1.1.5 Utilization of Plant Operating and Testing Experience at Other Reactor Facilities

Several mechanisms existed for utilizing operating and testing experience from other nuclear power plants to assure an effective, complete test program. All TWG members actively participated in at least one previous nuclear power plant startup. Published information on other plant operating and testing experience was available to the startup organization. Although no formal programs existed, all persons involved in the startup effort were made aware of other nuclear plant operating and testing experience through review of applicable periodicals, applicable NRC bulletins and internal AP&L, CE and Bechtel correspondence.

In addition, the Nuclear Services Organization was on distribution for "EEI Nuclear Power Subcommittee Abnormal Occurrence Reports" transmittals. These were reviewed by a Nuclear Services staff member who distributed copies of appropriate documents to applicable Nuclear Services supervisors. The EEI material was then sent to the plant staff accompanied by a note specifying particularly applicable pages to be noted by particular plant staff supervisors. Particular attention was paid to reports from similar CE-supplied reactor systems. When necessary, alterations in design or test methods were made based on this review.

Operating and testing experience at other facilities was also used as the basis for excluding the Reactor Coolant Piping from the more rigorous shock and vibration testing needed on other piping systems. The following provides discussion justifying this exclusion, and describes the alternate means used to demonstrate compliance with the ASME Code (NB-3622.3) and the intent of Regulatory Guide 1.68:

Examination of results of rigorous vibration testing programs at similar operating plants indicates the following:

A. Experience in monitoring similarly constructed reactor coolant piping on other units indicates that vibration is not a problem;

B. At Calvert Cliffs (a CE unit constructed by Bechtel) the smallest vibration amplitude limit (based on one-half the material endurance limit) was determined to be 0.010 inch single amplitude;

C. Any effects causing vibration of the reactor coolant piping other than reactor coolant pump vibration will only be secondary due to the piping size, routing, length and supports; and,

D. The Unit 2 reactor coolant pump vibration monitors will alarm between 0.002 and 0.003 inch single amplitude vibration.

Although the Unit 2 reactor coolant piping was instrumented for rigorous vibration testing, procedures were in place to ensure compliance with the acceptance criteria of 0.005 inch single amplitude vibration. In the event of an alarm of reactor coolant pump vibration monitors during steady state conditions, the actual vibration condition was to be verified with more reliable and accurate hand held monitors. If the piping vibration were confirmed to be greater than 0.005 inch single amplitude, steps would then be taken to determine the actual amplitude limit at the location of the vibration (based on one-half the material endurance limit) and compare the measured vibration against the rigorous acceptance criteria.

It should be noted that the above acceptance criteria was based on the Reactor Coolant Pump vibration monitors which were in use during the Initial testing and Start-up. The values given above are not comparable with the setpoints selected for the upgraded Reactor Coolant Pump Monitoring System installed by DCP 85-2111.

14.1.2 ADMINISTRATIVE PROCEDURES (MODIFICATIONS)

After a test procedure was approved, the test was conducted according to the procedure. However, the test procedure may have been modified, as necessary, to complete the test. All modifications made prior to issuance of an operating license must have been approved by the Production Startup Supervisor, or by one of the Assistant Production Startup Supervisors, in the absence of the Production Startup Supervisor.

Changes to test procedures made after issuance of an operating license were made in accordance with the Technical Specifications.

All modifications were documented on a special form which was be included within the Test Procedure Package. During review of test results, all changes were reviewed to ensure applicability and proper administration of the change.

14.1.3 TEST OBJECTIVES AND PROCEDURES

The tests prior to reactor fuel loading assured that the systems were complete and operated in accordance with design. These tests were classified as hydro/leak, operational, electrical, and functional, with the following definitions for each classification.

A. Hydro/Leak Test - Structural integrity leak test of the various systems and components at the appropriate pressure.

B. Operational Test - Operation of systems and equipment under operating conditions.

C. Electrical Test - Consisted of grounding, meggar, continuity, and phasing checks; circuit breaker operation and control checks; potential measurement and energizing of buses and equipment to ensure continuity, circuit integrity, and proper functioning of electrical apparatus.

D. Functional Test - Tests to verify that systems and equipment will function as intended.

Instruments and controls of each system or component were also subjected to a preoperational instrumentation and controls calibration test prior to the initial operation of that system or component to assure proper operation.

An Engineered Safety Features (ESF) system test was performed to assure proper actuation and operation for the ESF and to evaluate the test method and frequency for future testing. The operating times of ESF valves were measured as part of the ESF Response Time Test. The term "critical valves" used in several test summaries in connection with valve operating times refers to those valves in Table 6.2-26 and elsewhere in the original FSAR for which opening and/or closure times are specified.

The test program was divided into two phases: Preheatup Test Phase and Hot Functional Test Phase. In many instances, systems were tested during both the Preheatup Test Phase and the Hot Functional Test Phase.

A summary of the test program prior to fuel loading is provided in Table 14.1-1.

Note that testing of the High Pressure Safety Injection (HPSI) system was not performed at hot operating conditions, as the guidance of Regulatory Guide 1.68 suggests. The reasons are given below:

> Injecting ambient temperature water into a hot thick-walled system produces a significant thermally induced stress transient. This significance is likewise born out in the low number (5) of allowable cycles for this transient. To use one of the allowable cycles for testing unreasonably jeopardizes the warranted service life.
>
> Full consideration must also be given to the more likely event that a less severe (than a Loss of Coolant Accident (LOCA)) transient may cause initiation of ECCS, while the NSSS is at elevated temperatures. This may occur due to operator or equipment maloperation at any unexpected time in the serviceable life of the plant. Such unexpected injections would also claim one of the allowable transients. Using one of these allowable transients for an initial test may, in the future, cause unnecessary administrative restrictions on operations.
>
> As with any significant stress producing transient, recovery from an injection of ambient temperature water into the RCS at elevated temperatures requires significant post-test inspections such as ultrasonic, radiographic, and visual inspections followed by another high pressure hydrostatic pressure test to ensure that the integrity of the RCS has not been jeopardized and is satisfactory for warranted life. Such a test represents a major effort and will prolong the startup significantly.
>
> In lieu of injecting ambient temperature water into a hot system, the capability of the HPSI system to deliver water as required under accident conditions was verified by analysis based on as-built HPSI pump and system head capacity curves. The operability of the check valves for both the HPSI headers and the safety injection tank lines were, however, verified under hot operating conditions, as described in Section 6.3.4.2.

14.1.3.1 Preheatup Test Phase

The objective of the Preheatup Test Phase is to assure that the equipment and systems perform as required during hot functional testing. This phase of the testing included certain preoperational calibration and hydro/leak, operational, electrical, and functional tests, as required. The containment system underwent a structural integrity and integrated leakage rate test to verify the containment design and to ensure that leakage is within the design limit.

14.1.3.2 Hot Functional Test Phase

The Hot Functional Test Phase was a period of hot operation of the RCS and the associated auxiliary systems prior to the initial fueling of the reactor. The RCS was heated to no-load operating pressure and temperature during this phase.

The Hot Functional Test Phase continued the preparation toward the initial fuel loading. The objectives of this phase of the test program are:

A. Operational tests of systems, components, and non-nuclear instrumentation and controls at no load operating pressure and temperature.

B. Operator training.

C. Verification of normal and emergency operating procedures, where practical.

The following capabilities were demonstrated as part of the pre-core load hot functional tests:

A. The steam dump and bypass system can control RCS temperature satisfactorily.

B. The emergency feedwater system can supply feedwater to the steam generators at operating conditions.

C. The main steam isolation valves can be shut under hot, low steam flow conditions.

D. The plant can be cooled utilizing the emergency cooling pond.

E. The soluble poison concentration in the RCS can be changed at a rate consistent with accident analysis assumptions.

14.1.4 FUEL LOADING AND INITIAL OPERATION

Fuel was loaded into the reactor in accordance with a step-by-step written procedure. This procedure contained a number of safety precautions and operating limitations.

Upon completion of fuel loading operations, the final core loading was verified by visually surveying the core and recording the fuel assembly number versus core location on a core grid map. After completing the survey, the person surveying the core then signed the completed core map. A second individual then compared the core survey to the approved core loading plan. If the survey agreed with the loading plan, the individual comparing these documents signed the core survey to verify that the core loading was correct. The use of two independent persons verified that the location and orientation of the fuel was in agreement with prescribed core loading plan.

The fuel loading procedure included:

A. A sequence of loading temporary detectors, sources, Control Element Assemblies (CEAs), and fuel assemblies in order to assure shutdown margin requirements are maintained;

B. The conditions under which fuel loading may continue after any step;

C. An identification of responsibility and authority;

D. After insertion of the source, a minimum of two detectors operating and indicating neutron level whenever core geometry is being changed, or at least one detector indicating neutron level at all other times;

E. Checks of reactivity effects for each fuel assembly addition prior to the release of the fuel assembly by the fuel handling grapple;

F. Maintenance of two completely independent plots of reciprocal neutron multiplication as a function of the parameter causing reactivity change (used to estimate the reactivity effect of inserting additional fuel assemblies prior to their insertion);

G. Maintenance of the boron concentration in the reactor vessel, spent fuel pool, and RCS at a value to assure the required subcritical margin at all times;

H. Periodic check of the valve alignment of the auxiliary systems connected to the RCS to prevent dilution of the reactor coolant boron concentration;

I. Chemical analysis and water level monitoring to assure that inadvertent dilution of the reactor coolant boron concentration had not occurred;

J. Direct communication between control room and fuel handling areas;

K. Operation of the plant radiation monitoring systems, or if not, use of portable monitoring equipment with appropriate sensitivities and ranges in the area where radiation monitors are inoperable; and

L. Health physics and chemistry monitoring and services.

14.1.4.1 Preparation for Initial Criticality

Upon completion of the initial fuel loading, normal maintenance and operating procedures were used to take the plant from refueling condition to cold shutdown. These procedures detailed the installation of the remainder of the vessel internals including couplings of the CEAs, installation and tensioning of the head, installation of in-core instruments and other installations and checkouts necessary to bring the plant to the cold shutdown condition.

Following the completion of the above evolutions, the post-core hot functional testing was completed prior to the approach to initial criticality. This testing in conjunction with normal operating procedures, took the plant from cold shutdown to hot zero power conditions and back to hot shutdown in preparation for initial criticality. Testing was conducted under both hot shutdown (approximately 260 °F) and hot zero power conditions (approximately 545 °F). The testing included measurements of the RCS heat loss, RCS flow under various pump combinations, RCS flow coastdown, Control Element Drive Mechanism (CEDM) functioning and drop time testing, monitoring of RCS and steam generator water chemistry, and initial verification of COLSS and Core Protection Calculator (CPC) flow-related algorithms. RCS leakrate tests were covered by normal operating procedures and surveillance requirements. Table 14.1-2 and its test summaries provide a more complete picture of the testing to be performed.

The checkout of reactor protection trip circuits referred to in Appendix A, Section B.1.b of Regulatory Guide 1.68 was accomplished in conjunction with preoperational testing.

The checkout of source range monitors referred to in Appendix A, Section B.1.f of Regulatory Guide 1.68 was accomplished in conjunction with initial fuel loading.

Measurements of CEA drop time was done at cold shutdown with no reactor coolant pumps operating and at hot zero power conditions with four reactor coolant pumps operating. Five additional measurements of CEA drop time for both cold and hot flow conditions were performed on each of the fastest and slowest CEAs. Testing at hot zero power full flow conditions provided a conservative measure of the CEA drop time expected during power operation.

The vibration monitoring program referred to in Appendix A, Sections B.1.j and D.1.p of Regulatory Guide 1.68 was discussed in detail in the FSAR on pages Q110.28 through Q110.28c in the “AEC Questions” section.

14.1.4.2 Initial Criticality

A written procedure was followed during the approach to initial criticality. This procedure specified in detail the sequence to be followed, the limits and precautions, the required plant status, and the prerequisite system conditions. This procedure also specified the alignment of fluid systems to assure controlled boron dilution and core conditions under which the approach to initial criticality may proceed.

Initial criticality was achieved by the following method:

A. Begin with boron concentration sufficient for shutdown with all CEAs out.

B. Withdraw all CEAs to approximately six inches withdrawal and perform a manual trip to demonstrate trip capability.

C. Withdraw CEA groups to normal operating configuration.

D. Deborate until criticality is achieved.

Permissible group withdrawal and deboration was based on calculated reactivity effects. Two independent inverse neutron multiplication curves were maintained during group withdrawal and deboration. A predicted boron concentration for criticality was determined before group withdrawal or deboration is started.

The startup channels were verified to discriminate noise and gamma pulses such that the signal to noise ratio is at least two by a calibration with neutron and gamma calibration sources prior to the approach to initial criticality.

During the deboration to initial criticality, the neutron count rate was verified to be greater than one-half count per second above background when the RCS boron concentration was approximately 75 ppm from the estimated critical boron concentration.

During the approach to initial criticality, an overlap of one decade between the startup channels and the logarithmic range of the safety channels was demonstrated.

14.1.4.3 Post-Criticality Test Program

The post-criticality test program was performed to provide assurance that the plant is operating in a safe manner. Systems and components which could not be operationally tested prior to initial criticality were tested during the post-criticality test program to verify reactor parameters and to obtain information required for plant operation. The post-criticality tests are listed in Tables 14.1-3 and 14.1-4 and described in the test summaries.

14.1.4.3.1 Low Power Physics Tests

Following initial criticality, a program of reactor physics measurement was undertaken to verify the calculated parameters. Measurements were carried out at hot shutdown (~260 °F), heatup (260 – 545 °F) and hot zero power (~545 °F) conditions. Measurements were made of CEA group and individual worths, isothermal temperature coefficients, boron worths, and critical borons. The measurements carried out in the hot zero power condition were more extensive than those measurements at hot shutdown. Measurements during heatup were limited to critical borons, pressure coefficients, and isothermal temperature coefficients. Measurements to be carried out are listed in Table 14.1-3 and described in the associated summaries.

Detailed written procedures were used to specify the sequence of tests, parameters to be measured, and conditions under which each test was to be performed. These tests involved a series of prescribed CEA configurations and boron concentrations with intervening measurements of reactivity changes during boron concentration changes, moderator temperature changes, and CEA position changes.

14.1.4.3.2 Power Escalation Test Program

Following determination of the operating characteristics and physics parameters of the reactor at zero power, a power escalation test program was conducted. This program consisted of specified incremental increases in power levels up to full power, with appropriate testing conducted at each (20, 50, 80, and 100 percent) power level. An analysis of the significant parameters at each step was made prior to initiating an additional power escalation. The tests listed in Table 14.1-4 and described in the test summaries were carried out at either one or more of the four power level plateaus mentioned above or after completion of the 100 percent plateau.

14.1.4.4 Operating Restrictions

During initial operations and associated testing, the normal plant safety procedures and Technical Specifications were in effect. In addition, special safety precautions and limitations were included in the test procedure.

14.1.5 ADMINISTRATIVE PROCEDURES (SYSTEM OPERATION)

Operational and emergency procedures were referenced in test procedures, where applicable, throughout the preoperational testing and initial operating period.

14.1.6 STEAM GENERATOR REPLACEMENT AND POWER UPRATE

A comprehensive test program was conducted on Unit 2 following Steam Generator Replacement and again after Power Uprate. The purpose of these test programs were to assure that all modified systems/components of the BOP and NSSS were performing in compliance with the design and licensing bases, and to establish the new operating margins of the plant systems. The test program for NSSS and BOP systems was developed based upon a review of the ANO-2 Safety Analysis Report (SAR), new design specifications and contract warranty requirements, the scope of the modifications performed during each implementation outage, and industry experience for the other steam generator replacements, power uprate projects, and startup testing.

A Startup Test Group made up of qualified and trained test engineers was assembled to determine testing requirements, develop test procedures, perform tests, and review test results for compliance with design predictions, test requirements, and acceptance criteria. Written procedures were developed and approved by the Onsite Safety Review Committee. The test requirements and results for selected tests were reviewed and approved by the Test Working Group. This group was reestablished similar to the initial test program to provide experienced test personnel and management oversight to the test program. The Test Working Group controlled the Power Uprate power ascension by approving the test results and any deficiencies for each test plateau before recommending increases in plant power from approximately 90, 92.5, 95, 97.5 to 100% of the new licensed power level.

14.1.6.1 Cycle 15 Post Steam Generator Replacement Test Program

A summary of the testing performed following Steam Generator Replacement is provided in Table 14.1-5. The tests were performed to meet the requirements and acceptance criteria supplied in the 2R14 design change packages or similar to the Initial Test Program specified in this chapter.

14.1.6.2 Cycle 16 Post Power Uprate Test Program

A summary of the testing performed following Power Uprate is provided in Table 14.1-6. The tests were performed to meet the requirements and acceptance criteria supplied in the 2R15 design change packages or similar to the Initial Test Program specified in this chapter.

14.2 AUGMENTATION OF APPLICANT'S STAFF FOR INITIAL TESTS AND OPERATION

The normal operating organization was utilized throughout the startup program. During this period, the permanent staff was augmented by additional AP&L personnel plus additional engineers and technical consultants from Bechtel Corporation, Combustion Engineering and EDS Nuclear, Inc., as required. These consultants, reporting to the AP&L Manager, Nuclear Operations were personnel with extensive experience in mechanical, electrical, instrument and control, and physics testing activities who were assigned to the project to assist in specific phases of the startup.

14.2.1 ORGANIZATIONAL FUNCTIONS, RESPONSIBILITIES AND AUTHORITIES

The Arkansas Power & Light Startup Group provided the overall direction of the startup program. Consequently, the Production Project Startup Supervisor had overall responsibility for the startup program. He coordinated this effort with all of the involved parties. All of the consultants hired by the company for startup assistance reported to the Production Project Startup Supervisor.

Specific engineers from among the plant staff and/or the various consultants were assigned the responsibility of conducting the individual tests.

The plant staff provided all of the necessary mechanics, electricians and instrument technicians to repair, maintain, and properly calibrate the various pieces of equipment during the test program. In addition, the plant staff provided the necessary operating personnel, as required by the test program.

Participation by the plant staff was coordinated by the Production Project Startup Supervisor and the General Manager, Operating and Maintenance Manager, Plant Administrative Manager, and the Engineering and Technical Support Manager.

The project startup schedule was developed and maintained by the Production Startup Supervisor and consultants reporting to him.

The Production Project Startup Supervisor had the ultimate authority and responsibility for conducting the test program to meet the testing requirements. The General Manager had the ultimate responsibility for the safe operation of the plant.

14.2.2 INTERRELATIONSHIPS AND INTERFACES

During the cold and hot functional test programs, the augmenting groups involved, including various plant groups, company groups, Combustion Engineering consultants, Bechtel consultants and other outside consultants, worked under the supervision of the Production Project Startup Supervisor. During fuel loading and the post-fuel loading test program, the Production Project Startup Supervisor directed the program and provided technical support to the General Manager, who had the responsibility for the safe operation of the plant.

The Production Project Startup Supervisor could have assigned another supervisor to coordinate activities of the various groups for individual tests.

14.2.3 PERSONNEL FUNCTIONS, RESPONSIBILITIES AND AUTHORITIES

The Production Project Startup Supervisor was responsible for all startup and test programs. He had the authority to stop or discontinue any test he deemed unsafe or not in the best interests of the company. He functioned to schedule and coordinate all groups involved in a particular evolution. He could have assigned responsibility to other supervisors under him.

The General Manager was responsible for coordinating the operational and maintenance support required by the startup program and, as requested, by the Production Project Startup Supervisor. He had the authority to stop or discontinue any test he deemed unsafe or not in the best interest of the company.

The Operations and Maintenance Manager was responsible for the conduct and coordination of all operations during the startup and test programs. He had the authority to stop or discontinue any test he deemed unsafe or not in the best interest of the company.

The Plant Analysis Superintendent was responsible for directing reactor physics tests and neutron monitoring during initial core loading and zero and low power physics testing.

Other department supervisors were responsible for technical support for the test programs. They assigned staff members to various phases of the test program, as necessary.

14.2.4 PERSONNEL QUALIFICATIONS

Mr. Michael L. Alexander (EDS Nuclear), Supervising Engineer, is a Nuclear Engineer, having graduated from the University of Tennessee with a Bachelor of Science degree and a Master of Science degree in Nuclear Engineering. He has had extensive experience in the construction, startup and operation of commercial nuclear power plants, including: program planning, scheduling, and sequencing; procedure preparation review and approval; and performance and supervision of testing. Most recently, as Senior Operations Engineer for Burns and Roe, Inc., Mr. Alexander directed the startup activities at an 850 MWe BWR. Previously, as Lead Test Engineer for Virginia Electric Power Company, he was responsible for the direction and guidance of engineers and technicians in the development and performance of preoperational and startup test programs at an 800 MWe PWR. He joined EDS Nuclear in September 1974. Mr. Alexander is a registered professional Engineer in the State of California and is a member of the American Nuclear Society.

Mr. Alexander B. McGregor (Combustion Engineering), Lead Startup Engineer, is a graduate of Dartmouth College with a Bachelor of Arts in Biology. From 1968 to 1972, he served with the United States Navy. He attended USN Officer Submarine School, Nuclear Power School, and prototype training. He served as Reactor Controls Officer, Auxiliary Division Officer, and Refueling Officer on an operating nuclear submarine. During this time, he participated in the refueling and startup testing of the ship's reactor plant. He qualified as Engineering Officer of the Watch. Since 1974, he has been employed by Combustion Engineering as a Startup Engineer, with assignments including: Ft. Calhoun plant - procedure preparation and supervision of outage work plus assistance during refueling and subsequent startup; St. Lucie, Unit 1 - procedure review, assistance with system startup through power ascension testing, and procedure preparation plus assistance during onsite fuel reconstitution; Arkansas Nuclear One, Unit 2 - procedure review and assistance with system startup. Since June 1978, he has been assigned as Test Director for the Unit 2 Post-Fuel Load Test Program.

Mr. David L. Harris (Bechtel Corporation), Project Startup Engineer, is a graduate of the University of California with a Bachelor of Science Degree in Mechanical Engineering. Mr. Harris worked as a Control System Engineer from 1956 to 1960 for Standard Oil Company of California. In 1960, he joined the Los Alamos Scientific Laboratory Testing Division, responsible for design of testing equipment for nuclear weapons and nuclear rockets. From 1962 to 1972, he was located at the Nevada Test Site as Manager of the Equipment Testing Laboratory and later as Section Leader for Testing Services, supporting the Nuclear Rocket Test Program. In 1972, he joined Bechtel Power Corporation as a Senior Startup Engineer. He has been associated with the Arkansas Nuclear One Project since June 1972. He is experienced in the performance and supervision of testing, procedure preparation and review, and scoping and planning. He has been a Group Leader since May 1977, supervising engineers and technicians for the startup program. Mr. Harris is a registered Nuclear and Control Systems Engineer in the State of California and registered Mechanical Engineer in the State of Nevada. He is a member of the Instrument Society of America.

Mr. Joseph F. Weinman (Bechtel Corporation), Senior Startup Engineer, served in the United States Navy from 1961 to 1968, during which time he attended Navy Nuclear Power School and Prototype Training. Following this training, he was assigned to a nuclear submarine for new construction. During new construction, he qualified as reactor operator and participated in much of the initial startup testing. The remaining years of naval experience were spent on an operational nuclear submarine, during which time he continued to upgrade and qualify, achieving Engineering Officer of the Watch. Following honorable discharge, Mr. Weinman joined the Mining and Metals Division of Bechtel Corporation. His assignments consisted of Instrument Engineer on a fuel pelletizing plant and a uranium oxide conversion plant. In 1970, Mr. Weinman transferred to the Power Division of Bechtel Corporation. Since that time, he has participated in the startup of five conventional power plants and three nuclear plants.

Table 14.1-1

INITIAL TEST PROGRAM SUMMARIES

SAR sections referenced by this table are in the FSAR.
Components or systems described may have been modified since initial testing.
Refer to the appropriate section of the SAR for current system descriptions.

Table 14.1-1 (continued)

125-V DC POWER SYSTEM

1.0 OBJECTIVE

To demonstrate that the 125-V DC power system provides a reliable source of power for startup, operation, and shutdown under normal and emergency conditions, and to verify that the three separate power sources and their respective loads are independent of each other. The 125-V DC power system will be tested in accordance with IEEE-450-1972.0

2.0 PREREQUISITES

2.1 Construction activities completed on components to be tested.

2.2 Meters and relays calibrated.

2.3 Batteries fully charged with normal height of electrolyte.

2.4 Load resistor bank available for battery capacity test.

2.5 Construction activities completed on safety-related equipment supplied by the battery system for the integrated system test.

3.0 TEST METHOD

3.1 Battery capacity and charger performance verified.

3.2 Bus transfer devices tested.

3.3 Alarms and tripping devices tested.

3.4 The ground detector checked.

3.5 The load capacity of the battery measured by discharging the battery with a resistive load without the battery charger.

3.6 The operation of safety-related DC loads verified in a separate integral test procedure by disconnecting the battery and adjusting the battery charger voltage to the level obtained at the end of the discharge test.

4.0 DATA REQUIRED

4.1 Battery voltage & load current without charger.

4.2 Charger float voltage & current.

4.3 Charger voltage & current as battery eliminator.

4.4 Test discharge readings of voltage, current, temperature, & capacity in ampere hours. Individual cell voltage readings.

4.5 Bus voltage at maximum load current.

4.6 During the separate integrated test, the total load current of safety-related equipment will be recorded.

5.0 ACCEPTANCE CRITERIA

The 125-V DC power system will perform all of the functions described in Section 8.3.2.

Table 14.1-1 (continued)

VITAL AC POWER SYSTEMS

1.0 OBJECTIVE

To demonstrate that an uninterrupted 120-V AC power supply has been provided with an independent power source to each redundant protective channel.

2.0 PREREQUISITES

2.1 Construction activities complete on components to be tested.

2.2 Meters and relays calibrated.

2.3 One battery bank must be operational with charger.

2.4 A normal 480-V supply and an emergency 480-V supply must be available.

2.5 Four distribution panels must be available.

3.0 TEST METHOD

3.1 Control logic verified for each inverter.

3.2 Alarms and tripping devices verified.

3.3 The transfer devices checked.

3.4 Checks for DC grounds made.

4.0 DATA REQUIRED

4.1 Direct current and voltage of each inverter from each power source.

4.2 Alternating current voltage and frequency of each inverter from each power source.

4.3 Verify the alternating current voltage at each of the four distribution panels while the inverters are being fed from each of the three power sources.

5.0 ACCEPTANCE CRITERIA

The vital AC power systems will perform all of the functions outlined in Section 8.3.1.

EMERGENCY DC LIGHTING SYSTEM

1.0 OBJECTIVE

To demonstrate the adequacy of the emergency DC lighting system.

2.0 PREREQUISITES

2.1 Construction activities completed on the items to be tested.

2.2 Containment lighting system operational.

2.3 Auxiliary building lighting system operational.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 Verify that when the normal AC power supply for the containment lighting system is interrupted, the emergency containment lighting system is automatically energized.

3.2 Verify that when the normal AC power supply for the auxiliary building lighting system is interrupted, the emergency auxiliary building lighting system is automatically energized.

4.0 DATA REQUIRED

4.1 Control logic verification.

4.2 Automatic transfer switch transfer time (loss of AC to DC initiation).

4.3 Verify that the lighting systems cannot be energized from two sources simultaneously.

5.0 ACCEPTANCE CRITERIA

The emergency DC lighting system is capable of supplying lighting to the auxiliary building and the containment building upon loss of normal AC.

COMMUNICATION SYSTEMS

1.0 OBJECTIVE

To demonstrate the adequacy of the inplant communications systems to provide communications between vital plant areas and to test the operability of the emergency evacuation alarms.

2.0 PREREQUISITES

2.1 All possible plant equipment that contributes to the ambient noise level should be in operation.

2.2 Construction activities complete on the items to be tested.

3.0 TEST METHOD

3.1 Check the continuity and audibility of the Gai-Tronics phones.

3.2 Check the continuity and audibility of the Pax phones.

3.3 Check the audibility of the sound powered phones.

3.4 Check the audibility of the evacuation alarms in all plant locations.

3.5 Check the audibility of the page from the control room in all plant locations.

3.6 Check the audibility from all plant locations in the control room.

Table 14.1-1 (continued)

4.0 DATA REQUIRED

4.1 Operability of the Gai-Tronics at all locations.

4.2 Audibility of the page in all plant locations.

4.3 Operability of the Pax at all plant locations.

4.4 Operability of the sound powered phones.

4.5 Audibility of reactor building evacuation alarm.

4.6 Audibility of physical plant evacuation alarm.

5.0 ACCEPTANCE CRITERIA

The communications systems will perform the functions of Section 9.5.2.

INTAKE SCREENS AND SCREEN WASH SYSTEM

1.0 OBJECTIVE

To demonstrate the capability of the intake screens and screen wash system to perform the design function of removing debris from the reservoir water prior to use by the service water system.

2.0 PREREQUISITES

2.1 Unit 1 traveling water screens are operational.

2.2 Unit 1 screen wash system is available.

2.3 All associated instrumentation has been calibrated.

2.4 Construction activities are complete on the components to be tested.

3.0 TEST METHOD

3.1 Traveling screen performance will be checked.

3.2 Alarms and interlocks will be verified.

3.3 With the traveling screens in automatic, the screen wash cycle times will be verified.

4.0 DATA REQUIRED

4.1 Conditions under which alarms and interlocks operate.

4.2 Verification of adequate water supply through the screens to the service water pumps.

5.0 ACCEPTANCE CRITERIA

The intake screens and screen wash system operates to provide water to the service water system per Section 9.2.1.

Table 14.1-1 (continued)

SERVICE WATER SYSTEM

1.0 OBJECTIVE

To demonstrate the ability of the service water system to supply cooling water, as designed, under normal and emergency conditions.

2.0 PREREQUISITES

2.1 Instruments calibrated and operational.

2.2 Construction activities complete on items to be tested.

2.3 Emergency pond at normal level.

3.0 TEST METHOD

3.1 Pump performance will be checked.

3.2 Alarms and interlocks will be checked.

3.3 Pump suction will be taken from both the reservoir and the emergency pond.

3.4 Flow verifications will be performed.

3.5 ESF actuation is simulated.

4.0 DATA REQUIRED

4.1 Verification of adequate flow to the components served by the service water system.

4.2 Conditions under which alarms and interlocks actuate.

4.3 Restart of service water pumps following loss of AC power.

4.4 Performance of system during ESF actuation.

5.0 ACCEPTANCE CRITERIA

The service water system will meet the requirements of Section 9.2.1.

EMERGENCY COOLING WATER POND

1.0 OBJECTIVE

To verify the operation of the emergency cooling water pond sluice gates.

2.0 PREREQUISITES

2.1 Construction activities are complete on the sluice gates and emergency cooling water pond.

2.2 Emergency cooling water pond is at normal level.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 Functionally check the operation of the sluice gates both electrically and manually.

3.2 Interlocks will be verified with associated equipment.

4.0 DATA REQUIRED

4.1 Sluice gate performance.

4.2 Conditions under which interlocks actuate.

5.0 ACCEPTANCE CRITERIA

The emergency cooling water pond performs in accordance with Section 9.2.1.

FIRE PROTECTION SYSTEMS

1.0 OBJECTIVE

To demonstrate the ability of the fire protection systems to provide an adequate extinguishing agent to prevent the spread of fire.

2.0 PREREQUISITES

2.1 All associated instrumentation has been calibrated.

2.2 Construction activities are complete on the components to be tested.

2.3 Unit 1 fire pumps are available.

3.0 TEST METHOD

3.1 Alarms and interlocks checked.

3.2 Temperature and smoke sensors actuated where possible.

3.3 Sprinkler and deluge spray patterns verified where possible.

3.4 Fire alarm verified.

4.0 DATA REQUIRED

4.1 Conditions under which alarms and interlocks actuate.

4.2 Sprinkler and deluge spray patterns.

4.3 Fire alarm operability.

4.4 Temperature and smoke sensors operability.

5.0 ACCEPTANCE CRITERIA

The fire protection systems operate as described in Section 9.5.1.

Table 14.1-1 (continued)

COMPONENT COOLING WATER SYSTEM

1.0 OBJECTIVE

Demonstrate the capability of the component cooling water system to supply cooling water through two closed cycle, interconnected loops at a positive pressure to various reactor auxiliary components.

2.0 PREREQUISITES

2.1 Service water system is operational (at least one pump operating).

2.2 Instrumentation has been calibrated.

2.3 Construction activities are complete on items to be tested.

3.0 TEST METHOD

3.1 All manual modes of operation demonstrated, including proper pump/loop verifications.

3.2 All automatic and standby modes verified.

3.3 All alarms and interlocks checked.

3.4 Flow verifications made.

4.0 DATA REQUIRED

4.1 Differential pressure on the CCW heat exchangers (CCW side).

4.2 Pressure and flow measurements in each loop.

4.3 Actuation points of all alarms and interlocks.

5.0 ACCEPTANCE CRITERIA

The component cooling water system operates in accordance with Section 9.2.2.

INSTRUMENT AIR SYSTEM

1.0 OBJECTIVE

To demonstrate the ability of the instrument air system to supply clean, dry instrument air under all postulated conditions.

2.0 PREREQUISITES

2.1 Construction activities complete on items to be tested.

2.2 Instruments calibrated.

2.3 Component cooling water available.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 Check the capacity of the compressors.

3.2 System header pressure will be reduced to demonstrate start of the standby compressor.

3.3 With instrument air dryers in automatic operation, the cycle times and regeneration temperatures will be verified.

3.4 Alarms and interlock setpoints will be checked.

3.5 Air dryer dew point temperatures will be measured.

3.6 Air samples for cleanliness will be made.

4.0 DATA REQUIRED

4.1 Capacity data on compressors.

4.2 Conditions under which alarms and interlocks operate.

4.3 Cycle times and regeneration temperatures of air dryers.

4.4 Air dryer dew point temperatures.

4.5 Air sample results.

5.0 ACCEPTANCE CRITERIA

The instrument air system operates as described in Section 9.3.1.

DRAINS AND SUMPS

1.0 OBJECTIVE

To demonstrate that each drain line is correctly routed to its sump, that the sump pumps operate per design, and all alarms and interlocks actuate properly.

2.0 PREREQUISITE

2.1 Construction activities complete on items to be tested.

2.2 Water available for drain flow path checks.

2.3 Instruments calibrated.

3.0 TEST METHOD

3.1 Alarms and interlocks will be checked.

3.2 Sump water levels will be varied to determine sump pump operating setpoints.

3.3 Water is hosed into drain openings to verify that drains discharge to their designated design points.

Table 14.1-1 (continued)

4.0 DATA REQUIRED

4.1 Sump pump operating data.

4.2 Conditions under which alarms and interlocks operate.

4.3 Discharge point of drains.

5.0 ACCEPTANCE CRITERIA

5.1 Drains discharge at their designed discharge points.

5.2 All alarms and interlocks will function per design.

5.3 Sump pumps operating setpoints are as designed.

CONDENSATE STORAGE AND TRANSFER SYSTEM

1.0 OBJECTIVE

To demonstrate the ability of the condensate storage and transfer system to supply plant makeup water requirements while retaining the necessary volume required to bring the reactor to cold shutdown.

2.0 PREREQUISITES

2.1 Construction activities complete on items to be tested.

2.2 Makeup water plant in service.

2.3 Condensate system in service.

2.4 All associated instrumentation calibrated.

3.0 TEST METHOD

3.1 All manual modes of operation and water storage capabilities will be demonstrated.

3.2 All automatic modes of operation will be functionally verified.

3.3 All alarms and protective devices will be verified.

4.0 DATA REQUIRED

4.1 Automatic level control setpoints.

4.2 Level alarm setpoint initiations.

4.3 Transfer pump operating data.

5.0 ACCEPTANCE CRITERIA

The condensate storage and transfer system will meet the requirements of Section 9.2.6.

Table 14.1-1 (continued)

EMERGENCY DIESEL GENERATOR SYSTEMS

1.0 OBJECTIVE

To demonstrate the capability of the emergency diesel generators and their support equipment to provide emergency power to safely shut down the reactor, remove residual heat, and maintain safe shutdown conditions upon loss of preferred power.

2.0 PREREQUISITES

2.1 All construction activities are complete on items to be tested.

2.2 Provisions for loading the diesel generator are available.

2.3 All associated instrumentation has been calibrated.

3.0 TEST METHOD

3.1 All local/remote, manual/automatic mode combinations will be verified for all support equipment, including the fuel systems starting air and switchgear.

3.2 Manual control and starting of the diesel will be demonstrated and operating parameters monitored.

3.3 Emergency starting conditions will be demonstrated and recorded.

3.4 Load tests will be conducted to verify performance of the units.

3.5 Repetitive starting capability tests will be performed.

4.0 DATA REQUIRED

4.1 Shop test data verification where possible.

4.2 Actual test data traces.

4.3 Running data for all auxiliary equipment.

4.4 Starting and loading sequence timing.

5.0 ACCEPTANCE CRITERIA

Each diesel generator set will perform in accordance with the criteria of Section 8.3.1.1.7.

CONTROL AND COMPUTER ROOM HVAC SYSTEM

1.0 OBJECTIVE

To demonstrate the functional performance of the computer and control room HVAC units to ensure habitability for personnel and equipment under all postulated conditions.

2.0 PREREQUISITES

2.1 Construction activities are complete on all items to be tested.

2.2 All affiliated instrumentation has been calibrated.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 In the manual operating mode, all equipment will be checked, air flows verified, and adequate performance demonstrated.

3.2 In the automatic operating mode, all interlocks will be checked, including operation in the emergency modes resulting from 1) smoke detection or 2) radiation detection or 3) chlorine detection.

4.0 DATA REQUIRED

4.1 Air balancing verification.

4.2 Automatic operation at proper set-points.

5.0 ACCEPTANCE CRITERIA

Provide a suitable environment for personnel and equipment, per Section 9.4.

PLANT COMPUTER SYSTEM

1.0 OBJECTIVES

To verify that all system hardware is installed and operating properly and that all system software responds correctly to external inputs and provides proper outputs to the computer peripheral equipment.

2.0 PREREQUISITES

2.1 All construction and installation activities are completed on the items to be checked.

2.2 Applicable manufacturer's and owner's systems manuals are available.

2.3 Inherent and external test instrumentation is calibrated and available.

3.0 TEST METHOD

3.1 Test programs are to be run and sequenced as specified by the manufacturer to ascertain the reliability of computer systems to perform all required hardware functions.

3.2 External inputs to the system shall be simulated and the outputs measured using the external test instrumentation.

3.3 Computer functional programs shall be verified using proper software and/or control panel inputs, as applicable.

3.4 Alarm and indication functions shall be verified by the computer system instrumentation and/or the external test measurements, as applicable.

Table 14.1-1 (continued)

4.0 DATA REQUIRED

4.1 Hardware operating data.

4.2 Software performance verifications.

5.0 ACCEPTANCE CRITERIA

Plant computer system performance shall be in accordance with Chapter 7.

AUXILIARY BUILDING HVAC SYSTEMS

1.0 OBJECTIVE

To verify the functional performance of the auxiliary building HVAC systems for the non-contaminated areas of the auxiliary building.

2.0 PREREQUISITES

2.1 Construction has been completed on each component system to be tested.

2.2 All associated instrumentation has been calibrated.

3.0 TEST METHOD

3.1 All equipment will be operated in the manual operating modes.

3.2 All standby modes of operation will be demonstrated.

3.3 Air flow balancing data will be verified.

4.0 DATA REQUIRED

4.1 Air flow verification.

4.2 Standby operation at proper setpoints.

5.0 ACCEPTANCE CRITERIA

The auxiliary building HVAC systems perform in accordance with Section 9.4.2.

AUXILIARY BUILDING RADWASTE AREAS HVAC SYSTEMS

1.0 OBJECTIVE

To demonstrate the functional performance of the auxiliary building radwaste area HVAC systems.

Table 14.1-1 (continued)

2.0 PREREQUISITES

2.1 Construction activities are completed on the items to be tested.

2.2 All associated instrumentation has been calibrated.

3.0 TEST METHOD

3.1 In the normal mode, all equipment will be manually run, flows verified, and adequate performance demonstrated.

3.2 All interlocks with ESF equipment will be verified and documented.

3.3 All standby modes of operation will be tested.

4.0 DATA REQUIRED

4.1 Air flow balancing verifications.

4.2 Automatic actuation at the proper setpoints.

5.0 ACCEPTANCE CRITERIA

All equipment performs in accordance with Section 9.4.3.

CONTAINMENT PURGE SYSTEM

1.0 OBJECTIVE

To demonstrate the proper operation of the containment purge system for accessibility to the containment.

2.0 PREREQUISITES

2.1 Construction activities completed on the items to be tested.

2.2 All associated instrumentation has been calibrated.

3.0 TEST METHOD

3.1 All manual modes of operation will be demonstrated, including air flow verifications and adequate operation.

3.2 All automatic modes of operation, including interlocks with radiation monitoring equipment, will be verified.

4.0 DATA REQUIRED

4.1 Operation of all interlocks at proper setpoints.

4.2 Air balancing verification.

Table 14.1-1 (continued)

5.0 ACCEPTANCE CRITERIA

Equipment performs in accordance with Section 9.4.5 to provide accessibility to the containment.

EMERGENCY FEEDWATER SYSTEM

1.0 OBJECTIVE

To demonstrate the ability of the emergency feedwater system to:

1.1 Supply water to the intact steam generator(s) following a main steam line rupture.

1.2 Maintain steam generator water level during periods of reactor power less than 3.5 percent for startup, shutdown, or standby operation.

2.0 PREREQUISITES

2.1 Construction activities are completed on the items to be tested.

2.2 All associated instrumentation is calibrated.

2.3 Plant conditions are such that functional testing is possible.

3.0 TEST METHOD

3.1 All manual modes of operation will be verified on all equipment, including running data on drivers, pumps, and valves.

3.2 All normal, automatic modes of operation will be demonstrated.

3.3 All emergency, automatic modes of operation will be verified through trial operation with minimal simulation.

4.0 DATA REQUIRED

4.1 All initiating setpoint data.

4.2 Complete flow data on both pumps.

4.3 Complete pump driver data during operation.

4.4 Automatic valve operation data.

5.0 ACCEPTANCE CRITERIA

All equipment shall be capable of performing per Section 10.4.9.

Table 14.1-1 (continued)

CONTAINMENT HVAC SYSTEM

1.0 OBJECTIVE

To demonstrate the proper operation of the HVAC portions of the containment cooling system.

2.0 PREREQUISITES

2.1 Construction activities completed on the items to be tested.

2.2 All instrumentation associated with the containment HVAC system has been calibrated.

2.3 Containment at maximum design pressure (for selected portions of test).

2.4 Reactor coolant system at rated design temperature (for selected portions of test).

3.0 TEST METHOD

3.1 All normal modes of operation will be demonstrated, including manual and standby interlocks.

3.2 All automatic modes will be demonstrated including ESF actuations, and operation at maximum designed containment pressure.

3.3 Air flow verifications and system adequacy will be demonstrated at rated RCS temperature.

4.0 DATA REQUIRED

4.1 Air flow and thermal performance verification.

4.2 Interlock setpoint verifications.

4.3 ESF initiation and operation data.

5.0 ACCEPTANCE CRITERIA

The containment HVAC system performs in accordance with Section 9.4.5.

SAMPLING SYSTEMS

1.0 OBJECTIVE

To demonstrate that a specified quantity of representative fluid can be obtained safely at each sample point, as required to provide accurate laboratory chemical and radiochemical analysis.

2.0 PREREQUISITES

2.1 Construction activities complete on the items to be tested.

2.2 Fluid and pressure is available for withdrawing the required liquid samples.

2.3 Instruments associated with the sampling systems are calibrated.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 Fluid is withdrawn from each sample point into the appropriate vessel and/or sample sink.

3.2 Adequate flow is demonstrated from appropriate sample points.

3.3 Alarms and interlocks are checked.

3.4 Sample points will be verified as correct.

4.0 DATA REQUIRED

4.1 Conditions under which alarms and interlocks operate.

4.2 Capability of sampling with adequate flow.

4.3 Sample point verification.

5.0 ACCEPTANCE CRITERIA

5.1 Flow paths are as designed.

5.2 All alarms and interlocks function per design.

5.3 Representative samples can be collected from all sample points.

AUTOMATIC GAS ANALYZER

1.0 OBJECTIVE

To verify the gas analyzer package will automatically monitor hydrogen and oxygen concentrations.

2.0 PREREQUISITES

Sample points are hooked up to the gas analyzer package.

3.0 TEST METHOD

3.1 Check proper operation of the sequence selector for automatic monitoring of inputs.

3.2 Check ability to correctly measure and record known oxygen and hydrogen concentrations.

3.3 Check alarm setpoints.

4.0 DATA REQUIRED

4.1 Oxygen and hydrogen concentrations.

4.2 Alarm setpoints.

5.0 ACCEPTANCE CRITERIA

The automatic gas analyzer shall perform as described in Section 9.3.2.2.3.

Table 14.1-1 (continued)

PENETRATION ROOM VENTILATION SYSTEM

1.0 OBJECTIVE

To demonstrate the ability of the penetration room ventilation system to collect and process containment penetration leakage.

2.0 PREREQUISITES

2.1 Construction activities on the system are completed.

2.2 Construction activities on the associated room are completed.

2.3 All instrumentation has been calibrated.

3.0 TEST METHOD

3.1 All normal modes of operation will be demonstrated, including air flow verifications and interlocks.

3.2 All automatic and standby modes of operation will be demonstrated, including containment isolation system actuation of the system.

3.3 The ability of the system to maintain a slightly negative pressure in the penetration room will be ensured.

4.0 DATA REQUIRED

4.1 Air flow verification.

4.2 Operation of interlocks at the proper setpoints.

4.3 CIS actuation data.

4.4 Room air leakage data.

5.0 ACCEPTANCE CRITERIA

The penetration room ventilation system meets the criteria of Section 6.5.

CIRCULATING WATER SYSTEM

1.0 OBJECTIVE

To demonstrate the ability of the circulating water system to provide a continuous supply of cooling water to the main condensers and return the water to the cooling tower for heat dissipation.

2.0 PREREQUISITES

2.1 Construction activities are complete on the items to be tested.

2.2 Construction activities are complete on the main condenser tube side.

2.3 All associated instrumentation has been calibrated.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 Verify pump flow by measuring motor current and pump head.

3.2 Verify all required alarms and the corresponding actions.

3.3 Simulate high conductivity and verify automatic operation of the blowdown system.

4.0 DATA REQUIRED

4.1 Verification of all trips and alarms.

4.2 Pump operating parameters.

5.0 ACCEPTANCE CRITERIA

The circulating water system performance shall be as described in Section 10.4.5.

MAIN CONDENSER AND AIR REMOVAL SYSTEM

1.0 OBJECTIVE

To demonstrate the ability of the main condenser and air removal system to provide a continuous heat sink for normal operation as well as a sink for the steam dump and bypass system under certain conditions.

2.0 PREREQUISITES

2.1 Construction activities are completed on the items to be tested.

2.2 All associated instrumentation has been calibrated.

2.3 Plant conditions are suitable for condenser vacuum.

3.0 TEST METHOD

3.1 The main condenser will be functionally tested in conjunction with the operation of other systems, including automatic hotwell control.

3.2 The air removal system will be tested in both modes of operation: manual and standby.

4.0 DATA REQUIRED

4.1 Operating data for the condenser exhausters.

4.2 Instrument setpoint data.

5.0 ACCEPTANCE CRITERIA

The main condenser and air removal system shall perform in accordance with Sections 10.4.1 and 10.4.2.

Table 14.1-1 (continued)

CONDENSATE SYSTEM

1.0 OBJECTIVE

To demonstrate the ability of the condensate system to supply water at the required pressure to the main feedwater pumps under all anticipated steady state or transient conditions.

2.0 PREREQUISITES

2.1 All construction activities are completed on the items to be tested.

2.2 All associated instrumentation is calibrated.

2.3 Plant conditions provide for a flow path.

3.0 TEST METHOD

3.1 All normal modes of operations will be verified.

3.2 All standby modes of operation and other interlocks will be demonstrated with minimal simulation.

4.0 DATA REQUIRED

All interlock setpoint initiations.

5.0 ACCEPTANCE CRITERIA

The condensate system shall operate in accordance with the criteria of Section 10.4.7.

FEEDWATER SYSTEM

1.0 OBJECTIVE

To demonstrate the design intent of 2K2A and 2K2B main feedwater pump turbines.

2.0 PREREQUISITES

2.1 Construction complete on the feedwater and condensate system.

2.2 Construction complete on the condenser shell side.

2.3 Construction complete on all required support systems.

2.4 All system instrumentation is calibrated.

2.5 Steam is available to the pump drivers.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 Verify proper operation of the lube oil system.

3.2 Verify proper operation of the feedwater pump turbine turning gear.

3.3 Verify proper valve operation and lineup.

3.4 The feedwater pumps and turbine drivers will be operated as practical.

4.0 DATA REQUIRED

4.1 Gland seal steam pressure.

4.2 Lube oil pressure.

4.3 Feedwater flow and pressure, as obtainable.

4.4 Turbine operating data.

5.0 ACCEPTANCE CRITERIA

The feedwater system operates as described in Section 10.4.7.

FEEDWATER CONTROL SYSTEM

1.0 OBJECTIVE

To verify proper performance of the feedwater control system.

2.0 PREREQUISITES

2.1 Construction activities are complete on the items to be tested.

2.2 Instrumentation has been calibrated.

3.0 TEST METHOD

3.1 Using external test instrumentation, simulate and vary all input signals to the system.

3.2 In automatic control above 15 percent power, verify that the output signals to main and bypass feedwater control valves and also to the feed pump speed setpoints are functionally related to the system's input signals, such as feedwater flow, steam flow and steam generator downcomer water level.

3.3 Verify that at a present value of the steam generator downcomer level, the feedwater control valve is closed automatically.

3.4 Verify that in manual control from the master control panel, feedwater control valve positions and pump speed setpoints are adjusted simultaneously.

Table 14.1-1 (continued)

4.0 DATA REQUIRED

Record the values of signals simulating 15% power and steam generator's downcomer level required to close the feedwater control valve.

5.0 ACCEPTANCE CRITERIA

Feedwater control system shall perform as described in Section 7.7.

EXTRACTION STEAM SYSTEM

1.0 OBJECTIVE

To demonstrate the capability of the bleeder trip valves, the bleeder trip valve bypass drain valves, and the feedwater heater drain valves to operate per design intent.

2.0 PREREQUISITES

2.1 Construction checks complete on those items to be tested.

2.2 Associated instrumentation has been calibrated.

3.0 TEST METHOD

3.1 Alarms and interlocks will be checked.

3.2 Feedwater heater level controls will be verified.

4.0 DATA REQUIRED

4.1 Conditions under which alarms and interlocks operate.

4.2 Performance data on all valves will be taken.

5.0 ACCEPTANCE CRITERIA

The extraction steam system operates in conjunction with other systems in accordance with Section 10.3.

SAFETY INJECTION ACTUATION SYSTEM

1.0 OBJECTIVE

To verify the proper functional performance of the safety injection actuation system.

2.0 PREREQUISITES

2.1 Construction is complete on the items to be tested.

2.2 Instrumentation has been calibrated.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 Using external test instrumentation, monitor the status of all input signals and verify proper operation of the two-out-of-four redundancy circuits generating the Safety Injection Actuation Signal (SIAS).

3.2 Verify generation of SIAS by de-energizing any two circuits within the two-out-of-four matrix.

3.3 Manually block the safety injection actuation system.

3.4 Simulate a variable RCS pressure signal and determine the blocking limits of the system.

4.0 DATA REQUIRED

4.1 Values of all input signals.

4.2 Status of two-out-of-four redundancy circuits as a function of all possible configurations of input signals.

4.3 Status of two-out-of-four redundancy circuits as a function of power loss of any two circuits.

4.4 Value of the SIAS at all possible configurations of the input signals.

4.5 Value of the SIAS blocking removal signal.

5.0 ACCEPTANCE CRITERIA

Safety injection actuation system performance shall be as described in Sections 6.3 and 7.3.

CONTAINMENT ISOLATION ACTUATION SYSTEM

1.0 OBJECTIVE

To verify the proper functional performance of the containment isolation actuation system.

2.0 PREREQUISITES

2.1 Construction is complete on the items to be tested.

2.2 Associated instrumentation is calibrated.

3.0 TEST METHOD

3.1 Using external test instrumentation, monitor the status of all input signals and verify proper operation of the two-out-of-four redundancy circuits generating the containment isolation actuation signal (CIAS).

3.2 Verify generation of CIAS by disconnecting power to any two circuits within the two-out-of-four matrix.

Table 14.1-1 (continued)

4.0 DATA REQUIRED

4.1 Values of all input signals.

4.2 Status of two-out-of-four redundancy circuits as a function of all possible configurations of input signals.

4.3 Status of two-out-of-four redundancy circuits as a function of power loss of any two circuits.

5.0 ACCEPTANCE CRITERIA

Containment isolation actuation system performance shall be as described in Sections 6.2 and 7.3.

CONTAINMENT SPRAY ACTUATION SYSTEM

1.0 OBJECTIVE

To verify the proper functional performance of the containment spray actuation system.

2.0 PREREQUISITES

2.1 Construction activities are complete on the items to be tested.

2.2 Associated instrumentation is calibrated.

3.0 TEST METHOD

3.1 Simulate the SIAS using external test instrumentation, monitor the status of all input signals and verify proper operation of the two-out-of-four redundancy circuits generating the Containment Spray Actuation Signal (CSAS).

3.2 Verify generation of CSAS by disconnecting power to any two circuits within the two-out-of-four matrix.

4.0 DATA REQUIRED

4.1 Values of all input signals.

4.2 Status of two-out-of-four redundancy circuits as a function of all possible configurations of input signals.

4.3 Status of two-out-of-four redundancy circuits as a function of power loss to any two circuits.

5.0 ACCEPTANCE CRITERIA

Containment spray actuation system performance shall be as described in Sections 6.2 and 7.3.

Table 14.1-1 (continued)

CONTAINMENT COOLING ACTUATION SYSTEM

1.0 OBJECTIVE

Verify proper functional performance of the containment cooling actuation system.

2.0 PREREQUISITES

2.1 Construction activities are complete on the items to be tested.

2.2 Associated instrumentation is calibrated.

3.0 TEST METHOD

3.1 Using external test instrumentation, monitor the status of all input signals and verify operation of the two-out-of-four redundancy circuits generating the Containment Cooling Actuation Signal (CCAS).

3.2 Verify generation of CCAS by disconnecting power to any two circuits.

4.0 DATA REQUIRED

4.1 Values of all input signals.

4.2 Status of two-out-of-four redundancy circuits as a function of all possible configurations of input signals.

4.3 Status of two-out-of-four redundancy circuits as a function of power loss of any two circuits.

5.0 ACCEPTANCE CRITERIA

Containment cooling actuation system performance shall be as described in Sections 6.2 and 7.3.

RECIRCULATION ACTUATION SYSTEM

1.0 OBJECTIVE

To verify the proper functional performance of the recirculation actuation system.

2.0 PREREQUISITES

2.1 Construction activities are complete on the items to be tested.

2.2 Associated instrumentation is calibrated.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 Using external test instrumentation monitor the status of all input signals and verify proper operation of the two-out-of-four redundancy circuits generating the Recirculation Actuation Signal (RAS).

3.2 Verify generation of RAS by disconnecting power to any two circuits within the two-out-of-four matrix.

4.0 DATA REQUIRED

4.1 Values of all input signals.

4.2 Status of two-out-of-four redundancy circuits as a function of all possible configurations of input signals.

4.3 Status of two-out-of-four redundancy circuits as a function of power loss to any two circuits.

5.0 ACCEPTANCE CRITERIA

Recirculation actuation system performance shall be as described in Sections 6.2 and 7.3.

MAIN STEAM ISOLATION ACTUATION SYSTEM

1.0 OBJECTIVE

Verify functional performance of the main steam isolation actuation system.

2.0 PREREQUISITES

2.1 Construction activities are complete on the items to be tested.

2.2 Associated instrumentation is calibrated.

3.0 TEST METHOD

3.1 Using external test instrumentation, vary and monitor the status of all input signals and verify proper operation of the two-out-of-four redundancy circuits generating the main steam isolation signal (MSIS).

3.2 Verify generation of MSIS by disconnecting power to any two circuits within the two-out-of-four matrix.

3.3 Verify that MSIS (generated by the logic or by actuation of the remote manual control switch) produces signals to close both main steam isolation valves and both main feedwater isolation valves, stops both main feedwater pumps and stops all four condensate pumps.

3.4 Simulate steam generator pressure and verify that:

a. The pressure setpoint varies as a function of the steam pressure.

b. An automatic MSIS is initiated at a predetermined pressure setpoint.

Table 14.1-1 (continued)

4.0 DATA REQUIRED

4.1 Values of all input signals.

4.2 Status of two-out-of-four redundancy circuits as a function of all possible configurations of input signals and power losses.

4.3 Steam pressure generating automatic MSIS.

5.0 ACCEPTANCE CRITERIA

Main steam isolation actuation system performance shall be as described in Sections 7.3 and 10.3.

EMERGENCY FEEDWATER ACTUATION SYSTEM

1.0 OBJECTIVE

To verify proper functional performance of the emergency feedwater actuation system.

2.0 PREREQUISITES

2.1 Construction activities are complete on the items to be tested.

2.2 Associated instrumentation is calibrated.

3.0 TEST METHOD

3.1 Using external test instrumentation, vary and monitor the status of all input signals and verify proper operation of the two-out-of-four redundancy circuits generating the Emergency Feedwater Actuation Signal (EFAS).

3.2 Verify generation of EFAS by disconnecting power to any two circuits within the two-out-of-four matrix.

4.0 DATA REQUIRED

4.1 Values of all input signals.

4.2 Status of two-out-of-four redundancy circuits as a function of all possible configurations of input signals and power losses.

5.0 ACCEPTANCE CRITERIA

Emergency feedwater actuation system performance shall be as described in Sections 7.3 and 10.4.

Table 14.1-1 (continued)

INTEGRATED ENGINEERED SAFETY FEATURES ACTUATION

1.0 OBJECTIVE

To demonstrate the full operational sequence of the engineered safety features actuation system including the capability of each individual emergency diesel generator and its support equipment, to provide the required safeguards equipment during a simulated accident condition coupled with a loss of offsite power and subsequent transfer to alternate power sources.

2.0 PREREQUISITES

2.1 All construction activities are completed on items to be tested.

2.2 Provisions for loading the diesel generators are available.

2.3 All systems actuated by the engineered safety features actuation system should have their individual functional tests completed.

2.4 Individual engineered safety features preoperational and calibration tests completed.

3.0 TEST METHOD

3.1 One diesel generator will be disabled from automatic start.

3.2 The AC and DC systems for the associated diesel generator will be placed out of service.

3.3 The onsite distribution system will be divorced from the switchyard by opening breakers as required.

3.4 A simulated accident signal will be inserted into the plant protective circuitry.

3.5 Actuate all combinations of the engineered safety feature channels on emergency power sources.

3.6 Steps 3.1 through 3.5 will be repeated using the other diesel generator.

3.7 Actuate all combinations of the emergency safety feature channels on the normal engineered safety feature power sources.

4.0 DATA REQUIRED

4.1 Actual test data traces.

4.2 Starting and loading sequence timing.

4.3 Monitoring of all load groups.

4.4 Engineered safety features flows.

4.5 Diesel generator output.

Table 14.1-1 (continued)

5.0 ACCEPTANCE CRITERIA

5.1 The Engineered Safety Features System (ESFS) in conjunction with the normal and emergency electrical power systems, responds as described in Chapter 6 and Sections 7.3, 8.3.1.1.7 and 10.4.9.

5.2 Each diesel generator set energizes only its required load groups.

SHUTDOWN COOLING SYSTEM

1.0 OBJECTIVE

To functionally test the operation of the components within the shutdown cooling system.

2.0 PREREQUISITES

2.1 Refueling water tank is available for use.

2.2 Reactor vessel head is removed.

2.3 Reactor vessel is at a level above the hot leg nozzles.

3.0 TEST METHOD

3.1 LPSI pumps will be operated in the shutdown cooling mode.

3.2 Interlocks will be tested for proper operation.

3.3 Flow control valve functions will be demonstrated.

4.0 DATA REQUIRED

4.1 Reactor vessel water level shutdown cooling flow, and LPSI pump discharge pressure and suction pressures.

4.2 Interlock actuation setpoints.

5.0 ACCEPTANCE CRITERIA

The shutdown cooling system operates as described in Section 9.3.6.

HIGH PRESSURE SAFETY INJECTION SYSTEM

1.0 OBJECTIVE

To demonstrate proper functional performance of the high pressure safety injection system to the RCS.

2.0 PREREQUISITES

2.1 Construction activities are completed on those items to be tested.

2.2 HPSI ESF valves are lined up in normal operating position.

2.3 Reactor vessel head removed.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 Test each HPSI pump individually.

3.2 Simulate an ESF signal to the HPSI system.

3.3 Verify proper valve operation and pump performance.

3.4 Check all pump flow paths.

4.0 DATA REQUIRED

4.1 Record HPSI pump flow through loop A and loop B.

4.2 Record HPSI pump response time.

4.3 Record HPSI valve response time.

5.0 ACCEPTANCE CRITERIA

The high pressure safety injection system operates as described in Section 6.1.2.

SAFETY INJECTION TANKS

1.0 OBJECTIVE

To demonstrate that the flow path from the safety injection tanks to the reactor vessel is free from obstruction by discharging water from the tanks to the reactor vessel, and to functionally test the safety injection tank level and pressure instrumentation.

2.0 PREREQUISITES

2.1 Construction activities are completed on the items to be tested.

2.2 All associated instrumentation calibrations are completed.

2.3 Reactor vessel to pool seal is installed.

2.4 Reactor vessel filled above the hot leg nozzles.

3.0 TEST METHOD

3.1 Discharge the tanks into the open reactor vessel to verify valve operability.

3.2 Check level and pressure alarm actuation.

3.3 Record operating data on electrically operated valves.

3.4 Check tank isolation valve/pressurizer pressure interlock.

Table 14.1-1 (continued)

4.0 DATA REQUIRED

4.1 Safety injection tank level and pressure.

4.2 Valve operating data.

4.3 Time required for safety injection tanks to empty, as a function of safety injection tank level.

4.4 Setpoint data.

5.0 ACCEPTANCE CRITERIA

The safety injection tanks operate as described in Section 6.1.2.

LOW PRESSURE SAFETY INJECTION SYSTEM

1.0 OBJECTIVE

To demonstrate that the low pressure safety injection system operates per design.

2.0 PREREQUISITES

2.1 Construction activities completed on items to be tested.

2.2 Reactor pressure head removed.

2.3 ESF valves lined up in normal operating position.

3.0 TEST METHOD

3.1 Test each LPSI pump individually.

3.2 Simulate an ESF signal to the LPSI system.

3.3 Verify proper valve operation.

3.4 Check all pump flow paths.

4.0 DATA REQUIRED

4.1 Record LPSI pump flows and response times.

4.2 Record ESF valve response time.

4.3 Record all instrument setpoint data.

5.0 ACCEPTANCE CRITERIA

The low pressure safety injection system operates in accordance with Section 6.1.2.

Table 14.1-1 (continued)

REED SWITCH ACTUATION SYSTEM

1.0 OBJECTIVE

To verify proper operation of the reed switch actuation system CEA position-indicating system.

2.0 PREREQUISITES

2.1 Construction activities are completed on the items to be tested.

2.2 External test instrumentation calibrated.

2.3 CRT and CEA position indication is installed and calibration checks complete.

3.0 TEST METHOD

3.1 Using external test instrumentation, simulate the CEA position as determined by the Reed Switch string.

3.2 Monitor the CRT for proper indication.

3.3 Monitor the input signal to the CEA calculators.

4.0 DATA REQUIRED

Record CRT indication and CEA calculator inputs for various simulated signals.

5.0 ACCEPTANCE CRITERIA

The reed switch (CEA position-indicating system) actuation system shall perform as described in Sections 7.2 and 7.5.

CEDM CONTROL SYSTEM

1.0 OBJECTIVE

To verify proper operation of the Control Element Drive Mechanism Control System (CEDS) for all operating modes.

2.0 PREREQUISITES

2.1 Construction activities are complete on items to be tested.

2.2 Test instrumentation is calibrated.

2.3 Special CEDS test box is available.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 Connect cables for CEDM control circuits to be tested to test box.

3.2 Operate CEDS in various modes. Simulate necessary signals using external test instrumentation.

3.3 Check proper operation of digital CEA position indication.

4.0 DATA REQUIRED

4.1 Digital position and operating time.

4.2 Verification of proper operation for each CEDM control circuit in all modes.

5.0 ACCEPTANCE CRITERIA

The CEDM control system shall operate as described in Section 7.7.

REACTOR TRIP CIRCUIT BREAKERS

1.0 OBJECTIVE

To verify proper reactor trip circuit breaker performance upon initiation of manual or automatic trip signals.

2.0 PREREQUISITES

2.1 Construction activities are complete on all items to be tested.

2.2 Installed instrumentation is calibrated.

3.0 TEST METHOD

3.1 Simulate automatic trip signals from the plant protection system.

3.2 Manually actuate the reactor trip circuit breakers by the remote manual trips.

3.3 Actuate the reactor trip circuit breakers by the local emergency trips.

4.0 DATA REQUIRED

Record circuit breaker operation for the various initiating sources.

5.0 ACCEPTANCE CRITERIA

Reactor trip circuit breakers shall perform as described in Section 7.2.

Table 14.1-1 (continued)

PLANT PROTECTION SYSTEM

1.0 OBJECTIVE

To verify that the plant protection system is properly installed, calibrated, and ready for operation.

2.0 PREREQUISITES

2.1 All construction activities are completed.

2.2 Necessary technical manuals are available.

2.3 External test instrumentation is calibrated and available.

3.0 TEST METHOD

3.1 Verify that the operation of each trip unit is at the correct setpoint.

3.2 Check the operation of trip bypass features.

3.3 Verify that the trip bypasses are cancelled automatically at the proper setpoint, where applicable.

3.4 Check that high power and low steam generator pressure trip setpoints track the process variable in the conservative direction and can be manually reset to the proper margin above the process variable.

3.5 Verify that the installed testing devices operate properly.

3.6 Verify that the various combinations of 2 of 4 logic will trip the reactor trip circuit breakers.

3.7 Verify that response time of the reactor trip system is acceptable.

3.8 Verify proper operation of interlock features.

3.9 Check the proper alarm actuation.

3.10 Verify the proper actuation of ESF signals upon actuation of appropriate trip units.

4.0 DATA REQUIRED

4.1 Point of actuation of trip units.

4.2 Reset margin of variable setpoints.

4.3 Maximum and minimum values of variable setpoints.

4.4 Response time of reactor trip system.

5.0 ACCEPTANCE CRITERIA

The plant protection system shall operate as described in Sections 7.1, 7.2, 7.3, and 7.4.

Table 14.1-1 (continued)

CORE PROTECTION CALCULATOR SYSTEM

1.0 OBJECTIVE

To verify proper functional performance of the Core Protection Calculator (CPC) system.

2.0 PREREQUISITES

2.1 Construction activities are complete on the items to be tested.

2.2 CPC test panel is operable.

2.3 Associated instrumentation has been calibrated.

3.0 TEST METHOD

3.1 Using external test instrumentation, simulate all signals required to generate high local power density (HLPD) and low departure from nucleate boiling ratio (LDNBR) trips.

3.2 Verify that audible and visual pre-trip alarms are obtained when trip conditions are approached in both (HLPD and LDNBR) cases.

3.3 Using the CPC test panel, repeat the above test 3.2.

3.4 Verify that in case of loss of power, the CPC system will assume a fail-safe state.

4.0 DATA REQUIRED

4.1 Values of input signals generating pre-trip indications and trip actions.

4.2 Values of output signals representing pre-trip and trip conditions.

4.3 Status of the system in case of a power failure.

5.0 ACCEPTANCE CRITERIA

Core protection calculator system performance shall be described in Section 7.2, CEN-57(A), CEN-58(A), CEN-67(A), CEN-44(A), CEN-45(A), CEN-63(A) and the CPC Technical Manual.

CORE OPERATING LIMIT SUPERVISORY SYSTEM

1.0 OBJECTIVE

To verify the proper operation of the Core Operating Limit Supervisory System (COLSS).

2.0 PREREQUISITES

2.1 Construction activities are complete on the items to be tested.

2.2 Associated instrumentation has been calibrated.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 Using simulated test signals, vary the inputs of all parameters required for the monitoring of peak-linear heat rate, margin to DNB, total core power and aximuthal flux tilts.

3.2 Varying simulated inputs, verify the following:

a. Reactor core power indication and its operating limits indication.

b. Margin indications between reactor core power and the nearest reactor core power operating limit.

c. Alarms initiated by the reactor core power operating limits or excessive azimuthal flux tilts.

4.0 DATA REQUIRED

Record values of all simulated input signals providing operating limits, alarms and reactor trips.

5.0 ACCEPTANCE CRITERIA

The core operating limit supervisory system shall perform as described in Section 7.7.

CEA CALCULATOR SYSTEM

1.0 OBJECTIVE

To verify proper functional performance of the CEA calculator system.

2.0 PREREQUISITES

2.1 Construction activities are complete on the items to be tested.

2.2 Associated instrumentation has been calibrated.

3.0 TEST METHOD

3.1 Test hardware functions by input signal simulation and performance of hardware diagnostic tests which verify protected memory integrity and CPU, ALU and I/O system operability.

3.2 Test software functions by performance of system test cases which calculate deviation data, CEA sensor failures and penalty factors.

3.3 Verify system annunciators by software input of data simulating alarm conditions.

3.4 Verify system redundancy and CEAC-CPC data link operability by outputting penalty factors to each CPC.

4.0 DATA REQUIRED

Values of the inputs in 3.3 above generating alarm conditions.

Table 14.1-1 (continued)

5.0 ACCEPTANCE CRITERIA

The CEA calculator system shall perform as described in Section 7.2.

CONTAINMENT POLAR CRANE

1.0 OBJECTIVE

Verify the functional performance of the containment polar crane.

2.0 PREREQUISITES

2.1 Electric power available.

2.2 Instrumentation available and calibrated.

2.3 Construction activities are complete on the crane and associated equipment.

3.0 TEST METHOD

3.1 Verify operability of trolley, bridge, and hoist.

3.2 Check hoist and trolley speeds.

3.3 Check capability of crane to position over all required containment building equipment.

4.0 DATA REQUIRED

4.1 Hoist and trolley speeds.

4.2 Verification of proper operation of interlocks.

5.0 ACCEPTANCE CRITERIA

5.1 All interlocks operate as required.

5.2 Hoist and trolley speeds are within specification limits.

5.3 Crane can position over all required equipment.

CONTAINMENT INTEGRATED LEAK RATE TEST

1.0 OBJECTIVE

To verify that the potential leakage from the containment is within acceptable values as stated in the Technical Specifications.

2.0 PREREQUISITES

2.1 Containment penetrations are installed.

2.2 Containment ventilation system, personnel lock, and isolation valves are operable.

2.3 Structural integrity test is complete.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 Penetration tests shall be performed at peak design pressure using one of the following accepted methods: halogen gas detection, soap bubbles, pressure decay, hydrostatic flow or equivalent. Quantitative measurements will also be made.

3.2 The containment leak rate will be determined at calculated peak accident pressure and at one-half calculated peak accident pressure. Leakage will be verified by reference vessel method and/or absolute pressure method. Test accuracy shall be verified by supplementary means, such as measuring the quantity of air required to return to the starting point (pump back) of by imposing a known leak (known leak) rate to demonstrate the validity of measurement.

4.0 DATA REQUIRED

4.1 Individual penetration leak data.

4.2 Integrated leak rate data: pressure and humidity

4.3 Reference vessel temperature and pressure

4.4 Atmospheric pressure and temperature

4.5 "Known leakage" and/or "pump back" air flow

5.0 ACCEPTANCE CRITERIA

The leak rates must not exceed the allowable limits given in the Technical Specifications.

CONTAINMENT STRUCTURAL INTEGRITY TEST

1.0 OBJECTIVE

To demonstrate and verify the structural integrity of the containment building at 115% of design pressure.

2.0 PREREQUISITES

2.1 Construction activities are completed on the containment.

2.2 The equipment hatch, personnel hatch and escape hatch have been installed and are sealed.

3.0 TEST METHOD

3.1 The internal pressure in the containment building will be increased from atmospheric pressure to 1.15 times the postulated maximum loss-of-coolant accident pressure in at least four approximately equal increments and depressurized in the same increments.

3.2 At each pressure level, during pressurization and depressurization, data will be recorded to ascertain the radial and vertical displacement of the reactor building.

Table 14.1-1 (continued)

3.3 Crack patterns and crack widths shall be observed on its exterior surface at prescribed locations of high stress.

3.4 A visual inspection of the containment hatches, penetrations and gaskets will be made.

4.0 DATA REQUIRED

4.1 The readings of strain gauges, load cells and deflection rods will be recorded at selected pressure levels.

4.2 Selected areas of the exterior concrete surface shall be visually examined for cracking due to pressurization.

4.3 The displacement of the linear plate between anchor points shall be monitored at selected locations.

5.0 ACCEPTANCE CRITERIA

5.1 The structure is capable of withstanding an internal pressure of 1.15 times the design pressure.

5.2 The radial and vertical displacement of the structure is within the limits predicted by analyses.

5.3 Crack patterns and widths exhibit no unexpected response to the test.

5.4 The structure responds as described in Section 3.8.1.5.

CONTAINMENT SPRAY SYSTEM

1.0 OBJECTIVE

To functionally check the operation of the reactor building spray system, including the performance of the containment spray pumps, and to verify that the spray nozzles are free from obstructions.

2.0 PREREQUISITES

2.1 Construction activities are complete on the items to be tested.

2.2 Refueling water tank available.

2.3 Flow indicating sensors available for all spray nozzles.

2.4 Instruments are calibrated.

3.0 TEST METHOD

3.1 Flow will be established with each spray pump by recirculating water from the refueling water tank.

3.2 Pump performance will be checked.

3.3 Alarms will be checked.

3.4 Service air will be used to establish air flow in each spray header and flow will be verified from each nozzle.

Table 14.1-1 (continued)

4.0 DATA REQUIRED

4.1 Pump suction and discharge pressures versus flow rate.

4.2 Observation of flow through each spray nozzle.

4.3 Conditions under which alarms actuate.

5.0 ACCEPTANCE CRITERIA

The containment spray system will perform in accordance with Section 6.2.2.

VIBRATION AND LOOSE PARTS MONITORING SYSTEM

1.0 OBJECTIVE

To demonstrate that the vibration and loose parts monitoring system is properly installed, calibrated and ready for operation.

2.0 PREREQUISITES

2.1 Vibration and loose parts monitor panel is installed and construction activities are complete.

2.2 Sensors and preamplifiers are installed and operable.

2.3 X-Y plotter and chart recorder have been calibrated.

2.4 Spectrum analyzer has been checked for proper operation in accordance with technical manual.

2.5 Tape recorder is operable.

2.6 External test instrumentation is available and calibrated.

3.0 TEST METHOD

3.1 Measure and record all power supply voltages.

3.2 Utilizing external test instrumentation apply a known input signal and measure the resulting output signal. Vary the input signal until an alarm occurs.

3.3 Using the installed tape recorder, record and play back various frequencies.

3.4 Utilizing a known weight and pendulum, simulate a loose part at the sensor. Record resulting signal.

3.5 Verify automatic tape recorder start on alarm condition.

4.0 DATA REQUIRED

4.1 Power supply voltages.

4.2 Output versus input signal in all channels. Value of input signal that causes an alarm.

4.3 Chart recording of simulated loose part.

Table 14.1-1 (continued)

5.0 ACCEPTANCE CRITERIA

The vibration and loose parts monitoring system shall operate in accordance with design.

STEAM GENERATOR BLOWDOWN SYSTEM

1.0 OBJECTIVE

To demonstrate that the steam generator blowdown system is ready for operation.

2.0 PREREQUISITES

2.1 All associated instrumentation has been calibrated.

2.2 Construction activities on the components are complete.

2.3 Electrical power and instrument air are available.

3.0 TEST METHOD

3.1 Check the response of remotely operated valves.

3.2 Collect operating data on the blowdown tank drain pumps, condensate recycle pumps, and demineralizer regeneration pumps.

3.3 Verify open flow paths for steam generator blowdowns and subsequent condensate recycle.

3.4 Check the flow paths for regenerating resin.

3.5 Check the proper operation of pump, valve controls, and system instrumentation.

4.0 DATA REQUIRED

4.1 Pump operating data.

4.2 Valve position indication and opening and/or closing times on critical valve.

5.0 ACCEPTANCE CRITERIA

The steam generator blowdown system operates as described in sections 10.4.8 and 10.4.10.

REACTOR COOLANT LETDOWN SYSTEM

1.0 OBJECTIVE

To demonstrate that components in the reactor coolant letdown system are operable and meet design requirements.

Table 14.1-1 (continued)

2.0 PREREQUISITES

2.1 Construction activities on associated items are complete.

2.2 Associated instrumentation has been calibrated.

3.0 TEST METHOD

3.1 Check the response of both letdown control valves to a simulated automatic pressurizer level error signal and to a manual signal.

3.2 Check the response of both letdown backpressure valves to a simulated automatic pressure error signal and to a manual signal.

3.3 Check the proper operation of other remotely operated letdown valves.

4.0 DATA REQUIRED

4.1 Valve position indication and opening and/or closing on critical valves.

4.2 Valve responses versus simulated signal for letdown control valves and letdown backpressure valves.

5.0 ACCEPTANCE CRITERIA

5.1 Valve opening and closing times in agreement with specifications.

5.2 Valve indication working correctly.

5.3 Letdown control and backpressure valves give correct responses to simulated signals.

REACTOR COOLANT CHARGING SYSTEM

1.0 OBJECTIVE

To demonstrate the operation of the components in the reactor coolant charging system.

2.0 PREREQUISITES

2.1 Construction activities are complete on the items to be tested.

2.2 Associated instrumentation has been calibrated.

2.3 Charging pumps are operational.

2.4 Volume control tank system is available.

3.0 TEST METHOD

3.1 Check the proper operation of remotely operated valves.

3.2 Check the charging pump controls response to a simulated pressurizer level error signal.

3.3 Verify charging pump operation.

3.4 Demonstrate the charging pump seal lubrication system.

Table 14.1-1 (continued)

4.0 DATA REQUIRED

4.1 Valve position indication and opening and/or closing times on critical valves.

4.2 Charging pump running data.

4.3 Charging pump seal lubrication data.

5.0 ACCEPTANCE CRITERIA

The reactor coolant charging system performs in accordance with Section 9.3.4.

VOLUME CONTROL TANK

1.0 OBJECTIVE

To demonstrate that the volume control tank and associated components operate as designed.

2.0 PREREQUISITES

2.1 Construction activities are complete on the items to be tested.

2.2 All associated instrumentation has been calibrated.

2.3 Reactor coolant charging system is operational.

3.0 TEST METHOD

3.1 Check the proper operation of remotely operated valves.

3.2 Fill and drain the volume control tank and check the operation of alarms, nitrogen pressurization, letdown dump valve, auto makeup, and transfer of charging pump suction to refueling water tank.

3.3 Check the operation ESF components to simulated ESF signal.

4.0 DATA REQUIRED

4.1 Valve opening and closing times and proper indication.

4.2 Valve and alarm response versus volume control tank level.

4.3 Nitrogen pressure versus volume control tank level.

5.0 ACCEPTANCE CRITERIA

The volume control tank and associated equipment perform in accordance with Section 9.3.4.

Table 14.1-1 (continued)

REACTOR COOLANT PURIFICATION SYSTEM

1.0 OBJECTIVE

To demonstrate that components in the reactor coolant purification system operate as designed.

2.0 PREREQUISITES

2.1 Construction activities complete on the items to be tested.

2.2 All associated instrumentation has been calibrated.

3.0 TEST METHOD

3.1 Check the response of remotely operated valves.

3.2 Check the ability to change out the filter elements remotely.

3.3 Check the paths open to replace resin.

4.0 DATA REQUIRED

4.1 Valve position indication and opening and/or closing times on critical valves.

4.2 Quantitative purification data.

5.0 ACCEPTANCE CRITERIA

The reactor coolant purification system meets the requirements of Section 9.3.4.

BORIC ACID ADDITION SYSTEM

1.0 OBJECTIVE

To test the components and design functions of the boric acid addition system.

2.0 PREREQUISITES

2.1 Associated instrumentation has been calibrated.

2.2 Construction activities complete on items to be tested.

2.3 Volume control tank is operational.

3.0 TEST METHOD

3.1 Check the proper operation of all remotely operated valves and level alarms in the boric acid addition system.

3.2 Collect operating data during initial boric acid makeup pump runs.

Table 14.1-1 (continued)

3.3 Check the ability of the boric acid makeup pumps to provide water to the volume control tank and the charging pump suction header, to recirculate makeup tank contents, to pump from one makeup tank to the other, and to supply makeup to the refueling water tank.

4.0 DATA REQUIRED

4.1 Valve position indication and opening and/or closing times on critical valves.

4.2 Tank level versus alarm initiation.

4.3 Boric acid makeup pumps initial run data.

4.4 Valve and pump response to various positions of the makeup mode selector switch.

5.0 ACCEPTANCE CRITERIA

The boric acid addition systems meets the requirements of Section 9.3.4.

BORIC ACID BATCHING SYSTEM

1.0 OBJECTIVE

To demonstrate that the boric acid batching system meets the design requirements.

2.0 PREREQUISITES

2.1 Construction activities are complete on items to be tested.

2.2 Associated instrumentation has been calibrated.

2.3 Boric acid makeup tanks are operational.

2.4 Heaters are operational.

3.0 TEST METHOD

3.1 Fill the batching tank and check capacity of the heaters and operability of the temperature controller and mixer.

3.2 Drain the tank to each boric acid makeup tank.

4.0 DATA REQUIRED

4.1 Heatup rates.

4.2 Setpoint of temperature controller.

5.0 ACCEPTANCE CRITERIA

The boric acid batching system meets the requirements of Section 9.3.4.

Table 14.1-1 (continued)

CHEMICAL ADDITION SYSTEM

1.0 OBJECTIVE

To demonstrate that the chemical addition system operates per design.

2.0 PREREQUISITES

2.1 Construction activities are complete on items to be tested.

2.2 Associated instrumentation has been calibrated.

2.3 Charging system is operable.

3.0 TEST METHOD

3.1 All manual modes of chemical addition will be verified.

3.2 All automated modes of chemical addition will be demonstrated including verification of proper flows to charging pump suction.

4.0 DATA REQUIRED

4.1 All instrument setpoint verifications.

4.2 Flow data to charging pump suction.

5.0 ACCEPTANCE CRITERIA

The chemical addition system operates in accordance with the specifications of Section 9.3.4.

REACTOR MAKEUP WATER STORAGE AND TRANSFER SYSTEM

1.0 OBJECTIVE

To demonstrate that the reactor makeup waste storage and transfer system is operational.

2.0 PREREQUISITES

2.1 Construction activities complete on items to be tested.

2.2 Demineralized water is available.

2.3 Associated instrumentation has been calibrated.

3.0 TEST METHOD

3.1 Check the proper operation of makeup water tank level alarms and demineralized water inlet valve.

3.2 Collect operating data during initial reactor makeup water pump runs.

3.3 Check for unobstructed flow through all pump discharge paths.

Table 14.1-1 (continued)

4.0 DATA REQUIRED

4.1 Valve position indication and opening and/or closing times on critical valves.

4.2 Tank level versus alarm initiation.

4.3 Reactor makeup water pumps initial run data.

5.0 ACCEPTANCE CRITERIA

The reactor makeup water storage and transfer system operates in accordance with Section 9.3.4.

PROCESS RADIATION MONITORS

1.0 OBJECTIVE

To verify that the process radiation monitors installed in the reactor coolant letdown system, component cooling water system, service water system, steam generator blowdown system, and liquid radwaste system are ready for operation.

2.0 PREREQUISITES

2.1 The radiation monitor to be tested has been installed and construction activities are complete.

2.2 The radiation monitor has been calibrated.

2.3 Check source(s) are available.

2.4 External test instrumentation is available and calibrated.

3.0 TEST METHOD

3.1 Utilizing the check source and external test equipment, verify calibration and operation of the monitor.

3.2 Check the self-testing feature of the monitor.

3.3 Where applicable, verify proper control actuation by the monitor and record the response time.

3.4 Verify proper alarm actuation in the control room.

4.0 DATA REQUIRED

4.1 The monitor response to check source.

4.2 Technical data associated with the source.

4.3 The monitor response to test signals.

4.4 Signals necessary to cause alarm actuation.

4.5 Response time of the monitor to perform control functions.

Table 14.1-1 (continued)

5.0 ACCEPTANCE CRITERIA

The various process radiation monitors will perform as described in Section 11.4.2.1.

PRESSURIZER PRESSURE CONTROL SYSTEM

1.0 OBJECTIVE

To verify proper functional performance of the pressurizer pressure control system.

2.0 PREREQUISITES

2.1 Construction activities are complete on items to be tested.

2.2 Associated instrumentation has been calibrated.

3.0 TEST METHOD

3.1 Using external test instrumentation, simulate variations in pressurizer pressure and verify the following control functions for each channel:

a. Below low-pressure setpoint, signal will energize all heaters.

b. Above low-pressure setpoint, small group of heaters will be proportionally controlled as a function of pressure variations.

c. Above high-pressure setpoint, the spray valve position is proportionally controlled as a function of pressure variation signal.

4.0 DATA REQUIRED

4.1 Setpoint value for all heaters-energized condition.

4.2 Proportionality values signal to proportional heaters versus pressure function.

4.3 Setpoint value for high pressure condition.

4.4 Proportionality values signal to spray valves versus pressure function.

5.0 ACCEPTANCE CRITERIA

Pressurizer pressure control system performance shall be as described in Section 5.6.

Table 14.1-1 (continued)

PRESSURIZER RELIEF AND QUENCH TANK SYSTEM

1.0 OBJECTIVE

To demonstrate the functional performance of the pressurizer relief and quench tank system.

2.0 PREREQUISITES

2.1 Construction activities are complete on items to be tested.

2.2 Associated instrumentation has been calibrated.

2.3 Reactor makeup water is available.

3.0 TEST METHOD

3.1 Check the proper operation of all remotely operated valves.

3.2 Raise and lower the quench tank level and verify the level alarm.

4.0 DATA REQUIRED

4.1 Valve position indication and opening and/or closing times on critical valves.

4.2 Quench tank level alarms versus level.

4.3 Instrument setpoint verifications.

5.0 ACCEPTANCE CRITERIA

The pressurizer relief and quench tank system operates in accordance with Section 5.5.11.

PRESSURIZER SAFETY VALVE BENCH TEST

1.0 OBJECTIVE

To verify the setpoints of the pressurizer safety valves.

2.0 PREREQUISITES

2.1 A lifting device and associated support equipment is available.

2.2 The plant is in hot functional testing with the RCS at normal operating pressure and temperature.

3.0 TEST METHOD

3.1 With the pressurizer at normal operating pressure, increase the hydroset pressure until the safety valve starts to simmer.

3.2 With the safety valve simmering, reduce the hydroset pressure until the safety valve seats.

Table 14.1-1 (continued)

4.0 DATA REQUIRED

Pressure at which the safety valves start to open and close.

5.0 ACCEPTANCE CRITERIA

Safety valve lifting setpoints are 2485 psig ± 25 psig, as described in Section 5.5.13.

REACTOR REGULATING SYSTEM

1.0 OBJECTIVE

To demonstrate functional performance of the reactor regulating system.

2.0 PREREQUISITES

2.1 Construction activities are complete on items to be tested.

2.2 Associated instrumentation has been calibrated.

3.0 TEST METHOD

Utilizing installed test equipment, vary each input parameter to verify proper outputs of specified control programs, which provide power reference signals to the reactor coolant average temperature programmer and the direction and rate signals to the CEA drives.

4.0 DATA REQUIRED

Values of programmed outputs as a function of input parameter variations.

5.0 ACCEPTANCE CRITERIA

Reactor regulating system performance is as described in Section 7.7.

SPENT FUEL COOLING SYSTEM

1.0 OBJECTIVE

To verify the functional operation of the spent fuel cooling system.

2.0 PREREQUISITES

2.1 Construction activities completed on all items to be tested.

2.2 Associated instrumentation has been calibrated.

2.3 Fuel pool filled with water.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 Check flow path and pump capacity.

3.2 Collect operating data on the pumps.

3.3 Check operability of pump low pressure alarms.

4.0 DATA REQUIRED

4.1 Fuel pool pumps operating data.

4.2 Low pressure alarm setpoint.

5.0 ACCEPTANCE CRITERIA

The spent fuel cooling system operates as described in Section 9.1.3.

HOLDUP TANK SYSTEM

1.0 OBJECTIVE

To demonstrate that the holdup tank system operates as designed.

2.0 PREREQUISITES

2.1 Construction activities are complete on items to be tested.

2.2 Associated instrumentation has been calibrated.

2.3 Gaseous waste system is available.

3.0 TEST METHOD

3.1 Check the proper operation of remotely operated valves.

3.2 Verify the operability of the holdup tank level alarms.

3.3 Verify the operability of the holdup tank pressure alarms.

3.4 Collect operating data during initial run of holdup tank recirculation and drain pumps.

3.5 Demonstrate pump start and stop interlocks.

3.6 Verify pump and tank flow paths.

3.7 Check operability of pressure regulators.

4.0 DATA REQUIRED

4.1 Valve position indication and opening and/or closing times on critical valves.

4.2 Holdup tank level alarms setpoint.

4.3 Holdup tank pressure versus pressure alarms setpoint.

4.4 Holdup tank recirculation and drain pumps initial run data.

Table 14.1-1 (continued)

5.0 ACCEPTANCE CRITERIA

The holdup tank system operates in accordance with Section 11.2.

REACTOR DRAIN TANK SYSTEM

1.0 OBJECTIVE

To demonstrate the functional performance of the reactor drain tank system.

2.0 PREREQUISITES

2.1 Construction activities are complete on items to be tested.

2.2 Associated instrumentation has been calibrated.

2.3 Holdup tank system is available.

2.4 Gaseous waste system is available.

3.0 TEST METHOD

3.1 Check the proper operation of remotely operated valves.

3.2 Raise and lower the reactor drain tank level and verify the level alarms.

3.3 Collect operating data during initial reactor drain pump runs.

3.4 Check the reactor drain pump interlocks on reactor drain tank level and suction valve position.

4.0 DATA REQUIRED

4.1 Valve position indication and opening and/or closing times on critical valves.

4.2 Reactor drain tank level versus level alarms and reactor drain pump interlocks.

4.3 Reactor drain pumps initial run data.

5.0 ACCEPTANCE CRITERIA

The reactor drain tank system operates as described in Section 9.3.4.

Table 14.1-1 (continued)

BORIC ACID CONCENTRATOR FEED SYSTEM

1.0 OBJECTIVE

To demonstrate that the boric acid concentrator feed system operates as designed.

2.0 PREREQUISITES

2.1 Construction activities are complete on items to be tested.

2.2 Associated instrumentation has been calibrated.

2.3 Holdup tank system available.

3.0 TEST METHOD

3.1 Check the ability to recirculate water from the holdup tanks through the preconcentrator ion exchangers.

3.2 Verify the operability of the high differential pressure alarms across the preconcentrator filters, ion exchangers, and strainers.

3.3 Demonstrate the ability to change out filter elements remotely and replace resin.

3.4 Verify the operability of remotely operated valves.

4.0 DATA REQUIRED

4.1 Valve position indication and opening and/or closing times on critical valves.

4.2 Preconcentrator filters, ion exchanger, and strainer differential pressure indication and alarms.

5.0 ACCEPTANCE CRITERIA

The boric acid concentrator feed system operates as described in Section 9.3.4 and Section 11.2.

BORIC ACID CONCENTRATOR SYSTEM

1.0 OBJECTIVE

To demonstrate that the boric acid concentrator system operates as designed.

2.0 PREREQUISITES

2.1 Construction activities are complete on items to be tested.

2.2 Associated instrumentation has been calibrated.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 Check the ability to process liquid from the boron management holdup tanks to the boric acid concentrator.

3.2 Verify unobstructed flows through the liquid radwaste/BMS manifold.

3.3 Demonstrate proper operation of remotely operated valves.

3.4 Verify pump start and stop interlocks.

3.5 Check all pump flow paths.

4.0 DATA REQUIRED

4.1 Valve position indication and opening and/or closing times on critical valves.

4.2 Boric acid concentrator initial operating data.

4.3 Interlock setpoints.

5.0 ACCEPTANCE CRITERIA

The boric acid concentrator system operates in accordance with Section 9.3.4 and Section 11.2.

BORIC ACID CONDENSATE STORAGE AND TRANSFER SYSTEM

1.0 OBJECTIVE

To demonstrate the functional performance of the boric acid condensate storage and transfer system.

2.0 PREREQUISITES

2.1 Construction activities are complete on items to be tested.

2.2 Associated instrumentation has been calibrated.

3.0 TEST METHOD

3.1 Check the proper operation of remotely operated valves.

3.2 Verify remote valve indication.

3.3 Verify the flow path from the boric acid holdup tanks to the condensate tanks and vice versa.

3.4 Raise and lower the boric acid condensate tank level and check the level alarms and boric acid condensate pumps.

3.5 Demonstrate the operability of the high differential pressure alarms across the boric acid condensate ion exchangers and strainer.

3.6 Demonstrate the ability to replace resin.

Table 14.1-1 (continued)

4.0 DATA REQUIRED

4.1 Valve position indication and opening and/or closing times on critical valves.

4.2 Ion exchanger and strainer differential pressure indication and alarms.

4.3 Boric acid condensate tank level versus alarms.

4.4 Boric acid condensate pumps initial run data.

5.0 ACCEPTANCE CRITERIA

The boric acid condensate storage and transfer system operates in accordance with Section 9.3.4 and Section 11.2.

RADWASTE/BMS MANIFOLD

1.0 OBJECTIVE

To demonstrate that the radwaste/BMS manifold is operable.

2.0 PREREQUISITES

2.1 Associated instrumentation has been calibrated.

2.2 Construction activities are complete on items to be tested.

3.0 TEST METHOD

3.1 Check the operation and indication of all remotely operated and manual valves.

3.2 Verify valve and pump interlocks.

4.0 DATA REQUIRED

4.1 Valve position indication and opening and/or closing times on critical valves.

4.2 Valve and pump interlock operation.

5.0 ACCEPTANCE CRITERIA

5.1 Valve indication working correctly.

5.2 Valve and pump interlocks work as designed.

Table 14.1-1 (continued)

WASTE COLLECTION SYSTEM

1.0 OBJECTIVE

To demonstrate the functional performance of the waste collection system.

2.0 PREREQUISITES

2.1 Associated instrumentation has been calibrated.

2.2 Construction activities are complete on items to be tested.

3.0 TEST METHOD

3.1 Check the proper operation of the remotely operated valves.

3.2 Raise and lower waste tank level and verify the level alarms.

3.3 Collect operating data during the initial run of waste pumps.

3.4 Check the waste pumps start and stop interlocks and all pump flow paths.

3.5 Demonstrate the ability to change out the filter element remotely.

3.6 Verify the high differential pressure alarm across filter.

4.0 DATA REQUIRED

4.1 Valve position indication and opening and/or closing times on critical valves.

4.2 Waste tank level versus level alarms.

4.3 Waste pumps initial run data.

4.4 Waste filter differential pressure versus alarms.

5.0 ACCEPTANCE CRITERIA

The waste collection system operates in accordance with Section 11.2.

PIPING SHOCK AND VIBRATION TEST

1.0 OBJECTIVE

To determine the steady state vibration of the charging system and the transient response of the main steam line piping.

2.0 PREREQUISITES

2.1 Steady state vibration of the charging system is observed during initial hot functional testing.

2.2 Transient response of the main steam line between the steam generators and turbine stop valves is conducted during the power escalation test program. Test instrumentation is installed and calibrated.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 Pipe movement within the charging system during steady state operation is observed during initial hot functional testing. If unusual movement is noted, additional measurements will be made.

3.2 Pipe response data will be taken on the mainsteam line, as required.

4.0 DATA REQUIRED

4.1 Pipe response data.

4.2 Initial plant conditions.

5.0 ACCEPTANCE CRITERIA

Test results shall be within the calculated acceptable range.

RESIN SLUICE SYSTEM

1.0 OBJECTIVE

To demonstrate the functional performance of the resin sluice system.

2.0 PREREQUISITES

2.1 Construction activities are complete on all components to be tested.

2.2 All associated instrumentation has been calibrated.

3.0 TEST METHOD

3.1 Collect initial run data on the resin addition pump.

3.2 Verify the flow paths for new resin addition and resin sluice.

4.0 DATA REQUIRED

Resin addition pump initial run data.

5.0 ACCEPTANCE CRITERIA

The resin sluice system operates in accordance with Section 11.2.

Table 14.1-1 (continued)

GASEOUS WASTE DECAY SYSTEM

1.0 OBJECTIVE

To demonstrate the functional performance of the waste gas compressors and discharge valves.

2.0 PREREQUISITES

2.1 Construction activities are complete on all components to be tested.

2.2 All associated instrumentation has been calibrated.

2.3 Gaseous waste collection system available.

3.0 TEST METHOD

3.1 Check the control valves for proper operation.

3.2 Collect operating data during the initial run of waste gas compressors.

3.3 Check the waste gas compressor common alarms and start and stop interlocks.

4.0 DATA REQUIRED

4.1 Waste gas compressor initial run data.

4.2 Waste gas compressor alarm and interlock setpoints.

5.0 ACCEPTANCE CRITERIA

The gaseous waste decay system operates in accordance with Section 11.3.

GASEOUS WASTE COLLECTION SYSTEM

1.0 OBJECTIVE

To demonstrate that the waste gas surge tank and associated alarms and control valves function as designed.

2.0 PREREQUISITES

2.1 Construction activities are complete on all components to be tested.

2.2 All associated instrumentation has been calibrated.

2.3 Nitrogen system is available.

2.4 Radwaste/BMS manifold is operational.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 Check the remotely operated valves for proper operation.

3.2 Pressurize the waste gas surge tank.

3.3 Check the setpoints of the alarms and pressure regulation valves.

4.0 DATA REQUIRED

4.1 Valve position indication and opening and/or closing time on critical valves.

4.2 Setpoints of pressure regulation valves.

4.3 Setpoints of pressure alarms for the waste gas surge tank.

5.0 ACCEPTANCE CRITERIA

The gaseous waste collection system operates in accordance with Section 11.3.

GASEOUS WASTE DISCHARGE SYSTEM

1.0 OBJECTIVE

To demonstrate that the waste gas decay tanks and control valves to the plant vent plenum function as designed.

2.0 PREREQUISITES

2.1 Construction activities are complete on all components to be tested.

2.2 Associated instrumentation has been calibrated.

2.3 Nitrogen system is available.

3.0 TEST METHOD

3.1 Check the remotely operated valves for proper operation.

3.2 Pressurize the waste gas decay tanks.

3.3 Verify the setpoints of the alarms and pressure regulation valves.

3.4 Verify the flow paths to the waste gas analyzer.

4.0 DATA REQUIRED

4.1 Valve position indication and opening and/or closing times on critical valves.

4.2 Setpoint of pressure regulation valves.

4.3 Setpoints of pressure alarms.

5.0 ACCEPTANCE CRITERIA

The gaseous waste discharge system operates in accordance with Section 11.3.

Table 14.1-1 (continued)

GASEOUS RADIATION MONITORING SYSTEM

1.0 OBJECTIVE

The objective is to verify the proper operation of the gaseous radiation monitors installed in the main condenser, waste gas system, hydrogen purge system, fuel handling area ventilation system, radwaste area ventilation system, containment purge system, and control room air inlet.

2.0 PREREQUISITES

2.1 Monitors are installed and construction activities are complete.

2.2 Monitors have been calibrated.

2.3 External test instrumentation is available and has been calibrated.

2.4 The required check sources are available.

3.0 TEST METHOD

3.1 Utilizing a check source and external test equipment, verify the calibration and operation of the monitor.

3.2 Check the self-testing feature of the monitor.

3.3 Where applicable, verify the proper control actuation by the monitor, and record the response time.

3.4 Verify the proper alarm actuation in the control room.

3.5 Where applicable, check for the proper operation of the monitor failure alarms.

4.0 DATA REQUIRED

4.1 Monitor response to the check source.

4.2 Technical data associated with the source.

4.3 Monitor response (local and remote) to test signals.

4.4 Signals necessary to cause alarm actuation.

4.5 Response time of the monitor to perform control functions.

5.0 ACCEPTANCE CRITERIA

The gaseous radiation monitoring system performs as described in Section 11.4.2.2.

Table 14.1-1 (continued)

EXCORE MONITORING SYSTEM

1.0 OBJECTIVE

To verify the proper functional performance of the excore (neutron flux) monitoring system.

2.0 PREREQUISITES

2.1 Construction activities on the excore monitoring system are complete. (Detectors do not need to be installed.)

2.2 Associated instrumentation has been calibrated.

3.0 TEST METHOD

3.1 Using simulated test signals, vary all input signals to the startup, safety, and control channels of the excore monitoring system.

3.2 Monitor and record all output signals as a function of variable inputs provided by external test instrumentation.

3.3 Verify the proper performance of audio and visual indicators in response to changing input signals.

3.4 Verify the independent performance of channels by testing each channel separately.

3.5 Verify the fail-safe status of the system in case of power failure.

4.0 DATA REQUIRED

4.1 Values of input and output signals for correlation purposes, as required.

4.2 Values of all output signals triggering audio and visual alarms.

4.3 Status of the system when power is lost.

5.0 ACCEPTANCE CRITERIA

The excore monitoring system shall perform as described in Section 7.2.

INCORE MONITORING SYSTEM

1.0 OBJECTIVE

To verify the proper functional performance of the incore (neutron flux) monitoring system.

2.0 PREREQUISITES

2.1 Construction activities on the incore monitoring system are complete. (Detectors do not need to be installed.)

2.2 Associated instrumentation has been calibrated.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 Using external test instrumentation, simulate incore detector signals into the signal conditioning (amplifier) circuits.

3.2 Using internal test circuits, test each amplifier for proper operation in accordance with manufacturer's instruction manual.

3.3 Vary the simulated inputs to the amplifier and record its outputs to the plant computer.

4.0 DATA REQUIRED

4.1 Status and performance of the internal test circuits.

4.2 Values of simulated input and derived output signals for correlation purposes.

5.0 ACCEPTANCE CRITERIA

The incore monitoring system shall perform as described in Section 7.7.

MOVABLE INCORE DETECTOR DRIVE SYSTEM

1.0 OBJECTIVE

To verify the proper functional performance of the movable incore detector drive system.

2.0 PREREQUISITES

2.1 Construction activities on the movable incore detector drive system and its portable control box are complete. (Detectors do not need to be installed.)

2.2 Associated instrumentation has been calibrated.

3.0 TEST METHOD

3.1 Operate one set of drive and transfer machines at a time, and record all pertinent outputs, including encoder signals.

3.2 Using external instrumentation, simulate the plant computer command signals to drive the detectors and to change inlet to outlet instrument tube alignments. Monitor all feedback signals, as required for verification of simulated commands.

3.3 Operate the system from the main control room board and verify proper operation by monitoring the feedback signals.

3.4 Operate the system from a local position with the portable control box, and verify proper operation by monitoring the feedback signals.

Table 14.1-1 (continued)

4.0 DATA REQUIRED

4.1 Record simulated command signals and all output signals to the computer system for correlation purposes.

4.2 Record all commands initiated at the main control room board and corresponding feedback signals.

4.3 Record all commands initiated on the portable control box and corresponding feedback signals.

5.0 ACCEPTANCE CRITERIA

The movable incore detector drive system shall perform as described in Section 7.7.

AREA RADIATION MONITORS

1.0 OBJECTIVE

The objective is to verify the functional performance of the area radiation monitors.

2.0 PREREQUISITES

2.1 The area radiation monitor(s) to be tested is installed and construction activities are completed.

2.2 The radiation monitor(s) to be tested has been calibrated.

2.3 Check source is available.

2.4 External test instrumentation is available and calibrated.

3.0 TEST METHOD

3.1 Utilizing a check source and external test equipment, verify the calibration and operation of the monitor.

3.2 Check the self-testing feature of the monitor.

3.3 Compare the local and remote indications for several values.

3.4 Verify proper local and remote alarm actuations.

4.0 DATA REQUIRED

4.1 Monitor response to a check source.

4.2 Technical data associated with the source.

4.3 Local and remote responses to test signals.

4.4 Signals necessary to cause alarm actuation.

5.0 ACCEPTANCE CRITERIA

The various area radiation monitors will perform as described in Section 12.1.4.

Table 14.1-1 (continued)

REACTOR CAVITY FUEL HANDLING SYSTEM

1.0 OBJECTIVE

To demonstrate the proper functional performance of the reactor cavity fuel handling system.

2.0 PREREQUISITES

2.1 Construction activities are complete on all components to be tested.

2.2 Associated instrumentation has been calibrated.

2.3 Reactor vessel head removed.

2.4 Core support barrel installed and aligned.

3.0 TEST METHOD

3.1 Record the X-Y coordinates of each core position.

3.2 Check the bridge, trolley, and hoist speeds.

3.3 Verify the operability of all bridge, trolley, and hoist interlocks.

3.4 Check the overload and hoist cable slack limit switches.

3.5 Verify the interlocks between the upender, CEA change mechanism, and refueling machine.

3.6 Check the camera tilt operation.

3.7 Position the underwater lights and move a dummy fuel assembly between the upender and reactor vessel.

4.0 DATA REQUIRED

4.1 X-Y coordinates of each core position.

4.2 Bridge, trolley, and hoist speeds.

4.3 Conditions under which interlocks and limit switches operate.

4.4 CEA change mechanism and transfer position.

5.0 ACCEPTANCE CRITERIA

5.1 Refueling machine can be positioned over each core position within design tolerances.

5.2 All interlocks and limit switches operate as designed.

5.3 Bridge, trolley, and hoist speeds are within tolerances.

Table 14.1-1 (continued)

SPENT FUEL PIT HANDLING AND TRANSPORT SYSTEM

1.0 OBJECTIVE

To demonstrate the functional performance of the spent fuel handling and transport system including the new fuel elevator.

2.0 PREREQUISITES

2.1 Construction activities are completed on the items to be tested.

2.2 All associated instrumentation has been calibrated.

3.0 TEST METHOD

3.1 Check the bridge, trolley, and hoist speeds, position indication, and travel limit switches.

3.2 Verify the interlocks between the upender and spent fuel handling machine.

3.3 Check the spent fuel handling machine hoist overload and foot switch control of hoist.

3.4 Check the cable slack switch on the new fuel elevator.

3.5 Lower a dummy fuel assembly with the new fuel elevator, and transfer it to a spent fuel rack with the spent fuel handling machine.

4.0 DATA REQUIRED

4.1 Bridge, trolley, and hoist speeds.

4.2 Conditions under which limit switches and interlocks operate.

5.0 ACCEPTANCE CRITERIA

5.1 All interlocks and limit switches operate as designed.

5.2 Bridge, trolley, and hoist speeds are within tolerances.

5.3 Movement and transfer of a dummy fuel assembly with the new fuel elevator and spent fuel handling machine is verified.

FUEL TRANSFER CANAL HANDLING AND TRANSPORT SYSTEM

1.0 OBJECTIVE

To demonstrate the functional performance of the fuel transfer canal handling and transport system.

2.0 PREREQUISITES

2.1 Construction activities are complete on the items to be tested.

2.2 Associated instrumentation calibrations are complete.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 Raise and lower both upenders and check the interlocks with the transfer carriage, refueling machine, and spent fuel handling machine.

3.2 Operate the transfer carriage from both consoles, and check the overload limit.

3.3 Use the special tools provided to check the ability to remove the equipment remotely and to operate the upenders manually.

3.4 Transfer a dummy fuel assembly through the transfer canal.

4.0 DATA REQUIRED

4.1 Conditions under which interlocks operate.

4.2 Overload setting on transfer carriage.

4.3 Check all instrumentation indications, and verify proper instrumentation operation.

5.0 ACCEPTANCE CRITERIA

5.1 All interlocks and overloads operate as designed.

5.2 Upenders can be operated remotely and manually.

5.3 Upenders can be removed and replaced from the operating floor of the spent fuel pit area.

FUEL HANDLING CRANE

1.0 OBJECTIVE

To demonstrate the functional performance of the overhead crane in the Unit 2 spent fuel area.

2.0 PREREQUISITES

Construction activities are completed on the overhead crane.

3.0 TEST METHOD

3.1 Verify the operability of all bridge, trolley, and hoist interlocks.

3.2 Check the hoist and trolley speeds for the hoist.

3.3 Check the capability of the 4-ton hoist to position over all new fuel storage positions.

4.0 DATA REQUIRED

4.1 Overhead crane trolley and hoist speeds.

4.2 Conditions under which interlocks and limit switches operate.

Table 14.1-1 (continued)

5.0 ACCEPTANCE CRITERIA

5.1 All interlocks and limit switches operate as required.

5.2 Four-ton hoist - trolley and hoist speeds are within tolerances.

5.3 Four-ton hoist can position over all new fuel storage positions.

CEA CHANGE MECHANISM

1.0 OBJECTIVE

To demonstrate the functional performance of the CEA change mechanism.

2.0 PREREQUISITES

2.1 Construction activities are completed on all components to be tested.

2.2 Associated instrumentation has been calibrated.

3.0 TEST METHOD

3.1 Check the hoist speed, traverse speed, and position indication.

3.2 Check the hoist, fuel aligner, and traverse interlocks.

3.3 Remove and re-insert a dummy CEA in a dummy fuel assembly.

3.4 Check the hoist overload and no-load limits.

3.5 Traverse the CEA change mechanism, and check the interlocks with the upender and refueling machine.

4.0 DATA REQUIRED

4.1 Hoist and traverse positions and speeds.

4.2 Conditions under which interlocks operate.

4.3 Hoist load settings.

5.0 ACCEPTANCE CRITERIA

5.1 Interlocks and overloads operate as designed.

5.2 Hoist and traverse speeds are within tolerances.

5.3 Removal and re-insertion of a CEA is verified.

Table 14.1-1 (continued)

MAIN STEAM SYSTEM

1.0 OBJECTIVE

To demonstrate the functional performance of the main steam system, including the closing times of the main steam isolation valves, the adjustment of the main steam safety relief valves, and the operability of main steam system control valves.

2.0 PREREQUISITES

2.1 Construction activities are complete on the items to be tested.

2.2 Associated instruments have been calibrated.

2.3 Test equipment for testing main steam system safety relief valves installed.

2.4 Plant conditions are as necessary for testing.

3.0 TEST METHOD

3.1 Determine the lift pressure of the main steam safety relief valves by hydraulic assist.

3.2 Verify all interlocks.

3.3 Determine the closing times of the main steam isolation valves.

3.4 Determine the operability of main steam system control valves.

4.0 DATA REQUIRED

4.1 Conditions under which interlocks operate.

4.2 Closing times of main steam isolation valves.

4.3 Lift pressures of main steam safety relief valves.

5.0 ACCEPTANCE CRITERIA

The main steam system operates in accordance with Section 10.3.

STEAM DUMP AND BYPASS CONTROL SYSTEM

1.0 OBJECTIVE

To verify proper performance of the steam dump and bypass control system.

2.0 PREREQUISITES

2.1 Construction activities on the steam dump and bypass control system are complete.

2.2 Associated instrumentation has been calibrated.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 Using external test instrumentation, simulate and vary the actual steam pressure and steam pressure setpoint input signals to system controller, and observe modulation of valve groups.

3.2 De-energize the dump/bypass demand signals one at a time to verify that redundancy arrangement is intact and that no more than one valve will open.

3.3 In the automatic mode, simulate the valve quick-opening demand signal, check the redundant circuits, and verify that no more than one valve will open as a result of simulated signals.

3.4 Verify that an automatic withdrawal prohibit signal is generated whenever an automatic bypass valve opening demand signal exists.

3.5 Manually select the automatic-motion-inhibit threshold and verify that for load rejections, including turbine trip, to levels below 15 percent, the reactor regulatory system (RRS) will be prevented from withdrawing or inserting CEAs (by CEA motion inhibit signal when the reactor power output falls below the threshold).

4.0 DATA REQUIRED

4.1 Valve quick-opening demand signal.

4.2 Automatic Withdrawal Prohibit (AWP) signal amplitude.

4.3 CEA Motion Inhibit (CMI) signal amplitude.

5.0 ACCEPTANCE CRITERIA

Steam dump and bypass control system shall perform as described in Section 7.7.

MAIN TURBINE SYSTEMS

1.0 OBJECTIVE

Verify the functional performance of the main turbine systems.

2.0 PREREQUISITES

2.1 All construction activities are completed on the items to be tested.

2.2 Associated instrumentation has been calibrated.

2.3 The auxiliary support systems are functional and are in service.

3.0 TEST METHODS

3.1 All manual modes of operation of the turbine and auxiliary support systems will be demonstrated by operation or simulated.

3.2 All automatic modes of operation of the turbine and auxiliary support systems will be demonstrated by operation or simulated.

3.3 All alarms and protective devices will be verified.

Table 14.1-1 (continued)

4.0 DATA REQUIRED

4.1 Conditions under which alarms and interlocks operate.

4.2 Verification of all control logic combinations.

4.3 Valve stroke data and logic verification of electrohydraulic control system.

5.0 ACCEPTANCE CRITERIA

The main turbine system performance shall be as described in Section 10.2.

AUTOMATIC DISPATCH SYSTEM

1.0 OBJECTIVE

To demonstrate the functional performance of the automatic dispatch system.

2.0 PREREQUISITES

2.1 All construction activities are complete on the items to be tested.

2.2 All instrumentation associated with the automatic dispatch system has been calibrated.

2.3 Megawatt demand setter system and electrohydraulic control system are operational.

2.4 Conitel (control, indication and telemetry) system is operational.

2.5 Bulk Power Management System (BPMS) computer is available for testing with the system.

3.0 TEST METHOD

3.1 Check the capability of the Conitel system to be controlled by the BPMS computer at Pine Bluff.

3.2 Simulate signals or contacts to all inputs of the Conitel system to verify operability.

3.3 Check for proper output from all transducers, contact devices, and other telemetry sources external to the Conitel unit.

3.4 Check the ability to change the load demand within the limits set by the MDS from Pine Bluff.

3.5 All alarms and interlocks will be verified.

4.0 DATA REQUIRED

4.1 Alarm and interlock set point verification.

4.2 Response to load change commands.

4.3 System output signals for given test signals.

5.0 ACCEPTANCE CRITERIA

The automatic dispatch system shall perform as described in Section 7.7.

Table 14.1-1 (continued)

SEISMIC MONITOR

1.0 OBJECTIVE

To illustrate functional performance and calibrate the peak recording accelerographs provided in the Unit 2 reactor building.

2.0 PREREQUISITES

2.1 Accelerographs are properly installed.

2.2 Construction activities are complete.

3.0 TEST METHOD

Using techniques similar to those used for the strong motion accelerographs, calibrate the peak-recording accelerographs.

4.0 DATA REQUIRED

Accelerographs calibration data.

5.0 ACCEPTANCE CRITERIA

The seismic monitors are calibrated and function to provide data for a seismic event in accordance with Section 3.7.4.

STEAM GENERATOR HYDROSTATIC TEST

1.0 OBJECTIVE

To hydrostatically test the non-isolable feed and steam lines connected to the secondary side of the steam generator.

2.0 PREREQUISITES

2.1 Steam generator secondary side filled and vented.

2.2 RCS filled and vented above design transition temperature.

3.0 TEST METHOD

3.1 Using hydropumps, raise the system pressure to code requirements.

3.2 Check the system for leakage.

3.3 Depressurize the system.

4.0 DATA REQUIRED

Pressure, temperature, and results of visual inspection.

Table 14.1-1 (continued)

5.0 ACCEPTANCE CRITERIA

Conformance to the applicable code requirements.

RCS HYDROSTATIC TEST

1.0 OBJECTIVE

To hydrostatically test the RCS and connected 2,485 psig design piping and components, in accordance with code requirements.

2.0 PREREQUISITES

2.1 RCS filled and vented.

2.2 Steam generator secondary side filled and vented.

2.3 Fill water within chemistry specifications.

2.4 System temperatures maintained above NDTT.

3.0 TEST METHOD

3.1 Using hydropumps, raise the system pressure to code requirements.

3.2 Check the system for leakage.

3.3 Depressurize the system.

4.0 DATA REQUIRED

Pressure, temperature, and results of visual inspection.

5.0 ACCEPTANCE CRITERIA

Conformance to the applicable code requirements.

FILTER TESTS

1.0 OBJECTIVE

The objective of these tests is to insure that the as-installed air filtration systems perform as designed.

2.0 PREREQUISITES

2.1 Filters are installed per design, and construction is complete on the filters to be tested.

2.2 Fans and blowers are installed and are capable of supplying design flow rates to the filters.

Table 14.1-1 (continued)

3.0 TEST METHOD

Filter pressure differential and efficiency measurements will be conducted in accordance with Regulatory Guide 1.52, dated June 1973.

4.0 DATA REQUIRED

4.1 Air flow distribution to HEPA filters and absorbers.

4.2 Efficiency data on HEPA filters and iodine absorbers.

5.0 ACCEPTANCE CRITERIA

Acceptance limits on filter efficiency, leakage and air flow distribution will be per Regulatory Guide 1.52, dated June 1973.

PIPE/COMPONENT HOT DEFLECTION TEST

1.0 OBJECTIVE

To demonstrate that the piping system is free to expand thermally, as designed, and return to its baseline cold position after cooldown to ambient conditions.

2.0 PREREQUISITES

2.1 This test is carried out in conjunction with the initial RCS heatup, and all the conditions for initial heatup must be established.

2.2 Construction activities are complete on the pipes to be measured.

2.3 Adjustment, setting, and marking of initial positions of spring hangers, hydraulic restraints, and special devices of the systems has been completed.

2.4 Temporary scaffolding and ladders are installed, as required, to make observations and record data.

3.0 TEST METHOD

3.1 Prior to the start of hot functional testing, a complete set of position measurements will be made for the steam generators and reactor coolant pumps. In addition, the RCS shutdown cooling system, main steam system, and feedwater system both inside and outside containment, will be observed during testing to verify proper expansion.

3.2 During heatup, a complete set of position versus temperature measurements will be made.

3.3 On completion of plant cooldown, a complete set of position measurements is again taken at ambient temperature.

Table 14.1-1 (continued)

4.0 DATA REQUIRED

Position measurements versus temperature.

5.0 ACCEPTANCE CRITERIA

5.1 Unrestricted expansion for selected points on components and piping.

5.2 Verification that the components and piping return to their approximate baseline cold position.

PIPING SHOCK AND VIBRATION TEST

1.0 OBJECTIVE

To determine the steady state vibration of the charging system and the transient response of the main steam line piping.

2.0 PREREQUISITES

2.1 Steady state vibration of the charging system is observed during low power functional testing.

2.2 Transient response of the main steam line between the steam generators and turbine stop valves is conducted during the power escalation test program. Test instrumentation is installed and calibrated.

3.0 TEST METHOD

3.1 Pipe movement within the charging system during steady state operation is observed. If unusual movement is noted additional measurements will be made.

3.2 Pipe response data will be taken on the main steam line, as required.

4.0 DATA REQUIRED

4.1 Pipe response data.

4.2 Initial plant conditions.

5.0 ACCEPTANCE CRITERIA

Test results shall be within the calculated acceptable range.

Table 14.1-1 (continued)

REMOTE SHUTDOWN EQUIPMENT

1.0 OBJECTIVE

To demonstrate the functional control of all equipment associated with the remote shutdown panel prior to fuel loading.

2.0 PREREQUISITE

2.1 All construction activities are completed on the components to be tested.

2.2 Preoperational testing of systems with components on the remote shutdown panel is completed.

2.3 Plant status is such that all equipment on the panel may be operated.

3.0 TEST METHOD

3.1 Each display and indicating device (instruments, lights, etc.) on the remote shutdown panel will be verified to be in agreement with those devices in all other indicating locations.

3.2 All control devices will be tested in a manner to demonstrate their overriding control of the proper equipment regardless of the control positions in other locations.

3.3 Communications between the remote shutdown panel and all local control stations used in remote shutdown will be verified as adequate.

4.0 DATA REQUIRED

4.1 Verification of all control logic combinations.

4.2 Instrumentation readout cross references.

4.3 Indicating light cross references.

5.0 ACCEPTANCE CRITERIA

All equipment associated with the remote shutdown panel shall operate per design intent to ensure a safe, orderly shutdown from outside the control room.

RCS LEAKAGE MEASUREMENT

1.0 OBJECTIVE

To demonstrate that reactor coolant leakage at hot pressurized system conditions is within the limits set in the Technical Specifications.

2.0 PREREQUISITES

2.1 Hydrostatic tests of systems which form the RCS boundaries.

2.2 The chemical and volume control system and the RCS are operating as a closed system.

2.3 The RCS is hot and pressurized.

Table 14.1-1 (continued)

3.0 TEST METHOD

Calculate the reactor coolant inventory change by measuring changes in pressurizer and volume control tank levels during a specified time interval, with correction for reactor coolant temperature changes.

4.0 DATA REQUIRED

Record RCS average temperature, pressurizer level, and volume control tank level at the beginning and end of the time interval.

5.0 ACCEPTANCE CRITERIA

Reactor coolant leakage does not exceed limits set by the Technical Specifications.

HYDROGEN ANALYZERS

1.0 OBJECTIVE

To demonstrate the ability of the two hydrogen analyzers to accurately measure hydrogen concentrations inside the containment.

2.0 PREREQUISITES

2.1 All construction activities are complete on the items to be tested.

2.2 All initial analyzer calibrations have been made.

2.3 External test instrumentation is calibrated and available.

3.0 TEST METHOD

3.1 Using a known source and external test instrumentation, various hydrogen concentrations will be simulated.

3.2 The analyzer will be monitored for proper response.

4.0 DATA REQUIRED

4.1 Known source values and test instrument values.

4.2 Hydrogen analyzer responses.

5.0 ACCEPTANCE CRITERIA

The hydrogen analyzers perform per Section 6.2.5.

Table 14.1-1 (continued)

HYDROGEN RECOMBINER

1.0 OBJECTIVE

To demonstrate the ability of the hydrogen recombiners to control combustible hydrogen gas concentrations within the containment.

2.0 PREREQUISITES

2.1 Construction activities are completed on the items to be tested.

2.2 All associated instrumentation has been calibrated.

2.3 External test instrumentation is calibrated and available.

3.0 TEST METHOD

3.1 The manual mode of initiation will be verified.

3.2 The design convective air flow capacity will be verified.

3.3 The design thermal capacity will be demonstrated.

4.0 DATA REQUIRED

4.1 Convective air flow rates.

4.2 Thermal performance data.

5.0 ACCEPTANCE CRITERIA

Each hydrogen recombiner will be capable of performing per Section 6.2.5.

HYDROGEN PURGE SYSTEM

1.0 OBJECTIVE

To demonstrate the ability of the hydrogen purge system to act as a backup to the hydrogen recombiners to limit hydrogen gas concentrations by a controlled purge of the containment atmosphere.

2.0 PREREQUISITES

2.1 All construction activities are complete on the equipment to be tested.

2.2 All associated instrumentation has been calibrated and is operable.

Table 14.1-1 (continued)

3.0 TEST METHOD

3.1 All manual modes of operation will be demonstrated, including air flow verifications from the various purge headers.

3.2 All automatic modes of operation will be verified including Containment Isolation System (CIS) actuation.

3.3 All alarms and process trips will be checked.

4.0 DATA REQUIRED

4.1 Air flow verification.

4.2 Operation of alarms and interlocks at the proper set points.

4.3 CIS actuation data.

5.0 ACCEPTANCE CRITERIA

The hydrogen purge system functions per the criteria of Section 6.2.5.

THERMAL EXPANSION (HOT DEFLECTION) TEST

1.0 OBJECTIVE

To verify that the piping system expands in a manner consistent with design determinations.

2.0 PREREQUISITIES

2.1 All construction activities are complete on the system to be tested.

2.2 All associated instrumentation has been calibrated.

3.0 TEST METHOD

3.1 Thermal Expansion (Hot Deflection) Test was conducted for the following piping systems:

Main Steam
Steam Supply to Emergency Feedwater Pump Turbine
Main Feedwater
Emergency Feedwater
Pressurizer Relief Line (line cold with pressurizer hot)
Shutdown Cooling
Steam Generator Blowdown
Reactor Coolant System (including the pressurizer surge and spray lines)
Letdown line up to the letdown heat exchanger
Changing line from the Regen H.X. to the RCS

Table 14.1-1 (continued)

3.2 During the thermal expansion test, pipe deflections were measured or observed at locations based on the following criteria:

a. at every spring hanger,

b. at every snubber, and

c. at points where large displacement of the pipe is expected, based on analysis.

3.3 One complete thermal cycle, i.e., cold position to hot position to cold position, was monitored. If hot shimming was required for piping restraints, an additional thermal cycle was monitored.

3.4 For most systems, the thermal expansion was monitored at cold conditions and at normal operating temperature. Significant locations were observed during the transient. Intermediate temperatures are generally not practical due to the short time during which the normal operating temperature is reached. For the RCS and the main steam system, measurements were made at cold, 290°F, 450°F, and maximum temperature conditions.

3.5 Measurement or observation was made during either preoperational testing or power escalation.

4.0 DATA REQUIRED

4.1 Initial normal configurations of piping systems.

4.2 All piping hangers and restraints were adjusted and verified for the as-designed configuration by a piping stress analyst.

5.0 ACCEPTANCE CRITERIA

The acceptance of the thermal expansion test results are determined based on the following criteria:

a. The piping system is free to expand thermally, as intended, i.e., does not lock at the snubbers and spring hangers and there is no interference with structures or other pipes.

b. The measured global displacement shall be within ± 0.38 inch of the expected global displacement when the expected global displacement is less than 0.75 inches.

c. The measured global displacement shall be within 50 percent of the expected global displacement when the expected global displacement is greater than 0.75 inches but less than 2.0 inches.

d. The measured global displacement were within ±1.0 inch of the expected global displacement when the expected global displacement is greater than 2.0 inches.

Exceptions to the above criteria were approved by a qualified design engineer familiar with the system and stress analysis.

Table 14.1-1 (continued)

STEADY STATE VIBRATION TEST

1.0 OBJECTIVE

To monitor pipe vibrations of specific systems during all significant plant operating modes that are likely to cause vibration in the subject system and are postulated to have a moderate to high probability of occurrence during the plant's lifetime.

2.0 PREREQUISITES

2.1 All construction activities are complete on the system to be tested.

2.2 All associated instrumentation has been calibrated.

2.3 As much system operation as possible has occurred within the constraints of the plant startup schedule.

3.0 TEST METHOD

3.1 Testing was conducted on the following:

a. Main feedwater system

b. Emergency feedwater system

c. Main steam system

d. Reheat steam system

e. Condensate system

f. Extraction steam system

g. Service water system

h. Gaseous waste (2T17 to CV-2428)

i. Spent fuel pool cooling and purification

j. Penetration room ventilation

3.2 Vibration monitoring was limited to a qualitative examination of each system at the specified test mode.

3.3 The test was performed at various power plateaus during ascension from 50 percent to 100 percent full power. Each particular section was performed as dictated by the procedure.

3.4 The spent fuel pool cooling and purification system was not inspected at this time. The steady state vibration inspection of this system is to be performed at the first refueling outage when the pool is to be filled and all associated systems will be in operation.

Table 14.1-1 (continued)

4.0 DATA REQUIRED

4.1 Initial normal configurations of piping systems.

4.2 All piping hangers and restraints will be adjusted and verified for the as-designed configuration by a piping stress analyst.

4.3 Endurance limit for piping material.

5.0 ACCEPTANCE CRITERIA

There were a number of items that indicated higher than expected steady state vibrations. They were:

a. Train "B" main feed regulating valve bypass piping (2CV-0744, 3FW-0744-A, and 2FW-0744-1).

b. Main steam atmospheric dump valves 2CV-0305 and 2CV-0301.

c. Main steam dump to condenser, specifically 2CV-0306.

d. The No. 1 main steam header, snubbers of hanger 2EBD-1H13.

The above noted items were referred to Bechtel (S.F.) for engineering evaluation. Based upon this analysis and resulting calculation, the steady state vibration of the noted piping and systems was found to be acceptable and complies with the acceptance criteria for steady state vibration in the Unit 2 FSAR.

DYNAMIC TRANSIENT TEST

1.0 OBJECTIVE

To verify the adequacy of the piping restraint configuration for specific piping systems during a main steam stop valve trip at 80 and 100 percent reactor power.

2.0 PREREQUISITES

2.1 All construction activities are complete on the systems to be tested.

2.2 All associated instrumentation has been calibrated.

2.3 Dynamic transient analysis of subject lines has been performed to determine piping system response.

3.0 TEST METHOD

3.1 Testing was conducted on the following:

a. Main steam lines

b. Main steam dump line to the condenser

c. Main steam branch lines to the main feedwater pump turbine driver

d. Second stage reheat steam supply lines

Table 14.1-1 (continued)

3.2 The reactor was at the nominal power level (80 percent, 100 percent).

3.3 The instrumentation utilized to measure pipe displacement (measured as maximum pipe displacement in inches), restraint loads (measured in kilopounds), pipe pressure rise (measured as peak difference pressure of first pressure pulse in pounds per square inch), and valve displacement (measured as time required for valve to reach approximately 90 percent of full travel in seconds) verified to be connected to the test recorders with proper gain settings.

3.4 The recorders were started at a speed of ≥ 10 inches per second just prior to a turbine trip, from which a main stop valve closure resulted.

3.5 Data recording continued for a minimum of 10 seconds following main stop valve closure.

3.6 Recorder charts were removed, and required data points were analyzed.

4.0 DATA REQUIRED

4.1 Initial normal configurations of piping systems.

4.2 All piping hangers and restraints will be adjusted and verified for the as-designed configuration by a piping stress analyst.

4.3 Design values of snubbers and restraints.

5.0 ACCEPTANCE CRITERIA

The measured loads in the snubbers and restraint shall be below the design values of the snubbers and restraints.

TABLE 14.1-2

POST CORE HOT FUNCTIONAL TEST SUMMARIES

Components or systems described may have been modified since initial testing.
Refer to the appropriate section of the SAR for current system descriptions.

	Test Title	Page No.
1	REACTOR COOLANT SYSTEM HEAT LOSS	14.3-86
2	REACTOR COOLANT SYSTEM FLOW AND COASTDOWN MEASUREMENT	14.3-86
3	CONTROL ELEMENT DRIVE MECHANISM (CEDM) PERFORMANCE	14.3-87
4	REACTOR COOLANT SYSTEM CHEMISTRY	14.3-89
5	STEAM GENERATOR CHEMISTRY	14.3-90
6	INCORE INSTRUMENTATION MEASUREMENTS	14.3-90
7	COMPARISON OF PPS, CPCs, AND PROCESS COMPUTER INPUT	14.3-92
8	PRESSURIZER SPRAY EFFECTIVENESS	14.3-92

Table 14.1-2 (continued)

REACTOR COOLANT SYSTEM HEAT LOSS

1.0 OBJECTIVE

To measure the RCS heat loss under hot, zero power conditions.

2.0 PREREQUISITES

RCS conditions are approximately 545 °F and 2,250 psia with four reactor coolant pumps in operation.

3.0 TEST METHOD

Heat loss determination by steam flow

Secure feed to steam generators and maintain steady state RCS conditions solely by steam flow from the steam generators to remove excess RCS heat.

4.0 DATA REQUIRED

4.1 RCS temperatures

4.2 Pressurizer pressure

4.3 Steam generator levels

4.4 Steam generator pressures

4.5 General plant conditions

5.0 ACCEPTANCE CRITERIA

The RCS heat loss as is in satisfactory agreement with anticipated heat losses.

REACTOR COOLANT SYSTEM FLOW AND COASTDOWN MEASUREMENT

1.0 OBJECTIVES

1.1 To determine the as-built RCS flow.

1.2 To demonstrate that the RCS flow coastdown is consistent or conservative with respect to the safety analysis.

1.3 To demonstrate the validity of the flow-related algorithms and constants in the COLSS and the CPCs.

2.0 PREREQUISITES

2.1 RCS operating at nominal hot, zero power conditions (approximately 545 °F, 2,250 psia).

2.2 Desired reactor coolant pumps operating.

2.3 COLSS and CPCs in operation.

Table 14.1-2 (continued)

3.0 TEST METHOD

3.1 RCS flow determination

Operate the specified reactor coolant pump combinations and collect necessary data.

3.2 RCS flow coastdown measurements

With the specified reactor coolant pumps operating, trip the appropriate reactor coolant pump(s) for collection of coastdown data.

4.0 DATA REQUIRED

4.1 Conditions of the measurement

a. RCS temperatures
b. Pressurizer pressure
c. Reactor coolant pump rotational speeds
d. Reactor coolant pump differential pressures
e. Steam generator pressures
f. Flow-related inputs to the COLSS and to the CPCs.

4.2 Time dependent information

a. Reactor coolant pump differential pressures
b. Reactor coolant pump rotational speeds

5.0 ACCEPTANCE CRITERIA

5.1 RCS flow has been measured and is consistent or conservative with respect to flow rates used in safety analysis.

5.2 RCS flow coastdown has been measured and is consistent or conservative with respect to the coastdown used in the safety analysis.

5.3 Flow-related algorithms and constants in the COLSS and the CPCs have been verified, and appropriate modifications made for on-line flow determination, if necessary.

CONTROL ELEMENT DRIVE MECHANISM (CEDM) PERFORMANCE

1.0 OBJECTIVES

1.1 To demonstrate proper operation of CEDM under cold and hot shutdown conditions and hot, zero power conditions.

1.2 To verify the proper operation of the position indication systems and CEA alarms.

1.3 To measure CEA drop times.

Table 14.1-2 (continued)

2.0 PREREQUISITES

2.1 RCS conditions are being maintained in steady state at the desired temperature and pressure for the CEDM measurements.

2.2 Support systems required for operation of CEDMs are operational.

2.3 CEDM coil resistances have been measured for the RCS conditions of the test.

3.0 TEST METHOD

3.1 Cold shutdown conditions with no reactor coolant flow

a. Each CEA is withdrawn and inserted while appropriate position indications and alarm operation are recorded.

b. The drop time of each CEA is measured.

c. Five additional measurements of drop time are made for each of the fastest and slowest CEAs.

3.2 Hot shutdown conditions (approximately 260°F with two or three reactor coolant pumps)

a. The drop time of each CEA is measured.

b. Three additional measurements of drop time are made for each of the two fastest and two slowest CEAs.

c. Five additional measurements of drop time are made for each of the fastest and slowest CEAs.

3.3 Hot, zero power conditions (approximately 545°F with four reactor coolant pumps)

a. Each CEA is withdrawn and inserted while appropriate position indications and alarm operation are recorded.

b. The drop time of each CEA is measured.

c. Three additional measurements of drop time are made for each of the two fastest and two slowest CEAs.

4.0 DATA REQUIRED

4.1 RCS temperature

4.2 Pressurizer pressure

4.3 CEDM/CEA identifications

4.4 Position indications

4.5 Alarm operations

4.6 CEA drop times

Table 14.1-2 (continued)

5.0 ACCEPTANCE CRITERIA

5.1 The CEDM/CEAs and their associated position indication operate as designed.

5.2 CEA drop times are consistent or conservative with respect to the values assumed in the safety analysis and as specified by the Technical Specifications.

REACTOR COOLANT SYSTEM CHEMISTRY

1.0 OBJECTIVES

1.1 To maintain proper water chemistry for the RCS.

1.2 To establish the necessary sampling frequency to comply with Technical Specifications, and to provide assurance that chemistry limits are not exceeded.

2.0 PREREQUISITES

Sampling systems for the RCS and CVCS are operable.

3.0 TEST METHOD

The RCS will be sampled at specified intervals throughout the hot functional testing.

4.0 DATA REQUIRED

4.1 Conditions of the measurement

a. RCS temperatures

b. Pressurizer pressure

c. General plant conditions

4.2 Test data

Sample point locations and times of samples.

5.0 ACCEPTANCE CRITERIA

5.1 Water chemistry of the RCS is maintained within specifications.

5.2 Appropriateness of established sampling frequencies is demonstrated.

5.3 Baseline data for RCS chemistry is established.

Table 14.1-2 (continued)

STEAM GENERATOR CHEMISTRY

1.0 OBJECTIVES

1.1 To maintain proper water chemistry for the steam generators.

1.2 To establish the necessary sampling frequency to comply with Technical Specifications, and to provide assurance that chemistry limits are not exceeded.

2.0 PREREQUISITES

Sampling systems for the steam generators are operable.

3.0 TEST METHOD

The steam generators will be sampled at specified intervals throughout the hot functional testing.

4.0 DATA REQUIRED

4.1 Conditions of the measurement

a. RCS temperature

b. Pressurizer pressure

c. Steam generator levels

d. Feedwater temperatures

e. General plant conditions

4.2 Test data

Sample point locations and time of samples

5.0 ACCEPTANCE CRITERIA

5.1 Steam generator chemistry is maintained within specifications.

5.2 Appropriateness of established sampling frequencies is demonstrated.

5.3 Baseline data for steam generator chemistry is established.

INCORE INSTRUMENTATION MEASUREMENTS

1.0 OBJECTIVE

1.1 To provide in-place calibration data for the incore thermocouples.

1.2 To measure the leakage resistance of the fixed incore detectors.

1.3 To demonstrate operation of the movable incore detector system.

Table 14.1-2 (continued)

2.0 PREREQUISITES

2.1 RCS is being operated at the specified conditions.

2.2 Installation and preoperational checkout of incore instrumentation is complete.

3.0 TEST METHOD

3.1 Incore thermocouple readings

Record incore thermocouple readings in conjunction with the readings from the installed RCS RTDs during heatup and steady state operation of the RCS.

3.2 Incore detector leakage

Measure the leakage resistance of each incore detector at the nominal hot, zero power conditions.

3.3 Movable incore detector movement

Proper operation of the movable incore detector system will be demonstrated at the nominal hot, zero power conditions. This demonstration will include indexing and movement to all accessible locations.

4.0 DATA REQUIRED

4.1 Conditions of the measurement

a. RCS temperature

b. Pressurizer pressure

c. Reactor coolant pumps operating

4.2 Test data

a. Incore thermocouple readings

b. Incore detector leakage resistances

c. Movable incore detector positions

5.0 ACCEPTANCE CRITERIA

5.1 Leakage resistance of the incore detectors is satisfactory.

5.2 The movable incore detector system is demonstrated capable of properly accessing the various locations within the core.

Table 14.1-2 (continued)

COMPARISON OF PPS, CPCs AND PROCESS COMPUTER INPUT

1.0 OBJECTIVES

To demonstrate that the inputs and appropriate outputs of the PPS, the CPCs, and the process computer are consistent and correct.

2.0 PREREQUISITES

The plant operating at the desired conditions.

3.0 TEST METHOD

Simultaneous readings of related inputs and appropriate outputs of the PPS, the CPCs and the process computer are made.

4.0 DATA REQUIRED

Test data

a. RCS temperatures

b. Pressurizer pressures

c. Steam generator levels

d. Steam generator pressures

e. Reactor coolant pump rotational speeds

f. RCS flow

5.0 ACCEPTANCE CRITERIA

The input and appropriate outputs of the PPS, CPCs and the process computer are consistent and in agreement with the actual plant conditions.

PRESSURIZER SPRAY EFFECTIVENESS

1.0 OBJECTIVES

1.1 To establish the proper settings for the continuous spray valves.

1.2 To measure the rate at which pressurizer pressure can be reduced using pressurizer spray.

2.0 PREREQUISITES

The RCS is being operated at the nominal hot, zero power conditions with four reactor coolant pumps operating.

Table 14.1-2 (continued)

3.0 TEST METHOD

3.1 The continuous spray valves are adjusted to provide the desired amount of continuous spray.

3.2 RCS pressure is reduced using the three possible combinations of pressurizer spray valves.

4.0 DATA REQUIRED

4.1 Conditions of the measurement

a. RCS temperature

b. Pressurizer pressure

c. Spray line temperatures

d. Continuous spray valve positions

e. Spray valve operating status

4.2 Time dependent data

Pressurizer pressure

5.0 ACCEPTANCE CRITERIA

5.1 The continuous spray valves are adjusted to produce the desired continuous spray.

5.2 The ability of pressurizer spray to reduce pressurizer pressure consistent with the design rate is demonstrated.

Table 14.1-3

LOW POWER PHYSICS TEST SUMMARIES

Components or systems described may have been modified since initial testing. Refer to the appropriate section of the SAR for current system descriptions.

	Test Title	Page No.
1	BIOLOGICAL SHIELDING SURVEY	14.3-95
2	CONTROL ELEMENT ASSEMBLY SYMMETRY	14.3-95
3	ISOTHERMAL TEMPERATURE COEFFICIENT	14.3-96
4	REGULATING & SHUTDOWN CEA GROUP WORTH	14.3-97
5	BORON WORTH	14.3-98
6	CRITICAL CONFIGURATION BORON CONCENTRATIONS	14.3-99
7	PSEUDO DROPPED & EJECTED CEA WORTH	14.3-100

Table 14.1-3 (continued)

BIOLOGICAL SHIELD SURVEY

1.0 OBJECTIVE

1.1 To measure radiation in accessible locations of the plant outside the biological shield.

1.2 To obtain baseline levels for comparison with future measurements of level buildup with operation.

2.0 PREREQUISITES

2.1 Radiation survey instruments calibrated.

2.2 Background radiation levels measured in designated locations prior to initial criticality.

3.0 TEST METHOD

Measure gamma and neutron dose rates during low power physics tests.

4.0 DATA REQUIRED

4.1 Power level

4.2 Gamma and neutron dose rates at each specified location.

5.0 ACCEPTANCE CRITERIA

Radiation levels have been demonstrated acceptable.

CONTROL ELEMENT ASSEMBLY SYMMETRY

1.0 OBJECTIVE

1.1 To demonstrate that no loading or fabrication errors that result in measurable CEA worth asymmetries have occurred.

1.2 To demonstrate proper coupling of each CEA and its drive mechanism.

2.0 PREREQUISITES

2.1 The reactivity computer is in operation.

2.2 The reactor is critical at approximately 545 °F and 2,250 psia with CEA Group 6 partially inserted in manual control.

Table 14.1-3 (continued)

3.0 TEST METHOD

3.1 The first CEA of each group is fully inserted while compensating with motion of the last CEA of the previous group and Group 6.

a. The reactivity is adjusted to zero, as observed on the reactivity computer, and variations in the group's CEA worths are determined from the change in reactivity which occurs due to swapping CEAs.

b. The CEAs within a group are sequentially swapped until the relative worth of each CEA in the group has been determined.

3.2 The swapping process is then extended to the next group.

4.0 DATA REQUIRED

4.1 Conditions of the measurement

a. RCS temperature

b. Pressurizer pressure

c. Boron concentration

4.2 Data for individual CEA

a. CEA number

b. Position of Group 6

c. Net reactivity

5.0 ACCEPTANCE CRITERIA

5.1 The relative worths of symmetric CEAs are within measurement limitations.

5.2 All CEAs are demonstrated to be coupled.

ISOTHERMAL TEMPERATURE COEFFICIENT

1.0 OBJECTIVE

To measure the isothermal temperature coefficients (ITCs) for various CEA configurations at approximately 260 °F, 545 °F, and intermediate temperatures.

2.0 PREREQUISITES

2.1 The reactor is critical, with a stable boron concentration, at the desired CEA configuration and RCS temperature and pressure.

2.2 The reactivity computer is in operation.

Table 14.1-3 (continued)

3.0 TEST METHODS

3.1 Changes in reactor coolant temperature are introduced and the resultant changes in reactivity measured.

3.2 Reactivity and power swings are limited, when necessary, by compensation with CEA motion.

4.0 DATA REQUIRED

4.1 Conditions of the measurement

a. RCS temperature

b. Pressurizer pressure

c. CEA configuration

d. Boron concentration

4.2 Time dependent information

a. Reactivity variation (strip chart)

b. Changes in CEA positions

c. Temperature variations

5.0 ACCEPTANCE CRITERIA

5.1 The measured ITCs are in satisfactory agreement with the predicted values.

5.2 The moderator temperature coefficients (MTCs) derived from the measured ITCs are consistent with the Technical Specifications.

REGULATING AND SHUTDOWN CONTROL ELEMENT ASSEMBLY GROUP WORTH

1.0 OBJECTIVE

1.1 To determine regulating (including PLCEAs) and shutdown CEA group worth.

1.2 To verify that the CEA insertion limits are adequate to assure the shutdown margin.

2.0 PREREQUISITES

2.1 The reactor is critical.

2.2 The reactivity computer is operating.

Table 14.1-3 (continued)

3.0 TEST METHOD

3.1 Hot shutdown measurement of selected CEA groups

The CEA group worths will be measured by boron dilution/boration.

3.2 Hot, zero power measurement of CEA Groups 6 thru A

a. The CEA group worths will be measured by boron dilution/boration.

b. Where boron dilution is not feasible, worths will be determined by CEA drop and/or by use of alternate CEA configurations.

4.0 DATA REQUIRED

4.1 Conditions of the measurement

a. RCS temperature

b. Pressurizer pressure

c. CEA configuration

d. Boron concentration

4.2 Time dependent information

a. Reactivity variation (strip chart)

b. Changes in CEA positions

c. Temperature variation

5.0 ACCEPTANCE CRITERIA

5.1 Evaluation of the measurements verifies that the CEA insertion limits are adequate to assure shutdown margin.

5.2 The measured CEA group worths are in satisfactory agreement with predictions.

BORON WORTH

1.0 OBJECTIVE

To measure the boron reactivity worth for various CEA configurations at approximately 260 °F and 545 °F.

2.0 PREREQUISITES

2.1 Regulating and shutdown CEA group worth tests are completed.

2.2 Critical configuration boron concentration tests are completed.

Table 14.1-3 (continued)

3.0 TEST METHOD

The boron worths are determined by analyzing the measured boron concentrations associated with state points measured during the CEA group worth tests.

4.0 DATA REQUIRED

4.1 Conditions of the measurement for state points

a. RCS temperature

b. Pressurizer pressure

c. CEA configuration

d. Boron concentration

4.2 Integral reactivity changes between state points

5.0 ACCEPTANCE CRITERIA

The measured boron worths are in satisfactory agreement with predicted values.

CRITICAL CONFIGURATION BORON CONCENTRATIONS

1.0 OBJECTIVE

To measure critical boron concentrations for various CEA configurations at approximately 260°F, 545°F and intermediate temperatures and associated pressures.

2.0 PREREQUISITES

2.1 The reactor critical at the desired conditions.

2.2 The appropriate portion of the regulating and shutdown CEA group worth tests have been completed.

3.0 TEST METHOD

3.1 The reactor is critical with the desired CEA configuration (arrived at as endpoints of selected plateaus in the regulating and shutdown CEA group worth tests).

3.2 Circulation through the pressurizer and the volume control tank is maximized to bring their boron concentrations to equilibrium with the RCS.

3.3 Coolant samples are taken and chemically analyzed for boron content until it is established that an equilibrium state has been achieved.

Table 14.1-3 (continued)

4.0 DATA REQUIRED

Critical conditions:

a. Boron concentration

b. CEA positions

c. RCS temperature

d. Pressurizer pressure

5.0 ACCEPTANCE CRITERIA

The measured critical boron concentrations are in satisfactory agreement with the predictions.

PSEUDO DROPPED AND EJECTED CONTROL ELEMENT ASSEMBLY WORTH

1.0 OBJECTIVE

1.1 To measure the worth of the pseudo "dropped" CEA.

1.2 To measure the worth of the pseudo "ejected" CEA from the ZPDIL.

2.0 PREREQUISITES

2.1 Reactor critical at approximately 545 °F and 2250 psia, with the appropriate CEA configurations.

2.2 The reactivity computer is in operation.

3.0 TEST METHOD

3.1 Pseudo worst "dropped" CEA measurement

a. The pseudo worst "dropped" CEA worth is established on the basis of predictions and verified during the symmetry check.

b. The worst and next worst are then measured by boron dilution.

3.2 Pseudo worst "dropped" PLCEA and "dropped" PLCEA subgroup measurement

a. The pseudo worst "dropped" PLCEA and "dropped" PLCEA subgroups are established by prediction.

b. The worst single PLCEA and subgroup of PLCEAs are measured by boron dilution/boration and/or CEA compensation.

3.3 Pseudo worst "ejected" CEA measurement

a. The worth of the worst pseudo "ejected" CEA is established by means of a prediction.

b. The worst and next worst are measured by boration for the ZPDIL CEA configurations.

Table 14.1-3 (continued)

4.0 DATA REQUIRED

4.1 Conditions of the measurement

a. RCS temperature

b. Pressurizer pressure

c. CEA configuration

d. Boron concentration

4.2 Time dependent information

a. Reactivity variation (strip chart)

b. Changes in CEA positions

5.0 ACCEPTANCE CRITERIA

The measured worths are in satisfactory agreement with the predicted worths.

Table 14.1-4

Table 14.1-4 (continued)

NATURAL CIRCULATION

1.0 OBJECTIVE

To evaluate natural circulation flow conditions.

2.0 PREREQUISITES

The reactor has operated in a manner to ensure that it will be a satisfactory heat source after the trip.

3.0 TEST METHOD

3.1 All reactor coolant pumps are secured.

3.2 The plant is tripped.

3.3 The RCS temperatures and pressurizer pressure are recorded.

3.4 The steam generator levels and pressures are recorded.

4.0 DATA REQUIRED

4.1 Conditions of the measurement

a. Power

b. Power history

c. RCS temperatures

4.2 Time dependent information

a. RCS temperatures and pressurizer pressure

b. Steam generator level and pressure

5.0 ACCEPTANCE CRITERIA

The natural circulation power to flow ratio is less than 1.0.

Table 14.1-4 (continued)

VARIABLE T_{AVG} (ITC & POWER COEFFICIENT)

1.0 OBJECTIVE

To measure the power and isothermal temperature coefficients of reactivity at selected power levels.

2.0 PREREQUISITES

2.1 Measurement of the central CEA worth at zero power.

2.2 Calculated values for the zero power and at power conditions for the worth of the central CEA.

2.3 Equilibrium Xe and boron conditions at the desired power and CEA configurations.

3.0 TEST METHOD

3.1 ITC Measurement

a. The ITC is measured by changing the core average temperature while maintaining the power essentially constant.

b. Changes in reactivity are compensated for by means of movement of the central CEA.

3.2 Power coefficient measurement

a. The power coefficient is measured by changing the core power while maintaining the core average temperature essentially constant.

b. Changes in reactivity are compensated for by means of movement of the central CEA.

4.0 DATA REQUIRED

4.1 Conditions of the measurement

a. Power

b. RCS temperature

c. CEA configuration

d. Boron concentration

e. Burnup

4.2 Data required for the ITC measurement

a. Power level before and after temperature changes

b. RCS temperatures before and after temperature changes

c. Control CEA positions before and after temperature changes

1. Group 6

2. CEA 6-1

Table 14.1-4 (continued)

4.3 Data required for power coefficient measurement

a. Power level before and after power changes

b. RCS temperatures before and after power changes

c. Control CEA positions before and after power changes

1. Group 6

2. CEA 6-1

5.0 ACCEPTANCE CRITERIA

5.1 Satisfactory agreement with predicted values.

5.2 Conformance with the Technical Specifications.

UNIT LOAD TRANSIENT

1.0 OBJECTIVE

To demonstrate that load changes can be made at the desired rates.

2.0 PREREQUISITES

2.1 Unit operating at the desired power.

2.2 The RRS, FWCS, MDS, SDBCS, and the pressurizer level and pressure controls are in the mode of operation used during normal operation under the conditions existing for the test.

3.0 TEST METHOD

Perform load reductions and load increases at selected power levels between 15 percent and 100 percent power.

4.0 DATA REQUIRED

Time dependent data

a. Pressurizer level and pressure

b. RCS temperatures

c. CEA motion

d. Power level and demand

e. Steam generator levels and pressure

Table 14.1-4 (continued)

5.0 ACCEPTANCE CRITERIA

5.1 The reactor power, RCS temperatures, and pressurizer pressure and level are maintained within acceptable ranges during transient operation.

5.2 The steam generator levels and pressures are maintained within acceptable ranges during transient operation.

CONTROL SYSTEMS CHECKOUT

1.0 OBJECTIVE

To demonstrate that the automatic control systems operate satisfactorily during steady state and transient conditions.

2.0 PREREQUISITES

The RRS, FWCS, MDS, SDBCS, and the pressurizer level and pressure controls are in the mode of operation used during normal operation under the conditions existing for the test.

3.0 TEST METHOD

The performance of the control systems during normal operations, transients and trips will be monitored to demonstrate that the systems are operating satisfactorily.

4.0 DATA REQUIRED

Time dependent data

a. Pressurizer level and pressure

b. RCS temperatures

c. CEA motion

d. Power level and demand

e. Steam generator levels and pressure

5.0 ACCEPTANCE CRITERIA

5.1 The control systems maintain the reactor power, RCS temperature, and pressurizer pressure and level within acceptable ranges during both steady state and transient operation.

5.2 The control systems maintain the steam generator levels and pressures within acceptable ranges during both steady state and transient operation.

Table 14.1-4 (continued)

REACTOR COOLANT SYSTEM CHEMISTRY AND RADIOCHEMISTRY (PROCESS MONITOR)

1.0 OBJECTIVE

1.1 To verify the calibration of the process radiation monitor against an acceptable standard.

1.2 To monitor any activity buildup in the reactor coolant following fuel loading and power escalation, and to establish base activity levels.

2.0 PREREQUISITES

2.1 Plant stable at the desired power levels.

2.2 Sampling system for the RCS and CVCS are operable.

3.0 TEST METHOD

3.1 Samples will be collected from the process radiation monitor at various power levels during the initial escalation to full power.

The samples will be analyzed with lab instruments and compared with the radiation monitor results.

3.2 Sampling techniques will be verified and background activity levels will be established.

Sampling will start following fuel loading and continue through power operation to follow any buildup of activity.

4.0 DATA REQUIRED

4.1 Conditions of the measurement

a. Power

b. RCS temperature

c. Boron concentration

4.2 Samples for measurement of gross activities and isotopics

5.0 ACCEPTANCE CRITERIA

5.1 Procedures for sample collection and analysis are verified.

5.2 Base activities are established.

5.3 Laboratory analyses agree satisfactorily with radiation monitor.

Table 14.1-4 (continued)

STEADY STATE CORE PERFORMANCE

1.0 OBJECTIVE

1.1 To document the RCS and steam generator steady state parameters as a function of reactor power.

1.2 To determine core power distributions using incore instrumentation.

2.0 PREREQUISITES

2.1 Desired power level and CEA configuration.

2.2 Equilibrium Xe and boron conditions.

2.3 Steady state conditions at the desired power level.

2.4 Incore instrument system in operation.

3.0 TEST METHOD

3.1 Determine power by heat balance.

3.2 Determine the core power distribution using the incore detectors.

4.0 DATA REQUIRED

4.1 Conditions of the measurement

a. Power

b. RCS temperature

c. CEA configuration

d. Boron concentration

e. Core average burnup

4.2 Test data

a. RCS temperatures and flow

b. Pressurizer pressure and level

c. Steam generator pressures, levels, and steam flow

d. Turbine header pressure

e. Feedwater temperature and flow

f. Valve positions in feedwater system

g. Generator megawatts

h. Incore detector maps

Table 14.1-4 (continued)

5.0 ACCEPTANCE CRITERIA

5.1 Results of measurements at each power level indicate acceptable performance at the next power level.

5.2 Parameters do not exceed equipment or safety limits.

5.3 The agreement between predicted and measured power distributions is satisfactory.

5.4 Measured radial peaking factors are no higher than the corresponding values used in the CPCs.

TURBINE TRIP

1.0 OBJECTIVE

To demonstrate that the plant responds and is controlled as designed, following a 100 percent turbine trip.

2.0 PREREQUISITES

2.1 Reactor operating at or near 100 percent power.

2.2 The SDBCS, FWCS, RRS, and pressurizer pressure and level controls are in the mode of operation used during normal operation under the conditions existing for the test.

3.0 TEST METHOD

3.1 The turbine is tripped.

3.2 Plant behavior, is monitored to assure that the RRS, FWCS, and pressurizer pressure and level controls properly control the turbine trip.

4.0 DATA REQUIRED

4.1 Plant condition prior to trip

Power

4.2 Time dependent data

a. Pressurizer level and pressure

b. Steam generator levels and pressure

c. RCS temperatures

d. CEA positions

5.0 ACCEPTANCE CRITERIA

The plant control systems and operator actions satisfactorily control a 100 percent turbine trip.

Table 14.1-4 (continued)

LOAD REJECTION

1.0 OBJECTIVE

To demonstrate that the NSSS can sustain a 100 percent load rejection.

2.0 PREREQUISITES

2.1 Reactor operating at or near 100 percent power.

2.2 The SDBCS, FWCS, RRS, and pressurizer pressure and level control are in the mode of operation used during normal operation under the conditions existing for the test.

3.0 TEST METHOD

3.1 The generator main breaker is tripped.

3.2 Monitor the plant behavior to assure that the RRS, SDBCS, and FWCS and pressurizer pressure and level controls properly control the load rejection transient.

4.0 DATA REQUIRED

4.1 Plant condition prior to trip

Power

4.2 Time dependent data

a. Pressurizer level and pressure

b. Steam generator levels and pressure

c. RCS temperatures

d. CEA positions

5.0 ACCEPTANCE CRITERIA

The plant control systems and operator actions satisfactorily control a 100 percent load rejection.

SHUTDOWN FROM OUTSIDE THE CONTROL ROOM

1.0 OBJECTIVE

To demonstrate that the plant can be maintained in hot standby from outside the control room following a reactor trip.

2.0 PREREQUISITES

Plant operating at ≥ 10 percent generator output.

Table 14.1-4 (continued)

3.0 TEST METHOD

3.1 The operating crew evacuates the control room; standby crew remains in the control room.

3.2 Reactor is tripped.

3.3 The reactor is brought to hot standby by the operating crew from outside the control room.

4.0 DATA REQUIRED

Time dependent data

a. Pressurizer level and pressure

b. RCS temperature

c. Steam generator pressure and level

5.0 ACCEPTANCE CRITERIA

The ability to achieve and control the reactor at hot standby from outside the control room is demonstrated.

a. RCS temperatures are maintained in the desired range.

b. The pressurizer pressure and level are maintained in the desired range.

c. The steam generator levels are maintained at desired levels.

LOSS OF OFFSITE POWER*

1.0 OBJECTIVE

To verify that the unit can safely sustain a loss of offsite power without exceeding any safety limits, while maintaining the main turbine generator on line supplying auxiliary house load, but isolated from the power grid.

2.0 PREREQUISITES

2.1 Generator output ≥ 10 percent.

2.2 Unit supplying it's own auxiliary load.

2.3 Both diesel generators operable and prepared to supply emergency power.

3.0 TEST METHOD

3.1 The unit is isolated from all offsite power by isolating the startup transformers from the unit and then separating the unit from the grid.

3.2 The unit will continue to supply it's own auxiliary load through the auxiliary transformer.

Table 14.1-4 (continued)

4.0 DATA REQUIRED

Time dependent data

a. Steam generator pressure and levels

b. Pressurizer pressure and level

c. RCS temperatures

5.0 ACCEPTANCE CRITERIA

5.1 The unit is isolated from all sources of offsite power without a loss of house loads, or if the auxiliary transformer is lost, the unit is shutdown and maintained in hot standby with emergency power sources.

5.2 No safety limits are exceeded.

* This test method was subsequently modified. See letter 2CAN047809.

BIOLOGICAL SHIELD SURVEY

1.0 OBJECTIVE

1.1 To measure radiation in accessible locations of the plant outside of the biological shield.

1.2 To obtain baseline levels for comparison with future measurements of level buildup with operation.

2.0 PREREQUISITES

2.1 Radiation survey instruments calibrated.

2.2 Background radiation levels measured in designated locations prior to initial criticality.

3.0 TEST METHOD

Measure gamma and neutron dose rates.

a. 50 percent power

b. 100 percent power

4.0 DATA REQUIRED

4.1 Power level

4.2 Gamma and neutron dose rates at each specified location

5.0 ACCEPTANCE CRITERIA

5.1 Radiation levels are demonstrated acceptable for full power operation.

5.2 Accessible areas and occupancy times during power operation are defined.

Table 14.1-4 (continued)

XENON OSCILLATION CONTROL (PLCEA)

1.0 OBJECTIVE

To demonstrate a satisfactory technique for damping xenon oscillations using the PLCEAs.

2.0 PREREQUISITES

2.1 Reactor critical at approximately 65 percent power; PLCEAs inserted with xenon equilibrium.

2.2 Free xenon oscillations measured as part of proceeding power escalation testing.

2.3 The COLSS and the incore system are in operation.

3.0 TEST METHOD

3.1 A free oscillation is established.

3.2 Control schemes are implemented utilizing the PLCEAs.

4.0 DATA REQUIRED

4.1 Reactor conditions

a. Power level
b. Boron concentration
c. RCS temperatures
d. Burnup

4.2 Time dependent data

a. Incore detector maps
b. Excore readings
c. CEA positions
d. PLCEA positions

5.0 ACCEPTANCE CRITERIA

The ability to dampen xenon oscillations using the PLCEAs is demonstrated.

Table 14.1-4 (continued)

DROPPED CONTROL ELEMENT ASSEMBLY

1.0 OBJECTIVE

To determine the flux distribution resulting from a "dropped" CEA.

2.0 PREREQUISITES

2.1 The reactor is critical at approximately 50 percent power, with equilibrium conditions for the desired CEA configuration.

2.2 The incore detector system is in operation.

3.0 TEST METHOD

3.1 Full length CEA

a. The selected CEA is rapidly inserted to the full "in" position.

b. The CEA remains inserted for a preselected time.

c. Excore and incore instrument signals are recorded before, during and after the CEA insertion.

3.2 PLCEA

a. The selected PLCEA is rapidly inserted to the specified insertion.

b. The PLCEA remains inserted for a preselected time.

c. Excore and incore instrument signals are recorded before, during and after the CEA insertion.

4.0 DATA REQUIRED

4.1 Conditions of the measurement

a. Power

b. RCS temperatures

c. CEA configuration

d. Boron concentration

e. Burnup

4.2 Time dependent data

a. Incore and excore detector readings

b. RCS temperatures

c. CEA positions

d. Power

5.0 ACCEPTANCE CRITERIA

The measured incore maps are in satisfactory agreement with the predictions.

Table 14.1-4 (continued)

PSEUDO ROD EJECTION

1.0 OBJECTIVE

To determine that the power distribution associated with the pseudo CEA ejection from the FPDIL CEA configuration is adequately represented in the safety analysis.

2.0 PREREQUISITES

2.1 The reactor critical at approximately 50 percent power.

a. CEAs at the FPDIL

b. Equilibrium xenon

2.2 The incore detector system is in operation.

3.0 TEST METHOD

3.1 The pseudo CEA ejection test is performed at approximately 50 percent power by withdrawing the "worst" (selected by calculation) CEA from the FPDIL.

3.2 Incore detector maps are taken before and after withdrawal of the static "ejected" CEA.

3.3 The next worst "ejected" CEA is withdrawn while inserting the previous CEA.

3.4 An incore detector map is taken.

3.5 The CEAs are returned to a normal configuration.

4.0 DATA REQUIRED

4.1 Conditions of the measurement

a. Power

b. RCS temperature

c. CEA configuration

d. Boron concentration

e. Burnup

4.2 Time dependent data

a. Power

b. Incore and excore detector readings

c. RCS temperatures

d. CEA positions

5.0 ACCEPTANCE CRITERIA

Analyses of the incore maps indicate satisfactory agreement with predictions.

Table 14.1-4 (continued)

COMPARISON OF PPS, CPCs AND PROCESS COMPUTER INPUTS

1.0 OBJECTIVE

To demonstrate that the inputs and appropriate outputs of the PPS, the CPCs and the process computer are consistent and correct.

2.0 PREREQUISITES

The plant operating at desired conditions.

3.0 TEST METHOD

Simultaneous reading of related inputs and appropriate outputs of the PPS, the CPCs and the process computer are made.

4.0 DATA REQUIRED

4.1 Conditions of the measurement

a. Power
b. Boron concentration
c. Burnup

4.2 Test data

a. RCS temperatures and flows
b. Excore detector readings
c. Incore detector readings
d. CEA positions
e. Pressurizer pressure
f. Steam generator levels and pressure

5.0 ACCEPTANCE CRITERIA

The inputs to the PPS, the CPCs and the process computer are consistent and in satisfactory agreement.

Table 14.1-4 (continued)

VERIFICATION OF CPC POWER DISTRIBUTION-RELATED CONSTANTS

1.0 OBJECTIVE

1.1 To verify the planar radial peaking, shape annealing and boundary point correlation, and rod shadowing factors.

1.2 To verify the algorithms used in the CPCs to relate excore signals to incore power distribution.

2.0 PREREQUISITES

2.1 The incore detector systems has been demonstrated to operate satisfactorily.

2.2 The safety channels have been demonstrated to be operating satisfactorily.

2.3 The reactor is critical and at required power levels.

3.0 TEST METHOD

3.1 Planar radial peaking factors are verified at selected power levels for ARO and various CEA configurations (including misaligned CEAs) by comparison of the CPC values with values measured with the incore detector system.

3.2 The rod shadowing factors are verified in conjunction with peaking factor measurements by comparing the rodded and unrodded excore detector responses.

3.3 The shape annealing matrix and boundary point correlation will be determined from a series of Xe oscillations carried out during the 50 percent testing.

4.0 DATA REQUIRED

4.1 Conditions of the measurement

a. Power

b. RCS temperatures

c. Pressurizer pressure

d. CEA configuration

e. Boron concentration

f. Burnup

4.2 Time dependent data

a. Incore detector readings and corresponding excore detector readings.

b. Corresponding CEA configuration.

5.0 ACCEPTANCE CRITERIA

5.1 Measured radial peaking factors determined from incore flux maps are no higher than the corresponding values used in the CPCs.

5.2 Other CPC power distribution constants, used in the axial power distribution synthesis, are in satisfactory agreement with predictions.

Table 14.1-4 (continued)

STEAM GENERATOR CHEMISTRY

1.0 OBJECTIVE

1.1 To maintain proper water chemistry for the steam generators and the feedwater system.

1.2 To establish the necessary sampling frequency to provide assurance that chemistry limits are not exceeded.

2.0 PREREQUISITES

Sampling systems for the steam generators and the feedwater system are operable.

3.0 TEST METHOD

During power escalation, the steam generators and the feedwater system will be sampled to verify that chemistry specifications are maintained.

4.0 DATA REQUIRED

4.1 Conditions of the measurement

a. Power level

b. Power history

4.2 Test data

a. Sample point locations

b. Time of sample

5.0 ACCEPTANCE CRITERIA

Chemistry of the steam generators and the feedwater system are maintained within specifications.

STEAM DUMP VALVE AND BYPASS SYSTEMS

1.0 OBJECTIVE

1.1 To demonstrate that the maximum steam flow capacity of atmospheric steam dump valves upstream of the main steam isolation valves (MSIVs) is less than that assumed for the most severe excess heat removal incident.

1.2 To demonstrate that the operation of the Steam Dump and Bypass Control System (SDBCS) during operational transients and plant trips is satisfactory.

Table 14.1-4 (continued)

2.0 PREREQUISITES

2.1 The reactor is critical at approximately 15 percent power using the SDBCS to dump steam to the condenser.

2.2 The SDBCS is in automatic operation.

2.3 Control systems are in automatic, where applicable.

3.0 TEST METHOD

3.1 The individual steam flows through each of the steam dump valves upsteam of the MSIVS are measured.

3.2 The operation of the SDBCS is observed during planned and unplanned operational transients and trips.

4.0 DATA REQUIRED

4.1 Atmospheric dump valve test

a. Reactor power

b. RCS temperatures and pressurizer pressure

c. Steam generator levels and pressure

d. Steam dump and bypass valve positions

4.2 Demonstration of SDBCS

a. Reactor power

b. RCS temperature and pressurizer pressure

c. Steam generator flows, pressures, and levels

5.0 ACCEPTANCE CRITERIA

5.1 Atmospheric steam dump valve capacity

The individual steam dump valve capacities are less than the values used in the safety analysis.

5.2 SDBCS operation

The SDBCS functioned satisfactorily during operational transients and plant trips.

Table 14.1-4 (continued)

MAIN AND EMERGENCY FEEDWATER SYSTEMS

1.0 OBJECTIVE

To demonstrate that the operation of the main feedwater and emergency feedwater systems during normal operation, operational transients, and plant trips is satisfactory.

2.0 PREREQUISITES

The SDBCS, FWCS, RRS, and pressurizer pressure and level controls are in operation.

3.0 TEST METHODS

Performance of the feedwater systems will be monitored during normal operation, operational transients, and trips.

The resulting observations and/or data will be used to evaluate the performance of the feedwater systems.

4.0 DATA REQUIRED

Observations and/or data taken during normal operation, operational transients, and trips.

a. Reactor power

b. RCS temperatures and pressurizer pressure

c. Steam generator levels and pressures

d. Steam and feedwater flows

5.0 ACCEPTANCE CRITERIA

5.1 The main feedwater system operates consistent with design.

5.2 The emergency feedwater system operates consistent with design.

15.1.13	MAJOR RUPTURE OF PIPES CONTAINING REACTOR COOLANT UP TO AND INCLUDING DOUBLE-ENDED RUPTURE OF LARGEST PIPE IN THE REACTOR COOLANT SYSTEM (LOSS OF COOLANT ACCIDENT)	15.1-76
15.1.13.1	Identification of Causes	15.1-76
15.1.13.2	Analysis of Events and Consequences	15.1-77
15.1.13.3	Results	15.1-77

TABLE OF CONTENTS (continued)

Section	Title	Page
15.1.13.4	Post-Accident Leakage	15.1-77
15.1.14	MAJOR SECONDARY SYSTEM PIPE BREAKS WITH OR WITHOUT A CONCURRENT LOSS OF AC POWER	15.1-78
15.1.14.1	Steam Line Break Accident	15.1-78
15.1.14.2	Feedwater Line Break Accident	15.1-97
15.1.14.3	Additional Main Steam Line/Feedwater Line Break Information and Analyses	15.1-108
15.1.15	INADVERTENT LOADING OF A FUEL ASSEMBLY INTO THE IMPROPER POSITION	15.1-108
15.1.15.1	Identification of Causes	15.1-108
15.1.15.2	Analysis of Effects and Consequences	15.1-110
15.1.16	WASTE GAS DECAY TANK LEAKAGE OR RUPTURE	15.1-111
15.1.16.1	Identification of Causes	15.1-111
15.1.16.2	Analysis of Events and Consequences	15.1-111
15.1.17	FAILURE OF AIR EJECTOR LINES (BWR)	15.1-111
15.1.18	STEAM GENERATOR TUBE RUPTURE WITH OR WITHOUT A CONCURRENT LOSS OF AC POWER	15.1-111
15.1.18.1	Identification of Causes	15.1-111
15.1.18.2	Removed – Historical Data	
15.1.18.3	Removed – Historical Data	
15.1.18.4	SGTR Subsequent Analyses	15.1-113
15.1.19	FAILURE OF CHARCOAL OF CYROGENIC SYSTEM (BWR)	15.1-116
15.1.20	CONTROL ELEMENT ASSEMBLY EJECTION	15.1-116
15.1.20.1	Identification of Causes	15.1-116
15.1.20.2	Analysis of Effects and Consequences	15.1-116
15.1.20.3	Conclusion	15.1-120

TABLE OF CONTENTS (continued)

LIST OF TABLES

Table No.	Title	Page
15.1.0-1	REACTOR PROTECTIVE SYSTEM TRIPS USED IN THE SAFETY ANALYSES	15.3-1
15.1.0-2A	PRIMARY COOLANT SOURCE TERM FOR NON-FUEL FAILURE EVENTS and SECONDARY COOLANT SOURCE TERM FOR MAIN STEAM LINE BREAK ANALYSIS	15.3-4
15.1.0-2B	CORE ISOTOPIC INVENTORY FOR FUEL FAILURE EVENTS	15.3-5
15.1.0-3	FGR DATA FOR ISOTOPES	15.3-6
15.1.0-4	BREATHING RATES	15.3-6
15.1.0-5	ACCIDENT ATMOSPHERIC DILUTION FACTORS	15.3-6
15.1.0-6	INITIAL CONDITIONS	15.3-7
15.1.0-7	ENGINEERED SAFETY FEATURES RESPONSE TIMES	15.3-8
15.1.1-1	ASSUMPTIONS FOR THE UNCONTROLLED CEA WITHDRAWAL FROM A SUBCRITICAL CONDITION	15.3-10
15.1.1-2	SEQUENCE OF EVENTS FOR THE UNCONTROLLED CEA WITHDRAWAL FROM A SUBCRITICAL CONDITION	15.3-11
15.1.1-3	ASSUMPTIONS FOR THE CYCLE 12 UNCONTROLLED CEA WITHDRAWAL FROM A SUBCRITICAL CONDITION	15.3-12
15.1.1-4	ASSUMPTIONS FOR THE CYCLE 13 UNCONTROLLED CEA WITHDRAWAL FROM A SUBCRITICAL CONDITION	15.3-13
15.1.1-5	SEQUENCE OF EVENTS FOR THE CYCLE 13 UNCONTROLLED CEA WITHDRAWAL FROM SUBCRITICAL CONDITIONS CASE 1	15.3-14
15.1.1-6	SEQUENCE OF EVENTS FOR THE CYCLE 13 UNCONTROLLED CEA WITHDRAWAL FROM SUBCRITICAL CONDITIONS CASE 2	15.3-14
15.1.1-7	ASSUMPTIONS FOR THE CYCLE 16 UNCONTROLLED CEA WITHDRAWAL FROM A SUBCRITICAL CONDITION	15.3-15
15.1.1-8	SEQUENCE OF EVENTS FOR THE CYCLE 16 UNCONTROLLED CEA WITHDRAWAL FROM A SUBCRITICAL CONDITION WITH A RIR OF 2.5 X 10^{-4} $\Delta\rho$/SEC	15.3-16
15.1.1-9	SEQUENCE OF EVENTS FOR THE CYCLE 16 UNCONTROLLED CEA WITHDRAWAL FROM A SUBCRITICAL CONDITION WITH A RIR OF 2.0 X 10^{-4} $\Delta\rho$/SEC	15.3-16

LIST OF TABLES (continued)

Table No.	Title	Page
15.1.2-1	ASSUMPTIONS FOR THE UNCONTROLLED CEA WITHDRAWAL FROM ONE PERCENT POWER	15.3-17
15.1.2-2	ASSUMPTIONS FOR THE UNCONTROLLED CEA WITHDRAWAL FROM FULL POWER	15.3-18
15.1.2-3	SEQUENCES OF EVENTS FOR THE UNCONTROLLED CEA WITHDRAWAL FROM ONE PERCENT POWER, BOC CONDITIONS	15.3-19
15.1.2-4	SEQUENCE OF EVENTS FOR THE UNCONTROLLED CEA WITHDRAWAL FROM FULL POWER	15.3-19
15.1.2-5	ASSUMPTIONS FOR THE CYCLE 13 UNCONTROLLED CEA WITHDRAWAL FROM ONE PERCENT POWER	15.3-20
15.1.2-6	ASSUMPTIONS FOR THE CYCLE 12 UNCONTROLLED CEA WITHDRAWAL FROM FULL POWER	15.3-21
15.1.2-7	SEQUENCE OF EVENTS FOR THE CYCLE 13 UNCONTROLLED CEA WITHDRAWAL FROM ONE PERCENT POWER	15.3-22
15.1.2-8	ASSUMPTIONS FOR THE CYCLE 16 UNCONTROLLED CEA WITHDRAWAL FROM HOT ZERO POWER	15.3-23
15.1.2-9	SEQUENCE OF EVENTS FOR THE CYCLE 16 UNCONTROLLED CEA WITHDRAWAL FROM HOT ZERO POWER	15.3-24
15.1.2-10	ASSUMPTIONS FOR THE CYCLE 16 UNCONTROLLED CEA WITHDRAWAL AT HOT FULL POWER	15.3-24
15.1.2-11	SEQUENCE OF EVENTS FOR THE CYCLE 16 UNCONTROLLED CEA WITHDRAWAL AT HOT FULL POWER	15.3-25
15.1.3-1	ASSUMPTIONS FOR THE FULL LENGTH CEA DROP	15.3-26
15.1.3-2	RESULTS OF FULL LENGTH CEA DROP	15.3-27
15.1.3-3	INITIAL HOT CHANNEL AXIAL POWER DISTRIBUTIONS FOR CEA MISOPERATION ANALYSIS	15.3-28
15.1.3-4	SEQUENCE OF EVENTS FOR FULL LENGTH CEA DROP	15.3-30
15.1.3-5	ASSUMPTIONS FOR THE CYCLE 16 CEA MISOPERATION AT POWER	15.3-31
15.1.4-1	ASSUMPTIONS FOR UNCONTROLLED BORON DILUTION	15.3-32
15.1.5-1	ASSUMPTIONS FOR THE LOSS OF COOLANT FLOW	15.3-34

LIST OF TABLES (continued)

Table No.	Title	Page
15.1.5-2	ASSUMPTIONS FOR THE LOSS OF COOLANT FLOW RESULTING FROM A SHAFT SEIZURE	15.3-35
15.1.5-3	SEQUENCE OF EVENTS FOR THE 4-PUMP LOSS OF COOLANT FLOW FOR CYCLE 2	15.3-36
15.1.5-4	SEQUENCE OF EVENTS FOR THE 2-PUMP LOSS OF COOLANT FLOW FROM 4-PUMP OPERATION FOR CYCLE 1	15.3-36
15.1.5-5	SEQUENCE OF EVENTS FOR THE SINGLE REACTOR COOLANT PUMP SHAFT SEIZURE	15.3-37
15.1.5-6	FLOW COASTDOWN FOR A 6.47 HERTZ GRID FREQUENCY TRANSIENT	15.3-38
15.1.5-7	INITIAL NSSS PLANT PARAMETER FOR CENTRAN SIMULATION	15.3-38
15.1.5-8	ASSUMPTIONS FOR THE LOSS OF COOLANT FLOW ANALYSIS ASSUMING 30% STEAM GENERATOR TUBE PLUGGING	15.3-39
15.1.5-9	SEQUENCE OF EVENTS FOR THE 4-PUMP LOSS OF COOLANT FLOW ANALYSIS	15.3-39
15.1.5-10	AST RADIOLOGICAL DOSE RESULTS FOR REACTOR COOLANT PUMP SHAFT SEIZURE ASSUMING 14% FUEL FAILURE	15.3-40
15.1.5-11	CYCLE 15 FOUR REACTOR COOLANT PUMP FLOW COASTDOWN RESULTING FROM AN ELECTRICAL FAILURE	15.3-40
15.1.5-12	FOUR REACTOR COOLANT PUMP FLOW COASTDOWN RESULTING FROM AN ELECTRICAL FAILURE	15.3-41
15.1.5-13	ASSUMPTIONS FOR THE CYCLE 16 LOSS OF COOLANT FLOW ANALYSIS	15.3-41
15.1.5-14	SEQUENCE OF EVENTS FOR THE CYCLE 16 FOUR PUMP LOSS OF COOLANT FLOW ANALYSIS	15.3-42
15.1.5-15	ASSUMPTIONS FOR THE CYCLE 16 LOSS OF COOLANT FLOW RESULTING FROM PUMP SHAFT SEIZURE	15.3-43
15.1.5-16	SEQUENCE OF EVENTS FOR THE CYCLE 16 (TYPICAL CASE) LOSS OF COOLANT FLOW PUMP SHAFT SEIZURE ANALYSIS	15.3-44
15.1.6-1	ASSUMPTIONS FOR THE IDLE LOOP STARTUP	15.3-45
15.1.6-2	INITIAL CONDITIONS FOR IDLE LOOP STARTUP	15.3-45

LIST OF TABLES (continued)

Table No.	Title	Page
15.1.6-3	SEQUENCE OF EVENTS FOR THE IDLE LOOP STARTUP	15.3-46
15.1.7-1	ASSUMPTIONS FOR THE LOSS OF EXTERNAL LOAD/LOSS OF CONDENSER VACUUM	15.3-47
15.1.7-2	SEQUENCE OF EVENTS FOR THE LOSS OF EXTERNAL LOAD/LOSS OF CONDENSER VACUUM	15.3-48
15.1.7-3	REMOVED – HISTORICAL DATA	15.3-48
15.1.7-4	ASSUMPTIONS FOR THE CYCLE 13 LOSS OF EXTERNAL LOAD/LOSS OF CONDENSER VACUUM	15.3-49
15.1.7-5	SEQUENCE OF EVENTS FOR THE CYCLE 13 LOSS OF EXTERNAL LOAD/LOSS OF CONDENSER VACUUM	15.3-50
15.1.7-6	ASSUMPTIONS FOR CYCLE 15 AT 3026 MWT LOSS OF EXTERNAL LOAD/LOSS OF CONDENSER VACUUM	15.3-51
15.1.7-7	SEQUENCE OF EVENTS FOR CYCLE 15 AT 3026 MWT LOSS OF EXTERNAL LOAD/LOSS OF CONDENSER VACUUM	15.3-52
15.1.8-1	ASSUMPTIONS FOR THE LOSS OF NORMAL FEEDWATER FLOW	15.3-52
15.1.8-2	PRINCIPAL RESULTS FOR THE LOSS OF NORMAL FEEDWATER FLOW	15.3-53
15.1.8-3	ASSUMPTIONS FOR THE CYCLE 13 LOSS OF NORMAL FEEDWATER FLOW	15.3-53
15.1.8-4	PRINCIPAL RESULTS FOR THE CYCLE 13 LOSS OF NORMAL FEEDWATER FLOW	15.3-54
15.1.8-5	ASSUMPTIONS FOR CYCLE 15 AT 3026 MWT LOSS OF NORMAL FEEDWATER FLOW	15.3-55
15.1.8-6	SEQUENCE OF EVENTS FOR CYCLE 15 AT 3026 MWT LOSS OF NORMAL FEEDWATER FLOW	15.3-56
15.1.9-1	ASSUMPTIONS FOR THE LOSS OF ALL NORMAL AC POWER TO THE STATION AUXILIARIES	15.3-57
15.1.9-2	SEQUENCE OF EVENTS FOR THE LOSS OF NORMAL AND PREFERRED AC POWER TO THE STATION AUXILIARIES	15.3-58
15.1.10-1	ASSUMPTIONS FOR THE FEEDWATER SYSTEM MALFUNCTION	15.3-59
15.1.10-2	ASSUMPTIONS FOR THE STEAM BYPASS SYSTEM MALFUNCTION	15.3-60

LIST OF TABLES (continued)

Table No.	Title	Page
15.1.10-3A	SEQUENCE OF EVENTS FOR FEEDWATER SYSTEM MALFUNCTION INVOLVING 160% FEEDWATER FLOW TO BOTH STEAM GENERATORS	15.3-61
15.1.10-3B	SEQUENCE OF EVENTS FOR FEEDWATER SYSTEM MALFUNCTION INVOLVING 160% FEEDWATER FLOW TO ONE STEAM GENERATOR	15.3-61
15.1.10-4	SEQUENCE OF EVENTS FOR THE STEAM BYPASS SYSTEM MALFUNCTION ACCIDENT	15.3-62
15.1.10-5	ASSUMPTIONS FOR CYCLE 15 AT 3026 MWT FEEDWATER SYSTEM MALFUNCTION	15.3-63
15.1.10-6	SEQUENCE OF EVENTS FOR CYCLE 15 AT 3026 MWT FEEDWATER SYSTEM MALFUNCTION	15.3-64
15.1.10-7	ASSUMPTIONS OF CYCLE 15 AT 3026 MWT STEAM BYPASS SYSTEM MALFUNCTION	15.3-64
15.1.10-8	SEQUENCE OF EVENTS FOR CYCLE 15 AT 3026 MWT STEAM BYPASS SYSTEM MALFUNCTION	15.3-65
15.1.13-1	ASSUMPTIONS FOR DESIGN BASIS LOSS OF COOLANT ACCIDENT	15.3-66
15.1.13-2	LOSS OF COOLANT ACCIDENT DOSES	15.3-67
15.1.13-3	RELEASE FRACTIONS AND TIMING	15.3-67
15.1.14-1	AVERAGE MOISTURE CARRYOVER FOR VARIOUS STEAM GENERATOR CONDITIONS	15.3-68
15.1.14-2	ASSUMPTIONS FOR STEAM LINE BREAK ANALYSIS	15.3-68
15.1.14-3 – 15.1.14-10	REMOVED - HISTORICAL DATA	15.3-69
15.1.14-11	SEQUENCE OF EVENTS FOR THE STEAM LINE BREAK ACCIDENT (NO LOAD, ONE-LOOP CONDITION, RUPTURE OUTSIDE CONTAINMENT)	15.3-69
15.1.14-12	SEQUENCE OF EVENTS FOR THE STEAM LINE BREAK ACCIDENT WITH LOSS OF AC POWER (FULL LOAD, TWO-LOOP INITIAL CONDITION, SMALL BREAK)	15.3-70
15.1.14-13	SEQUENCE OF EVENTS FOR THE STEAM LINE BREAK ACCIDENT WITH LOSS OF AC POWER (NO LOAD, ONE-LOOP INITIAL CONDITION, SMALL BREAK)	15.3-71

LIST OF TABLES (continued)

Table No.	Title	Page
15.1.14-14	SEQUENCE OF EVENTS FOR THE STEAM LINE BREAK ACCIDENT WITH AC POWER (FULL LOAD, TWO-LOOP INITIAL CONDITION, NOZZLE BREAK, WITHOUT MOISTURE CARRYOVER)	15.3-72
15.1.14-15	SEQUENCE OF EVENTS FOR THE STEAM LINE BREAK ACCIDENT WITHOUT AC POWER (FULL LOAD, TWO-LOOP INITIAL CONDITION, NOZZLE BREAK, WITHOUT MOISTURE CARRYOVER)	15.3-73
15.1.14-16	SEQUENCE OF EVENTS FOR THE STEAM LINE BREAK ACCIDENT WITH AC POWER (NO LOAD, TWO-LOOP INITIAL CONDITION, NOZZLE BREAK, WITHOUT MOISTURE CARRYOVER)	15.3-74
15.1.14-17	SEQUENCE OF EVENTS FOR THE STEAM LINE BREAK ACCIDENT WITHOUT AC POWER (NO LOAD, TWO-LOOP INITIAL CONDITION, NOZZLE BREAK, WITHOUT MOISTURE CARRYOVER)	15.3-75
15.1.14-18	ASSUMPTION FOR FEEDWATER LINE BREAK ANALYSIS	15.3-76
15.1.14-19	SEQUENCE OF EVENTS FOR THE FEEDWATER LINE BREAK ACCIDENT WITH AC AVAILABLE	15.3-77
15.1.14-20	SEQUENCE OF EVENTS FOR THE FEEDWATER LINE BREAK ACCIDENT WITH LOSS OF AC	15.3-78
15.1.14-21	STEAM GENERATOR LIQUID INVENTORIES FOR FEEDWATER LINE BREAK ACCIDENT WITH AC POWER AVAILABLE	15.3-79
15.1.14-22	STEAM GENERATOR LIQUID INVENTORIES FOR FEEDWATER LINE BREAK ACCIDENT WITH LOSS OF AC POWER	15.3-79
15.1.14-23	ASSUMPTIONS FOR THE CYCLE 3 FEEDWATER LINE BREAK ANALYSIS	15.3-80
15.1.14-24	ASSUMPTIONS FOR THE CYCLE 13 FEEDWATER LINE BREAK ANALYSIS	15.3-81
15.1.14-25	SEQUENCE OF EVENTS FOR THE CYCLE 13 FEEDWATER LINE BREAK ACCIDENT WITH LOSS OF AC	15.3-82
15.1.14-26	ASSUMPTIONS FOR CYCLE 12 STEAM LINE BREAK ANALYSIS FULL LOAD	15.3-83
15.1.14-27	ASSUMPTIONS FOR CYCLE 12 STEAM LINE BREAK ANALYSIS NO LOAD	15.3-83

LIST OF TABLES (continued)

Table No.	Title	Page
15.1.14-28	SEQUENCE OF EVENTS FOR THE CYCLE 12 STEAM LINE BREAK EVENT WITH LOSS OF AC, 1 HPSI PUMP, HFP	15.3-84
15.1.14-29	SEQUENCE OF EVENTS FOR THE CYCLE 12 STEAM LINE BREAK EVENT WITH AC AVAILABLE, 2 HPSI PUMPS, HFP	15.3-85
15.1.14-30	SEQUENCE OF EVENTS FOR THE CYCLE 12 STEAM LINE BREAK EVENT WITH LOSS OF AC, 1 HPSI PUMP, HZP	15.3-86
15.1.14-31	SEQUENCE OF EVENTS FOR THE CYCLE 12 STEAM LINE BREAK EVENT WITH AC AVAILABLE, 1 HPSI PUMP, HZP	15.3-87
15.1.14-32	ASSUMPTIONS FOR THE CYCLE 14 STEAM LINE BREAK ANALYSIS FROM HOT FULL POWER AND HOT ZERO POWER	15.3-88
15.1.14-33	SEQUENCE OF EVENTS FOR THE CYCLE 14 STEAM LINE BREAK HOT FULL POWER WITH LOSS OF AC	15.3-89
15.1.14-34	SEQUENCE OF EVENTS FOR THE CYCLE 14 STEAM LINE BREAK HOT FULL POWER WITH AC AVAILABLE	15.3-90
15.1.14-35	SEQUENCE OF EVENTS FOR THE CYCLE 14 STEAM LINE BREAK HOT ZERO POWER WITH LOSS OF AC	15.3-91
15.1.14-36	SEQUENCE OF EVENTS FOR THE CYCLE 14 STEAM LINE BREAK HOT ZERO POWER WITH AC AVAILABLE	15.3-92
15.1.14-37	REMOVED – HISTORICAL DATA	15.3-93
15.1.14-38	EVENT GENERATED IODINE SPIKE RADIOLOGICAL DOSE RESULTS FOR AST MAIN STEAM LINE BREAK EVENT	15.3-93
15.1.14-39	PRE-EXISTING IODINE SPIKE RADIOLOGICAL DOSE RESULTS FOR AST MAIN STEAM LINE BREAK EVENT	15.3-93
15.1.14-40	REMOVED – HISTORICAL DATA	15.3-93
15.1.14-41	ASSUMPTIONS FOR CYCLE 15 AT 3026 MWT STEAM LINE BREAK ANALYSIS FROM HOT FULL POWER TO HOT ZERO POWER	15.3-94
15.1.14-42	SEQUENCE OF EVENTS FOR CYCLE 15 AT 3026 MWT STEAM LINE BREAK HOT FULL POWER WITH LOSS OF AC	15.3-95
15.1.14-43	SEQUENCE OF EVENTS FOR CYCLE 15 AT 3026 MWT STEAM LINE BREAK HOT FULL POWER WITH AC AVAILABLE INSIDE CONTAINMENT	15.3-96

LIST OF TABLES (continued)

Table No.	Title	Page
15.1.14-44	SEQUENCE OF EVENTS FOR CYCLE 15 AT 3026 MWT STEAM LINE BREAK HOT ZERO POWER WITH LOSS OF AC	15.3-97
15.1.14-45	SEQUENCE OF EVENTS FOR CYCLE 15 AT 3026 MWT STEAM LINE BREAK HOT ZERO POWER WITH AC AVAILABLE OUTSIDE CONTAINMENT	15.3-98
15.1.14-46	ASSUMPTIONS FOR CYCLE 15 FEEDWATER LINE BREAK	15.3-99
15.1.14-47	PRINCIPAL RESULTS FOR CYCLE 15 FEEDWATER LINE BREAK	15.3-100
15.1.14-48	ASSUMPTIONS FOR CYCLE 16 FEEDWATER LINE BREAK	15.3-101
15.1.14-49	SEQUENCE OF EVENTS FOR THE CYCLE 16 FEEDWATER LINE BREAK	15.3-102
15.1.15-1	DELETED	15.3-103
15.1.16-1 – 15.1.16-2	DELETED	15.3-103
15.1.18-1 – 15.1.18-4	REMOVED – HISTORICAL DATA	15.3-103
15.1.18-5	ASSUMPTIONS FOR CYCLE 16 STEAM GENERATOR TUBE RUPTURE WITH A CONCURRENT LOSS OF AC POWER	15.3-104
15.1.18-6	SEQUENCE OF EVENTS FOR THE CYCLE 16 STEAM GENERATOR TUBE RUPTURE WITH A CONCURRENT LOSS OF AC POWER	15.3-105
15.1.18-7	STEAM GENERATOR TUBE RUPTURE WITH A CONCURRENT LOSS OF AC POWER DOSE RESULTS FOR EVENT GENERATED IODINE SPIKE	15.3-105
15.1.18-8	STEAM GENERATOR TUBE RUPTURE WITH A CONCURRENT LOSS OF AC POWER PRE-EXISTING IODINE SPIKE RADIOLOGICAL DOSE RESULTS	15.3-106
15.1.20-1	FULL POWER CEA EJECTION ACCIDENT VARIABLES	15.3-106
15.1.20-2	ZERO POWER CEA EJECTION ACCIDENT VARIABLES	15.3-107
15.1.20-3	FULL POWER CEA EJECTION ACCIDENT RESULTS	15.3-108
15.1.20-4	ZERO POWER CEA EJECTION ACCIDENT RESULTS	15.3-108
15.1.20-5	CEA EJECTION CASES AT HOT FULL POWER	15.3-109

LIST OF TABLES (continued)

Table No.	Title	Page
15.1.20-6	CEA EJECTION CASES AT HOT ZERO POWER	15.3-110
15.1.20-7	AXIAL POWER DISTRIBUTION USED FOR CEA EJECTION ACCIDENT ANALYSIS	15.3-111
15.1.20-8	KEY PARAMETERS ASSUMED IN THE CYCLE 2 CEA EJECTION ANALYSIS	15.3-112
15.1.20-9	CYCLE 2 CEA EJECTION EVENT RESULTS	15.3-113
15.1.20-10	ASSUMPTIONS FOR THE CYCLE 10 CEA EJECTION ACCIDENT ANALYSIS	15.3-114
15.1.20-11	RESULTS FOR THE CYCLE 10 CEA EJECTION ACCIDENT ANALYSIS	15.3-114
15.1.20-12	AXIAL POWER DISTRIBUTION USED FOR CYCLE 10 AND 12 CEA EJECTION ACCIDENT ANALYSES	15.3-115
15.1.20-13	ASSUMPTIONS FOR THE CYCLE 12 CEA EJECTION ACCIDENT ANALYSIS	15.3-116
15.1.20-14	RESULTS FOR THE CYCLE 12 CEA EJECTION ACCIDENT ANALYSIS	15.3-116
15.1.20-15	ASSUMPTIONS FOR THE CYCLE 13 CEA EJECTION ACCIDENT ANALYSIS	15.3-117
15.1.20-16	AXIAL POWER DISTRIBUTION USED FOR CYCLE 13 CEA EJECTION ACCIDENT ANALYSIS	15.3-118
15.1.20-17	RESULTS FOR THE CYCLE 13 CEA EJECTION ACCIDENT ANALYSIS	15.3-118
15.1.20-18	RESULTS FOR THE CYCLE 14 CEA EJECTION ACCIDENT ANALYSIS	15.3-119
15.1.20-19	ASSUMPTIONS FOR THE CYCLE 16 CEA EJECTION ANALYSIS	15.3-119
15.1.20-20	CYCLE 16 CEA EJECTION ANALYSIS RESULTS	15.3-120
15.1.20-21	AST CEA EJECTION RADIOLOGICAL DOSE RESULTS	15.3-120
15.1.20-22	RESULTS FOR THE CYCLE 18 CEA EJECTION ANALYSIS	15.3-121
15.1.20-23	RESULTS FOR THE CYCLE 20 CEA EJECTION ANALYSIS	15.3-121
15.1.23-1	REMOVED – HISTORICAL DATA	15.3-121

LIST OF TABLES (continued)

Table No.	Title	Page
15.1.23-2	FUEL HANDLING ACCIDENT DOSES CALCULATED WITH REGULATORY GUIDE 1.83 ASSUMPTIONS FOR 3086.52 MWt AND ASSUMING FAILURE OF TWO COMPLETE FUEL ASSEMBLIES	15.3-121
15.1.34-1	IDENTIFICATION OF SAFETY-RELATED AIR OPERATED VALVES AND THEIR FAILURE MODES	15.3-122

15 ACCIDENT ANALYSIS

15.1 GENERAL

Previous chapters describe the major systems and components of the plant and evaluate their reliability from a safety standpoint. In this section, the occurrence of certain accidents is postulated despite the precautions taken to prevent their happening. The potential consequences of such occurrences are then examined to determine their effect on the plant, to determine whether plant design is adequate to minimize the consequences of such occurrences, and to assure that the health and safety of the public and plant personnel are protected from the consequences. The events analyzed in this section are listed in Table 15-1 in the "Standard Format and Content of Safety Analysis Reports for Nuclear Power Plants," Revision 1, issued October 1972.

The sections of this chapter generally represent the most limiting analyses performed for the operation of all fuel cycles.

15.1.0 INTRODUCTION

15.1.0.1 Initial Conditions

The parameters used in the analyses are consistent with those listed in preceding sections and are primarily based on those generated in the design of a specific fuel cycle. Based on experience, it is not anticipated that a significant number of these parameters will change from cycle to cycle. Nonetheless, for each core reload, the calculated parameters for the proposed core will be compared with the values used for the analysis of record. The impact of any parameter changes on the safety analysis will be evaluated. Then, any reanalysis required will be performed and evaluated per 10 CFR 50.59 for determination of acceptable results. The ultimate core power level of 2,900 MWt is assumed in all analyses prior to Cycle 15. Starting with Cycle 15, most analyses were performed at a rated power level of 3026 MWt plus 2% uncertainty. For Cycle 16 and beyond, all analyses will be performed at a rated power level of 3026 MWt plus a 2% uncertainty.

The initial conditions, i.e., reactor power, pressurizer pressure, reactor coolant temperature at the core inlet, core power distribution, etc., are selected for the analysis to be consistent with the core operating limits allowed by the Limiting Conditions for Operation (LCOs) as maintained by the operators using the Core Operating Limit Supervisory System (COLSS) or CPCs, when COLSS is out of service. The core operating limits are defined as a set of initial conditions for which the specified acceptable fuel design limits are not violated as a result of the most rapid decrease in thermal margin caused by an anticipated operational occurrence. The set of initial conditions used in the analyses in this section forms a representative case which has been determined to require the largest initial margin to Departure from Nucleate Boiling (DNB), e.g., CE-1 Departure from Nucleate Boiling Ratio (DNBR) of 2.25, using a conservative value for the trip delay time and an axial power distribution that has the most adverse effect on the required initial margin. These are not the only initial conditions which represent core operating limits allowed by the LCOs, in that operation is allowed with less margin to DNB, i.e., a CE-1 DNBR as low as 1.50, for more favorable axial power distributions (see the Technical Specifications). In addition, a reduction in the initial margin to DNB would be allowed by changes such as the use of a more realistic trip delay time, the use of improved calculational techniques, or the use of more favorable data based on measured plant parameters.

The margin to DNB incorporated in the core operating limits is typically established by the 4-pump loss of coolant flow event, the asymmetric steam generator transient (ASGT), full length Control Element Assembly (CEA) drop, and CEA withdrawal. The margin to fuel centerline melting is typically established by the initial linear heat rate used in the Loss of Coolant Accident (LOCA) analysis.

The range of core inlet temperatures and pressures permitted by the LCOs is determined by parametric analyses performed to determine the margin to DNB required by the loss of coolant flow events. As indicated in Section 15.1.3.2.2, the CEA misoperation events are not sensitive to variation in initial Reactor Coolant System (RCS) temperatures and pressures. The required margin is determined by the combinations of permitted inlet temperature and pressure which require the largest margin to DNB. This procedure ensures adequate margin to the DNB for all Anticipated Operational Occurrences (AOOs) since the LCO limit on DNB is based on the combined requirements of each of the limiting AOOs.

The range of values of each of the principal process variables that were considered in analyses of all events discussed in this chapter are listed in Table 15.1.0-6.

No credit is taken in the analysis for any automatic action, e.g., load demand reduction as safety limits are approached, which could normally mitigate the consequences of the transient.

The plant safety analysis is performed on the basis that the plant is operated within all limiting conditions for operation at the initiation of all events. One of these limiting conditions for operation is the specified required DNB margin.

The theoretical basis for a core operating limit on DNBR, i.e., the margin required to a DNBR representative of DNB, which varies as a function of axial shape index as given in Technical Specification 3.2.4 is explained by considering the principal parameters which determine the reduction in minimum DNBR during the design basis event which is the limiting AOO. The limiting AOO is the AOO producing the most rapid reduction of margin to DNB and is the 4-pump Loss of Reactor Coolant Flow (LOF) for Arkansas Nuclear One - Unit 2.

The rate of reduction of DNBR during a LOF and the time at which the minimum DNBR is reached are determined by the competing effects of a reduction of reactor coolant mass flow rate and a reduction of heat flux in the hot channel. The reduction of mass flow rate produces a reduction of DNBR. The rate of flow reduction is determined by the Reactor Coolant Pump (RCP) design and the RCS hydraulic parameters and is relatively insensitive to core power distribution. The reduction of heat flux produces retardation and eventual reversal of the reduction of DNBR. The rate of heat flux reduction is primarily determined by the rate of negative reactivity insertion into the core following a Reactor Trip (RT). The rate of negative reactivity insertion is determined by the CEA insertion rate and the core axial power distribution.

The more power there is in the upper half of the core, the faster is the rate of negative reactivity insertion. Thus, the rate of heat flux reduction is determined by the axial shape index which is defined as the ratio of the amount of power produced in the lower half of the core minus the amount of power produced in the upper half of the core divided by the total core power.

The effect of these opposing influences on reduction of DNBR during a LOF is illustrated schematically in Figure 15.1.0-2. The mass flow rate as a function of time is shown in Figure 15.1.0-2a. The heat flux as a function of time is shown in Figure 15.1.0-2b for two axial shapes illustrated in Figure 15.1.0-2c. The time of RT is assumed to be the same for both

shapes. The axial shape peaked in the upper half of the core, labeled U, produces a faster rate of heat flux reduction following trip than the shape peaked in the lower half of the core, labeled L. The minimum DNBR as a function of time is shown in Figure 15.1.0-2d for the two axial shapes illustrated in Figure 15.1.0-2c. The initial DNBR is assumed to be the same for both shapes for convenience of illustration. Beginning a LOF transient with the axial shape peaked in the upper half of the core results in less reduction of DNBR and an earlier minimum DNBR than with the shape peaked in the lower half of the core. This is because (1) the more rapid heat flux reduction after RT with shape U lessens the rate of reduction of DNBR and (2) the flow rate at any particular heat flux is greater with shape U. Hence, with shape U the minimum DNBR occurs sooner with a correspondingly higher reactor coolant flow rate and, thus, it has a greater value.

The core operating limit on DNBR is defined as the minimum DNBR which must be maintained to ensure that the reduction in DNBR during a 4-pump LOF will not produce a DNBR which is less than the Specified Acceptable Fuel Design Limit (SAFDL). Thus, referring to Figure 15.1.0-2, if the minimum DNBR during the LOF with shape L is the SAFDL, the initial DNBR is a core operating limit with shape L. Similarly, since the minimum DNBR during the LOF with shape U is greater than the SAFDL, the initial DNBR is not a core operating limit. Assuming for illustration that the reduction of DNBR during the LOF for a given axial power shape is independent of initial DNBR, the core operating limit with shape U equals the initial DNBR shown in Figure 15.1.0-2d minus the difference between the minimum DNBR shown for shape U and the SAFDL. The DNBR transient for shape U from its associated core operating limit, defined in this way, is shown by the curve labeled U' in Figure 15.1.0-2d.

The preceding discussion illustrates conceptually that the core operation limit on DNBR depends on axial power shape. Thus, using the axial shape index to characterize the axial power shape, the core operating limit on DNBR can be defined.

The method used to develop the correlation of the core operating limit on DNBR with axial shape index, as presented in Technical Specification 3.2.4, is discussed in this section.

The CE-1 Critical Heat Flux (CHF) correlation has been replaced with the WSSV-T and ABB-NV CHF correlations (Reference 58) due to the implementation of a full core of Next Generation Fuel (NGF). Cycle 21 is the first time application of a full core of NGF (Reference 57) and Optimized ZIRLO™ cladding (Reference 56).

15.1.0.2 Reactivity Coefficients

15.1.0.2.1 Doppler Coefficient

The Cycle 1 core average fuel temperature coefficient of reactivity (Doppler Coefficient) is shown in Figure 4.3-24 and is multiplied by a weighting factor to conservatively account for higher feedback effects in the higher power density portions of the core. The Doppler weighting factor, which is specified for each analysis, is 0.85 for cases where less Doppler feedback produces more adverse results and 1.15 or greater for cases where more Doppler feedback produces more adverse results. A similar set of data with uncertainty factors is generated for each core reload and evaluated with respect to the following analyses of record assumptions. Due to the changes in the Doppler coefficient over the years, various Doppler coefficient curves may be used in some of the following analyses. Figure 15.1.0-3 is a curve of more bounding Doppler data that is used in some of the following analyses (as noted in the specific analysis).

New Doppler coefficient curves were generated for Cycle 13 and subsequent cycles. Figure 15.1.0-4 represents the fuel temperature reactivity curves for BOC and EOC. These curves already include a 0.85 multiplier for uncertainty on BOC reactivity and a 1.4 multiplier for uncertainty on EOC reactivity. This curve has been used in some of the following analyses as specified in the specific analysis.

15.1.0.2.2 Moderator Temperature Coefficient

The range of moderator temperature coefficient of reactivity at Beginning of Cycle (BOC) operating conditions is +0.5 x $10^{-4}\Delta\rho/°F$ to -2.0 x $10^{-4}\Delta\rho/°F$ and the corresponding End of Cycle (EOC) conditions of -3.4 x 10^{-4} $\Delta\rho/°F$ for a power rating of 2815 MWt and -3.8 x $10^{-4}\Delta\rho/°F$ for uprated power rating of 3026 MWt. Allowances are included in the preceding to account for: (1) changes from cycle to cycle; (2) changes in coefficient that might occur due to design changes; (3) changes in coefficient that might occur due to difference between design parameters and as-built parameters (such as shim loadings, enrichments, etc.); (4) any changes in parameters that might occur during a cycle; and, (5) calculational uncertainties or biases. In addition, the moderator coefficient varies with changes in coolant temperature and the inserted CEA worth. The most unfavorable value of the moderator coefficient is assumed for a particular analysis. A less limiting moderator temperature coefficient within the ranges defined above may be assumed in some of the following analyses. Such an assumption would be based on the cycle specific predictions and limits defined in the COLR.

15.1.0.2.3 Shutdown CEA Reactivity

The shutdown reactivity is dependent on the CEA worth available on Reactor Trip (RT), the axial power distribution, the position of the CEA Groups 1-6 and Group P, and the time in cycle life. The minimum total negative reactivity worth of the CEAs available for a RT at full power and zero power is assumed to be -5.4 percent $\Delta\rho$ and -2.4 percent $\Delta\rho$, respectively, for the Cycle 1 safety analyses. These values include the most reactive CEA stuck in the fully withdrawn position and the effects of cooldown to hot zero power temperature conditions. The full power value consists of -2.4 percent $\Delta\rho$ for shutdown and accident analysis allowance of -1.4 $\Delta\rho$ for fuel temperature variation from full power to hot standby. The actual cycle specific CEA worth may vary from cycle to cycle. Credit for greater worth on a cycle specific basis may be taken, as noted in some of the following analyses.

The shutdown worth versus position is calculated by assuming that the axial power distribution is peaked in the bottom half of the core and that the core is initially unrodded, i.e., all CEAs fully withdrawn. These assumptions are made (1) since the unrodded core allows the highest permissible axial peak to be used for the transient calculation; (2) since dropping CEAs into an initially unrodded core is more conservative in terms of the initial negative reactivity insertion during the transient; and, (3) since the higher the axial peak and the lower in the core it occurs, the lower the initial shutdown reactivity as the shutdown CEAs are inserted.

The shutdown reactivity worth versus position curve employed in the Section 15 Safety Analyses for Cycle 1 is shown in Figure 15.1.0-1A. This shutdown worth versus position curve was calculated assuming a more highly bottom peaked axial shape than is expected to occur during operation, including power maneuvering. Accordingly, it is a conservative representation of shutdown reactivity insertion rates for RTs which occur as a result of anticipated transients or accidents.

The shutdown reactivity versus position curves in Figure 15.1.0-1A were calculated using the static neutronic methods for the Cycle 1 safety analyses. In order to support the Technical Specification requirement of an increased CEA drop time (from 3.0 to 3.2 seconds) for Cycle 7, new shutdown reactivity versus position curves were calculated based on space time neutronic methods. These space time shutdown reactivity versus position curves remove some of the excess conservatisms inherent in static neutronic methods. The HERMITE computer code was used for the space-time neutronic calculations.

The Cycle 7 space-time shutdown reactivity versus position curves for the minimum total negative reactivity of -5.4 and -2.4% $\Delta\rho$ are shown in Figure 15.0.1-1B for full power and zero power, respectively. Comparing to the Cycle 1 shutdown reactivity insertion in Figure 15.1.0-1A, Figure 15.1.0-1B shows more realistic but still conservative shutdown reactivity insertion.

Figure 15.1.0-1C presents normalized reactivity inserted with CEA position consistent with more recent cycle specific data used in some of the following analyses, as noted in the analysis. This curve is based on a +0.3 ASI. The CEA insertion curve assumed with Figure 15.1.0-1C utilizes a 0.6 second holding coil delay time and a 3.2 second arithmetic average drop time to 90% inserted. A maximum CEA drop time of up to 3.5 seconds to the 90% insertion limit with an arithmetic average drop time of 3.2 seconds has been justified using HERMITE space-time methods.

A new reactivity insertion curve was developed for the Cycle 13 and subsequent analyses. This new curve is presented in Figure 15.1.0-1D. The scram curve is based on an ASI of + 0.3. A CEA insertion curve consistent with Figure 15.1.0-1E utilizing a 0.6 second holding coil delay time and a 3.2 second arithmetic average drop time to 90% inserted was assumed. A shutdown worth of 5% $\Delta\rho$ is incorporated into Figure 15.1.0-1D. Figure 15.1.0-1D and 15.1.0-1E have been used in the following analyses as specified in the analysis.

The individual CEA drop time limit was increased to a maximum of 3.7 seconds for Cycle 20 when the Next Generation Fuel design was implemented. The limit for the average for all the CEA drop times did not change. Engineering evaluations illustrate that increasing the drop time limit for individual CEAs, while maintaining the average drop time limit, will not result in actual “fission power versus time during a scram” being non-conservative with respect to what is currently assumed in the safety analyses.

15.1.0.3 Effective Delayed Neutron Fraction

The effective neutron lifetime and delayed neutron fraction are functions of fuel burnup. For each analysis, one of the following values of the neutron lifetime and the delayed neutron fraction is selected, depending upon the time in life analyzed. The first set of data was used in the Cycle 1 analyses. Subsequent analyses have used the second set of data unless indicated differently in the analysis.

	Neutron Lifetime (10^{-6} sec.)	Delayed Neutron Fraction
Beginning of Cycle	30.5	0.00713
End of Cycle	31.1	0.00497
Beginning of Cycle	15.0	0.00725
End of Cycle	33.7	0.00443

A new set of data was developed for the Cycle 13 and subsequent analyses. All of the Cycle 13 and subsequent analyses use the following data unless indicated differently in the analysis.

	Neutron Lifetime (10^{-6} sec.)	Delayed Neutron Fraction
Beginning of Cycle	13	0.007252
End of Cycle	36	0.004341

15.1.0.4 Reactor Protective System Trips and Engineered Safety Features Response Times

15.1.0.4.1 Reactor Protective System Trips

Table 15.1.0-1 lists the assumed Reactor Protective System (RPS) trip setpoints and the trip delay time associated with each trip utilized in the analyses. Some of the following analyses may use more conservative analysis setpoints and trip delay times than those noted in Table 15.1.0-1. No credit was taken in the analyses for those channels with response times indicated as not applicable.

The analyses of the accidents take into consideration the response times of actuated devices after the trip setting is reached. The elapsed time between the time when the setpoint condition exists at the sensor and the time when the trip breakers are open is defined as the trip delay time, as shown in Table 15.1.0-1. The following CEA drop time was assumed up to Cycle 7 analysis efforts. The interval between trip breaker opening and the time at which the magnetic flux of the CEA holding coils has decayed enough to allow CEA motion is conservatively assumed to be 0.3 seconds. Finally, a conservative value of 2.7 seconds is assumed for CEA insertion, defined as the elapsed time from the beginning of CEA motion to the time of 90 percent insertion of the CEAs in the reactor core. As indicated above in Section 15.1.0.2.3, this quicker drop time than that used in more recent analysis efforts was evaluated to be acceptable.

An arithmetic average of the CEA drop times of all CEAs of 3.2 seconds to 90% insertion is the current analysis limit. Of the 3.2 seconds, 0.6 seconds is attributed to the holding coils. For example, the total time from the occurrence of a high linear power level condition at the sensor until the CEAs reach the 90 percent insertion position is 3.6 seconds, i.e., 0.4 second for trip delay, plus 0.6 second for CEA holding coil flux decay, plus 2.6 seconds for CEAs to reach 90 percent insertion position.

The trip delay times shown in Table 15.1.0-1 are divided, for test purposes, into sensor delay time and Plant Protection System (PPS) delay time. Sensor delay time is defined as the elapsed time between the time the condition exists at the sensor until the sensor output signal reaches the trip setpoint. This time is determined by manufacturer's tests on typical sensor models. The PPS delay time is defined as the elapsed time between the input signal reaching the trip setpoint until the trip circuit breakers open. This time is determined during the preoperational test of the PPS. For the Reactor Protective System Trips listed in Table 15.1.0-1, the delay time can also be defined as the time interval from when the monitored parameter exceeds its trip setpoint at the channel sensor until electrical power is interrupted to the CEA drive mechanism. The sum of the sensor delay time and the PPS delay time must be less than or equal to the appropriate value listed in Table 15.1.0-1.

RTD response time is defined as the time interval required for the RTD output to achieve 63.2% of its total change when subjected to a step change in RTD temperature. The RTD response time for the Core Protection Calculator System (CPCS) is expressed as an effective time constant. For hot leg temperatures, the effective time constant for a given CPC channel is defined as the mean time constant for averaged pairs of hot leg RTD inputs to the channel. This is done because the CPCS utilizes the mean hot leg temperature in its calculations. The maximum hot leg effective time constant allowable for use in the CPCS is 13.0 seconds. For cold leg temperatures, the effective time constant is the maximum time constant of the two cold leg RTD inputs for a given channel. The CPCS utilizes the more conservative cold leg temperature in the various DNBR and LPD calculations. The maximum cold leg effective time constant allowable for use in the CPCS is 8.0 seconds.

15.1.0.4.2 Engineered Safety Features Response Times

The minimum response times of Engineered Safety Features functions assumed in the safety analyses are listed in Table 15.1.0-7. (More conservative response time assumptions may be used in some analyses.) The response times for the functions are given for each initiating signal that actuates the function. No credit was taken in the analyses for those channels with response times indicated as not applicable.

The Engineered Safety Features Response Times are defined as the time interval from when the monitored parameter exceeds its ESF actuation setpoint at the channel sensor until the ESF equipment is capable of performing its safety function (i.e., the valves travel to their required positions, pump discharge pressures reach their required values, etc.). Times include diesel generator starting and sequence loading delays where applicable.

15.1.0.5 Radiological Parameters

15.1.0.5.1 Secondary Side Activity

Several of the accidents discussed are accompanied by atmospheric release of steam. However, the radioactivity due to primary-to-secondary leakage is much greater than the radioactivity pre-existing in the main steam system, such that only the dose results of a main steam line break (MSLB) may be significantly affected by secondary side activity.

To assess the radiological consequences of a MSLB, the pre-existing fission product inventory in the main steam system is determined based on the maximum allowable concentration specified in the plant Technical Specifications (TSs). Table 15.1.0-2A provides the secondary side activity (i.e. secondary coolant source term) used in the MSLB radiological analyses.

15.1.0.5.2 Dose Model Assumptions

In order to determine the doses resulting from plant accidents, a five percentile criterion is used to determine atmospheric dispersion characteristics. The criterion is selected as being conservative on the basis that it represents unusually severe conditions. The actual conditions may be more severe only five percent of the time and less severe the remaining 95 percent of the time.

The following assumptions are basic to the radioactivity dose models.

A. Direct radiation from the source point is negligible compared to whole body radiation due to submersion in the radioactive materials cloud.

B. All radioactivity releases are treated as ground level releases regardless of the point of discharge.

C. The dose receptor is a standard man and dose conversion factors (DCFs) are from Federal Guidance Reports (FGR) Nos. 11 and 12.

D. Radioactive decay from the point of release to the dose receptor is neglected.

The DCF and breathing rate data are given in Tables 15.1.0-3 and 15.1.0-4. The atmospheric dilution factors used in the analysis of the environmental consequences of accidents are given in Table 15.1.0-5 for all offsite doses and in Table 15.1.13-1 for LOCA control room doses. The atmospheric dilution factors for control room dose analyses of other events are provided in Reference 25.

15.1.0.5.3 REMOVED – HISTORICAL INFORMATION

15.1.0.5.4 TEDE Dose

The total effective dose equivalent (TEDE) dose delivered to a dose receptor is obtained by considering the dose receptor to be immersed in a cloud containing radioactive material that is infinite in all directions above the ground plant, i.e., semi-infinite cloud. The concentration of radioactive material within this cloud is uniform and equal to the maximum centerline ground level concentration that would exist in the cloud at the approximate distance from the point of release.

15.1.0.5.5 Analysis to Support Replacement Steam Generator and Power Uprate

A radiological analysis was performed to support replacement steam generators and power uprate. The following inputs and assumptions used in this analysis differed from those of previous analyses. These differences were merely more conservative analysis assumptions.

A. A constant secondary side activity equal to 0.1 μCi/g DEQ I-131;

B. A constant primary side activity equal to 1.0 μCi/g DEQ I-131;

C. A constant primary side noble gas activity of 100/E_{bar} μCi/g for non-fuel failure analyses, where E_{bar} is defined as the average of the sum of the average beta and gamma energies per disintegration (in MeV) for isotopes other than iodines;

D. RCS activity for fuel failure analyses was based on ORIGEN2 generated pin activities;

E. A continuous primary to secondary leak rate of 150 gallons per day per steam generator, except for events which result in a significant primary to secondary pressure differential (main steam line breaks and main feedwater line breaks) which use 0.5 gallons per minute;

F. An activity discharged through steaming determined by a time dependent mathematical model;

G. Isotopic data given by Tables 15.1.0-3A and B;

H. Whole Body dose consequences defined by:

$$D_{wb} = (X/Q) \times \sum_{j} A_j \times DCF_j$$

where

D_{wb} = Whole body dose (rem)

A_j = Activity release of isotope j (Ci), for all isotopes

DCF_j = Whole Body Dose Conversion Factor isotope j (rem-m^3/s-Ci)

(X/Q) = Atmospheric dilution (s/m^3) from Table 15.1.0-5

ICRP-2 values for the DCF were used for events without fuel failure. These values are given in Table 15.1.0-3B. For these events, the DCF_j were calculated by:

DCF_j = $DCF_{\gamma j}$ + $DCF_{\beta j}$

ICRP-30 values for the DCF_j were used for events with fuel failure. These values are given in Table 15.1.0-3A.

I. Thyroid dose consequences defined by:

$$D_{Thyroid} = (X/Q) \times B \times \sum_{i} A_{I,i} \times DCF_{I,i}$$

where

$D_{Thyroid}$ = Thyroid dose (rem)

$A_{I,i}$ = Activity release of Iodine isotope i (Ci)

$DCF_{I,i}$ = Thyroid Dose Conversion Factor for Iodine Isotope i (rem-m^3/s-Ci)

B = Breathing Rate (m^3/s) from Table 15.1.0-4

(X/Q) = Atmospheric dilution (s/m^3) from Table 15.1.0-5

ICRP-2 values for the $DCF_{I,i}$ were used for events without fuel failure.

ICRP-30 values for the $DCF_{I,i}$ were used for events with fuel failure.

J. Iodine Release from the Steam Generators was determined by:

For events that result in steam generator dryout, all of the iodine activity of the dry steam generator is released.

For the Steam Generator Tube Rupture (SGTR) event, all of the iodine contained in the fraction of the primary coolant that flashes to steam is released.

For all other events, an iodine partition factor of 100 is assumed.

K. For iodine spiking considerations in the MSLB event and SGTR event, a pre-existing spike of 60 times the normal, and an event generated spike with a spiking factor of 500 assuming normal operation with one charging pump running;

L. A core power of 3087 MWt;

M. The Exclusion Area Boundary (EAB) doses are based on a 2 hour release (approximately 670,000 lbm). The Low Population Zone (LPZ) doses are based on an 8 hour cooldown to shutdown cooling entry conditions (approximately 1,770,000 lbm). Offsite releases are assumed to cease upon initiation of shutdown cooling.

15.1.0.5.6 <u>Adoption of Alternate Source Term Methodology</u>

A complete set of radiological analyses that use the alternate source term methodology of NRC Regulatory Guide 1.183 were performed to support an increase in allowed control room unfiltered air inleakage and to remove the previous ECCS pump seal passive failure assumption. The following is a partial list of inputs and assumptions used in the new analyses that differ from those listed in Section 15.1.0.5.5. The differences are typically the result of differences in the methodology.

A. The TEDE acceptance criterion of 10 CFR 50.67(b)(2) replaced the previous whole body and thyroid dose guidelines of 10 CFR 100.11.

B. ICRP-2 and ICRP-30 DCF values are no longer used. DCFs for inhalation and submersion were taken from Federal Guidance Reports (FGR) Nos. 11 and 12, respectively.

C. The primary side noble gas activity of $100/E_{bar}$ μCi/g for non-fuel failure analyses was replaced by assumed concentrations of each noble gas isotope possibly present during normal operation. Note: The assumed concentrations were then converted into a dose equivalent Xe-133, which then replaced $100/E_{bar}$ μCi/g in the plant TSs. These activities are now shown in Table 15.1.0-2A.

D. The ORIGEN-generated pin activities were revised to accommodate potential future variations in reload fuel designs. These activities are now shown in Table 15.1.0-2B.

E. Main feedwater line break (MFLB) dose consequences are no longer calculated, since the MSLB dose consequences would be bounding.

F. For iodine spiking considerations in the SGTR event, an event-generated iodine spike of 335 times the maximum TS allowed RCS iodine activity was assumed.

G. Releases following a MSLB event were assumed to terminate when the RCS temperature reached 212 °F.

15.1.0.6 <u>Computer Programs</u>

The computer programs for the analyses in this chapter are described below. The input data used in the execution of these programs is consistent with the plant design and the plant operating limits described previously.

15.1.0.6.1 CESEC

The CESEC computer program is used to simulate the NSSS. This program is described in References 7 and 13.

CESEC computes key system parameters during a transient including core heat flux, pressures, temperatures, and valve actions. Symmetric and asymmetric plant responses over a wide range of operating conditions can be determined by CESEC. The following is a partial list of the dynamic functions included in this NSSS simulation:

- point kinetics
- doppler and moderator reactivity feedback
- boron and CEA reactivity effects
- multi-node average and hot channel reactor core thermal hydraulics
- reactor coolant pressurization and mass transport
- Reactor Coolant System safety valve behavior
- steam generation
- steam generator water level
- main steam bypass
- secondary safety and turbine valve behavior (and alarms)
- control system functions
- protective system functions
- engineered safety feature system functions

The turbine and its associated controls are not included in the simulation. Steam generator feedwater enthalpy and flowrate are provided as input to CESEC.

During execution, CESEC obtains steady-state and transient solutions to the set of equations that mathematically models the NSSS dynamic functions mentioned above. Simultaneous numerical integration of a set of nonlinear, first-order ordinary differential equations with time-varying coefficients is carried out by means of a predictor corrector Runge-Kutta scheme. As the time variable evolves, edits of the principle system parameters are printed at specified intervals. An extensive library of the thermodynamic properties of uranium dioxide, water and zircaloy is incorporated into this program.

15.1.0.6.2 CHIC-KIN

The CHIC-KIN code is described in WAPD-TM-479, J. A. Redfield, "CHIC-KIN - A Fortran Program for Intermediate and Fast Transients in a Water Moderated Reactor," January 1965. The use of this code is described in Section 15.1.20.

15.1.0.6.3 TWIGL

The TWIGL Program is described in WAPD-TM-743, J. B. Yasinsky, M. Natelson and L. A. Hageman, "TWIGL - A Program to Solve the Two-Dimensional Two Group, Space-Time Neutron Diffusion Equations with Temperature Feedback," February 1968. Use of the code is described in Section 15.1.20.

15.1.0.6.4 COAST

The COAST code analyzes reactor coolant flow under any combination of active and inactive pumps in a 2-loop, 4-pump plant. The equation of conservation of momentum is written for each of the seven flow segments of the model assuming unsteady one-dimensional flow of an incompressible fluid. The equation of conservation of mass is written for the appropriate nodal points. Pressure losses due to friction, bend and shock losses are assumed proportional to the flow velocity squared. Pump dynamics are modeled with the aid of the head-flow curve for fully operational pumps and by four quadrant curves, which are parametric diagrams of pump head and torque on coordinates of speed versus flow.

Calculations using this code have been made for the Palisades plant (Docket No. 50-255). Subsequently, the flows have been measured during the test program at Palisades. The comparison of predicted and test data has demonstrated the accuracy of the CE calculational model. The model, input parameters, and the experimental basis for parameter selection for the COAST computer program have been described in CENPD-98 (Reference 1).

15.1.0.6.5 REMOVED – HISTORICAL INFORMATION

15.1.0.6.6 RADTRAD

RADTRAD estimates the radiological doses at offsite locations and in the control room of nuclear power plants as consequences of postulated accidents. The code considers the timing, physical form (i.e., vapor or aerosol) and chemical species of the radioactive material released into the environment.

15.1.0.6.7 STRIKIN-II

The STRIKIN-II computer program is used to simulate the heat conduction within a reactor fuel rod and its associated surface heat transfer. The STRIKIN-II program is described in Reference 20.

The STRIKIN-II computer program provides a single, or dual, closed channel model of a core flow channel to calculate the clad and fuel temperatures for an average or hot cylindrical fuel rod, and the extent of the zirconium water reaction for that fuel rod. STRIKIN-II includes.

A. Incorporation of all major reactivity feedback mechanisms

B. A maximum of six delayed neutron groups

C. Both axial (maximum of 20) and radial (maximum of 20) segmentation of the fuel element

D. CEA trip initiation on high neutron power

15.1.0.6.8 TORC AND CETOP

The TORC and CETOP computer programs are used to simulate the fluid conditions within the reactor core and to predict the existence of DNB on the fuel rods. The TORC program is described in Section 4.4. The CETOP computer program is also described in Section 4.4 and in Reference 21.

15.1.0.6.9 HERMITE

The HERMITE space-time kinetics computer code is used for the analysis of transients by means of numerical solution to the multi-dimensional, few-group, time-dependent neutron diffusion equation including feedback effects of fuel temperature, coolant temperature, coolant density and control rod motion. The time-dependent neutron diffusion equation is solved by a finite element method. The heat conduction equation in the pellet, gap and clad is solved by a finite difference method. Continuity and energy conservation equations are solved for the coolant enthalpy and density. Further information on HERMITE is found in Reference 23.

15.1.0.6.10 CENTS

CENTS is an interactive, high fidelity computer code for simulation of the Nuclear Steam Supply System (NSSS) components. It calculates the transient behavior of a PWR for normal and abnormal conditions including accidents. CENTS determines the core power and heat transfer throughout the NSSS. It also computes the thermal and hydraulic behavior of the reactor coolant in the primary and secondary systems. Primary and secondary thermal-hydraulic behavior is calculated with detailed multi-node and flowpath models. It includes the primary and secondary control systems and the balance-of-plant fluid systems.

CENTS incorporates a number of features that enhance its usefulness. First-principle models provide a high degree of fidelity and flexibility. Use of nonequilibrium, nonhomogeneous models allows a full range of fluid conditions to be represented, including forced circulation, natural circulation, and coolant voiding. The code simulates a wide range of variations in plant state from steady state conditions to severe accidents. It provides a full range of interactions between the analyst, the reactor control systems and the NSSS. Further information on CENTS can be found in Reference 24.

15.1.0.6.11 ARCON96

ARCON96 is an atmospheric dispersion code intended for use in control room habitability assessments. The code uses hourly meteorological data and refined methods for estimating dispersion in the vicinity of buildings to calculate relative concentrations at control room air intakes that would be exceeded no more than 5% of the time. These calculations are calculated for averaging periods ranging from one hour to 30 days in duration. The ARCON96 program is described in Reference 51.

15.1.0.6.12 ORIGEN-S

ORIGEN-S is a computer code system for calculating buildup, decay, and processing of radioactive materials. ORIGEN-S is a revised version of ORIGEN and incorporates updates of the reactor models, cross sections, fission product yields, decay data, and decay photon data as well as the source code. The ORIGEN-S program is described in Reference 52.

15.1.1 UNCONTROLLED CONTROL ELEMENT ASSEMBLY WITHDRAWAL FROM A SUBCRITICAL CONDITION

15.1.1.1 Identification of Causes

The withdrawal of CEAs from subcritical conditions (less than 10^{-4} percent power) adds reactivity to the reactor core, causing both the core power level and the core heat flux to increase. Since the transient is initiated at low power levels, the normal reactor feedback mechanisms, moderator feedback, and Doppler feedback do not occur until power generation in the core is large enough to cause changes in the fuel and moderator temperatures. The RPS is designed to prevent such a transient from resulting in a minimum DNBR less than 1.25 (CE-1 Correlation) or 1.23 (WSSV-T /ABB NV Correlations) by a high logarithmic power level reactor trip. The high linear power level trip, the CPC variable overpower trip (VOPT), the high local power density trip, and the low DNBR trip provide backup protection while the high pressurizer pressure trip provides protection for the Reactor Coolant Pressure Boundary (RCPB).

A continuous withdrawal of CEAs could result from a malfunction in the Control Element Drive Mechanism Control System (CEDMCS) or by operator error.

Startup of the reactor involves a planned sequence of events during which certain CEA groups are withdrawn, at a controlled rate and in a prescribed order, to increase the core reactivity gradually from subcritical to critical. To ensure that rapid shutdown by CEAs is always possible when the reactor is critical or near critical, Technical Specifications require that specified groups of CEAs be withdrawn before reaching criticality. These groups of assemblies combined with soluble boron concentration will have a total negative reactivity worth that is sufficient to provide at least the Technical Specification required shutdown margin at the hot standby condition, with the most reactive CEA of the groups assumed to remain in the fully withdrawn position. Once criticality has been achieved, the control groups are withdrawn in a programmed sequence as discussed in Section 7.7.

In order to ensure the SAFDLs and the RCS pressure boundary limits are not exceeded, the following criteria was ensured for this event:

- RCS pressure less than 2750 psia (i.e., 110% of the 2500 psia design pressure),
- Mininum DNBR greater than or equal to 1.25 (CE-1 Correlation) or 1.23 (WSSV-T /ABB NV Correlations), and
- Fuel centerline temperatures are below those corresponding to fuel centerline melting.

15.1.1.2 Analysis of Effects and Consequences

15.1.1.2.1 Method of Analysis

The subcritical CEA withdrawal is analyzed as a CEA withdrawal initiated at the source power level. In addition to the parameters described in Section 15.1.0, Table 15.1.1-1 lists the conservative assumptions made for this analysis. The key parameters for the transient analysis are the reactivity addition rate due to rod motion, moderator temperature feedback effects, and initial axial power distribution. The input values selected maximize the power increase and thus the margin degradation.

15.1.1.2.2 Results

Table 15.1.1-2 list the reactivity control and RPS responses for the case analyzed. Figures 15.1.1-1 through 15.1.1-4 present the corresponding transient behavior of core power, core average heat flux, RCS pressure, and the RCS coolant temperatures. This transient results in a minimum DNBR greater than 1.25 (CE-1 Correlation) or 1.23 (WSSV-T /ABB NV Correlations). Also, the analysis shows that the fuel centerline temperatures are well below those corresponding to the fuel centerline melt limit.

15.1.1.3 Conclusion

As shown by the analysis, the high logarithmic power level trip affords the required protection such that specified acceptable fuel design limits are not exceeded.

15.1.1.4 Subsequent Analyses

15.1.1.4.1 Cycle 12 CEA Withdrawal From Subcritical Conditions

Two separate bank subcritical CEA withdrawal events were analyzed for Cycle 12 using CESEC-III. CETOP was used to perform the DNB calculations. The first case is the withdrawal of Bank B with Bank A already withdrawn. The second case is the withdrawal of Bank P with Banks A and B already withdrawn. These analyses were performed essentially consistent with the analysis described above using the inputs from Table 15.1.1-3 and Section 15.1.0 with the following assumptions:

A. A high logarithmic power trip setpoint of 4% of full power was assumed.

B. A steam generator tube plugging limit of 15% was modeled.

C. CEA scram worth was not credited on trip, rather, a CEA coil decay time of 0.6 seconds was assumed followed by negative reactivity proportionate to the CEA position post trip. (A 0.6 second delay after the trip breakers open is assumed prior to the CEAs beginning to drop into the core.) Reactivity is held constant for the 0.6 second delay time. After the 0.6 second delay, negative reactivity is reinserted at the same rate of the positive insertion relative to the rod position, up to the total positive reactivity added. The CEA position versus time post trip is consistent with Figure 15.1.0-1C.

D. The BOC Doppler curve in Figure 15.1.0-3 with a 0.85 multiplier is conservatively used.

E. The amount of initial subcriticality assumed is large enough to compensate for the worth of the withdrawn CEAs.

The high logarithmic power trip function is only credited at low power levels; however, the logarithmic channel instrument calibration is routinely performed at 100% power. To account for the total decalibration under these conditions, including drift, processing uncertainties and an allowance for power distribution changes during the cycle, an analytical trip setpoint of 4% rated power is assumed.

At power levels below 10^{-4}% power, the CPCs are bypassed prior to the trip matrix relays. With this bypass in place, the trip matrix is presented with a no-trip condition for the CPCs even if the CPCs are tripped or are unpowered (or otherwise inoperable). This bypass permits the CEDMs to be powered even if the CPCs are in a 'tripped' condition. The CPC operating bypass is present at highly subcritical conditions and is automatically removed at 10^{-4}% rated power during power escalation. This removal of the CPC operating bypass is performed via a bistable from the Logarithmic Power channels.

The power level, as indicated by the Logarithmic Power Level channels, is increasing as criticality is approached during a CEAW event. Actual criticality occurs at a power level of $\sim 10^{-5}$% of rated. The postulated CEAW continues the power increase until, at a power level of 10^{-4}% of rated power, the CPC operating bypass is automatically removed.

Protective action will result by either the removal of the CPC operating bypass or by action of the High Logarithmic Power Trip. Since two equipment trip functions effectively exist for this event, the most conservative (0.75% power) is used to determine the consequences and the lower (10^{-4}% power) is used to define the set of conditions for which equipment decalibration must be assessed. The initial conditions for the evaluation of the decalibration of the High Logarithmic Power Trip function are limited as follows:

A. RCS inlet temperature > 495 °F

B. CEA shadowing of shutdown banks excluded

C. Only four pump operation considered

These conditions satisfy the CPC range checks and would result in a no-trip condition when, at 10^{-4}% power, the CPC operating bypass is removed. Such conditions would require the High Logarithmic Power trip function to terminate this event.

Amendment 196 to Facility Operating License revised the requirements for the CPC operating bypass. Automatic bypass removal occurs prior to exceeding 10^{-2}% power and manual initiation of the operating bypass is permitted below 10^{-2}% Power. The revised operating range does not impact the conditions for decalibration or the decalibration factor used in the analysis described above.

The results from this analysis are bounded by those given above. A peak power level of 24% and 87% of full power, a peak heat flux of 7% and 26% full power, a minimum DNBR of 8.1 and 2.1, a peak linear heat rate of 13.2 kW/ft and centerline melt temperature of 1670 °F, and a peak RCS pressure of 2022 psia and 2062 psia for the Bank B and Bank P withdrawal respectively have been calculated for this analysis.

15.1.1.4.2 <u>Cycle 13 CEA Withdrawal From Subcritical Conditions</u>

The CEA withdrawal from subcritical conditions was analyzed for Cycle 13 using CENTS and CETOP computer codes. CENTS is described in Section 15.1.0.6.10. Two reactivity addition rates were considered for Cycle 13, 0.00025 $\Delta\rho$/sec and 0.0002 $\Delta\rho$/sec. These reactivity addition rates are consistent with the maximum addition rates expected for bank withdrawals near critical conditions. Only bank withdrawals which will result in critical conditions are considered for this event. The inputs used in these analyses are provided in Table 15.1.1-4 and Section 15.1.0 with the following assumptions:

A. A steam generator tube plugging limit of 30% was modeled.

B. CEA scram worth was not credited on trip, rather a CEA coil decay time of 0.6 seconds was assumed followed by negative reactivity proportionate to the CEA position post trip. Reactivity is held constant for the 0.6 second delay time. After the 0.6 second delay, negative reactivity is reinserted at the same rate of the positive insertion relative to the rod position, up to the total positive reactivity added. The CEA position versus time post trip is consistent with Figure 15.1.0-1C.

C. The BOC Doppler curve of Figure 15.1.0-4, which includes a 0.85 multiplier, is conservatively used.

D. The Cycle 13 EOC delayed neutron fraction and effective neutron lifetime consistent with Section 15.1.0.3 was assumed.

The sequence of events for these transients is provided in Tables 15.1.1-5 and 15.1.1-6. The maximum fuel centerline temperature is less than 2800 °F. The results from these analyses are bounded by those given above. The conclusions of Section 15.1.1.3 remain the same: the SAFDLs and the RCS pressure boundary limits are not violated.

15.1.1.4.3 Cycle 16 CEA Withdrawal from Subcritical Conditions

The CEA Withdrawal from Subcritical conditions was analyzed for Cycle 16 using CENTS computer code for the transient analysis simulation and CETOP computer code for the minimum DNBR evaluation.

Two reactivity addition rates were considered for Cycle 16, 0.00025 $\Delta\rho$/sec and 0.0002 $\Delta\rho$/sec. These reactivity addition rates are consistent with the maximum addition rates expected for bank withdrawals near critical conditions. Only bank withdrawals which will result in critical conditions are considered for this event. Operating procedures are credited to ensure greater than critical boron concentration is maintained whenever the CEDMCS are energized. Procedural controls on rod withdrawal sequences limit the potential inadvertent bank withdrawal which could result in critical core condition.

Input parameters from Table 15.1.1-7 and the core physics data from Section 15.1.0 have been incorporated in this analysis with the following clarifications:

A. The BOC Doppler curve of Figure 15.1.0-4 is conservatively used.

B. An EOC delayed neutron fraction and effective neutron lifetime consistent with Section 15.1.0.3 was assumed.

C. CEA scram worth was not credited on trip, rather a CEA coil decay time of 0.6 seconds was assumed followed by negative reactivity proportionate to the CEA position post trip. Reactivity is held constant for the 0.6 second delay time. After the 0.6 second delay, negative reactivity is reinserted at the same rate of the positive insertion relative to the rod position, up to the total positive reactivity added. The CEA position versus time post trip is consistent with Figure 15.1.0-1E.

D. A high logarithmic power level trip setpoint of 4% and a response time of 0.4 seconds were assumed.

E. An initial power of 9.63×10^{-7} MWt was assumed.

F. Installation of the Replacement Steam Generators (RSGs) was assumed.

G. Parametric analyses were performed on the number of plugged U-tubes per steam generator. It was determined that 10% plugged U-tubes per steam generator was slightly more limiting.

The sequence of events for these transients is provided in Tables 15.1.1-8 and 15.1.1-9. Figures 15.1.1-5 through 15.1.1-8 present the transient response of key parameters for the 0.00025 $\Delta\rho$/sec case. The maximum fuel centerline temperature is well below centerline melt. The conclusions of Section 15.1.1.3 that the SAFDLs and the RCS pressure boundary limits are not violated, remain the same.

15.1.1.4.4 Cycle 20 CEA Withdrawal from Subcritical Conditions

The CEA Withdrawal from Subcritical conditions was analyzed for Cycle 20 using the CETOP computer code for the minimum DNBR evaluation.

The implementation of a half core of Next Generation Fuel (NGF) resulted in an increase in core flow area and a decrease in fuel mass. The increase in core flow area resulted in a decrease in core mass flux. No CENTS cases were repeated as all other current input parameters in Table 15.1.1-7 remained unchanged. Both the 0.00025 $\Delta\rho$/second and 0.0002 $\Delta\rho$/second cases' minimum DNBRs and centerline melt values were re-evalutated.

The half core of NGF resulted in a very small decrease in core mass flux compared to Cycle 16. This decrease was offset by crediting margin between the cycle-specific hot full power heat flux and the bounding hot full power heat flux used for Cycle 16. Consequently, the mDNBR values remain above the CE-1 DNB SAFDL of 1.25 as delineated in Tables 15.1.1-8 and 15.1.1-9.

The Cycle 16 centerline melt analysis used a Total Nuclear Heat flux Factor of 9.5 to bound the values reported in Table 15.1.1-7. The decrease in core fuel mass was offset by reducing the Total Nuclear Heat Flux Factor down to the Table 15.1.1-7 values. Hence, the maximum fuel centerline temperature is well below centerline melt.

Based on the evaluation above, the SAFDLs are not violated. As no CENTS cases were repeated the RCS pressure boundary limits are not violated. Consequently, the conclusions in SAR Section 15.1.1.3 for the SAFDLs and the RCS pressure boundary limits remain the same.

15.1.1.4.5 Cycle 21 CEA Withdrawal from Subcritical Conditions

The CEA Withdrawal from Subcritical conditions was analyzed for Cycle 21 using the CETOP computer code and the WSSV-T and ABB-NV critical heat flux correlations for the minimum DNBR evaluation.

The implementation of a full core of Next Generation Fuel (NGF) resulted in an increase in core flow area and a decrease in fuel mass. The increase in core flow area resulted in a decrease in core mass flux. No CENTS cases were repeated, as all other current input parameters in Table 15.1.1-7 remained unchanged. Both the 0.00025 $\Delta\rho$/second and 0.0002 $\Delta\rho$/sec cases minimum DNBRs and centerline melt values were evaluated.

The full core of NGF resulted in a very small decrease in core mass flux from Cycle 20. The mDNBRs for these two reactivity insertion rate (RIR) events were re-evaluated using the WSSV-T and ABB-NV critical heat flux correlations, the CENTS input from Cycle 16, and the lower core mass flux. The mDNBR values were larger than the WSSV-T / ABB-NV SAFDL of 1.23. Tables 15.1.1-8 and 15.1.1-9 have been revised for NGF to include the WSSV-T / ABB-NV CHF correlations and a 1.23 DNB SAFDL.

The Cycle 16 centerline melt analysis used a Total Nuclear Heat Flux Factor of 9.5 to bound the values reported in Table 15.1.1-7. The decrease in core fuel mass was offset by reducing the Total Nuclear Heat Flux Factor down to the Table 15.1.1-7 values. Hence, the maximum fuel centerline temperature is well below centerline melt.

Based on the evaluation above, the SAFDLs are not violated. As no CENTS cases were repeated, the RCS pressure boundary limits are not violated. Consequently, the conclusions in SAR Section 15.1.1.3 for the SAFDLs and the RCS pressure boundary limits remain the same.

15.1.2 UNCONTROLLED CEA WITHDRAWAL FROM CRITICAL CONDITIONS

15.1.2.1 <u>Identification of Causes</u>

The withdrawal of CEAs from a critical condition (greater than 10^{-4} percent power) adds reactivity to the reactor core, causing the core power level to increase. A continuous withdrawal of CEAs could result from a malfunction in the CEDMCS or by operator error.

No failure which can cause CEA withdrawal or insertion can prevent the insertion of CEAs upon receipt of any protective system reactor trip signal.

In the event of inadvertent CEA withdrawal, the RPS and pressurizer safety valves assure applicable safety limits are not exceeded as follows:

A. The low DNBR trip assures a minimum DNBR of 1.25 (CE-1 Correlation) or 1.23 (WSSV-T /ABB NV Correlations) is not violated.

B. The high local power density trip assures that the kW/ft value corresponding to fuel centerline melting safety limit is not exceeded.

C. The high pressurizer pressure trip, in conjunction with the pressurizer safety valves, assures the 110 percent of 2,500 psia reactor coolant pressure safety limit is not violated.

D. The low steam generator water level trip and automatic emergency feedwater initiation assure against the loss of steam generator heat removal capability.

The CPC DNBR trip based on the Variable Overpower Trip (VOPT) setpoints in CPCs also provides protection to ensure the SAFDLs are not exceeded.

15.1.2.2 Analysis of Effects and Consequences

15.1.2.2.1 Method of Analysis

The uncontrolled CEA withdrawal was analyzed with the CESEC computer program described in Section 15.1.0. In addition to the parameters described in Section 15.1.0, Tables 15.1.2-1 and 15.1.2-2 list the conservative assumptions made for this analysis.

The regulating CEA groups (Groups 1 through 5) are programmed for withdrawal in a specified sequence having a predetermined group overlap. Reactivity addition by withdrawal of CEA groups is dependent on the initial position of the groups prior to the withdrawal and on the integral worth of the groups.

Analyses have shown that the most adverse results for the CEA withdrawal events occur with the maximum reactivity addition rates. The analysis of the CEA withdrawal from critical conditions therefore utilizes the maximum reactivity addition rate with the CEA withdrawal speed (30 in/minute).

15.1.2.2.2 Results

15.1.2.2.2.1 Results of the Uncontrolled Sequential Withdrawal of CEAs From One Percent Power

The sequence of events for the CEA withdrawal from one percent power is shown in Table 15.1.2-3. Figures 15.1.2-1 through 15.1.2-4 show the transient response of the Nuclear Steam Supply System (NSSS). For this limiting case, the transient is terminated by a high pressurizer pressure trip and results in a maximum RCS pressure of 2662 psia. Since the high pressurizer pressure trip occurs before the time at which a high LPD or low DNBR trip would be required, DNBR and centerline melt (CTM) temperature limits are not exceeded.

15.1.2.2.2.2 Results of the Uncontrolled Sequential Withdrawal of CEAs From Full Power

Protection against exceeding the DNB and CTM limits for a CEA withdrawal at full power is provided by the CPCs which provide an automatic reactor trip on low DNB or high LPD. When initiated from the extremes of the LCOs, the CPC low DNBR trip will be initiated prior to 14.6 seconds for the most severe full power case. Key parameters for the full power case are detailed in Table 15.1.2-2. The sequence of events is given in Table 15.1.2-4 and NSSS parameter responses are shown in Figures 15.1.2-5 through 15.1.2-9.

15.1.2.3 Conclusion

As shown by the analysis, the uncontrolled CEA withdrawal from critical conditions does not lead to the violation of specified acceptable fuel design limits or the RCS pressure boundary safety limits. For the initial power levels and withdrawal rates analyzed, the high pressurizer pressure trip, low DNBR trip, high local power density trip, and low steam generator water level trip function to assure that the minimum transient DNBR does not fall below 1.25 (CE-1 Correlation) or 1.23 (WSSV-T /ABB NV Correlations), that the maximum local power density is below the value that would cause centerline fuel melting, and that the RCPB safety limit is not exceeded.

15.1.2.4 Subsequent Analyses

15.1.2.4.1 CEA Withdrawal From One Percent Power Subsequent Analyses

15.1.2.4.1.1 Cycle 13 CEA Withdrawal From One Percent Power

A CEA withdrawal from HZP conditions was analyzed for Cycle 13 using CENTS and CETOP computer codes. CENTS is described in Section 15.1.0.6.10. The inputs used in this analysis are provided in Table 15.1.2-5 and Section 15.1.0 with the following assumptions:

A. A steam generator tube plugging limit of 30% was modeled.

B. The worth of the CEAs at trip was assumed to be 2%. The CEA drop time is consistent with Figure 15.1.0-1C with the 0.6 second holding coil delay time: however, a more conservative normalized reactivity insertion versus CEA position for a +0.6 ASI curve was assumed.

C. The BOC Doppler curve of Figure 15.1.0-4, which includes a 0.85 multiplier, is conservatively used.

D. The Cycle 13 delayed neutron fraction and effective neutron lifetime consistent with Section 15.1.0.3 was assumed.

The sequence of events for this transient is provided in Table 15.1.2-7. The maximum fuel centerline temperature is less than 3330 °F. The conclusions of Section 15.1.2.3 remain the same: the SAFDLs and the RCS pressure boundary limits are not violated.

15.1.2.4.1.2 Cycle 16 CEA Withdrawal From Hot Zero Power

The CEA withdrawal from HZP conditions was analyzed for Cycle 16 using CENTS computer code for the transient analysis simulation and CETOP computer code for the minimum DNBR evaluation.

Input parameters from Table 15.1.2-8 and the bounding physics data from Section 15.1.0 have been incorporated in this analysis with the following clarifications:

A. The BOC Doppler curve of Figure 15.1.0-4 is conservatively used.

B. A delayed neutron fraction and effective neutron lifetime consistent with Section 15.1.0.3 was assumed.

C. The CEA insertion curve (scram curve) is based on an ASI of +0.6. A CEA insertion curve consistent with Figure 15.1.0-1E was assumed utilizing a 0.6 second holding coil decay time. A CEA worth of 2.0% $\Delta\rho$ was conservatively assumed.

D. A positive MTC of $0.5 \times 10^{-4} \Delta\rho/°F$ was assumed.

E. A conservative VOPT setpoint of 36% of rated power and a response time of 0.6 seconds were assumed. The response time for the neutron flux power from the neutron excore detectors was increased to 0.40 seconds and is included in the 0.6 seconds.

F. An initial core power of 0.0003026 MWt (10-5 % initial power) was assumed. This is conservative to the high log power trip bypass permissive setpoint of 10^{-4} % initial power. The use of a lower initial power results in the largest power spike.

G. Installation of the RSGs was assumed with 10% plugged U-tubes per steam generator.

H. A minimum initial RCS flow rate of 315,560 gpm was assumed.

I. A Reactivity Insertion Rate (RIR) of 1.8×10^{-4} $\Delta\rho$/sec was assumed.

J. A nuclear heat flux factor of 7.7 was assumed.

The sequence of events for this transient is provided in Table 15.1.2-9. Figures 15.1.2-11 through 15.1.2-14 present the transient response of key parameters for the 1×10^{-5}% initial power analysis. The maximum fuel centerline temperature is well below centerline melt. The conclusions of Section 15.1.2.3, namely the SAFDLs and the RCS pressure boundary limits are not violated, remain the same.

15.1.2.4.1.3 <u>Cycle 20 CEA Withdrawal from Hot Zero Power</u>

The CEA Withdrawal from HZP conditions was analyzed for Cycle 20 using the CETOP computer code for the minimum DNBR evaluation.

The implementation of a half core of Next Generation Fuel (NGF) resulted in an increase in core flow area and a decrease in fuel mass. The increase in core flow area resulted in a decrease in core mass flux. No CENTS cases were repeated as all other current input parameters in Table 15.1.2-8 remained unchanged.

The half core of NGF resulted in a very small decrease in core mass flux compared to Cycle 16. This decrease was offset by crediting margin between the cycle-specific hot full power heat flux and the bounding hot full power heat flux used for Cycle 16. Consequently, the mDNBR values remain above the CE-1 DNB SAFDL of 1.25 as delineated in Tables 15.1.2-9.

The Cycle 16 centerline melt analysis used a Total Nuclear Heat flux Factor of 9.5 to bound the values reported in Table 15.1.2-8. The decrease in core fuel mass was offset by reducing the Total Nuclear Heat Flux Factor down to the Table 15.1.2-8 value. Hence, the maximum fuel centerline temperature is well below centerline melt.

Based on the evaluation above, neither the SAFDLs nor the RCS pressure boundary limits are violated. Consequently, the conclusions in SAR Section 15.1.2.3 for the SAFDLs and the RCS pressure boundary limits remain the same.

15.1.2.4.1.4 <u>Cycle 21 CEA Withdrawal From Hot Zero Power</u>

The CEA Withdrawal from HZP was analyzed for Cycle 21 using the CETOP computer code and the WSSV-T and ABB-NV critical heat flux correlations for the minimum DNBR evaluation. The implementation of full core of Next Generation Fuel (NGF) resulted in an increase in core flow area and a decrease in fuel mass. The increase in core flow area resulted in a decrease in core mass flux. No CENTS cases were repeated, as all other current input parameters in Table 15.1.2-8 remained unchanged.

The full core of NGF resulted in a very small decrease in core mass flux from Cycle 20. The mDNBR for this event was re-evaluated using the WSSV-T and ABB-NV critical heat flux correlations, the CENTS input from Cycle 16, and the lower core mass flux. The mDNBR value was larger than the WSSV-T / ABB-NV SAFDL of 1.23. Table 15.1.2-9 has been revised for NGF to include the WSSV-T / ABB-NV CHF correlations and a 1.23 DNB SAFDL.

The Cycle 16 centerline melt analysis used a Total Nuclear Heat Flux Factor of 9.5 to bound the value reported in Table 15.1.2-8. The decrease in core fuel mass was offset by reducing the Total Nuclear Heat Flux Factor down to the Table 15.1.2-8 value. Consequently, the maximum fuel centerline temperature is well below centerline melt.

Based on the evaluation above, the SAFDLs are not violated. As no CENTS cases were repeated, the RCS pressure boundary limits are not violated. Consequently, the conclusions in SAR Section 15.1.2.3 for the SAFDLs (mDNBR remains above the DNB SAFDL) and the RCS pressure boundary limits remain the same.

15.1.2.4.2 <u>CEA Withdrawal From Full Power Subsequent Analyses</u>

15.1.2.4.2.1 <u>Cycle 12 CEA Withdrawal From Full Power</u>

The full power CEA withdrawal event was reanalyzed for Cycle 12 using CESEC-III. CETOP was used to perform the DNB calculations. This analysis was performed consistent with the analysis described above using the inputs from Table 15.1.2-6 and Section 15.1.0 with the following assumptions:

A. The CPC DNBR VOPT ceiling was not credited. The CPC DNBR VOPT follow trip (DELSPV) of 15.4% was assumed resulting in a power trip at 118.4% of full power.

B. A steam generator tube plugging limit of 15% was modeled.

C. The CPC DNBR trip (based on VOPT) response time was assumed to be 0.39 seconds.

D. The CEA coil decay time of 0.3 seconds was increased to 0.6 seconds. (A 0.6 second delay after the trip breakers open is assumed prior to the CEAs beginning to drop into the core.) Reactivity is held constant for the 0.6 second delay time. After the 0.6 second delay, negative reactivity is reinserted at the same rate of the positive insertion relative to the rod position, up to the total positive reactivity added. The CEA position versus time post trip is consistent with Figure 15.1.0-1C.

E. The BOC Doppler curve in Figure 15.1.0-3 with a 0.85 multiplier is conservatively used.

The objective of this analysis was to perform a CPC filter verification that is to ensure that the CPCs and COLSS will protect the DNB SAFDL. Input parameters are selected to maximize the margin degradation. Results from this analysis indicate that the CPC DNBR trip (based on the VOPT follow setpoint) is reached before 11.3 seconds. COLSS and CPCs are verified to ensure enough margin exists to prevent a minimum DNB of less than 1.25.

15.1.2.4.2.2 Cycle 13 CEA Withdrawal From Full Power

The effect of up to 30% steam generator tube plugging and a 10% reduction in RCS flow was assessed with respect to the impact on the CEA withdrawal event from full power. The CEA bank withdrawal event is examined as the fastest rate of increasing power with respect to the anticipated operational occurrences (AOOs) for which the CPCs ensure that the SAFDLs would not be violated. An evaluation was performed to validate that the response to the CPC compensated neutron flux power for a CEA withdrawal event is conservative with respect to the actual rates for both the core power and core heat flux increase given this event. By ensuring the CPC protective calculations are conservative, the SAFDLs would not be violated.

This event is simulated with the CENTS code. The time dependent plant parameters calculated using CENTS are then input into the CPC simulation code (referred to as “CPC FORTRAN”). The output for the CPC FORTRAN code is then compared to CENTS to judge the conservatism of the CPC filtering process.

Cycle 13 physics data consistent with that defined in Section 15.1.0 was assumed for this assessment. An initial power level of 90%, Tcold of 540 °F, RCS flow of 135.3E6 lbm/hr, MTC of 0.0E-4 $\Delta\rho$/°F, 30% steam generator tube plugging, and a reactivity insertion rate of 1.0E-4 $\Delta\rho$/sec were assumed. Based on the results of this analysis, the CPC power exceeds CENTS power and heat flux illustrating acceptable functioning of the CPC filters.

15.1.2.4.2.3 Cycle 15 CEA Withdrawal from Full Power

The full power CEA Withdrawal event was evaluated to determine the impact of the replacement steam generators (RSGs) and the increase in RCS flow for Cycle 15. One key parameter that changed for the CEA Withdrawal from HFP event is the maximum RCS flow range, which has increased to account for the RSGs. A CPC Dynamic Filter analysis was performed for Cycle 15 with RSG at an uprate power of 3026 MWt to assure that the CPCs can accurately sense the power increase associated with the CEA withdrawal event.

The CPC Dynamic Filter analysis used the CENTS computer code for the transient analysis simulation. The time dependent plant parameters calculated using CENTS are then input into the CPC Simulation code (CPC FORTRAN).

Previously defined input parameters and the bounding physics data from Section 15.1.0 have been incorporated in this analysis with the following clarifications:

1. The BOC Doppler curve in Figure 15.1.0-4 was assumed.

2. The Cycle 13 delayed neutron fractions and neutron lifetimes consistent with those defined in Section 15.1.0.3 were assumed.

3. The CEA reactivity insertion curve in Figure 15.1.0-1D was assumed. This curve accounts for a 0.6 second holding coil delay. CEA worths dependent on initial core power were conservatively assumed.

4. RCS flow of 147.3 x 10^6 lbm/hr was assumed.

5. An MTC of 0.0 x $10^{-4}\Delta\rho$/°F was assumed.

6. Installation of the RSGs was assumed.

7. An initial temperature of 540 °F was assumed.

8. Steam Generator tube plugging of 10% was assumed.

9. Reactivity insertion rate of 1.0 x $10^{-4}\Delta\rho$/sec was assumed.

The CPC transient filters analysis was performed to assure that the CPCs could conservatively respond to a power increase associated with CEA bank withdrawal with the changes due to the RSGs, an increase in rated power, and an increase in RCS flow.

The CPC transient filter analysis verifies that the CPC adjusted process parameters are conservative with respect to the expected values for a CEA bank withdrawal event. The CPC coefficients are adjusted as necessary to assure the CPCs action prevents SAFDL violation during the transient.

The effects of the RSGs, the increase in rated power, and the increase in RCS flow have been evaluated. This evaluation ensures that the CPCs and RPS will provide the necessary trip functions to protect the SAFDLs.

15.1.2.4.2.4 <u>Cycle 16 CEA Withdrawal From Full Power</u>

A CEA Bank Withdrawal from HFP conditions was reanalyzed for Cycle 16 using the CENTS and CETOP computer codes. The CEA Bank Withdrawal at power is protected by the Core Protection Calculator System (CPCS). Specifically, the CPCS has dynamic compensation lead-lag filters that project increases in core heat flux and core power. These dynamic compensation filters in conjunction with static power correction factors ensure that the CEA withdrawal transients are terminated before the SAFDLs are violated.

Input parameters provided in Table 15.1.2-10 and the bounding physics data from Section 15.1.0 have been incorporated in this analysis with the following clarifications:

A. The BOC Doppler curve of Figure 15.1.0-4 is conservatively used.

B. A delayed neutron fraction and effective neutron lifetime consistent with Section 15.1.0.3 was assumed.

C. The CEA insertion curve in Figure 15.1.0-1E was assumed. A 0.6 second CEA holding coil delay after the trip breakers open is assumed prior to the CEA Bank beginning to drop into the core. After the 0.6 second delay, negative reactivity is reinserted at the same rate of positive insertion caused by the CEA Bank withdrawal. A CEA worth of -5%$\Delta\rho$ was assumed.

D. An initial core power of 3087 MWt was assumed based on a rated power of 3026 MWt and a 2% measurement uncertainty.

E. A Moderator Temperature Coefficient (MTC) of 0.0 x 10^{-4} $\Delta\rho$/°F is assumed.

F. The response time for the neutron flux power from the ex-core neutron detectors was increased to 0.40 seconds.

G. A Reactivity Insertion Rate (RIR) of 1 x 10^{-4} $\Delta\rho$/sec was modeled.

H. The Core Protection Calculator System (CPCS) Variable Overpower Trip (VOPT) ceiling was not credited. The CPCS VOPT follow trip of 10.2% was assumed resulting in a power trip at 112.4% of full power.

I. Installation of the RSGs was assumed with a tube plugging limit of 10%.

The sequence of events is listed in Table 15.1.2-11. Figures 15.1.2-15 through 15.1.2-19 present transient response of key parameters for full power plus uncertainty (3087 MWt). The peak heat flux results in a minimum DNBR greater than 1.25. The peak core power results in a peak linear heat rate of less than 21 kW/ft. This is not a limiting peak RCS pressure event. Thus, there is no violation of SAFDLs.

15.1.2.4.2.5 <u>Cycle 18 CEA Withdrawal from Full Power</u>

The CEA Bank Withdrawal event from HFP conditions was evaluated at a higher LOCA Limit of 14.4 KW/ft. Only the peak LHR margin was affected. There was no impact on DNB margin.

The methodology was the same as that used in the current analysis presented in Section 15.1.2.4.2.4. The LOCA Limit value of 14.4 KW/ft was used in place of the previous value of 13.7 KW/ft. No new computer cases were required.

The CEA Bank Withdrawal at power is protected by the Core Protection Calculator System (CPCS). Specifically, the CPCS increasing power filters provide conservative neutron and thermal power input into the CPCS Low DNBR and High Local Power Density (LPD) trips. Thus, sufficient SAFDL protection is provided for a power increase due to a positive reactivity insertion from a full power CEA bank withdrawal in conjunction with the higher LOCA Limit value of 14.4 KW/ft.

15.1.2.4.2.6 <u>Cycle 21 CEA Withdrawal From Full Power</u>

The CEA Withdrawal from HFP was evaluated for Cycle 21 for Next Generation Fuel (NGF). Only the DNB margin was affected. There was no impact on the LHR margin.

The methodology was the same as that used in the current analysis presented in Section 15.1.2.4.2.4. The CEA Withdrawal from full power was evaluated for Cycle 21 using the WSSV-T and ABB-NV critical heat flux correlations and the lower DNB SAFDL of 1.23 for the minimum DNBR evaluation. No CENTS cases were repeated, as all other current input parameters in Table 15.1.2-10 remained unchanged.

The CEA Bank Withdrawal at power is protected by the Core Protection Calculator System (CPCS). Specifically, the CPCS increasing power filters provide conservative neutron and thermal power input into the CPCS Low DNBR and High Local Power Density (LPD) trips. Thus, sufficient SAFDL protection is provided for a power increase due to a positive reactivity insertion from a full power CEA bank withdrawal in conjunction with the new CHF correlations and the lower DNB SAFDL value.

Based on the evaluation above, the SAFDLs are not violated. As no CENTS cases were repeated, the RCS pressure boundary limits are not violated. Table 15.1.2-11 has been revised for NGF to include the WSSV-T / ABB-NV CHF correlations and 1.23 DNB SAFDL. Consequently, the conclusions in SAR Section 15.1.2.4.2.4 for the SAFDLs and the RCS pressure boundary limits remain the same.

15.1.3 CEA MISOPERATION

15.1.3.1 Identification of Causes

A CEA misoperation is defined as any event which could result from a single malfunction in the reactivity control system, with the exception of sequential group withdrawals which are considered in Sections 15.1.1 and 15.1.2. A list of the events which could be caused by a single malfunction in the reactivity control system is included in Chapter 7. CEA misalignment may be caused by a malfunction of the Control Element Drive Mechanism (CEDM), CEDMCS or by operator error.

A stuck CEA may be caused by mechanical jamming of the CEA fingers or grippers or by failure of a gripper coil. A dropped CEA may be caused by electrical failure in the CEDMCS or by opening an individual CEA breaker. A dropped CEA subgroup could be caused by an electrical fault in the CEDMCS, opening a subgroup breaker, or by failure of the hold bus during maintenance activities.

The core protection calculator (CPC) and control element assembly calculator (CEAC) algorithms detect and compensate for the effect of CEA misoperation on the core power distribution by providing heat flux and radial peaking factor penalties to the on-line DNBR and linear heat rate calculations. For the first 5 cycles, a single CEA inward deviation (drop) incident resulted in penalties which quickly tripped the plant. The penalties associated with a single inward CEA deviation have since been removed and operator action is credited to mitigate these events.

Protection for CEA misoperation events is provided either by a Core Protection Calculator System (CPCS) trip or, for events which do not require a trip, by providing adequate initial DNBR and local power density margin to preclude violation of the SAFDLs prior to the reactor operator taking action to restore plant conditions and CEA alignment.

The results of a CEA drop are presented below. Section 15.1.3.2 and 15.1.3.3 present results consistent with the original design considerations. See Section 15.1.3.4 for the latest analysis considerations.

Prior to Cycle 12, ANO-2 had 8 part-length CEAs. Because these CEAs were replaced with full length CEAs, the PLCEA drop analyses have been deleted.

A full length CEA drop can result from a single failure which causes power to be interrupted to a single CEDM. In order to provide a rapid shutdown function upon a reactor trip signal, the CEDMs are designed to release the CEAs when power to the CEA holding coils is interrupted. Power to the CEA holding coils is provided through the trip breakers which are operated by the output signal from the RPS.

15.1.3.2 Analysis of Effects and Consequences (Prior to Cycle 16)

15.1.3.2.1 Method of Analysis (Prior to Cycle 16)

The transient following a dropped CEA was analyzed with the CESEC computer program, described in Section 15.1.0.6.1, which simulates the NSSS. The heat flux in the hot channel, following the CEA drop, was analyzed with the STRIKIN computer program, described in Section 6.3. In addition to the parameters described in Section 15.1.0, the conservative assumptions shown in Table 15.1.3-1 were used in the analysis. The most negative Doppler and moderator temperature coefficients were chosen for the full length CEA drop. These negative values result in the largest power overshoot in response to the drop in core average temperature.

The worst full length CEA drop incident is the case in which the maximum increase in radial peaking factor is produced by the dropped CEA. Basis for this choice lies in the results of studies of the CEA drop event which indicate that the results of the analysis are much more sensitive to the radial peaking factor input than to the associated reactivity worths. The largest calculated increase in radial peaking factor for any dropped CEA is 24 percent. A +10 percent uncertainty is applied to this nominal value prior to use in the analysis. The nominal calculated reactivity worth for this is -0.10 percent.

An uncertainty factor is not applied to this value since application in the same direction as that for changes in radial peak has been shown to produce more favorable results, i.e., 10 percent increase in worth, and application in a direction opposite, i.e., 10 percent decrease in worth, to that for changes in radial peak is considered to be physically inconsistent.

Even though the RRS automatic mode has been physically removed from operation, the most adverse reactor control condition for the full length CEA drop results from postulating that control is in the automatic mode and that a CEA withdrawal prohibit signal does not initiate upon detection of core conditions caused by the dropped CEA. With control in this mode, reduction in average reactor coolant temperature and a mismatch of reactor turbine power will initiate a withdrawal of regulating CEAs causing positive reactivity to be inserted. The effect of this action is simulated in a conservative manner by assuming that regulating CEAs begin to withdraw at the maximum speed of 30 in/min immediately after the dropped CEA becomes fully inserted and that they produce a positive reactivity addition at the maximum rate of $0.7 \times 10^{-4} \Delta\rho$/sec.

15.1.3.2.2 Results (Prior to Cycle 16)

The results of the CEA drop cases are summarized in Table 15.1.3-2. The detailed sequence of events for the CEA drop transients from initial DNBRs of 1.39 and 2.25 are presented in Table 15.1.3-4 and the transient is shown in Figures 15.1.3-1 through 15.1.3-10. A rapid decrease in reactivity occurs which causes a corresponding decrease in power. Reactivity contributions from moderator and Doppler feedback and regulating CEA motion then override the negative reactivity effects of the dropped CEA causing the power to rise.

The power rises to 90 percent of full power at 1.7 seconds at which time a low DNBR trip condition exists and the CEA drop transient is subsequently terminated with a minimum DNBR of 1.3. The DNBR, as shown in Figure 15.1.3-4 is calculated to initially decrease due only to the conservative combination of the average density and the radial peaking factor following the full length CEA drop. The initial rate of decrease in the average core power as predicted by the point kinetics is less than the assumed rate of increase in the radial peak, resulting in an initial increase in the hot channel heat flux and a corresponding decrease in DNBR.

The peak linear heat rate during the transient is below the value of linear heat rate which would result in fuel centerline melting.

15.1.3.2.3 Effect of Varying Initial Conditions (Prior to Cycle 16)

The basis for the selection of initial conditions for the CEA misoperation incident is discussed in Section 15.1.0.1; parameter values used in the analyses are provided for the CEA drop incident in Table 15.1.3-1. The effect of varying initial conditions for RCS pressure, reactor inlet temperature, reactor coolant flow and core power distribution while maintaining a fixed margin to a 1.3 DNBR, i.e., same initial DNBR, is discussed below.

For the CEA drop incident, no impact will be made on the results when the transients are initiated from different initial reactor inlet temperatures, RCS pressures and RCS flows with the initial DNBR remaining in accordance with Technical Specification 3.2.4. Under the constraint of a constant initial DNBR, the time and value of the minimum transient DNBR is solely dependent on the rate of change of DNBR which for these transients is governed by changes in local heat flux and, therefore, is essentially independent of initial inlet temperature, RCS pressure, and reactor coolant flow.

Varying the core average axial power distribution while maintaining a constant initial DNBR has an effect on the results of the incidents which is due to the dependence of scram reactivity insertion rate on axial flux distribution. The rate at which shutdown reactivity is inserted will affect both the value and time of the minimum transient DNBR. The scram reactivity functions which were used in the CEA drop analysis describe scram reactivity insertion in a conservative manner and were chosen based on power distributions permitted to occur during both normal operating and accident situations as a function of axial shape index. Further discussion of the scram reactivity input to the analyses is provided in Section 15.1.0.2.3.

The reactivity worths and changes in peaking factors produced by a dropped CEA directly affect the results of the transients and are dependent on the initial axial power distribution. The analysis of this event has, therefore, been carried out as a function of axial shape index.

As stated in Section 15.1.0, the COLSS monitors conditions which affect the margin to DNBR including the reactor coolant mass flow rate. The flow measurement techniques and instrumentation are described in Section 7.7.1.3. In addition, the Technical Specifications (TS 3.2.4) define the bases for DNBR and state the requirements that depend on the availability status of COLSS and operability of CEACs. In summary, since the margin to DNB is monitored directly in the Unit 2 plant, it is not necessary to provide a Technical Specification on flow in order to assure the required margin to DNB.

15.1.3.2.4 Assumptions Concerning Pressurizer, Steam Bypass & Feedwater Regulating Systems (Prior to Cycle 16)

For the CEA drop analysis, steam release via the steam bypass system does not occur prior to the time of reactor trip and, therefore, the assumptions concerning mode of operation of this system have no effect on the results of these incidents. The assumption that this system is operating in the automatic mode is consistent with normal plant operating conditions.

The assumption that the feedwater regulating system is in the automatic mode is also based on assuming normal plant operating conditions. For the CEA misoperation analysis, a variation in feedwater flow rate of less than one percent of the full power value occurs prior to the time of

reactor trip. The slight steam generator mass flow imbalance that would result if the feedwater regulating system were operating in the manual mode has been investigated with regard to the results of the CEA misoperation event and determined to have negligible impact.

The pressurizer is assumed to be in the normal automatic operating mode as described in Section 5.5.10. The CESEC code, which is described in Section 15.1.0.6.1, was used to simulate pressurizer operation during the CEA misoperation incident. For the CEA misoperation analysis, the time interval between initiation of the event and reactor trip is sufficiently small such that the assumption concerning mode of pressurizer control has negligible impact on the results.

15.1.3.3 Conclusion (Prior to Cycle 16)

Based on the analysis presented in this section, operation of Cycle 1 within the limits on allowable initial DNBR as a function of axial shape index assures that no CEA misoperation event will result in violation of specified acceptable fuel design limits. This information is presented in Figure 15.1.3-23.

15.1.3.4 Subsequent Analysis

15.1.3.4.1 Cycle 16 CEA Misoperation Analysis Approach (Normal Operation)

The Core Protection Calculator (CPC) and Control Element Assembly Calculator (CEAC) algorithms detect and compensate for the effect of CEA misoperations on the core power distribution by providing appropriate peaking factors and power penalties to the on-line DNBR and linear heat rate calculations. The single CEA drop event will not generate and does not require a reactor trip. Adequate initial DNBR and local power density margin provides protection against this CEA misoperation event.

A single CEA drop is defined as the inadvertent release of a CEA causing it to drop into the core. After the drop of a single CEA, a rapid decrease in power follows. This is accompanied by a decrease in reactor coolant temperatures and pressure. In the presence of a negative moderator temperature coefficient (MTC), positive reactivity is added. Since the turbine is in manual and there is a power mismatch between the secondary side and the primary side, the primary side responds and attempts to restore itself to the initial power level.

The purpose of the analysis is to review the CEA misoperation DNB thermal margin requirements that must be reserved in the technical specification Limiting Conditions for Operation (LCOs). This assures that the minimum DNBR for these events does not exceed the DNB SAFDL.

The methodology employed for the single CEA drop event is to “back-calculate” the maximum radial distortion factor (Fr) allowed assuming the minimum required thermal margin reserved by the LCOs. This maximum sensitivity of DNBR to Fr is calculated based on the range of initial conditions possible for the event. For Cycle 16 and beyond, the reload analysis process will confirm that these radial distortion factors are not exceeded for the as-built core. The increase in rated power, the range of initial conditions (temperature, pressure and RCS flow), and the “Required Power Reduction After Inward CEA Deviation” figure increase from 1 hour to 2 hours have been accounted for in the DNBR to Fr sensitivity.

In the analysis of the CEA drop event, power is assumed to return to the original power level driven by turbine demand, with negligible change in temperature, pressure, or RCS flow. This is the most adverse possible outcome of a CEA drop that changes the power distribution without any accompanying power or temperature reduction. This conservative modeling assumption eliminates the need for explicit transient analysis with CENTS. The change in margin to DNB is evaluated using the maximum sensitivity of DNBR to Fr for the range of conditions of the event.

DNBR margin degradation for the single CEA drop event is determined crediting the operator response requirements of Technical Specification 3.1.3.1, “CEA Position,” and COLR Figure 2, “Required Power Reduction After Inward CEA Deviation.” This technical specification requires that the operator initiate a power reduction as specified in the COLR figure shortly after the occurrence of a CEA drop.

For the single CEA drop event, the change in margin to the linear heat rate limit is smaller than the change in margin to the DNBR limit. The margin requirements for CEA drop events (which do not result in a reactor trip) clearly bound the margin requirements for CEA misoperation events that result in reactor trip.

The change in sensitivity of DNBR to Fr is based on the input parameter ranges from Table 15.1.3-5.

15.1.3.4.2 Results

The single CEA drop event is a subset of the anticipated operational occurrences (AOOs) that are analyzed to determine the minimum required thermal margin that must be maintained by the Technical Specification Limiting Conditions for Operation (LCOs) such that, in conjunction with the Reactor Protection System (RPS), the DNB and centerline-to-melt SAFDLs are not violated. The required thermal margin is monitored by COLSS when it is in service and by the operators using the CPCS and COLR specified limits when COLSS is out of service.

Single CEA drop event radial power peaking distortion factor limits have been determined to assure that the DNBR and LHR SAFDLs are not exceeded. For Cycle 16 and beyond, the reload analysis process will confirm that these radial distortion factor limits are not exceeded for the as-built core based on the CEA Positions” (TS 3.1.3.1), “Required Power Reduction After Inward CEA Deviation” figure (COLR Figure 2).

15.1.4 UNCONTROLLED BORON DILUTION INCIDENT

15.1.4.1 Identification of Causes

The Chemical and Volume Control System (CVCS) regulates both the chemistry and the quantity of coolant in the RCS. Changing the boron concentration in the RCS is a part of normal plant operation, compensating for long-term reactivity effects, such as fuel burnup, xenon buildup and decay, and plant cooldown. For refueling operations, borated water is supplied from the Refueling Water Tank (RWT).

Boron dilution is a manual operation conducted under strict procedural controls, which specify permissible limits on the rate and magnitude of any required change in boron concentration. Boron concentration in the RCS can be decreased either by controlled addition of unborated makeup water, with a corresponding removal of reactor coolant (feed and bleed), or by using one of the letdown ion exchangers. The letdown ion exchangers are used for boron removal

when the boron concentration is low (< 30 ppm), since the feed-and-bleed method becomes inefficient at low concentrations. A discussion of normal reactor coolant boron concentration control is presented in Section 9.3.4.

To effect boron dilution, the makeup controller mode selector switch must be set to "Dilute" and the demineralized water batch quantity selector set to the desired quantity. When the specified amount has been injected, the demineralizer water control valve shuts automatically. A charging pump must be running in addition to a reactor makeup water pump for boron dilution to take place.

Dilution of the reactor coolant can be terminated by isolating the reactor makeup water system; by stopping either the reactor makeup water pumps or the charging pumps; or by closing the charging system isolation valve 2CV-4840-2.

The CVCS is equipped with the following indications and alarm functions which will inform the reactor operator when a change in boron concentration in the RCS may be occurring:

A. VCT level indication and high and low alarms;

B. Makeup controller flow indication and alarms;

C. Letdown diverter valve position indication.

Depending upon the mode of plant operation at the initiation of a dilution event, other alarms and indications are available to the operator to detect the event.

Because of the procedures involved and the numerous alarms and indications available to the operator, the probability of a sustained or erroneous dilution is very low.

15.1.4.2 Analysis of Effects and Consequences

15.1.4.2.1 General

The time required to achieve criticality from a subcritical condition due to boron dilution is based on the initial and critical boron concentrations, the boron reactivity worth, and the rate of dilution. Reactivity increase rates due to boron dilution are based on the boron worth and the dilution rate.

Six different general operational modes were analyzed for the boron dilution incident: dilution during refueling, cold shutdown, hot shutdown, hot standby, and during low and full power operation. During normal plant operation, operation of more than one charging pump is not the normal mode. However, operation of more than one charging pump may result from a system transient or direct operator control. Nevertheless, in each case it is assumed that the boron dilution results from pumping unborated demineralized water into the RCS at the maximum possible rate of 138 gpm (the combined capacity of three charging pumps). The boron concentration within the minimum volume considered in each analyzed mode is uniform at all times since sufficient circulation exists to maintain a uniform mixture. During refueling, cold shutdown, and occasionally during hot shutdown conditions this circulation is provided by the operation of the shutdown cooling system. Operation of the shutdown cooling system does not assure complete mixing of the RCS under all conditions. Consequently, a reduced RCS volume is assumed in these conditions. During hot shutdown, hot standby, and power conditions, the

reactor coolant pumps are normally operating. If both pumps are off in one loop, there is sufficient reverse flow through the idle loop to ensure a uniform concentration throughout the system.

The method of analysis used to determine the rate of change in core reactivity due to uncontrolled boron dilution is dependent on the boron reactivity and the dilution time constant τ, which is defined by the ratio of the "reactor coolant mass inventory" to the "maximum charging rate". The reactivity held down by soluble boron is determined by the time in core life and the degree of subcriticality at shutdown. For any shutdown condition, the maximum negative reactivity contributed by soluble boron and, therefore, the maximum boron concentration, occurs at the BOC. Therefore, BOC conditions are assumed in these analyses. This assumption results in minimum calculated times to loss of shutdown.

For Cycle 14 and subsequent cycles, a different approach was taken in that the dilution equations were rearranged to solve for relationships between inverse boron worth (IBW) and critical boron concentration (CBC). That is, for a given dilution time constant (τ_{BD}), subcriticality at time of alarm ($\%\Delta\rho$), and time from alarm to criticality (Δt_{crit}), various values of CBC were input into the equations and the corresponding IBWs were calculated. The resulting CBC/IBW “limit lines” are used to determine the acceptability of a cycle’s core design with respect to Uncontrolled Boron Dilution Incident (UBDI) by verifying that the cycle specific CBC and IBW values fall within the “acceptable” region.

In February 2004, (Cycle 17), Westinghouse issued a Nuclear Safety Advisory Letter (NSAL-04-2) concerning some non-conservative boron dilution analyses.

The boron dilution alarm monitors the neutron flux from the excore detectors using the startup channels. When the count rate increased by a fixed factor (i.e., the boron dilution alarm setpoint (BDAS)), an alarm is activated. For ANO-2 boron dilution event analysis of record, BDAS was used to determine the amount of shutdown margin (SDM) remaining at the time of the alarm using the linear $1/\rho$ approach in Modes 3, 4, and 5. The SDM is used to determine the boron concentration at the time of the boron dilution alarm. From this concentration, the IBW versus CBC limit lines for physics is generated, such that sufficient time for operator action is preserved.

For those Westinghouse fleet plants that Westinghouse prepares the boron dilution calculations for, the Inverse Count Rate Ratio (ICRR) method is used. The ICRR method uses the measured detector count rate versus boron concentration at a fixed rod position and temperature. As the RCS boron concentration decreases to the critical concentration, the detector response for large differences between the initial and critical boron concentrations begins as a linear function. However, as the boron concentration approaches the critical boron concentration (~150 ppm from the critical boron concentration), the detector count rate increases at a faster non-linear rate. Westinghouse has collected measured data from numerous Westinghouse fleet plant startups and generated a generic, conservative ICRR curve. Westinghouse fleet plants use this generic ICRR curve or have alternately used a plant-specific ICRR curve in the boron dilution analyses for subcritical modes of operation.

CE fleet plants use a detector signal that is proportional to the subcritical multiplication factor (M). CE reviewed similar startup data for the CE fleet plants and concluded that the subcritical multiplication was inversely proportional to the reactivity and was an acceptable approximation. In a direct comparison between the two methods, the non-linear method resulted in a longer time to reach the BDAS from the start of the event and thus a shorter time to criticality after the BDAS is reached.

During the aforementioned CE fleet boron dilution analysis, plant-specific startup data was reviewed and was found to be non-linear and consistent with the generic Westinghouse ICRR data. Upon a second review of the CE-fleet startup data, it was concluded that the CE fleet methodology for the BDAS using the linear approximation had introduced some degree of non-conservatism into the calculation involving the BDAS.

The only impact of the non-conservative linear approximation is in the calculation of the time that the BDAS is reached and the calculation of the time from the alarm to the time of criticality. The overall time of criticality from the start of the event is not affected. There is no impact on the analyses that do not use the boron dilution alarm.

Based on the above, the alarm operable limit lines for IBW versus CBC for Modes 3, 4, and 5 (filled and drained) are non-conservative and have been evaluated. The Mode 3, 4, and 5 (filled and drained) alarms inoperable limit lines for IBW versus CBC are not impacted by this error and remain valid.

This concern does not impact the limit lines for Modes 1, 2, and 6 since the boron dilution alarm is not used in these modes.

This analysis of the change in the detector response characteristic is for Cycle 17 only.

The criterion for the modes of operation in question is that the operators have at least 15 minutes from the time the alarm comes in to respond to the event.

Cycle 17 specific physics data for IBW and CBC were used to determine the Modes 3, 4, and 5 (filled and drained) times from alarm to criticality assuming non-linear excore response for the conditions when the boron dilution alarm is operable. The shortest time from time of alarm to time of criticality is 27.8 minutes for Mode 5 drained. All other times from time of alarm to time of criticality for the modes of concern are greater than 27.8 minutes (e.g., Mode 3 – 39.7 minutes; Mode 4 – 45.1 minutes; Mode 5 filled – 44.5 minutes). Since all the times are greater than the 15 minute acceptance criteria, the current alarm setpoint of 1.5 in conjunction with calculation Cycle 17 specific data does not result in an unsafe or unanalyszed condition.

To evaluate the results of the analyzed events, the time between the beginning of the event and the loss of shutdown margin is determined for events initiated from critical conditions. The consequences of a UBDI event initiating from Mode 1 conditions are demonstrated to be bounded by the CEA Bank Withdrawal event as described in Section 15.1.4.2.6. For events initiated in other modes of operation, the time from a control room alarm or other indication of the event to the loss of shutdown margin is determined. For those events initiated from non-critical conditions, the time from an alarm until the loss of shutdown margin must exceed 15 minutes or 30 minutes for events during refueling.

15.1.4.2.2 <u>Dilution During Refueling</u>

The limiting case for boron dilution during refueling occurs for the cold clean initial cycle fuel loading. In addition to Table 15.1.4-1, the following assumptions are made to determine the most rapid boron dilution that could occur during refueling:

A. The initial shutdown reactivity is determined by the difference between the minimum refueling water boron concentration allowed by Technical Specifications and a bounding beginning of cycle critical boron concentration for refueling conditions. The initial boron concentration was chosen to be consistent with a Keff = 0.95, with a 1% $\Delta k/k$ uncertainty being accounted for in the physics calculations. That is, the physics calculated refueling boron concentration is based on Keff = 0.94.

B. All fuel assemblies are installed in the core.

C. During refueling, the uniformity of boron concentration is assured by operation of one Low Pressure Safety Injection (LPSI) pump or Containment Spray pump at ≥ 2,000 gpm. Under refueling conditions, the LPSI pump takes suction from and provides discharge to the RCS.

D. A combination of inserted CEAs and soluble boron is used to maintain the core at the required subcriticality state, including uncertainty.

E. In order to cause inadvertent boron dilution, the reactor operator would have to carry out the following sequence of misoperations:

   1. Open valve to divert letdown purification flow to the Boron Management System;

   2. Open valve to connect makeup water supply to the charging pump suction;

   3. Set makeup flow controller at 138 gpm;

   4. Start reactor makeup water pumps and charging pumps.

   The sequence will permit 138 gpm charging of unborated water and a letdown flow of 138 gpm of water contained in reactor vessel.

The positive reactivity addition due to dilution of the boron concentration would cause the neutron flux to increase above the source level value. The operator is made aware of this increase by startup channel indicators registered on a recorder in the control room, by audible count rate, and by redundant startup channel alarms. In addition, the logarithmic ex-core safety channels will detect the increase in neutron flux level. Recorded indications of these channels are also provided in the control room. Finally, the following alarms/indicators would alert the control room operator to the fact that systems necessary for the uncontrolled boron dilution during refueling were operating:

A. "Charging Pump Header Flow Low" annunciator would clear (annunciators slow-flash when clear and are extinguished when subsequently cleared by the Operator).

B. "Reactor Makeup Water Pump to Blender Flow HIGH/LOW" annunciator would be actuated.

C. Other indications available are: a) charging pump header pressure, b) charging pump discharge flow, c) charging pump operating, and d) makeup water flow.

These alarms and indications would alert the operator to the starting of the first charging pump coincident with the start of the dilution event.

For conservatism, the initial boron concentration was chosen to be consistent with the Technical Specification limit of k_{eff} = 0.95. The CBC/IBW limit lines as presented in Figure 15.1.4-1 were based on 31 minutes from alarms to loss of shutdown margin.

15.1.4.2.3 Dilution During Cold Shutdown

The allowable RCS configuration during cold shutdown conditions leads to two separate analyses of the uncontrolled dilution event. The RCS may be partially drained to support maintenance. In this condition, the charging pumps are not operating and the analysis is similar to the refueling event. The RCS may also be filled and a charging pump may be in operation, which precludes reliance on the charging pump alarm to notify the operator of the onset of the event. These two conditions are treated separately.

15.1.4.2.3.1 Dilution During Cold Shutdown with the RCS Filled

In addition to the assumptions for Cold Shutdown presented in Table 15.1.4-1, the following conditions were assumed:

A. The minimum shutdown margin required by Technical Specifications is available prior to the start of the event.

B. Although the RCS is filled, the operation of the Shutdown Cooling System does not always assure complete mixing of the RCS volume. Only part of the RCS volume is considered in the analysis. Since at least one loop of shutdown cooling will be in operation, the volume of one shutdown cooling loop is also included.

C. A charging pump may or may not be operating before the dilution flow of 138 gpm from the operation of all three pumps is assumed to start. If a charging pump is in operation, the alarm available on initial operation of a pump will not notify the operator of the beginning of the event. The analysis conservatively assumes that a charging pump is running.

D. To provide indication of the event, one of the following two conditions is assumed:

   1. An operable boron dilution count rate monitor is available to provide an alarm when the startup range excore neutron detectors indicate an increasing count rate. The monitors are set to provide the alarm when the count rate reaches 1.5 times the background count rate.

   2. If the monitors are not operable, Control Element Assemblies (CEA) have been withdrawn to provide trippable reactivity. In this condition, a boron dilution event would eventually cause reactor power to increase to the high logarithmic power trip setpoint which would result in the insertion of the CEAs and numerous alarms to notify the operator of the event.

If the boron dilution count rate monitors are operable and no CEAs are withdrawn, the operator will receive an alarm from the count rate monitors more than 15 minutes before the loss of all shutdown margin. If the count rate monitors are not operating and assuming the withdrawn CEAs are worth a minimum of 2.0% $\Delta k/k$, the high logarithmic power trip will alert the operator more than 15 minutes before the loss of all shutdown margin. In both of these conditions, the

operator will be alerted to the event with more than the minimum 15 minutes of response time available. The CBC / IBW limit lines presented in Figures 15.1.4-3 and 15.1.4-4, for alarms inoperable and operable, respectively were based on 16 minutes from alarms to loss of shutdown margin.

15.1.4.2.3.2 Dilution During Cold Shutdown with the RCS Partially Drained

In addition to the assumptions for Cold Shutdown presented in Table 15.1.4-1, the following conditions are assumed:

A. The minimum shutdown margin required by Technical Specifications is available prior to the start of the event.

B. The RCS is filled only to the bottom of the hot leg nozzles. The volume of one Shutdown Cooling System loop is included in the analysis.

C. As in the RCS filled case of the cold shutdown analysis, (see 15.1.4.2.3.1) a charging pump is assumed to be operating such that the charging pump alarm will not alert the operator to the start of the remaining pumps.

D. To provide indication of the UBDI, an alarm on initial operation of a charging pump or an alarm when the startup range excore neutron detectors indicate an increasing count rate is available. The monitors are set to provide the alarm when the count rate reaches 1.5 times the background count rate.

For the partially drained condition, the operator will receive an alarm from the count rate monitors or charging pump start more than 15 minutes before the loss of all shutdown margin. The operator will be alerted to the event with more than the minimum 15 minutes response time available. The CBC / IBW limit line presented in Figure 15.1.4-2 was based on 16 minutes from alarms to loss of shutdown margin.

15.1.4.2.4 Dilution During Hot Shutdown

In addition to the assumptions for Hot Shutdown presented in Table 15.1.4-1, the following conditions are assumed:

A. The minimum shutdown margin required by Technical Specifications is available prior to the start of the event. A 0.5% $\Delta k/k$ reactivity conservatism is accounted for in the plant operating procedures.

B. In some cases, shutdown cooling may be in operation rather than the reactor coolant pumps. Consequently, a reduced RCS volume is assumed. The volume of one shutdown cooling loop is included in the analysis.

C. As in the RCS filled case of the cold shutdown analysis, (see 15.1.4.2.3.1) a charging pump is assumed to be operating such that the charging pump alarm is not assumed to alert the operator to the start of the remaining pumps.

D. As in the RCS filled case of the cold shutdown analysis, one of the following two conditions exists to alert the operator of a dilution event:

   1. An operable dilution count rate monitor is available, set at 1.5 times the background count rate.

   2. If the monitors are not operable, CEAs have been withdrawn to provide trippable reactivity.

If the boron dilution count rate monitors are operable and no CEAs are withdrawn, the operator will receive an alarm more than 15 minutes before the loss of all shutdown margin. If the monitors are not operating and assuming the withdrawn CEAs are worth a minimum of 2.0% $\Delta k/k$, the high logarithmic power trip will alert the operator more than 15 minutes before the loss of all shutdown margin. In both of these conditions, the operator will be alerted to the event with more than the minimum 15 minutes response time available. The CBC / IBW limit lines for Hot Shutdown are presented in Figures 15.1.4-5 and 15.1.4-6, for alarms inoperable and operable, respectively. The limit lines associated with Hot Shutdown were based on 16 minutes from alarms to loss of shutdown margin.

15.1.4.2.5 Dilution During Hot Standby

In addition to the assumptions for Hot Standby presented in Table 15.1.4-1, the following conditions are assumed:

A. The minimum shutdown margin required by Technical Specifications is available prior to the start of the event. A 0.5% $\Delta k/k$ reactivity conservatism is accounted for in the plant operating procedures.

B. In some cases, shutdown cooling may be in operation rather than the reactor coolant pumps. Consequently, a reduced RCS volume is assumed. The volume of one shutdown cooling loop is included in the analysis.

C. As in the RCS filled case of the cold shutdown analysis, (see 15.1.4.2.3.1) a charging pump is assumed to be operating such that the charging pump alarm is not assumed to alert the operator to the start of the remaining pumps.

D. As in the RCS filled case of the cold shutdown analysis, one of the following two conditions exists to alert the operator of a dilution event:

   1. An operable dilution count rate monitor is available, set at 1.5 times the background count rate.

   2. If the monitors are not operable, CEAs have been withdrawn to provide trippable reactivity.

If the boron dilution count rate monitors are operable and no CEAs are withdrawn, the operator will receive an alarm more than 15 minutes before the loss of all shutdown margin. If the monitors are not operating and assuming the withdrawn CEAs are worth a minimum of 2.0% $\Delta k/k$, the high logarithmic power trip will alert the operator more than 15 minutes prior to the loss of all shutdown margin. In both of these conditions, the operator will be alerted to the event with more than the minimum 15 minutes response time available. The CBC / IBW limit

lines for Hot Standby are presented in Figures 15.1.4-7 and 15.1.4-8, for alarms inoperable and operable, respectively. The limit lines associated with Hot Standby were based on 16 minutes from alarms to loss of shutdown margin.

15.1.4.2.6 Dilution During Critical Operation

For a boron dilution transient with the reactor critical, reactor power would increase due to the positive reactivity addition and reactor coolant temperature and pressure would increase.

For an unplanned boron dilution with the reactor critical, the following RPS responses will prevent violation of the associated limits:

A. Low DNBR trip;

B. High local power density trip;

C. High pressurizer pressure trip;

D. Variable overpower trip.

The addition of positive reactivity may cause system parameters to change in such a manner that the margin to specified acceptable fuel design limits is reduced. These parameters are sensed and supplied to the CPCs where the DNBR and local power density (LPD) are continually calculated. If the variation in parameters were to result in either the DNBR or LPD fuel design limits being approached, a reactor trip would occur to prevent the limits from being violated. A reactor trip on high pressurizer pressure would prevent reaching the safety limit on RCS pressure.

When considering an UBDI event in Modes 1 and 2 care needs to be taken to ensure that the DNBR and centerline melt (CTM) limits are not exceeded. The concern is the rate of power increase. For example, inadvertent charging of unborated water into the RCS, while the reactor is at full power could result in a maximum rate of reactivity addition of ~1.5×10^{-5} $\Delta\rho$/sec. If boron dilution occurs at this rate, and the operator fails to take corrective action, reactor power, coolant temperature, and coolant pressure would increase. These changes are such that a low minimum DNBR or variable overpower trip would occur. During a CEA Bank Withdrawal event, the reactivity insertion rate at full power is ~1.0×10^{-4} $\Delta\rho$/sec (0% power is ~1.8×10^{-4} $\Delta\rho$/sec). Hence, the rate of reactivity addition (and corresponding power increase) during an UBDI event as compared to that of a full power CEA Bank Withdrawal event would result in a less limiting event. Therefore, the concern of violating the peak LHR and DNBR criteria, which would be present for Modes 1 and 2 are bounded by the CEA bank withdrawal event.

15.1.4.3 Conclusion

A sustained uncontrolled boron dilution event is unlikely in view of the administrative procedures and system design and in view of numerous indications available to the operator. However, should the postulated events discussed above occur, the maximum reactivity addition due to the dilution is slow enough to allow the operator to determine the cause of the dilution and take corrective action before significant shutdown margin is lost.

15.1.4.4 Cycle 17/18 Uncontrolled Boron Dilution Incident

For Cycle 17 / 18 the modeling of the excore/dilution alarm response for the subcritical operational modes was changed from a linear response to a non-linear response based on generic plant startup data for the uncontrolled boron dilution event (UBDE).

The boron dilution alarm monitors the neutron flux from the excore detectors using the startup channels. When the count rate increases by a fixed factor [i.e., boron dilution alarm setpoint (BDAS)], an alarm is activated. During the boron dilution event, the BDAS is used to determine the amount of shutdown margin (SDM) remaining at the time of the alarm using the non-linear response approach in Modes 3, 4, and 5. As described in Section 15.1.4.2.1, the SDM was then used to determine the boron concentration at the time of the boron dilution alarm. From this boron concentration, the inverse boron worth (IBW) versus critical boron concentration (CBC) "limit lines" were generated such that sufficient time for operator action is preserved. Hence, the Alarms-Operable IBW versus CBC "limit lines" for Modes 3, 4, and 5 (filled and drained) were revised using a non-linear response based on generic plant start-up data to determine boron concentration (or SDM in this case). The Mode 3, 4, and 5 (filled and drained) Alarms-Inoperable IBW vs. CBC "limit lines" were not impacted since they do not rely on the boron dilution alarm and thus remain valid.

The change in excore response did not impact Modes 1, 2, and 6 since the boron dilution alarm was not used. In Modes 1 and 2, protection is provided by the reactor protection system on the variable high power trip or thermal margin trip. In Mode 6, there are a number of alarms/indications other than the boron dilution alarm that alert the operator that an uncontrolled dilution is in progress as discussed in Section 15.1.4.2.2. Thus, in Mode 6 the operator is alerted at the start of the UDBE and does not rely on the boron dilution alarm to alert him that an UBDE is occurring, and Mode 6 was not impacted by the response of the boron dilution alarm. Since Modes 2 and 6 did not rely on the boron dilution alarm to alert the operator of an ongoing UBDE, the Mode 2 and 6 EPAC limit lines for IBW versus CBC were not impacted by the BDAS and remained valid.

Only Modes 3, 4, and 5 (filled and drained) with the boron dilution alarm-operable were impacted. Figures 15.1.4-2 [Mode 5 Drained Boron Dilution (Alarms Operable)], 15.1.4-4 [Mode 5 Filled Boron Dilution (Alarms Operable)], 15.1.4-6 [Mode 4 Boron Dilution (Alarms Operable)], and 15.1.4-8 [Mode 3 Boron Dilution (Alarms Operable)] were updated to include the non-linear response of the excore detectors.

The Mode 6 (refueling operation) IBW versus CBC "limit line" was revised to credit the Technical Specification 3/4.9 requirement that the refueling boron concentration is greater than or equal to 2500 ppm. By limiting initial boron concentration to values greater than or equal to 2500 ppm, the "Unacceptable Region" for Mode 6 IBW versus CBC "limit line" was reduced. The method utilized was the same as described in Section 15.1.4.2.1 in conjunction with finding the limiting CBC/IBW pair. The Mode 6 "limit line" was restricted from showing points with CBC values associated with initial boron concentration values below 2500 ppm. Hence, Figure 15.1.4-1 produced a "limit line" that satisfies the Mode 6 requirements.

15.1.5 TOTAL AND PARTIAL LOSS OF REACTOR COOLANT FORCED FLOW

15.1.5.1 Identification of Causes

A loss of reactor coolant forced flow can result from the occurrence of a mechanical or electrical failure. A partial loss of flow can occur as the result of a mechanical or electrical failure in a reactor coolant pump or from a loss of power to the pump bus. A complete loss of coolant flow results from a simultaneous loss of electrical power to all operating reactor coolant pumps.

During power operation, electrical power to the reactor coolant pumps is supplied through buses from the unit AC power source, i.e., main generator. An alternate supply to the pump buses is also provided from the preferred (off-site) AC power source. Automatic fast transfer is provided to restore the preferred AC power source to the auxiliary power distribution system in the event that the unit AC power source is lost for any reason. If the main generator trips, the pump buses are transferred and there is no significant effect on coolant flow through the core. See Chapter 8 for further discussion of the electrical system.

15.1.5.1.1 Loss of Coolant Flow Resulting From an Electrical Failure

Loss of flow during power operation causes an increase in reactor coolant temperature and results in a reduction in the margin to DNB. The low DNBR trip will prevent the minimum DNBR from falling below allowable limits at any time during the transient.

In the event that this does occur, the flow coastdown energy of the pump motor assembly determines the rate at which the core flow rate drops. The decrease in the reactor coolant flow rate during a free-wheeling coastdown is primarily governed by the rotational inertia of the reactor coolant pump and motor, including a flywheel. However, if the coolant pumps remain connected to their power supply buses, a sufficiently rapid transient frequency reduction could force the coolant pump induction motors to develop negative torque and act as generators. This would cause a coolant flow reduction more rapid than that caused by a loss of power, since some of the kinetic energy of the coolant and flywheel would be converted to electrical energy through the pump and motor.

An analysis demonstrating that an underfrequency condition will not prevent the pumps from performing their coastdown function is contained in Section 15.1.5.2.2.1.

In the event that this does occur, the flow coastdown energy of the pump-motor assembly determines the rate at which the core flow rate drops.

The 4-pump loss of flow is presented because it is the most severe loss of flow resulting from an electrical failure. Although the loss of power to one of the 2-pump buses results in loss of power to one pump in each loop the loss of power to two pumps in the same loop is presented as a limiting case for a 2-pump loss of flow.

15.1.5.1.2 Loss of Coolant Flow Resulting From a Pump Shaft Seizure

The single reactor coolant pump shaft seizure is not an anticipated operational occurrence. This accident is postulated to occur as a consequence of an instantaneous seizure of the pump shaft due to a mechanical failure. The reactor coolant flow is rapidly reduced to the 3-pump value. Since a rapid reduction in coolant flow results in a rapid reduction in the margin to DNB, a low DNBR trip will occur.

15.1.5.2 Analysis of Effects and Consequences

15.1.5.2.1 Method of Analysis

15.1.5.2.1.1 Loss of Coolant Flow Resulting from an Electrical Failure

Two loss of coolant flow incidents resulting from an electrical failure were analyzed: the loss of power to all four reactor coolant pumps; and the loss of power to two reactor coolant pumps in one loop during 4-pump operation. The conservative assumptions used for the analysis, listed in Table 15.1.5-1, are used in addition to the parameters described in Section 15.1.0. The analysis was carried out in the following steps:

A. The time-dependent core and individual loop flow rates and steam generator pressure drops are determined using the COAST program (Section 15.1.0) which solves the conservation equations for mass flow rate and momentum. The general forcing functions for the fluid momentum equations consist of the pump torque values from the manufacturer's four quadrant curves, wherein the torque is related to the pump angular velocity and discharge rate.

B. The resultant flow rates are used as input to CESEC, a digital computer code, described in Section 15.1.0, which simulates the NSSS.

C. The transient heat flux generated by CESEC and average channel mass velocity are used as input to the CETOP computer program which determines the DNBR for the hot channel.

15.1.5.2.1.2 Loss of Coolant Flow Resulting from a Shaft Seizure

In addition to the assumptions stated in Section 15.1.0, the conservative initial conditions in Table 15.1.5-2 are used for this analysis.

The analysis encompassed the following steps:

A. Upon initiation of this transient, the core flow rate reduces rapidly to the asymptotic 3-pump core flow rate of 89.8 x 106 lbm/hr. The coastdown curve is obtained from the COAST code (Section 15.1.0).

B. The resultant flow rates are used as input to CESEC, a digital computer code, described in Section 15.1.0, which simulates the NSSS. The transient results in a minimum DNBR that is below 1.3; however, this condition exists for only a short period of time.

C. The analysis is repeated with the above assumptions, using the COSMO computer code to determine the minimum DNBR for fuel pins of various radial peaks. An integral fuel damage calculation is then performed by combining the results from the COSMO code with the number of fuel rods having a given radial peaking factor. The number of fuel rods versus radial peaking factor is taken from the "cumulative distribution of the fraction of fuel rods versus nuclear radial peaking factor" (Figure 15.1.5-13).

The radiological consequences of the loss of coolant flow resulting from a shaft seizure was analyzed, using the information presented in Section 15.1.0.5. The effects of gas transport in the condenser hotwell are also included in the determination of the radiological consequences. The amount of iodine that leaves the condenser hotwell via the condenser vacuum pump discharge is assumed to be 0.1 percent of all the iodine that passes through the condenser during the entire course of the incident. After discharge from the vacuum pump, the gases are filtered by the Auxiliary Building Ventilation System (ABVS). All the noble gas leaked into the main steam system is continuously released with the steam to the main condenser evacuation system.

15.1.5.2.2 Results

15.1.5.2.2.1 Loss of Coolant Flow Resulting From an Electrical Failure

The 4-pump loss of coolant flow produces an approach to the DNBR limit due to the decrease in the core coolant flow. Protection against exceeding the DNBR limit for this transient is provided by the initial steady state thermal margin which is maintained by adhering to the Technical Specifications LCOs on DNBR margin and by the response of the RPS which provides an automatic reactor trip on low DNBR as calculated by the CPCs.

The loss of coolant flow transient is characterized by the flow coastdown curve given in Figure 15.1.5-1. Table 15.1.5-1 lists the key transient parameters used in the analysis for Cycle 2. The integrated radial peaking Factor (F_r) was chosen so that the transient is initiated from conditions which would correspond to a POL.

Table 15.1.5-3 presents the NSSS and RPS responses during a four pump loss of flow initiated from an axial shape with a negative shape index of -0.18 performed for Cycle 2. The COLSS and CPC data bases are established parametrically as a function of axial shape index. The representative case shown is one of the limiting cases. The CPCs initiate the low DNBR trip at 0.6 seconds and the scram rods start dropping into the core 0.45 seconds later. A minimum CE-1 DNBR of 1.24 is reached at 2.90 seconds. Figures 15.1.5-2 to 15.1.5-5 present the core power, heat flux, RCS pressure, and core coolant temperatures as a function of time. Figure 15.1.5-6 presents a trace of hot channel DNBR vs. time for the limiting case presented.

Subsequent cycle analyses have been performed with more restrictive values for scram worth. These analyses have shown that Technical Specification LCOs maintain sufficient margin to DNBR limits applicable to the respective cycle.

A study was also conducted for Unit 2 to establish the maximum probable frequency decay rates following a system disturbance resulting in an overload on the available generation and the effects of such decay rates on reactor coolant flow. The engineering analysis used to determine these decay rates is based on the maximum electrical load which a generator-transformer combination will accept. The maximum overload is a function of the impedance characteristics of the generator overload and its connected system, and the initial operating conditions of the plant.

The rates of system frequency decay during grid disturbances are not monitored. However, this is not uncommon since very little recorded data exists on an industry-wide basis on the subject. Those decay rates which are recorded are, in general, considerably lower than those calculated in the following analysis.

Analysis

When the electrical power output of a generator exceeds the mechanical power input, there will be a tendency for the unit to change speed. The rate at which the speed of a rotating mass can change is shown by Newton's second law of motion applied to rotation.

$$T = J\frac{dw}{dt}$$

By neglecting losses in the unit and by use in a 60 hertz system, we have the equation

$$\frac{df}{dt} = \frac{30}{H}(P_T - P_G)$$

where

P_T = turbine power in per unit on the generator MVA base.

P_G = electrical power of the generator in per unit on the generator rated MVA base.

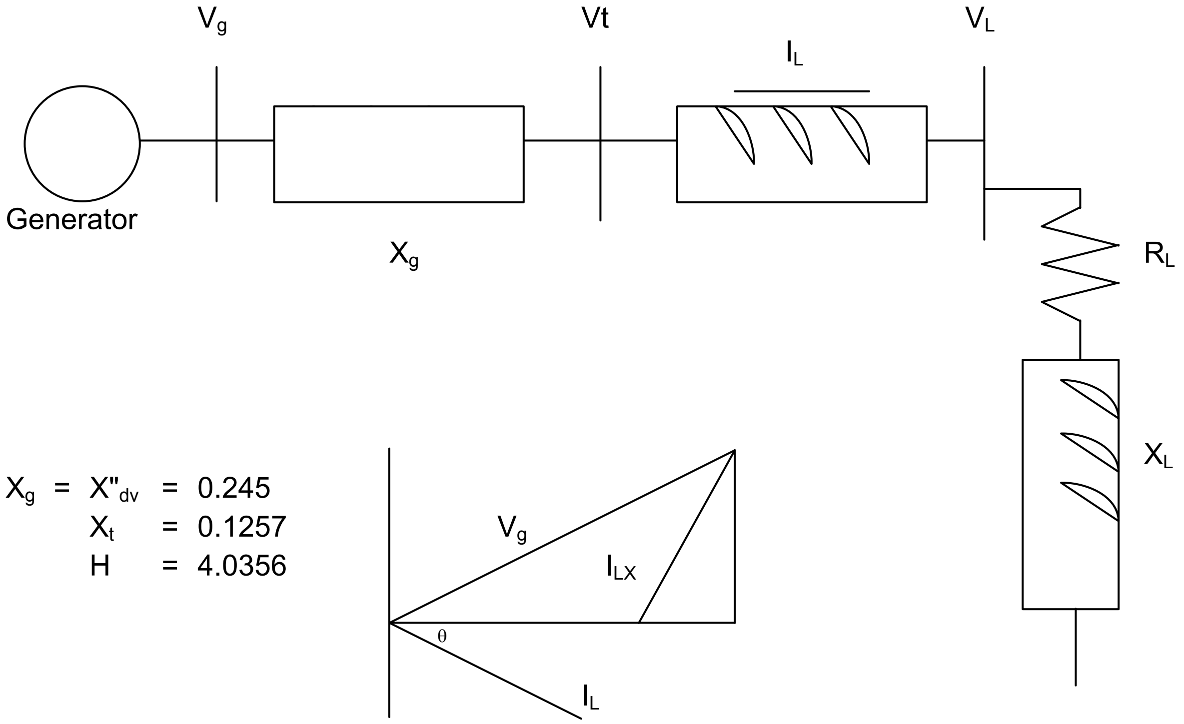
H = inertia constant in Kw-secs per KVA of generator rating.

It is seen that the maximum decay rate must occur when the greatest power mismatch exists.

When a generator becomes overloaded without changing load power factor, the current must increase with a resulting voltage decrease. However, because of the relationship of load voltage and load current, load power does not increase linearly as load current increases. The maximum overload that can be imposed on a generator can therefore be found analytically.

The system and its phasor diagram shown below has its load power shown by the equation

$$P_L = [PF_L]\left[I_L\sqrt{V_g^{\,2} - I_L^{\,2}X^2(PF_L)^2} - I_L^{\,2}X\sqrt{1 - PF_L^{\,2}}\right]$$



X_g = X''_{dv} = 0.245
X_t = 0.1257
H = 4.0356

The maximum power (P_{Lmax}) is therefore found by differentiating this equation with respect to load current, the result being

$$P_{L\,max} = \left[\frac{V_g^{\,2}}{2X}\right]\left[PF_L - \frac{RF_L}{PF_L}\left(1 - RF_L\right)\right]$$

where

PF_L = power factor of the load

RF_L = the load reactive factor

It follows that the greatest power mismatch is $P_{Lmax} - P_T$

With regard to curves and the associated discussion of Reference 1, it is shown that the initial decay rate immediately following the disturbance will be the maximum occurring for a single disturbance. It is also shown that the maximum mismatch occurs at high load power factor and turbine power.

ANO-2 is normally base loaded at or very near 100 percent power. Therefore, the possibility of encountering accelerated frequency decay rates due to low turbine power are minimized.

An analysis of the frequency decay rate for ANO-2 under typical conditions has been performed. Figure 15.1.5-14 shows the decay rates for various initial conditions.

Conservatively assuming that these calculated frequency transients are characterized by a sustained linear decay rate, a review of the final LOFA DBE indicates that the maximum decay rate with the unit at 100 percent power is acceptably considered by the 4-pump loss of flow analysis because of the similarity of the pump coastdown rate with the frequency decay rate.

The higher frequency decay rate from 30 percent initial plant load was analyzed with the CENTRAN Code which provides simulation data of the CPCs as well as CESEC simulation data for the response of the NSSS. A reactor scram was initiated upon a trip signal generated by the CPC system. The flow coastdown was generated by the CPC flow algorithm using the pump speed as input. The pump speed was assumed to decrease at a rate of 10.7 percent per second. Table 15.1.5-6 summarizes the resultant normalized core flow rate as a function of time which was also used in the CESEC simulation. Table 15.1.5-7 summarized the initial NSSS parameters which are important relative to DNBR.

The simulation results of the CPC system verifies that a CPC low DNBR trip would occur at 0.656 seconds. The CESEC simulation data verifies that the minimum DNBR occurs at 3.2 seconds and is greater than 1.3, the acceptable fuel design limit.

Graphical results of the CESEC DNBR data are provided in Figure 15.1.5-15 for one of the cases analyzed.

15.1.5.2.2.2 Loss of Coolant Flow Resulting From a Shaft Seizure

The reduction of the coolant rate to the asymptotic 3-pump value is shown in Figure 15.1.5-8. In Table 15.1.5-5 and Figures 15.1.5-9 through 15.1.5-12, the NSSS and RPS responses for the single reactor coolant pump seized shaft are shown. For this transient, it was conservatively determined that less than two percent of the fuel is expected to experience DNB for a short period of time.

In the course of the 3-hour cooldown period following the seized shaft accident, which presumably results from dumping steam to the main condenser with the aid of the steam bypass valves, approximately 820,000 lbs. of steam is required to cool the plant to 350 °F. At 350 °F, the main condenser is shut down and vacuum pump discharge to the ABVS is terminated.

The resulting quantities of activity released via the vacuum pump to the atmosphere over this period of time is 7×10^{-4} dose equivalent curies of I^{131} and 100 dose equivalent curies of Xe^{133}. This results in a 3-hour inhalation dose value at the site boundary less than 2.34×10^{-5} rem and a 3-hour whole body dose value at the site boundary less than 2.97×10^{-3} rem.

15.1.5.2.3 Subsequent Evaluation

15.1.5.2.3.1 Cycle 12 Seized Rotor

The Seized Rotor event was reanalyzed for Cycle 12 to evaluate the impact of a more adverse Cycle 12 seized rotor pin census.

There has been a change in the methodology for analysis of the Seized Rotor event. The current methodology includes determining POL with CETOP and conservatively reducing the mass flow rate to 3-pump asymptotic flow maintaining 100% heat flux. Therefore, no transient response was performed and the only physics data required is the pin census.

Employing the current methodology demonstrates that the calculated fuel failure for Cycle 12 is less than the value determined in the previous analysis of record (Cycle 3). The offsite dose remains well within 10 CFR 100 limits.

15.1.5.2.3.2 Loss of Flow Analysis to Support RCS Flow Reduction and 30% Steam Generator Tube Plugging

To determine the impacts of a 10 percent reduction in RCS design flow and 30 percent steam generator tube plugging on the Four Pump Loss of Flow analysis, the following evaluation was performed. This evaluation has employed the HERMITE computer code instead of the CESEC code used previously for this event. The CENTS computer code has replaced the COAST program for calculating the RCS flow coastdown.

For a loss of flow at any power operating condition, a reactor trip will be initiated when any one of four Reactor Coolant Pump (RCP) shaft speeds drops to 95 percent of its nominal speed. In this method, the partial loss of flow resulting from a loss of electrical power to three or less RCPs is less limiting than a four pump loss of flow. This is because the reactor will trip at the same time for both cases but the partial loss of flow has a slower flow coastdown. Therefore, only the four pump loss of flow event is presented herein.

The analysis was carried out in the following steps:

A. The RCP coastdown data for the loss of flow event was generated using the CENTS code. The use of the CENTS code is a change from the original coastdown analysis which used the COAST code.

   Coastdown data to account for 30% steam generator tube plugging was determined by first benchmarking the CENTS coastdown results against the original coastdown data from the COAST code and plant specific coastdown data. The CENTS basedeck was then adjusted to account for the 30% steam generator tube plugging. The CENTS coastdown analysis considered the affects of both symmetric and asymmetric steam generator tube plugging (up to 1000 tube asymmetry). The coastdown analysis also considered the effects of initial RCS pressure, temperature, and flow. The resulting coastdown data generated from CENTS was used as input to the HERMITE code.

B. The HERMITE code is used to determine the reactor core response during the postulated loss of flow event. The HERMITE code solves the few-group, space and time dependent neutron diffusion equation including the feedback effects of fuel temperature, coolant temperature, coolant density, and control rod motion for a one-dimensional average fuel bundle.

C. The time dependent thermal hydraulic information generated from the HERMITE code is transferred directly to the CETOP computer code for thermal margin and DNBR evaluation. The CETOP method was used to calculate both the time of occurrence and value of the minimum DNBR during the transient.

The four pump loss of flow event used the conservative assumptions provided in Table 15.1.5-8 including the Cycle 13 physics data and the following assumptions:

A. A CEA insertion curve consistent with the CEA position versus time used to develop Figure 15.1.0-1D was assumed. This curve accounts for a 0.6 second holding coil delay and a 3.2 second arithmetic average drop time to 90% inserted.

B. A BOC delayed neutron fraction of 0.0072546 was assumed.

C. A BOC fuel temperature coefficient of –0.0013 $\Delta\rho/\sqrt{°K}$ was assumed.

D. For this analysis, a trip on low RCP speed is the primary trip for the loss of flow event, replacing the trip on low flow-projected DNBR. A CPC trip is initiated when the RCP shaft speed drops to 95 percent of its normal speed.

The four pump loss of coolant flow produces an approach to the DNBR limit due to the decrease in the core coolant flow. Protection against the DNBR limit for this transient is provided by the initial steady state thermal margin which is maintained by adhering to the Technical Specification LCOs on DNBR margin and by the response of the RPS which provides an automatic reactor trip as calculated by the CPCs.

The principal process variables that determine thermal margin to DNB in the core are monitored by the COLSS. The COLSS computes a power operating limit which ensures that the thermal margin available in the core is equal to or greater than that needed to cause the minimum DNBR to remain greater than the DNBR limit. The minimum thermal margin required (reserved) in COLSS for the loss of flow event is set equal to the maximum thermal margin degradation observed during a loss of flow event.

The initial conditions are selected such that the system is at a very subcooled state. Initiating the event from such a state results in the least amount of negative reactivity inserted due to generation of voids in the RCS. In this manner the system undergoes the greatest amount of thermal margin degradation due to the RCP coastdown.

To demonstrate explicitly that the DNBR SAFDL is not violated during a loss of flow event, a sample case is provided in which the initial conditions are chosen such that at the onset of the event the minimum thermal margin required by the COLSS power operating limit is preserved. This analysis has used an RCS flow of 108.36 Mlbm/hr which is 90 percent of the minimum design flow corresponding to 30 percent tube-plugging. Figure 15.1.5-16 provides a graph of the RCS flow coastdown used for the loss of flow event with 30% steam generator tube plugging. The consequences following a total loss of forced reactor coolant flow, with respect to approaching the DNBR SAFDL, initiated from any set of initial conditions which preserve the minimum COLSS margin would be no more adverse than those presented herein.

The results of this analysis is the calculation of minimum thermal margin required to be reserved in COLSS to prevent the violation of the DNBR SAFDL during a loss of flow event. With a minimum thermal margin reserved in COLSS, the minimum DNBR observed during this event is 1.29 at 2.8 seconds. The sequence of events for the four pump loss of flow assuming 30% steam generator tube plugging is provided in Table 15.1.5-9. Figure 15.1.5-17 provides a graph of DNBR versus time for the event.

For the loss of flow event, the CPC trip on pump low speed in conjunction with the initial margin reserved in COLSS is sufficient to prevent the violation of the DNBR SAFDL from any set of initial conditions.

15.1.5.2.3.3 Seized Rotor Event Analysis for RCS Flow Reduction and 30% Tube Plugging

When analyzing the seized rotor event, the event is initiated from a power operating limit with the minimal acceptable thermal margin to the DNBR limit. Based on this consideration, the initial RCS flow does not have a significant impact on the analysis results. Rather, the change in flow rate from the initial value to the final flow rate is a critical parameter. Due to the potential that increased tube plugging may affect the change in flow rate, an evaluation was performed to determine the effective change in flow rate due to 30% steam generator tube plugging.

This analysis concluded that the final “steady state” flow fraction for the 30% steam generator tube plugging case is essentially equal to the “steady state” flow fraction used in the analysis of record. The coastdown data for the seized rotor event was generated using the CENTS code. The use of the CENTS code is a change from the original coastdown analysis which used the COAST code.

The analysis of record seized rotor event assumes an instantaneous drop from the initial flow rate to the reduced “steady state” flow fraction. Based on the above, this assumption remains valid; therefore, a reanalysis of the seized rotor event was not required.

15.1.5.2.3.4 Cycle 15 Loss of Coolant Flow Resulting From a Pump Shaft Seizure-Radiological Assessment

A subsequent radiological analysis was performed to support steam generator replacement and power uprate. Radiological consequences were calculated for a loss of AC power. These results will bound an AC power available case due to the unavailability of the condenser for steam release.

The analysis input and assumptions used in the calculation of the radiological dose releases for the seized shaft event are discussed in Section 15.1.0.5.5 and have been incorporated in this analysis with the following clarifications:

1. The condenser is assumed unavailable for cooldown (this is a conservative assumption with respect to the method defined in Section 15.1.5.2.2.2). Thus, the entire cooldown was performed by dumping steam to the atmosphere from the steam generators.

2. The radiological doses were conservatively calculated at a higher rated power of 3026 MWt (3087 MWt including uncertainties) and parametric in 0.5% fuel failure intervals.

3. An RCS primary to secondary leakage rate of 150 gpd per steam generator was assumed.

The effect of the increase in RCS and steam generator inventories, due to steam generator replacement, was combined with the 3026 MWt (3087 MWt including uncertainties) rated power physics radiological dose data to calculate the doses in fuel failure increments of 0.5%. The results of the analysis demonstrated that the EAB and LPZ radiological doses remained a small fraction (10%) of 10 CFR 100 limits up to 14% fuel failure.

15.1.5.2.3.5 Cycle 15 Loss of Reactor Coolant Flow Resulting from an Electrical Failure

The previous LOF event analysis was analyzed using the HERMITE code. The HERMITE code described in Reference 23 does not employ a steam generator model, but does use as an input the four RCP flow coastdown data. The effect of the replacement steam generators (RSGs) was modeled by supplying the core flow rate as a function of time as input data to model the four-RCP flow coastdown.

The method used in this evaluation performed a comparison of key plant and physics input parameters between those used in the previous analysis and that of the new input data due to the RSGs and other plant changes.

The evaluation was carried out in the following steps to determine the impact of key plant and physic input data changes:

1. The RCP coastdown data for the loss of flow event were generated using the CENTS code (Reference 24).

2. The impact of a 0.15% decrease in four-pump RCS flow for the first four seconds was assessed. Table 15.1.5-11 documents the flow coastdown for the first ten seconds.

3. The increase in initial maximum RCS flow assumption from 355,200 gpm to 386,400 gpm was assessed.

4. An increase in CPC response time from 0.3 seconds to 0.4 seconds was assessed.

5. The least negative Doppler coefficient becoming less negative, changing from 0.00131 $\Delta\rho$/K to -0.00128 $\Delta\rho$/K was assessed.

The HERMITE code was not used. Instead, an engineering evaluation of changes in key input data was employed to assess the impact on the LOF event. Based on previous sensitivity studies, the required thermal margin increase was conservatively calculated based on the above input data changes.

The overall impact on the required thermal margin increase is less than 1%. Thus, the minimum DNBR in the previous analysis was decreased from 1.29 to no less than 1.277, but remains above the DNB SAFDL value of 1.25. Table 15.1.5-9 provides a modified sequence of events for Cycle 15.

The four pump loss of coolant flow produces an approach to the DNBR limit due to the decrease in the core coolant flow. Protection against the DNBR limit for this transient is provided by the initial steady state thermal margin which is maintained by adhering to the Technical Specification LCOs on DNBR margin and by the response of the RPS which provides an automatic reactor trip as calculated by the CPCs.

The principal process variables that determine thermal margin to DNB in the core are monitored by the COLSS. The COLSS computes a power operating limit which ensures that the thermal margin available in the core is equal to or greater than that needed to cause the minimum DNBR to remain greater than the DNBR limit. The minimum thermal margin required (reserved) in COLSS for the loss of flow event is set equal to the maximum thermal margin degradation observed during a loss of flow event.

For the loss of flow event, the CPC trip on pump low speed in conjunction with the initial margin reserved in COLSS is sufficient to prevent the violation of the DNBR SAFDL from any set of initial conditions.

15.1.5.2.3.6 <u>Cycle 15 Loss of Coolant Flow Resulting from a Pump Shaft Seizure</u>

The Loss of Flow from a Pump Shaft Seizure was evaluated to determine the impact of the replacement steam generators (RSGs) for Cycle 15.

The method of the previous analysis for the seized rotor assumes an instantaneous drop from the initial flow rate to the reduced three-pump steady-state flow fraction. Only the final asymptotic three-pump flow fraction is important and not the actual RCS flow coastdown. The evaluation was carried out in the following steps to determine the impact of key plant and physics input data changes:

1. The RCS flow coastdown data for the seized rotor flow event was generated using the CENTS code. A slightly lower final asymptotic three-pump RCS flow value of 0.6% was assessed.

2. The increase in initial maximum RCS flow limit from 355,200 gpm to 386,400 gpm was assessed.

3. The increase in RCS and steam generator inventories was assessed using the new radiological dose method (see Section 15.1.5.2.3.4).

No explicit cases were analyzed. An engineering evaluation of changes in key input data has been employed to assess the impact on the seized shaft event.

The difference in the three-pump asymptotic percentage flow value was lower by 0.6%. This difference has a small impact on the calculated fuel failure for the seized rotor event.

The increase in maximum initial RCS flow was determined to be bounded by the results of the minimum initial RCS flow results; hence increasing the maximum initial RCS flow has no impact on the analysis results.

15.1.5.2.3.7 <u>Cycle 16 Loss of Coolant Flow Resulting from an Electrical Failure</u>

The following analysis was performed to address Power Uprate. The implementation of Power Uprate resulted in a slightly faster four reactor coolant pump flow coastdown, which can be found in Table 15.1.5-12 and Figure 15.1.5-18.

For a loss of flow at any power operating condition, a reactor trip will be initiated when any one of four Reactor Coolant Pump (RCP) shaft speeds drops to 95 percent of its nominal speed. Crediting this trip, the partial loss of flow resulting from a loss of electrical power to three or fewer RCPs is less limiting than a four pump loss of flow. This is because the reactor will trip at the same time for both cases but the partial loss of flow has a slower flow coastdown. Therefore, only the four pump loss of flow event is presented herein.

The analysis was carried out in the following steps:

A. The RCP coastdown data for the loss of flow event was generated using the CENTS code. Coastdown data to account for up to 10% steam generator tube plugging was determined. The CENTS coastdown analysis considered the affects of both symmetric and asymmetric steam generator tube plugging (up to 10% tube asymmetry). The coastdown analysis also considered the affects of initial RCS pressure, temperature, and flow. The resulting coastdown data generated from CENTS was used as input to the HERMITE code.

B. The HERMITE code is used to determine the reactor core response during the postulated loss of flow event. The HERMITE code solves the few-group, space and time dependent neutron diffusion equation including the feedback effects of fuel temperature, coolant temperature, coolant density, and control rod motion for a one-dimensional average fuel bundle.

C. The time dependent thermal hydraulic information generated from the HERMITE code is transferred directly to the CETOP computer code for thermal margin and DNBR evaluation. The CETOP method was used to calculate both the time of occurrence and value of the minimum DNBR during the transient.

Input parameters from Tables 15.1.5-12 and 15.1.5-13 including bounding physics data from Section 15.1.0 have been incorporated in this analysis with the following clarifications:

A. The CEA insertion curve in Figure 15.1.0-1D was assumed. This curve accounts for a 0.6 second holding coil delay. A CEA worth of -5.0% $\Delta\rho$ was conservatively assumed.

B. A BOC delayed neutron fraction consistent with those defined in Section 15.1.0.3 was assumed.

C. A least negative Doppler coefficient of -0.00128 $\Delta\rho/\sqrt{°K}$ was assumed.

D. A CPCS trip is initiated when the RCP shaft speed drops to 95 percent of its normal speed with a response time of 0.4 seconds.

E. An initial core power of 3087 MWt was assumed, based on a rated power of 3026 MWt and a 2% uncertainty.

F. A MTC of 0.0 x 10^{-4} $\Delta\rho$/°F was assumed.

G. The following RCS flow, temperature, and pressure ranges in conjunction with a radial peaking factor range are assumed as a basis for input into the maximum and minimum subcooled cases.

- 118.0 x 10^6 lbm/hr ≤ RCS flow ≤ 142.1 x 10^6 lbm/hr
- 540 °F ≤ core inlet temperature ≤ 556.7 °F
- 2000 psia ≤ RCS pressure ≤ 2300 psia
- 1.28 ≤ radial peak factor ≤ 1.71

The four pump loss of coolant flow produces an approach to the DNB limit due to the decrease in the core coolant flow. Protection against the DNB limit for this transient is provided by the initial steady state thermal margin which is maintained by adhering to the Technical Specification LCOs on DNBR margin and by the response of the RPS, which provides an automatic reactor trip as calculated by the CPCs.

The COLSS monitors the principal process variables that determine thermal margin to DNB in the core. The COLSS computes a power operating limit, which ensures that the thermal margin available in the core is equal to or greater than that needed to cause the minimum DNBR to remain greater than the DNB limit.

The initial conditions are typically selected such that the system is at a very subcooled state. Initiating the event from such a state results in the least amount of negative reactivity inserted due to generation of voids in the core. In this manner, the system undergoes the greatest amount of thermal margin degradation due to the RCP coastdown.

To demonstrate explicitly that the DNB SAFDL is not violated during a loss of flow event, two sample cases are provided in which the initial conditions are chosen such that at the onset of the event the minimum thermal margin required by the COLSS power operating limit is preserved.

The results of these analyses are the calculation of minimum thermal margin required to be reserved in COLSS to prevent the violation of the DNB SAFDL during a loss of flow event. With a minimum thermal margin reserved in COLSS, the minimum DNBR observed during this event is greater than 1.25 for the maximum subcooled case. The sequence of events for the four pump loss of flow is provided in Table 15.1.5-14. Figures 15.1.5-19 & 15.1.5-20 provide graphs of DNBR versus time for the maximum and minimum subcooled cases, respectively.

Two cases are presented in this section to demonstrate the conservatism in starting at a maximum subcooled state. One case is based on the conservative assumptions used in the Loss of Flow analysis to maintain the core as subcooled as possible to prevent bulk boiling and negative reactivity feedbacks. The second case analyzed uses assumptions, which minimize subcooling and were selected to be within the LCOs. As can be seen by comparing the DNBR traces for these two cases, the DNBR trace using the maximum subcooling assumptions (Figure 15.1.5-19) is more adverse than the DNBR trace using minimal subcooling assumptions (Figure 15.1.5-20).

For the loss of flow event, the CPC trip on low pump speed in conjunction with the initial margin reserved in COLSS is sufficient to prevent the violation of the DNBR SAFDL from any set of initial conditions.

15.1.5.2.3.8 Cycle 16 Loss of Coolant Flow Resulting from a Seized Rotor

The Seized Rotor event was reanalyzed for Cycle 16 to evaluate the impact of increasing the core power to 3026 MWt. The analytical bases for the seized rotor simulation are discussed below.

A. Upon initiation of this transient, the core flow rate reduces rapidly to the asymptotic (steady state) 3-pump flow fraction. The RCP coastdown data for the seized rotor event was generated using the CENTS code.

B. The method of the analysis for the seized rotor conservatively assumes an instantaneous drop from the initial flow rate to the reduced 3-pump "steady state" flow fraction calculated previously. Only the final asymptotic 3-pump flow fraction is important to calculation of potential fuel failure and not the actual RCS flow coastdown.

C. A minimum thermal margin power operating limit is modeled using the CETOP code. Then the mass flow is conservatively reduced to the 3-pump asymptotic flow fraction value while maintaining all the other initial conditions. Therefore, no transient response is required and the only physics data is the pin census.

D. The analysis is repeated with the above assumptions, using the TORC computer code to determine the minimum DNBR for fuel pins of various radial peaks. An integral fuel damage calculation is then performed by combining the results from the TORC code with the number of fuel rods having a given radial peaking factor. The number of fuel rods versus radial peaking factor is taken from the "cumulative distribution of the fraction of fuel rods versus nuclear radial peaking factor." Figure 15.1.5-21 presents the results of the TORC computer code determined minimum DNBR for fuel pins of various radial peaks. The total number of calculated fuel failures is compared to the 14% fuel failure limit that assures dose limits are met.

Although no transient response is required, a representative pump shaft seizure was performed from the limiting thermal margin conditions to provide the NSSS response to the event and determine the time of minimum DNBR. The results from the typical NSSS response have no impact on the calculated fuel failure due to the conservative methods discussed above. The CENTS digital computer code is used to simulate the NSSS response and calculate the time of minimum DNBR assuming a CPCS low reactor coolant pump shaft speed trip and response time to mitigate the event. The minimum DNBR condition exists for only a short period of time below the DNB SAFDL. The parameters from Table 15.1.5-15 and the bounding physics data from Section 15.1.0 have been incorporated into the NSSS system response with the following clarifications:

A. The BOC Doppler curve in Figure 15.1.0-4 was assumed.

B. A BOC delayed neutron fraction consistent with that defined in Section 15.1.0.3 was assumed.

C. The CEA insertion curve in Figure 15.1.0-1D was assumed. This curve accounts for a 0.6 second holding coil delay. A CEA worth of -5.0% $\Delta\rho$ was conservatively assumed.

D. An initial core power of 3087 MWt was assumed, based on a rated power of 3026 MWt and a 2% uncertainty.

E. A MTC of -0.2×10^{-4} $\Delta\rho/°F$ was assumed.

F. A maximum RCS flow of 386,400 gpm was assumed.

G. A maximum RCS pressure of 2300 psia was assumed.

H. A CPCS low reactor coolant pump shaft speed trip setpoint of 95% and a conservative total delay time of 0.5 seconds were assumed. CPCS initiates a reactor trip when the reactor coolant pump shaft speed drops below 95% of its nominal speed.

I. The asymptotic flow for the one-pump reactor coolant pump flow coastdown was assumed to be 73%. A representative one-pump flow coastdown can be found in Figure 15.1.5-22.

Table 15.1.5-16 and Figures 15.1.5-23 through 15.1.5-26 show the NSSS and RPS responses for a typical loss of reactor coolant flow from a pump shaft seizure event. Employing the current methodology demonstrates a calculated fuel failure of less than 14% for Cycle 16, thus the radiological assessment of the seized rotor event found in Section 15.1.5.2.3.4 remains valid.

15.1.5.2.3.9 Cycle 21 Loss of Coolant Flow Resulting from an Electrical Failure

The Loss of Flow event was evaluated for Cycle 21 for Next Generation Fuel (NGF). Only the DNB margin was affected. The mDNBR for this event was re-evaluated using the WSSV-T and ABB-NV critical heat flux correlations, the input from Cycle 16, and the lower DNB SAFDL of 1.23.

There are no changes to the input, results, and conclusions other than the DNB SAFDL and the time of mDNBR for the maximum subcooled case. The Cycle 16 NSSS analysis remains valid for NGF. The initial assumptions shown in Table 15.1.5-13 remain unchanged for the Cycle 21 analysis. Thus the Cycle 16 thermal hydraulic data was re-evaluated using the current method from Section 15.1.5.2.3.7 with the NGF WSSV-T and ABB-NV CHF correlations. Figures 15.1.5-19 and 15.1.5-20 document the new DNBR versus Time Figures of maximum and minimum subcooled conditions for the WSSV-T and ABB-NV CHF correlations and a DNB SAFDL of 1.23. Table 15.1.5-14 provides the revised Sequence of Events for the full core implementation of NGF.

The minimum DNBR values for the maximum and minimum subcooled condition cases remain above the DNB SAFDL value of 1.23. Consequently, the conclusions in SAR Section 15.1.5.3.1 remain the same.

15.1.5.2.3.10 Cycle 21 Loss of Coolant Flow Resulting from a Seized Rotor

The Seized Rotor event was evaluated for Cycle 21 for Next Generation Fuel (NGF). Only the DNB margin was affected. The mDNBR for this event was re-evaluated using the WSSV-T and ABB-NV critical heat flux correlations, the input from Cycle 16, and the lower DNB SAFDL of 1.23.

There are no changes to the input, results, or conclusions other than the Fr versus DNBR data required to calculate the level of fuel failure. The Cycle 16 NSSS analysis remains valid for NGF. The initial assumptions shown in Table 15.1.5-15 remain unchanged for the Cycle 21 analysis. Thus, the Cycle 16 thermal hydraulic data was re-evaluated using the current method from Section 15.1.5.2.3.8 with the NGF WSSV-T and ABB-NV CHF correlations. The CETOP and TORC code results, described by SAR Section 15.1.5.2.3.8, Items C and D, are impacted. Figure 15.1.5-21 documents the new DNBR versus integrated radial peak factor (Fr) responses. Table 15.1.5-16 provides the revised Sequence of Events for the full core implementation of NGF.

The calculated fuel failures remain below the maximum value used for the radiological dose evaluation. Consequently, the conclusions in SAR Section 15.1.5.3.2 for the radiological releases remain the same.

15.1.5.2.3.11 Cycle 22 Loss of Coolant Flow Resulting from a Seized Rotor

The Seized Rotor event was evaluated for Cycle 22 to reduce the calculated fuel failure to below the radiological dose input limit. Only the DNB margin was affected. The mDNBR for the event was re-evealuated using the input from Cycle 21.

There are no changes to the input, results, or conclusions other than the Fr versus DNBR data required to calculate the level of fuel failure. The Cycle 16 NSSS analysis remains valid for Cycle 22. The initial assumptions shown in Table 15.1.5-15 remain unchanged for the Cycle 22 analysis. The sequence of events in Table 15.1.5-16 remains valid for Cycle 22.

The calculated fuel failures remain below the maximum value used for the radiological dose evaluation. Consequently, the conclusion in SAR Section 15.1.5.3.2 for the radiological releases remained the same.

15.1.5.2.3.12 AST Seized Rotor Analysis

The analysis input and assumptions used in the AST calculation of the radiological dose releases due to a seized rotor event are discussed in Section 15.1.0.5 with the following clarifications:

1. Fission product gap fractions of 0.08 for I-131, 0.10 for Kr-85, 0.05 for other noble gases and iodines and 0.12 for alkali metals, consistent with RG 1.183, Table 3, were used;

2. Secondary release iodine species distribution of 0% particulate, 97% elemental and 3% organic, consistent with RG 1.183, was assumed;

3. A minimum SG secondary mass of 1.253×10^8 gm was used to maximize activity concentration.

The calculated results for 14% fuel failure are presented in Table 15.1.5-10.

15.1.5.3 Conclusion

15.1.5.3.1 Loss of Coolant Flow Resulting From an Electrical Failure

For the cases of the loss of coolant flow arising from the simultaneous loss of power to four reactor coolant pumps or from loss of power to two reactor coolant pumps, the low DNBR trip assures that the minimum DNBR is maintained above its limits. Also, the study conducted to establish the maximum probable frequency decay rates has shown that the rates established are acceptable in their effect on DNBR due to reactor coolant pump speed effects.

15.1.5.3.2 Loss of Coolant Flow Resulting From a Shaft Seizure

For the loss of reactor coolant flow resulting from a seized shaft, the low DNBR trip assures that the radiological releases are less than 10 CFR 50.67 limits.

15.1.6 IDLE LOOP STARTUP

15.1.6.1 Identification of Causes

Idle loop startup is defined as the startup of a reactor coolant pump, without observance of prescribed operating procedures, assuming that both reactor coolant pumps in that loop were idle. The RCS consists of two loops connected parallel to the reactor vessel. Each loop includes two single suction, centrifugal pumps located between the steam generator outlet and the reactor vessel inlet nozzles. The pump motors have non-reversing mechanisms to prevent reverse rotation and also to limit backflow through the pump while the pump is out of service.

The Unit 2 plant was originally designed to permit continued operation with one or two reactor coolant pumps idle. The final Technical Specifications for Unit 2, however, precluded critical operation with any inoperative pumps. An analysis of the idle loop startup was completed prior to the initial issuance of the ANO-2 Technical Specifications, and is presented here for completeness.

15.1.6.2 Analysis of Effects and Consequences

15.1.6.2.1 Method of Analysis

Analysis of the idle loop startup incident was performed with the CESEC computer program, described in Section 15.1.0, for Cycle 1 operation.

The most adverse case involving startup of an idle reactor coolant pump results from EOC initial conditions with two reactor coolant pumps operating in one loop (both reactor coolant pumps idle in the other loop), and with reactor power at nominal conditions for 2-pump operation. At time zero, one of the pumps is started.

In addition to the parameters described in Section 15.1.0, the conservative assumptions given in Table 15.1.6-1 are used for this analysis.

The time zero conditions are summarized in Table 15.1.6-2.

15.1.6.2.2 Results

The RPS and the NSSS responses are shown in Table 15.1.6-3 and in Figures 15.1.6-1 through 15.1.6-6.

15.1.6.3 Conclusion

For the idle reactor coolant pump startup, the minimum DNBR is significantly greater than 1.3.

15.1.7 LOSS OF EXTERNAL LOAD AND/OR TURBINE TRIP

15.1.7.1 Identification of Causes

Loss of external load and/or turbine trip results in a reduction of steam flow from the steam generators to the turbine generator. Cessation of steam flow to the turbine generator occurs because of closure of the turbine stop valves or turbine control valves. The cause of loss of load may be abnormal events in the electrical distribution network or turbine trip. In either of these situations, off-site power is available to provide AC power to the auxiliaries. The loss of all off-site AC power is discussed in Section 15.1.9.

For a turbine generator trip, Reactor Trip (RT) depends on the initial reactor power and the number of turbine bypass valves in the automatic mode. If a sufficient number of turbine bypass valves are in the automatic mode to release steam, then the reactor will not trip. Otherwise, RT will follow turbine trip. In this analysis, all turbine bypass valves are assumed to be in the manual mode.

In the event that the turbine admission valves closed and the steam bypass system valves did not open, and if no credit is taken for RT on turbine trip, RT would occur as a result of high pressurizer pressure. The main steam system pressure and the RCS pressure will be limited to within 110 percent of their design values by action of the pressurizer and steam generator safety valves and the RT on high pressurizer pressure.

The bounding event considered is a Loss of Load (LOL) event initiated by a turbine trip without a simultaneous reactor trip and assuming the Steam Dump and Bypass system is inoperable. If the turbine trip were caused by a Loss of Condenser Vacuum (discussed in Section 15.1.28), the main feedwater pump steam turbines would trip at the same time. Therefore, a LOL concurrent with loss of feed was analyzed to cover these events. The loss of load causes steam generator pressure to increase to the opening pressure of the main steam safety valves. The reduced secondary heat sink leads to a heatup of the RCS. The transient is terminated by a reactor trip on high pressurizer pressure.

15.1.7.2 Analysis of Effects and Consequences

15.1.7.2.1 Method of Analysis

The analysis of a complete loss of load incident was performed with the CESEC-III computer program, described in Section 15.1.0.

In addition to the parameters described in Section 15.1.0 for subsequent analyses, this event was initiated at the conditions shown in Table 15.1.7-1. The combination of parameters shown in Table 15.1.7-1 maximizes the calculated peak RCS pressure. The key parameters for this event are the initial primary and secondary pressures and the moderator and fuel temperature coefficients of reactivity.

The initial core average axial power distribution for this analysis was assumed to be a bottom peaked shape. This distribution is assumed because it minimizes the negative reactivity inserted during the initial portion of the scram following a reactor trip and maximizes the time required to mitigate the pressure and heat flux increases. The CEA position versus time of Figure 15.1.0-1C and a 0.6 second holding coil delay time are assumed in this analysis. A Moderator Temperature Coefficient (MTC) of $0.0X10^{-4}$ $\Delta\rho$/°F was assumed in this analysis. This MTC, in conjunction with the increasing coolant temperatures, enhances the rate of change of heat flux and the pressure at the time of reactor trip. A Fuel Temperature Coefficient (FTC) (Doppler Coefficient) corresponding to beginning of cycle conditions was used in the analysis consistent with Figure 15.1.0-3. This FTC causes the least amount of negative reactivity feedback to mitigate the transient increases in both the core heat flux and the pressure. The Doppler Coefficient multiplier used in the analysis for uncertainty is shown in Table 15.1.7-1. The lower initial RCS pressure is used to maximize the rate of change of pressure and thus peak pressure following trip. The lower coolant inlet temperature and lower steam generator pressure combination made the secondary transient more severe by delaying opening of the main steam safety valves.

15.1.7.2.2 Results

In Table 15.1.7-2, the RPS and the NSSS responses are listed for the case analyzed. In Figures 15.1.7-1 through 15.1.7-5, the core power, core average heat flux, reactor system pressure, steam generator pressure and coolant temperatures are shown as a function of time.

The Loss of Load event, initiated at the conditions given in Table 15.1.7-1, results in a high pressurizer pressure trip condition at 7.4 seconds. At 10.6 seconds, the primary pressure reaches its maximum value of 2747 psia. The increase in secondary pressure is limited by the opening of the main steam safety valves, which open at 9.6 seconds. The secondary pressure reaches its maximum value of less than 1169 psia at 15.1 seconds after initiation of the event.

The steam generator safety valves continue to relieve to the atmosphere until the steam dump and bypass system is returned to operation or until the atmospheric dump valves are opened. If operation of the steam dump and bypass system is assumed (1) within 30 minutes, no more than 130,000 pounds of steam will have been discharged and (2) within 60 minutes, no more than 260,000 pounds will be discharged. If, however, the steam bypass system continues to be unavailable and it becomes necessary to cool the plant to 350°F by dumping steam to the atmosphere, approximately 700,000 pounds would be discharged during the 3-hour cooldown, at which point shutdown cooling is initiated.

15.1.7.3 Conclusion

In the case of a complete loss of load which occurs without an immediate reactor trip, the protection provided by the high pressurizer pressure trip, pressurizer safety valves and the steam generator safety valves is sufficient to ensure that the RCS and main steam system pressure is maintained within 110 percent of design values and specified acceptable fuel design limits are not exceeded.

15.1.7.4 Loss of External Load and /or Turbine Trip Subsequent Analyses

15.1.7.4.1 Cycle 13 Loss of External Load and/or Turbine Trip

This subsequent analysis to the loss of external load and/or turbine trip was undertaken to account for Cycle 13 input parameter variations. This analysis was performed essentially consistent with the analysis described above. For the analysis presented herein, the CENTS computer code described in Section 15.1.0.6.10 was utilized.

Input parameters from Table 15.1.7-4 and Section 15.1.0 have been incorporated in this subsequent analysis with these following clarifications:

A. The BOC Doppler curve in Figure 15.1.0-4, which includes a 0.85 multiplier, is conservatively used.

B. The Cycle 13 delayed neutron fraction and effective neutron lifetime consistent with Section 15.1.0.3 was assumed.

C. The Cycle 13 CEA insertion curve in Figure 15.1.0-1D was utilized. This curve accounts for a 0.6 second holding coil delay.

A summary of the principal results for the loss of external load/loss of condenser vacuum are given in Table 15.1.7-5. These results indicate that the peak primary pressure is 2683 psia and the peak secondary pressure is 1162 psia. A separate analysis was performed to determine a conservative peak secondary pressure, as the input assumptions described above and denoted in Table 15.1.7-4 are established to ensure a peak primary pressure. This second analysis is effectively the same as the peak primary analysis except the input assumptions delineated above are adjusted to ensure a conservative peak secondary pressure. The results of this second effort indicate a peak secondary pressure of 1195 psia.

The results of these subsequent analyses shows that the peak RCS and secondary side pressures are maintained less than 110% of design values.

15.1.7.4.2 Cycle 15 at 3026 MWt Loss of External Load and/or Turbine Trip

Subsequent evaluation to the previously described Loss of Load concurrent with a Loss of Condenser Vacuum analysis has been performed to address the installation of the Replacement Steam Generators and a Power Uprate to 3026 MWt at hot full power. The methodology used in this analysis was the same as that used for the previous analysis. This analysis has utilized the CENTS computer code for the transient analysis simulation.

Input parameters from Table 15.1.7-6 and the bounding physics data from Section 15.1.0 have been incorporated in this analysis with the following clarifications:

1. The BOC Doppler curve in Figure 15.1.0-4 was assumed.
2. A BOC delayed neutron fraction and neutron lifetime consistent with those defined in Section 15.1.0.3 was assumed.
3. The CEA reactivity insertion curve in Figure 15.1.0-1D was assumed. This curve accounts for a 0.6 second holding coil delay. CEA worth of –5.0 %$\Delta\rho$ was conservatively assumed.
4. A High Pressurizer Pressure Trip setpoint of 2392 psia and a response time of 0.65 seconds were assumed.
5. An MSSV tolerance of +3% was conservatively assumed.
6. An initial core power of 3087 MWt, based on a rated power of 3026 MWt and a 2% uncertainty, was assumed.
7. An MTC of 0.0 x 10^{-4} $\Delta\rho$/°F at HFP was assumed.
8. The minimum HFP core inlet temperature of 540 °F was assumed.
9. A PSV tolerance of 3.2% was conservatively assumed.
10. Parametric analyses were performed on the number of plugged U-tubes per steam generator. It was determined that zero plugged U-tubes per steam generator was limiting.
11. Installation of the RSGs was assumed.
12. A maximum RCS flow of 386,400 gpm was assumed.
13. The PSV flow was adjusted by the Napier correction.

A similar analysis was performed to determine a conservative peak secondary pressure, as the input assumptions described above and denoted in Table 15.1.7-6 are established to ensure a peak primary pressure. This second analysis is effectively the same as the peak primary analysis except the input assumptions delineated above are adjusted to ensure a conservative peak secondary pressure.

The peak RCS and steam generator pressures (2688 psia and 1180 psia, respectively) remained well below the RCS criterion of 2750 psia and the main steam system criterion of 1210 psia. The NSSS and RPS responses for the LOCV event are shown in Table 15.1.7-7 and in Figures 15.1.7-6 through 15.1.7-10. The results of the second analysis to determine peak secondary pressure resulted in a steam generator dome pressure of 1209 psia, which remained below the 1210 psia main steam system criterion.

A subsequent radiological analysis was performed to support steam generator replacement and power uprate. No radiological doses were explicitly calculated for this event due to the bounding nature of the MSLB doses.

15.1.8 LOSS OF NORMAL FEEDWATER FLOW

15.1.8.1 Identification of Cause

The loss of normal feedwater flow is defined as a reduction in feedwater flow to the steam generators when operating at power, without a corresponding reduction in steam flow from the steam generators. The result of this mismatch is a reduction in the water inventory in the steam generators.

The condensate and feedwater system is described in Section 10.4.7 and the emergency feedwater system in Section 10.4.9. The emergency feedwater system is available to automatically provide sufficient feedwater flow to remove residual heat generation from the RCS following RT from rated power. This system consists of one motor-driven and one turbine-driven emergency feedwater pump, and a non-safety Auxiliary Feedwater pump.

A complete loss of both main feedwater pumps or a complete loss of all four condensate pumps results in the loss of all normal feedwater. Closure of the Main Feedwater Block valves or all feedwater regulating or and regulating bypass valves also results in loss of normal feed flow.

The PPS provides protection against loss of the secondary heat sink by the steam generator low water level trip and automatic initiation of the emergency feedwater system. The high pressurizer pressure trip provides protection in the event that the RCS pressure limit is approached.

15.1.8.2 Analysis of Effects and Consequences

15.1.8.2.1 Methods of Analysis

For the loss of feedwater flow analysis, a complete loss of feedwater flow is assumed, since this condition requires the most rapid response from the PPS.

The analysis of a complete loss of feedwater was performed with the CESEC computer program, described in Section 15.1.0.6. Table 15.1.8-1 lists the conservative assumptions made for this analysis.

15.1.8.2.2 Results

The loss of normal feedwater flow is analyzed by assuming an instantaneous complete stoppage of feedwater flow to both steam generators. The emergency feedwater system is automatically actuated following the low steam generator water level trip at 36.4 seconds. To be conservative, it was assumed in the analysis that emergency feedwater would not reach the steam generators for an additional 65 seconds. The principal results for the transients are shown in Table 15.1.8-2. Figures 15.1.8-1 through 15.1.8-4 show the dynamic behavior of the parameters of interest during the transient.

15.1.8.3 Conclusion

For the loss of normal feedwater, the plant protective system assures that the DNB ratio is not less than 1.25 (CE-1 Correlation) or 1.23 (WSSV-T /ABB NV Correlations) and that the steam generator heat removal capability is maintained.

15.1.8.4 Loss of Normal Feedwater Subsequent Analyses

15.1.8.4.1 Cycle 13 Loss of Feedwater Analysis

This subsequent evaluation to the previously described Loss of Feedwater analysis has been performed using essentially the same inputs except those described in this subsection. In addition to the input modifications, the evaluation has utilized the CENTS computer code described in Section 15.1.0.6.10.

This analysis was performed using the inputs from Table 15.1.8-3, Section 15.1.0, and the following assumptions:

A. An EFW response time of 97.4 seconds was assumed. EFW flow was determined based on steam generator pressure. Prior analysis efforts assumed a constant flow rate regardless of steam generator pressure.

B. The EOC Doppler curve in Figure 15.1.0-4 which includes a 1.4 multiplier is conservatively used.

C. The Cycle 13 delayed neutron fraction and neutron lifetime consistent with Section 15.1.0.3 was assumed.

D. The Cycle 13 CEA insertion curve in Figure 15.1.0-1D was utilized. This curve accounts for a 0.6 second holding coil delay.

E. An MSSV tolerance of -3% is conservatively assumed.

A summary of the principal results for the loss of normal feedwater flow is given in Table 15.1.8-4. The conclusions of Section 15.1.8.3, that the steam generator heat removal capability is maintained, is unchanged.

15.1.8.4.2 Cycle 15 at 3026 MWt – Loss of Feedwater Analysis

Subsequent analysis of the previously described Loss of Feedwater analysis has been performed to address the installation of the Replacement Steam Generators and a Power Uprate to 3026 MWt at hot full power. The methodology used in this analysis is the same as that used for the previous analysis. This analysis utilized the CENTS computer code for the transient analysis simulation.

Input parameters from Table 15.1.8-5 and the bounding physics data from Section 15.1.0 have been incorporated in this analysis with the following clarifications:

1. The EOC Doppler curve in Figure 15.1.0-4 was assumed.

2. A BOC delayed neutron fraction and neutron lifetime consistent with those defined in Section 15.1.0.3 were assumed.

3. The CEA reactivity insertion curve in Figure 15.1.0-1D was assumed. This curve accounts for a 0.6 second holding coil delay. CEA worth of -5.0 %$\Delta\rho$ was conservatively assumed.

4. An EFW analytical response time of 97.4 seconds was assumed. EFW flow was determined based on steam generator pressure.

5. An MSSV tolerance of -3.5% was conservatively assumed.

6. An initial core power of 3087 MWt, based on a rated power of 3026 MWt and a 2% uncertainty, was assumed.

7. The most negative MTC of -3.8×10^{-4} $\Delta\rho$/°F was assumed.

8. Low Steam Generator Level Trip and EFAS analytical setpoints of 9% of narrow range indication were assumed.

9. Installation of the RSGs was assumed.

10. An RCS flow of 315,560 gpm was assumed.

11. The PSV flow was adjusted by the Napier correction.

The minimum steam generator inventory occurred at 212 seconds for steam generator A (RCS loop with pressurizer) and 288 seconds for steam generator B.

The NSSS, RPS, and EFW system responses for the LOFW event are shown in Table 15.1.8-6 and in Figures 15.1.8-5 through 15.1.8-9.

The combination of the replacement steam generators, an increase in rated power, and the change in Low Steam Generator Level Trip and EFAS setpoints did not result in steam generator dryout. Since a minimum steam generator liquid inventory was maintained, there was no loss of secondary heat sink.

15.1.9 LOSS OF ALL NORMAL AND PREFERRED AC POWER TO THE STATION AUXILIARIES

15.1.9.1 Identification of Causes

The loss of AC power is defined as a complete loss of preferred (off-site) AC electrical power and a concurrent turbine generator trip. As a result, electrical power would be unavailable for the station auxiliaries such as the reactor coolant pumps, the steam generator main feedwater pumps and the main circulating water pumps. Under such circumstances, the plant would experience a simultaneous loss of load, feedwater flow, and forced reactor coolant flow.

The loss of all station power is followed by automatic startup of the emergency diesel generators, the power output of which is sufficient to supply electrical power to all engineered safety features and to provide the capability of maintaining the plant in a safe shutdown condition.

Subsequent to reactor trip, stored heat and fission product decay heat must be dissipated. In the absence of forced reactor coolant flow, convective heat transfer throughout the core is maintained by natural circulation. Initially, the residual water inventory in the steam generators is used and steam is released to atmosphere via the steam generator safety valves. With the availability of standby power, emergency feedwater is automatically initiated on a low steam generator water level signal. Plant cooldown is controlled via the path provided by the upstream ADVs which fail open on loss of instrument air, and the remotely controlled motor operated isolation valves or the downstream ADVs.

The low DNBR trip will prevent the DNB safety limit from being violated as a result of this transient. In addition, the pressurizer and secondary safety valves, will prevent the RCS pressure and secondary system pressure from exceeding 110 percent of their design values.

15.1.9.2 Analysis of Effects and Consequences

15.1.9.2.1 Method of Analysis

The analysis of the loss of all normal and preferred AC power was performed using the digital computer simulation of the NSSS, CESEC (see Section 15.1.0). The transient heat flux generated by CESEC and average channel mass velocity are used as input to the COSMO computer program, described in Section 4.4.3, which determines the DNBR for the hot channel as a function of time and axial position. The RCS pressure is held constant at 2,250 psia for all the DNBR calculations; this is conservative since pressure will increase. In addition to the parameters described in Section 15.1, the conservative assumptions given in Table 15.1.9-1 are used for the analysis.

During the transient the following actions are assumed.

A. At time zero, when all electrical power is lost to the station auxiliaries, the following assumptions are made:

    1. The turbine stop valves close, and the area of the turbine admission valves is instantaneously reduced to zero;

    2. The steam generator feedwater flow to both steam generators is instantaneously reduced to zero;

3. The reactor coolant pumps begin to coast down. Following coastdown, the coolant flow necessary to remove decay heat is maintained by natural circulation. Reactor coolant pump coastdown and natural circulation flow is calculated by the digital computer code, COAST (Section 15.1.0).

B. Emergency diesel generators start automatically after the loss of AC power. The motor driven emergency feedwater pump and the turbine driven emergency feedwater pump are started automatically on low steam generator water level.

C. Manual action may be taken to:

1. Actuate the steam generator atmospheric dump and isolation valves 15 minutes subsequent to initiation of the incident;

2. Cool the plant by means of the atmospheric dump and isolation valves, to hot standby temperature of 547.6 °F in less than 30 minutes subsequent to initiation of the incident.

15.1.9.2.2 Results

The RPS and the NSSS responses are shown in Table 15.1.9-2 and in Figures 15.1.9-1 through 15.1.9-4.

15.1.9.3 Conclusion

Analysis shows that for the loss of normal and preferred AC power the minimum hot channel DNBR during the transient is not less than 1.3.

15.1.9.4 Subsequent Analysis

15.1.9.4.1 Cycle 15 at 3026 MWt Loss of All Normal and Preferred AC Power to the Station Auxiliaries

The LOAC event was evaluated to determine the impact of the replacement steam generators (RSGs) for Cycle 15 up to 3026 MWt rated power. The method for evaluation was to identify other DBEs that have behavior similar to the LOAC event, with the same acceptance criteria, and result in more adverse consequences.

An evaluation of the LOAC has verified that:

1. The LOAC event's minimum DNB SAFDL is bounded by the Loss of Forced Reactor Coolant Flow event (Section 15.1.5).

2. The LOAC event's peak RCS and steam generator pressures are bounded by the Loss of External Load/Turbine Trip event (Section 15.1.7).

3. The LOAC event's radiological doses for the EAB and LPZ are acceptable due to the bounding nature of the MSLB doses.

Based on this evaluation, no subsequent LOAC analyses have been performed and none need be performed for Cycle 15 and for power uprate as well, since the results of the three bounding events listed meet the acceptance criteria for the respective event.

15.1.10 EXCESS HEAT REMOVAL DUE TO SECONDARY SYSTEM MALFUNCTION

15.1.10.1 Identification of Causes

Excess heat removal due to secondary system malfunction can occur as a result of feedwater system or main steam system valve malfunction.

Excess heat removal causes a decrease in the temperature of the reactor coolant, an increase in reactor power due to the negative moderator temperature coefficient and a decrease in the RCS and steam generator pressures. Detection of these conditions is accomplished by the RCS and steam generator pressure alarms and the high reactor power alarm.

Protection against the violation of specified acceptable fuel design limits as a consequence of an excessive heat removal accident is provided by the low DNBR and high local power density trips.

15.1.10.1.1 Excess Heat Removal Due to Feedwater System Malfunction

Excess heat removal due to feedwater system malfunction may be caused by:

A. Loss of one of several feedwater heaters. The loss could be due to interruption of steam extraction flow. The high pressure heaters are conservatively assumed to increase the feedwater enthalpy by 54 Btu/lb at full load. In order to lose this heating, four valves (one per extraction line) would need to be operated. The loss of any of the low pressure heaters before the feedwater pumps will produce a lesser effect due to the compensating effect of the high pressure heater in that cycle.

B. Startup of emergency feedwater. The emergency feedwater system supplies 950 gpm of relatively cold water from the condensate storage tank to the steam generators; starting of this system would decrease feedwater temperature and increase feedwater flow.

C. An increase in feedwater flow may be caused by further opening of a feedwater control valve or an increase in feedwater pump speed. The maximum flow increase at full power is approximately 60 percent above normal.

15.1.10.1.2 Excess Heat Removal Due to Main Steam System Valve Malfunction

Excess heat removal due to main steam system valve malfunctions may be caused by:

A. Rapid opening of the turbine admission valves. The maximum increase in steam flow due to opening of the turbine admission valves is limited by the turbine load limit control.

B. Opening of one of the steam dump and bypass system valves at power due to a control system failure. One of the valves in the steam dump and bypass system may be opened as a result of a single failure in the steam dump and bypass control system.

C. Opening of one of the steam dump and bypass system valves at hot standby conditions due to a control system failure. One of the secondary valves in the system can be opened as a result of a single failure in the steam dump and bypass control system.

D. Inadvertent opening of an atmospheric dump valve. This valve has a flow capacity of 11.5 percent of full power steam flow rate. The analysis is conservatively based upon the original design capacity of 13 percent.

15.1.10.2 Analysis of Effects and Consequences

15.1.10.2.1 Methods of Analysis

The analysis was performed with the CESEC computer program described in Section 15.1.0.

For the feedwater system malfunction cases, the increase in feedwater flow causes the largest decrease in the feedwater enthalpy and is therefore the most severe incident. The conservative initial conditions, shown in Table 15.1.10-1, are used in addition to the parameters described in Section 15.1.0.

A parametric study was performed to determine the most adverse case considering initial power level and opening of either the turbine admission valves (from their steady state position to full open with no credit taken for the turbine load limit control) or one of the valves in the steam dump and bypass system (total original design capacity 13 percent of full power steam flow at rated conditions).

The excess heat removal incident due to the opening of one of the steam dump and bypass system valves which vent to the atmosphere has been determined to be the most severe incident. The conservative initial conditions, shown in Table 15.1.10-2, are used in addition to the parameters described in Section 15.1.0.

15.1.10.2.2 Results

The NSSS and RPS responses for excess heat removal due to feedwater system malfunction are shown in Tables 15.1.10-3A and B, and in Figures 15.1.10-1A through 15.1.10-4A and Figures 15.1.10-1B through 15.1.10-4B.

The NSSS and RPS responses for steam dump and bypass system malfunction are shown in Table 15.1.10-4 and in Figures 15.1.10-5 through 15.1.10-8.

As stated above, a remotely operated atmospheric steam dump valve is assumed to have the original design flow capacity of 13 percent of the full power steam flow rate. Under full power conditions this valve can release 470 lb/sec of steam. If this steam release were to continue, a low steam generator water level trip would occur. The associated decrease in steam generator pressure would eventually lead to the closure of the main steam isolation valves. For the case presented here, the atmospheric dump valve opened is assumed to be positioned upstream of the main steam isolation valve and therefore steam release through this valve must be terminated by the operator. It is assumed that in 30 minutes the operator will close this valve and assume control of the plant.

The transient results in a total steam discharge to atmosphere of 400,000 lbs of steam. Associated with this steam release is the release of less than 0.0208 dose equivalent curies of I^{131} and 3.03 dose equivalent curies of Xe^{133}. For this situation, the inhalation dose at the site boundary is conservatively evaluated to be 3.34×10^{-3} rem and the whole body dose at the site boundary is conservatively evaluated to be 9.01×10^{-5}rem.

15.1.10.3 Conclusion

As shown by the analysis, a feedwater system malfunction will attain a new steady state with sufficient margin to DNB and maximum local power density below the value that would result in centerline melting.

A steam dump and bypass system malfunction may cause a reactor trip but no core damage results since the minimum DNBR for the most severe case is greater than 1.3 and the maximum local power density remains below a value that would result in centerline melting. The radioactivity release resulting from the opening of one of the steam dump and bypass system valves will be below the limits set forth in 10 CFR 20.

15.1.10.4 Subsequent Analyses

15.1.10.4.1 Cycle 13 Excess Heat Removal Assessment (Excess Heat Removal Due to Secondary System Malfunction)

To assure that the CPCs can accurately sense the cooldown associated with an excess heat removal event, even with the change in transient dynamics due to tube plugging and RCS flow reduction, a CPC transient filters analysis was performed for Cycle 13. The CPC transient filters analysis verifies the CPC adjusted process parameters are conservative with respect to the expected values for a given transient event. The CPC coefficients are adjusted as necessary to assure the CPC action prevents SAFDL violation during the transient. A spectrum of potential turbine admission valve driven increases in steam flow was analyzed to ensure that the filters are conservative in the decreasing temperature direction over the spectrum of possible power to load imbalances.

Cycle 13 physics data consistent with that defined in Section 15.1.0 was assumed for this assessment. A Tcold of 556.7°F, initial RCS pressure of 2000 psia, a low steam generator trip setpoint of 620 psia, Cycle 13 BOC Doppler curve, and an MTC of –1.5E-4 $\Delta\rho$/°F were also assumed for this analysis.

This analysis included parametric studies on RCS flow and tube plugging to determine the limiting values of these inputs. The design minimum RCS flow reduced by 10% and 0% tube plugging were limiting assumptions to a CENTS analysis of an excess heat removal event. The results of the analysis verifies proper detection of significant overcooling transient and conservative CPC actions. Consequently, the effects of tube plugging and reduced flow on the significant excess heat removal events have been evaluated. This evaluation ensures that the CPCs and RPS will provide the necessary trip function to prevent the SAFDLs from being violated.

15.1.10.4.2 Lower Low Steam Generator Pressure Setpoint Assessment

The inadvertent opening of an ADV has been determined to be the most severe excess heat removal incident due to a main steam valve malfunction. Lowering the MSIS low steam generator pressure setpoint from 678 psia to 620 psia will not affect this event with respect to the time of plant trip. Plant trip is initiated in this event based on a low steam generator level condition. Lowering the low steam generator pressure trip setpoint will delay the time at which an MSIS signal is generated. An MSIS signal is credited as isolating the unaffected steam generator. For this event it was assumed that one of the ADVs upstream of the MSIVs inadvertently opened and operator action was required to isolate the affected steam generator. A longer delay in isolating the unaffected steam generator will result in a slightly larger steam generator mass release than that presented above. Less than a 10% increase in the amount of mass release indicated above for this event is conservatively estimated. As a result, the total mass released under these conditions are well within those considered for the MSLB (Section 15.1.14.1.4.4). Based on the bounding nature of the MSLB release, the results of the MSLB event can be used to bound this event.

A lower low steam generator pressure setpoint does not affect the results of this event with respect to the timing of reactor trip and thereby does not affect the conclusion with respect to the minimum DNBR, maximum local power density, and peak primary and secondary system pressures. A steam dump and bypass system malfunction may cause a reactor trip but no core damage results since the minimum DNBR and maximum local power density remain within acceptance criteria. The radioactivity release for this event is bounded by the results of the MSLB event.

15.1.10.4.3 Cycle 15 at 3026 MWt Excess Heat Removal Due to Feedwater System Malfunction

The Excess Heat Removal due to Feedwater System Malfunction event analysis was performed to assess the impact of the replacement steam generators at a rated power of 3026 MWt. The methodology used in this analysis is similar to the methodology used in the previous analysis, except that the CENTS code is used instead of the CESEC code. The minimum DNBR evaluation was determined using the CETOP code.

Two different types of feedwater malfunction events were reviewed:

1. An instantaneous increase in main feedwater to 160% of initial flow to both steam generators with a decrease in feedwater enthalpy of 152 Btu/lbm.

2. A loss of two feedwater heaters in both main feedwater trains that resulted in a decrease in feedwater enthalpy of 86 Btu/lbm.

Of the two feedwater malfunction events, the instantaneous increase in main feedwater to 160% of initial main feedwater flow with a decrease in feedwater enthalpy of 152 Btu/lbm was determined to be the more adverse event of the two.

Input parameters from Table 15.1.10-5 and the bounding physics data from Section 15.1.0 have been incorporated in this analysis with the following clarifications:

1. The BOC Doppler curve in Figure 15.1.0-4 was assumed.

2. A delayed neutron fraction and neutron lifetime consistent with those defined in Section 15.1.0.3 were assumed.

3. The CEA reactivity insertion curve in Figure 15.1.0-1D was assumed. This curve accounts for a 0.6 second holding coil delay. A CEA worth of -5.0 %$\Delta\rho$ was assumed.

4. The CPC VOPT was employed in the analysis. A cold leg RTD response time of 8 seconds was accounted for along with a CPC trip delay time of 0.60 seconds.

5. An initial core power of 3087 MWT, based on a rated power of 3026 MWt and a 2% uncertainty, was assumed.

6. The most negative MTC of -3.8×10^{-4} $\Delta\rho$/°F was assumed.

7. Initial RCS pressure was assumed to be 2300 psia.

8. Initial RCS flow was assumed at the minimum value of 315,560 gpm.

9. It was assumed that the main feedwater flow to both steam generators increased from 102% to 160% of the flow at 3026 MWt instantaneously (0.5 seconds) with a decrease in feedwater enthalpy of 152 Btu/lbm.

10. Installation of the RSGs was assumed.

11. An initial steam generator pressure of 1003 psia was assumed.

An increase in main feedwater can cause an overcooling of the RCS as a result of the decreasing cold leg inlet temperature. Core power also increases due to the reactivity feedback interaction caused by the lower cold let inlet temperature. The CPC VOPT terminates the transient.

The NSSS and RPS responses for excess heat removal due to feedwater system malfunction are shown in Table 15.1.10-6 and in Figures 15.1.10-9 through 15.1.10-13.

For the limiting feedwater malfunction event, the increase in feedwater flow to 160% with a 152 Btu/lbm decrease in feedwater enthalpy, the minimum DNBR is greater than 1.25 and the peak linear heat rate is less than 21 KW/ft. Thus, the SAFDLs are protected.

15.1.10.4.4 Cycle 15 at 3026 MWt Excess Heat Removal Due to Main Steam System Valve Malfunction

The Excess Heat Removal due to Main Steam System Valve Malfunction event analysis was performed to assess the impact of replacement steam generators (RSGs) at a rated power of 3026 MWt. The methodology used in this analysis was similar to the methodology used in the previous analysis, except that the CENTS code was used instead of the CESEC code. The minimum DNBR evaluation was determined using the CETOP code.

The CPCs will terminate this transient on either a VOPT or low DNBR trip to protect the SAFDLs.

Of the main steam system valve malfunctions listed above that can initiate excess steam flow, inadvertent opening of an ADV is the most adverse. The increase in steam flow caused by rapid opening of the turbine admission valves from their steady state 100% power position to full open position is typically less than the design flow capacity of a fully open atmospheric dump valve. The high pressure turbine was modified for Cycle 15 to accommodate the RSG pressures and anticipated power uprate efforts. The excess capacity of the turbine admission valves will be less than that of the ADV event analyzed below, assuming the plant is operating at normal 100% power conditions with a steam generator pressure of approximately 940 psia. The turbine admission valve capacity under high steam generator pressure conditions (1000 psia) will slightly exceed the ADV capacity by approximately 2%. This excess capacity is only available in an off normal operating regime (plant operation at the high end of the TS Tcold operating range). This analysis assumes the inadvertent opening of one ADV upstream of the MSIV associated with steam generator A. At the full open position, this analysis conservatively assumed 13% flow capacity for the dump valve at power uprate conditions.

Input parameters from Table 15.1.10-7 and the bounding physics data from Section 15.1.0 have been incorporated in the excess heat removal analysis with the following clarifications:

1. The BOC Doppler curve in Figure 15.1.0-4 was assumed.

2 A delayed neutron fraction and neutron lifetime consistent with those defined in Section 15.1.0.3 were assumed.

3. The CEA reactivity insertion curve in Figure 15.1.0-1D was assumed. This curve accounts for a 0.6 second holding coil delay. A CEA worth of -5.0 %$\Delta\rho$ was assumed.

4. The analysis was conservatively based on an inadvertent opening of an ADV with a flow capacity of approximately 13% full power flow. By maintaining this conservative assumption, the impact of increasing the rated power was very small.

5. The CPC VOPT was employed in the analysis. A cold leg RTD response time of 8 seconds was included along with a CPC trip delay time of 0.60 seconds.

6. An initial core power of 3087 MWt, based on a rated power of 3026 MWt and a 2% uncertainty, was assumed.

7. The most negative MTC of -3.8 x 10^{-4} $\Delta\rho$/°F was assumed. This results in the largest radial power distortion in the core due to the core temperature asymmetry.

8. The analytical MSIS setpoint was 693 psia. The MSIVs, MFIVs, and Back-up MFIVs all receive an MSIS signal to close. An analytical response time of 4.9 seconds (which includes a 1.4 second MSIS response time) was assumed for the MSIVs. The MFIVs were assumed to close in 26.4 seconds (including the 1.4 second MSIS response time) which is longer than the time to close the Back-up MFIVs.

9. Installation of the RSGs was assumed.

10. An initial RCS pressure of 2300 psia was assumed.

11. An initial RCS flow of 315,560 gpm was assumed.

12. An initial steam generator pressure of 1003 psia was assumed.

13. An analytical SIAS setpoint of 1400 psia was assumed. A response time of 40 seconds for the HPSI pumps to reach full speed was also assumed.

14. The MSSVs are assumed to lift early at -3.5%.

The impact of the ADV malfunction is an overcooling of the RCS. Core power also increases due to the reactivity feedback interaction caused by the lower cold leg inlet temperature. The CPC VOPT terminates the transient. The NSSS and RPS responses for excess heat removal due to opening of an ADV are shown in Table 15.1.10-8 and in Figures 15.1.10-14 through 15.1.10-18.

For the opening of an atmospheric dump valve event, the minimum DNBR is greater than 1.25 and the peak LHR is less than 21 KW/ft. Thus, the SAFDLs are protected.

Additionally, the excess load event is analyzed from different initial power levels, MTC values, and load demands as part of the CPC filter verification analysis. The object of this is to verify that the CPC Tcmax and Tcmin algorithms provide conservative input into the CPC VOPT and CPC Low DNBR calculations. If the CPC filter coefficients/algorithms are non-conservative, then a penalty factor is provided for inclusion in the CPC constants calculation. The fastest events present the most challenge to the CPCs, since input is changing rapidly. If the CPC provides adequate protection for the faster events, then the slower events are also protected.

The initial conditions assumed in the CPC transient filter analysis are different than those assumed in the excess load transient discussed above. The initial conditions are selected to provide the greatest challenge to the CPCs (temperature decreasing filters).

The CPC transient filter analysis verifies that the CPC adjusted process parameters are conservative with respect to the expected values for the excess heat removal event. The CPC coefficients are adjusted as necessary to assure the CPCs action prevents SAFDL violation during the transient.

No dose calculation was performed for this excess heat removal event because doses for this and other AOOs are deemed to be acceptable due to the bounding nature of the MSLB doses.

15.1.10.4.5 Cycle 18 Excess Heat Removal Due to Feedwater System Malfunction

The Excess Heat Removal Due to Feedwater System Malfunction event was evaluated at a higher LOCA Limit of 14.4 KW/ft. Only the peak LHR margin was affected. There was no impact on DNB margin.

The methodology was the same as that used in the current analysis in Section 15.1.10.4.3. The LOCA Limit value of 14.4 KW/ft was used in place of the previous value of 13.7 KW/ft. No new computer cases were required.

The combination of the radial power distortion and core power results from the current analysis were combined with the higher LOCA Limit value of 14.4 KW/ft to determine the new peak LHR value. The calculated value remained less than the 21 KW/ft SAFDL value.

15.1.10.4.6 Cycle 18 Excess Heat Removal Due to Main Steam System Valve Malfunction

The excess heat removal due to main steam system valve malfunction event was evaluated at a higher LOCA Limit of 14.4 KWIft.

The methodology was the same as that used in the current analysis in Section 15.1.10.4.4. The LOCA Limit value of 14.4 KW/ft was used in place of the previous value of 13.7 KW/ft. No new computer cases were required.

The CPCS transient filters analysis verified that the CPCS adjusted process parameters were conservative with respect to the expected values for a given transient event. The CPCS coefficients were adjusted as necessary to assure the CPCS action prevents SAFDL violation during the transient. The results of the analysis verified proper detection of significant overcooling transients and conservative CPCS actions. Consequently, the effects of the increase in the LOCA Limit to 14.4 KW/ft had been evaluated for the excess load events. The current CPCS coefficients ensured that the CPCS DNBR / LPD calculations are sufficiently conservative to generate a reactor trip in sufficient time to prevent violation of the SAFDLs. This change in LOCA Limit does not impact the radiological dose results.

15.1.10.4.7 Cycle 21 Excess Heat Removal Due to Feedwater System Malfunction

The Excess Heat Removal Due to Feedwater System Malfunction event was evaluated for Cycle 21 for Next Generation Fuel (NGF). Only the DNB margin was affected. There was no impact on the LHR margin.

The methodology was the same as that used in the current analysis presented in Section 15.1.10.4.3. The Excess Heat Removal Due to Feedwater System Malfunction event was evaluated for Cycle 21 using the WSSV-T and ABB-NV critical heat flux correlations and the lower DNB SAFDL of 1.23 for the minimum DNBR evaluation. No CENTS cases were repeated as all other current input parameters in Table 15.1.10-5 remained unchanged.

The Excess Heat Removal Due to Feedwater System Malfunction event is less adverse than the Excess Heat Removal Due to Main Steam System Valve Malfunction event and is protected by the Core Protection Calculator System (CPCS). The current CPCS coefficients and setpoints ensure that the calculations are sufficiently conservative to generate a reactor trip in sufficient time to prevent violation of the SAFDLs.

Table 15.1.10-6 provides the revised Sequence of Events for the full core implementation of NGF. The minimum DNBR value remains above the DNB SAFDL value of 1.23. Consequently, the conclusions in SAR Sections 15.1.1.10.4.3 (mDNBR remains above the DNB SAFDL) and 15.1.10.4.5 (peak LHR remains below the LHR SAFDL) remain the same.

15.1.10.4.8 Cycle 21 Excess Heat Removal Due to Main Steam System Valve Malfunction

The Excess Heat Removal Due to Main Steam System Valve Malfunction event was evaluated for Cycle 21 for Next Generation Fuel (NGF). Only the DNB margin was affected. There was no impact on the LHR margin.

The methodology was the same as that used in the current analysis presented in Section 15.1.10.4.4. The Excess Heat Removal Due to Main Steam System Valve Malfunction event was evaluated for Cycle 21 using the WSSV-T and ABB-NV critical heat flux correlations and the lower DNB SAFDL of 1.23 for the minimum DNBR evaluation. No CENTS cases were repeated, as all other current input parameters in Table 15.1.10-7 remained unchanged.

The CPCS transient filters analysis verified that the CPCS adjusted process parameters were conservative with respect to the expected values for a given transient event. The CPCS coefficients were adjusted as necessary, to assure the CPCS action prevents SAFDL violation during the transient. The results of the analysis verified proper detection of significant overcooling transients and conservative CPCS actions. The current CPCS coefficients ensure that the CPCS DNBR / LPD calculations are sufficiently conservative to generate a reactor trip in sufficient time to prevent violation of the SAFDLs.

Table 15.1.10-8 provides the revised Sequence of Events for the full core implementation of NGF. Consequently, the conclusions in SAR Sections 15.1.1.10.4.4 (mDNBR remains above the DNB SAFDL) and 15.1.10.4.6 (peak LHR remains below the LHR SAFDL) remain the same.

15.1.11 FAILURE OF THE REGULATING INSTRUMENTATION

15.1.11.1 Identification of Causes

A reactor coolant flow controlled malfunction is not possible. Unit 2 does not include coolant flow controllers.

Malfunction of failure of other regulating systems (control systems described in Section 7.7) could result in deviation of plant process parameters from prescribed values. Such deviations would initiate a reactor trip in the event a core safety limit were approached.

15.1.12 INTERNAL AND EXTERNAL EVENTS INCLUDING MAJOR AND MINOR FIRES, FLOODS, STORMS, AND EARTHQUAKES

Improbable naturally occurring events and events caused by mechanical or electrical failure of plant components are discussed in this section. Internal events include major and minor fires. External events include storms, flooding, and earthquakes, caused by atmospheric or geological disturbances.

15.1.12.1 Fires

15.1.12.1.1 Identification of Causes

Sources of both major and minor fires are assumed to be equipment malfunctions, personnel negligence, or natural phenomena.

15.1.12.1.2 Analysis of Effects and Consequences

Fire prevention methods, operational procedures of the Fire Protection System (FPS) and incident fire analyses are presented and discussed in Section 9.5.1. Physical separation of redundant safety-related equipment precludes the possibility that one fire could damage more than one train or channel.

15.1.12.2 Floods

Unit 2 has been designed to withstand the probable maximum flood. Under these conditions, the plant will be able to attain and sustain a safe shutdown condition with no loss of integrity to safety-related systems or Seismic Category 1 structures, systems and components.

15.1.12.2.1 Identification of Causes

The origins of a possible flood are assumed to be excessive precipitation, spring snow runoff and/or the failure of an upstream dam. The Arkansas river navigation project provides 17 locks and dams and is expected to eliminate flood hazards based on maximum probable flood flows computed by the Corps of Engineers as described in Section 2.4.

15.1.12.2.2 Analysis of Effects and Consequences

Flood design criteria are presented in Section 3.4, Flood Protection Methods. Operational procedures and analyses are given in Section 2.4.

15.1.12.3 Storms

15.1.12.3.1 Identification of Causes

Considering its inland location, a tornado was analyzed to be the most destructive type of storm that could possibly affect the plant. Unit 2 has been designed to withstand wind loadings, pressure differentials and missiles generated by tornadoes. The Probable Maximum Precipitation (PMP) has been determined according to methods presented in Section 2.4.

15.1.12.3.2 Analysis of Effects and Consequences

Tornado loadings and missile analyses are presented and discussed in Sections 3.3.2 and 3.5, respectively. The effects of the PMP are discussed in Section 2.4. Neither of these natural phenomena will prevent the safe shutdown of the plant.

15.1.12.4 Earthquakes

15.1.12.4.1 Identification of Causes

Unit 2 is located in an area of relative geologic stability. However, safety-related structures, systems, and components have been designed to withstand a Design Basis Earthquake (DBE). Unit 2 seismology is discussed in Section 2.5.

15.1.12.4.2 Analysis of Effects and Consequences

Sections 3.7, 3.8, 3.9 and 3.10 describe the seismic design methods and results. Vibratory ground motion up to and including the DBE will not prevent the safe shutdown of the plant.

15.1.13 MAJOR RUPTURE OF PIPES CONTAINING REACTOR COOLANT UP TO AND INCLUDING DOUBLE-ENDED RUPTURE OF LARGEST PIPE IN THE REACTOR COOLANT SYSTEM (LOSS OF COOLANT ACCIDENT)

15.1.13.1 Identification of Causes

Regulatory Guide 1.4 describes a design basis LOCA as one of the hypothetical accidents used to evaluate the adequacy of various plant structures, systems, and components used to protect the public health and safety. Such an evaluation is required in Section 50.34 of 10 CFR 50 and is the subject of this analysis. LOCA analyses for the purpose of demonstrating the satisfactory performance of the safety injection system are given in Section 6.3.3 for a full spectrum of pipe break sizes.

The design basis LOCA is postulated as a break in the RCPB piping. A release of the core's radioactive inventory to the containment in two phases over 1.8 hours is assumed. The fractions of the core's radioactive inventory assumed to be airborne within the containment and available for release by leakage to the environment is shown in Table 15.1.13-3.

For halogens, of the 40 percent which becomes available, it is assumed that 4.85 percent is elemental iodine, 95 percent is particulate iodine and 0.15 percent are organic iodides.

Because of the extreme care taken in design and construction of the plant, and because of the periodic testing and inspection required, the probability of a LOCA is considered to be extremely low. Nevertheless, because of the potential consequences, several important systems, identified as engineered safety feature systems have been provided to prevent clad and fuel melting, to limit chemical reactions, and to protect the health and safety of the public.

These systems, described in Chapter 6, are the Safety Injection System (SIS) (Emergency Core Cooling System (ECCS)); the containment heat removal systems (Containment Spray System (CSS) and Containment Cooling System (CCS)); the Containment Isolation System (CIS); the Penetration Rooms Ventilation System (PRVS); and the combustible gas control system (hydrogen recombiners). Containment air purification (iodine removal) is accomplished by the CSS as described in Section 6.2.3.

The radioactive source terms for this analysis are based on ORIGEN-S (Reference 52) and exceed that which would result from Section 6.3.3. Section 6.3.3 effects can be summarized as follows:

A. A small amount of zirconium clad oxidation (Zr - steam reaction; < 1.0 percent);

B. No significant fuel or clad melting; and,

C. Some clad perforation.

Damage to the reactor core would be limited to clad swelling and perforation, and to a negligible amount by clad oxidation. Thus, the activity released to the containment by a LOCA would be limited to the gases and volatile fission products present in the gas gap (plenum) of those fuel rods which perforate.

15.1.13.2 Analysis of Events and Consequences

For a conservative analysis of the accident, the containment is assumed to reach and remain at its design pressure for the first 24 hours, yielding a maximum containment leak rate during this period.

TEDE doses which result from the design basis LOCA have been calculated.

The RADTRAD code was used to calculate off site and control room doses using dose conversion factors from FGR-11 and FGR-12. Table 15.1.13-1 indicates the basic assumptions used in the analysis. The dose models used are described in Section 15.1.0.5.

15.1.13.3 Results

Table 15.1.13-2 summarizes the calculated doses at the exclusion area boundary (1,046 meters), at the low population zone boundary (4,184 meters), and for the control room operator resulting from the design basis LOCA, including doses due to the containment release and due to post accident leakage.

15.1.13.4 Post-Accident Leakage

15.1.13.4.1 Recirculation Leakage

Subsequent to the injection phase of Engineered Safety Features (ESF) system operation during which the ESF pumps discharge the contents of the RWT to the containment spray header and the RCS, the water in the containment sump is recirculated by the High Pressure Safety Injection (HPSI) and containment spray pumps. The transfer of the pump suctions from the RWT to the containment sump is accomplished automatically by the Recirculation Actuation Signal (RAS) (see Section 7.3.1.1.11.6). The Low Pressure Safety Injection (LPSI) pumps are also secured by the RAS. Because the LOCA will cause the sump water to contain much of the radioiodine, the potential off-site dose due to operation of this external recirculation path with leakage has been evaluated.

The dose calculations of ESF leakage are conservatively based on 100 percent of the released core iodine being homogeneously mixed in the sump at the beginning of recirculation.

The total assumed leakage from the ECCS is 4120 cc/hr, i.e. double the total allowed leakage during normal plant operation. This leakage rate assumes two containment spray and three HPSI pumps are in operation. Both ESF trains were assumed to operate at 100 percent capacity for the 30 days following the accident.

The off-site and control room doses resulting from this leakage were obtained using the dilution factors of Table 15.1.0-5 and Table 15.1.13-1 respectively. The control room dilution factors were recalculated using ARCON96 (see Section 15.1.0.6.11) and meteorological data from 1995 through 1999. An iodine-water partition factor of 0.1 was used to calculate the amount of iodine which is available for release from the pump rooms (Reference 39). Activity was assumed to be dispersed instantaneously from the pump rooms to the atmosphere with no further nuclide holdup or decay. No credit was taken from adsorption and filtration of exhaust air from the auxiliary building.

The total doses due to ESF leakage are included in Table 15.1.13-2.

The doses resulting from this source are small compared to those resulting from the activity released due to containment leakage.

The results of this analysis are believed to be extremely conservative for the following reasons:

A. It is expected that only the gap radioiodine activity would be present in the sump water and this would be only about one percent of the radioiodine activity assumed in the analysis.

B. Release of radioiodine to the atmosphere is not instantaneous as assumed, since the majority of the components within the ESF pump rooms are isolated from the remainder of the auxiliary building atmosphere.

C. No consideration or credit was included in the analysis for any plate out of iodine on metal surfaces.

15.1.13.4.2 Other Leakage

Gross leakage from any piping system in an ESF pump room would be detected by a level detector located in each room. Each level switch actuates an alarm in the control room.

Operator action is initiated when the liquid level in the floor drain piping or room has reached the high level alarm point. Equipment and floor drainage systems for the auxiliary building are discussed in Section 9.3.3. This action would consist of determining the source of leakage, manually draining the room floor drain piping or in the case of gross leakage, isolation of all piping systems that could conceivably drain to the room that has alarmed high level. For the limiting configuration, the quantity of leakage prior to an alarm that would initate operator action is approximately 35 gallons based upon the volume of pipe or floor area below the lowest alarm level switch.

Operator action for isolation of piping systems is to close the isolation valves and secure the pumps for the piping systems involved. The time required for operator action and valve closure is estimated to be five minutes.

ESF pump rooms in the auxiliary building are equipped with watertight doors. Separation is maintained between redundant trains of ESF equipment by isolating separate trains in separate rooms. Independent drainage systems are provided for each train to preclude flooding via a drainage system.

15.1.14 MAJOR SECONDARY SYSTEM PIPE BREAKS WITH OR WITHOUT A CONCURRENT LOSS OF AC POWER

15.1.14.1 Steam Line Break Accident

15.1.14.1.1 Identification of Causes

Major secondary system pipe breaks are those ruptures in the main steam system which result in action of the plant protection system. Inadvertent opening of valves in the main steam system is discussed in Section 15.1.10. A rupture in the main steam system reduces the steam generator pressure, increases steam flow rate, and causes cooldown of the RCS. Depending

on initial conditions, break size, and break location, any of several plant protection system actions may occur. A severe decrease in main steam pressure will initiate a reactor trip signal on low steam generator pressure and a Main Steam Isolation Signal (MSIS) and will cause the main steam isolation valves to trip closed. Increased flow rate from the steam generator reduces the steam generator inventory and may result in a low steam generator water level trip. Additional protection against loss of the secondary heat sink is provided by automatic initiation of emergency feedwater to the intact steam generator. Emergency Feedwater Actuation Signal logic prevents EFW flow to the faulted steam generator. Cooldown of the RCS coupled with a negative moderator coefficient of reactivity, results in a positive reactivity addition and causes reactor power to increase. This increase in reactor power can result in the following:

A. High linear power level trip signal;

B. Low DNBR trip signal;

C. High local power density trip signal.

In addition, cooldown of the RCS reduces the reactor coolant volume and pressurizer pressure. These reductions may result in:

A. Emptying of the pressurizer;

B. A low pressurizer pressure trip signal;

C. A Safety Injection Actuation Signal (SIAS).

A major secondary system pipe break with a concurrent loss of AC power is defined as a rupture in the main steam system with a simultaneous complete loss of AC electrical power and a concurrent turbine-generator trip. As a result, electrical power would be unavailable for the station auxiliaries such as the reactor coolant pumps, the steam generator feedwater pumps and the main circulating water pumps. Under such circumstances, the plant would experience a simultaneous loss of load, feedwater flow, forced reactor coolant flow, cooldown of the RCS and depressurization of the main steam system which in turn may result in:

A. High linear power level trip signal;

B. DNBR trip (based on low RCP speed) signal;

C. Low steam generator pressure trip signal;

D. Low pressurizer pressure trip signal;

E. SIAS; and,

F. Emptying pressurizer or steam generator depending on the initial condition and break size.

The loss of all station power is followed by automatic startup of the standby diesel generators, the power output of which is sufficient to supply electrical power to all necessary ESF systems and to provide the capability of maintaining the plant in a safe shutdown condition.

Subsequent to reactor trip, stored and fission product decay energy must be dissipated by the RCS and main steam system. In the absence of forced reactor coolant flow, convective heat transfer into and out of the reactor core is supported by natural circulation reactor coolant flow. Initially, the residual water inventory in the steam generators is used and the resultant steam is released to atmosphere by the spring-loaded secondary safety valves. With the availability of

standby power, emergency feedwater is assumed to be automatically initiated on a low steam generator water level signal. Plant cooldown may be operator controlled via the remotely operated atmospheric steam dump valves.

Each steam generator has one 34-inch ID main steam nozzle (6.3 ft^2). A flow measuring venturi with an area of 2.49 ft^2 is located in each steam line.

In the case of ruptures inside containment, the maximum effective break area assumed is 6.3 ft^2. For ruptures outside containment maximum effective break area assumed is 2.49 ft^2. If the steam line rupture occurs between the steam generator and isolation valve, blowdown of the affected steam generator continues. However, flow from the intact steam generator terminates with closure of the main steam block valve.

15.1.14.1.2 Analysis of Effects and Consequences

15.1.14.1.2.1 Discussion of Cases and Parameters

The analysis of the steam line rupture is performed using CESEC, a digital simulation of the NSSS described in Section 15.1.0.

The major factor affecting the results of the steam line break analysis relates to the moisture carryover which occurs during the blowdown of the steam generator. An analysis similar to the one presented in Reference 26 was performed for this steam generator. The results of this analysis give conservatively low estimates of the average moisture carryover versus break size for both full load and no load initial conditions. Table 15.1.14-1 gives the conservative average moisture carryover fraction used for this analysis for both the complete blowdown of the steam generator connected to the ruptured steam line and for the intact steam generator blowdown which occurs through 560 feet of main steam piping and is terminated by the closure of the main steam block valves.

An extensive parametric analysis of the transients associated with the various combinations of steam line break size and average moisture carryover fraction indicates that the most severe pressure transients occur for full nozzle and/or pipe breaks. The most severe NSSS power transients occur for the largest of the steam line break sizes which do not result in moisture carryover, conservatively assumed to be one-half of the total effective turbine admission valve area (1.0 square foot) for no load initial conditions, and the total effective turbine admission valve area (2.0 square feet) for full load initial conditions.

Therefore, a total of 11 cases including the two most severe steam line break cases with a concurrent loss of AC power, i.e., no load, 1-loop and full load, 2-loop case both with outside small breaks, were originally presented covering the most severe pressure and power transients for the following initial conditions:

A. Full load and no load initial conditions;

B. Two-loop and 1-loop operation; and,

C. Inside and outside containment breaks.

D. With or without AC power.

At the time the original 11 cases were performed the moisture carryover methods had not been approved; hence, the NRC requested that additional analyses be performed assuming no moisture carryover. Four no moisture carryover analyses are presented in Section 15.1.14.1.4.1. The results from the no moisture carryover analyses were determined to be limiting with respect to the shutdown margin required to assure conditions no worse than those presented in the original 11 cases were bounding. As a result of the more limiting nature of these events and the moisture carryover methods not being approved, the original shutdown margin cases have been removed and can be found in the FSAR. Of the original 11 cases, 3 cases were used for radioactivity release purposes. These 3 cases are presented in this section.

Table 15.1.14-2 lists some of the conservative assumptions used in each analysis with the following explanation:

A. The variation of reactivity with fuel temperature is included. For conservatism, the slope of the reactivity versus fuel temperature function is decreased 15 percent for the no load case to account for calculational uncertainty. For full load initial conditions, the slope of the reactivity versus fuel temperature function has been increased by 15 percent; this assures that the calculation of the reactivity increase due to the cooldown of the fuel from its nominal temperature is conservative.

B. For the cases analyzed, the most reactive CEA is stuck in the fully withdrawn position. The minimum CEA worth available for shutdown when the reactor is tripped is -5.8 percent $\Delta\rho$ for the full load conditions, and -2.4 percent $\Delta\rho$ for the no load conditions. If all CEAs insert, there is no return to criticality and no power transient following trip. Analyses are performed, however, including the effects of the most reactive CEA being stuck in the out position.

   The -5.8 percent $\Delta\rho$ full power CEA worth is 0.4 percent $\Delta\rho$ higher than the worth assumed for other Cycle 1 accidents starting from full power. This 0.4 percent $\Delta\rho$ is due to the effect of changing the core power distribution during the cooldown from full power to zero power temperature with CEAs in the core. This effect is accounted for in the moderator reactivity density function described below and, therefore, credit is taken for this effect in the reactivity insertion on trip. The effect is not directly accounted for in the moderator coefficients assumed for the other accidents, i.e., the +0.5 to -3.5 x $10^{-4}\Delta\rho$/°F range of moderator coefficients are for cases without insertion of the shutdown CEAs, therefore, credit is not taken for this effect in other analyses in Chapter 15.

C. For the steam line break cases analyzed without a concurrent loss of AC power, the total reactor coolant volumetric flow rate is assumed constant during the transient. The design values, 322,000 gpm for 2-loop operation and 153,915 gpm for 1-loop operation, are used. The total steam generator heat transfer area is assumed to be active during the transient. The overall steam generator heat transfer coefficient used in the analysis is a dynamic function of reactor coolant flow rate and steam generator heat flux.

D. Feedwater flow at the start of the transient corresponds to initial steady state operation. For the full load initial condition without loss of AC power, it is automatically reduced from 100 percent to zero percent in 20 seconds following reactor trip. For the no load initial condition without loss of AC power, feedwater flow is assumed to match energy input by the reactor coolant pumps and the 1 MWt core power.

E. For the analysis at time zero, when all electrical power is lost to the station auxiliaries, the following events are assumed to occur:

   1. The turbine stop valves close and it is assumed that the area of the turbine admission is instantaneously reduced to zero;

   2. The feedwater flow to both steam generators is instantaneously assumed to go to zero; and,

   3. The reactor coolant pumps begin to coastdown.

Following coastdown, the coolant flow necessary to remove residual heat and to cool the reactor core is maintained by natural circulation. Reactor coolant pump coastdown and natural circulation flow is calculated by the digital computer code, COAST (See Section 15.1.0).

As the transient progressed, the emergency diesel generators, which start automatically after the loss of AC power, provide power to the emergency feedwater pumps which start automatically on low steam generator water level.

Manual action may be taken to actuate the atmospheric steam dump and isolation valves 30 minutes subsequent to initiation of the accident.

The following three steam generator levels may be important:

A. Downcomer liquid level;

B. Tube bundle 2-phase level; and,

C. Steam dome 2-phase level.

The downcomer liquid level is important for those transients which require a steam generator low water level trip to terminate the transients. This downcomer level and associated steam generator inventory are established by steady state design codes and then input into the transients analysis code.

The tube bundle 2-phase level is important in determining the heat transfer between the RCS and the Main Steam System (MSS). For conservatism, the full heat transfer surface area is assumed to be available, i.e., the tubes are assumed to always be covered by the 2-phase level, until a steam generator becomes empty.

The steam dome 2-phase level is important in determining the moisture carryover which occurs during the steam line break transient. This level is conservatively determined using the methodology presented in Reference 26.

The following assumptions are made for the steam line break analyses:

A. The cooldown due to a steam line rupture results in the greatest reactivity increase when the moderator temperature coefficient is most negative. The conditions selected for the analyses, i.e., materials inventories in the core and the power distributions, are those expected for later fuel cycles.

The moderator temperature coefficient of reactivity varies significantly over the range of moderator temperatures covered in the analysis; therefore, a reactivity versus moderator density function is employed rather than a single value coefficient. The most adverse moderator function is calculated assuming all CEAs except the most reactive are inserted. This function (shown in Figure 15.1.14-30) is increased by 10 percent to account for calculational uncertainties.

In addition, the effect of uneven temperature distribution on the moderator reactivity is accounted for conservatively, by assuming that the moderator reactivity is a function of the lowest cold leg temperature.

B. Following CEA insertion, the power distribution is distorted by the stuck CEA; however, the power produced by the decay of the initial condition delayed neutron precursors and by nominal decay power is distributed according to the nominal power distribution. The coincident high radial peaking and low reactor coolant pressure can lead to local boiling at moderate power levels. The power flattening effect of the voids and of the locally high fuel temperature is included in the analysis, but no credit is taken for the corresponding reactivity feedback. The computed maximum average core power after trip is thus conservative.

   The power flattening effect during a Steam Line Break (SLB) transient has been verified as conservative by a series of two-dimensional PDQ analyses which assume one stuck CEA. An input function of moderator density versus radial peak was determined from a separate analysis using a 2-channel version of the STRIKIN thermohydraulic code which models the core average channel and a hot channel as two parallel closed channels. For this STRIKIN analysis average core conditions (inlet flow, inlet temperature, core power, RCS pressure, etc.) were taken from a typical SLB transient to determine the average core pressure drop. This pressure drop, along with a variable radial peak and other parameters, i.e., geometry, inlet temperature, etc, are used as input for the hot channel to obtain functions of the hot channel flow rate, moderator density at the core midplane and minimum hot channel DNBR versus radial peak. The moderator density versus radial peak functions are used in the 2-D PDQ calculations to determine the maximum expected peak for the chosen SLB conditions. The STRIKIN analysis then gives the DNBR for this radial peak. Parametric analyses show that as average core power increases the maximum expected radial peak decreases from values as high as 30 (for zero power) to values less than 2.0 while DNBR associated with the expected peak decreases from a value near infinity (for zero power) to a value near 1.0 as the expected peak drops below 2.0. For conservatism, it is assumed that the expected radial peak does not decrease below a value of 3.0, thus, DNBR values are conservatively predicted for SLB power transients.

C. The fast cooldown following a steam line rupture results in rapid contraction of the reactor coolant. After the pressurizer is emptied, the reactor coolant pressure is assumed to be equal to the saturation pressure corresponding to the highest temperature in the RCS.

D. Determination of the critical heat flux for the fuel elements is based on a method utilizing a correlation developed by R. V. MacBeth (Reference 19).

E. The SIAS is generated when the pressurizer pressure falls below 1,600 psia.

F. Critical flow is assumed through the steam line break for the moisture carryover fractions given by Table 15.1.14-1. The flow rate is determined from the same functional relationship used in the moisture carryover study (Reference 26).

15.1.14.1.2.2 Results

15.1.14.1.2.2.1 No Load, One-Loop Initial Condition Nozzle Break Outside Containment Without Loss of AC Power

The RPS and NSSS responses are summarized in Table 15.1.14-11, while the reactivity transient is shown in Figure 15.1.14-29.

15.1.14.1.2.2.2 Full Load, Two-Loop, Initial Condition, Small Break Outside Containment With Loss of AC Power

For this case, the RPS and NSSS responses are summarized in Table 15.1.14-12 while the reactivity transient is shown in Figure 15.1.14-31.

After complete CEA insertion, the steam generator blowdown results in a maximum 145 °F cooldown of the reactor coolant which increases the total reactivity to -0.15 percent $\Delta\rho$. This negative reactivity is large enough to prevent any return to power even with the delayed neutron precursors as a source.

15.1.14.1.2.2.3 No Load, One-Loop, Initial Condition, Small Break Outside Containment With Loss of AC Power

For this case, the RPS and NSSS responses are summarized in Table 15.1.14-13 while various NSSS transient parameters are shown in Figures 15.1.14-32 through 15.1.14-37.

Prior to complete insertion of CEAs on reactor trip at 32.0 seconds, a peak transient heat flux of 7.0 percent occurs. Due to high RCS pressure, reduced reactor coolant temperature, and normal power distribution, i.e., stuck CEA distribution does not apply until after shutdown CEAs are inserted, the minimum DNBR for this peak heat flux is greater than 2.0. After the complete CEA insertion, the steam generator blowdown results in a maximum 139.6 °F cooldown of the reactor coolant which increases the total reactivity to a positive value. As a result of this, a peak transient heat flux after complete CEA insertion of 5.0 percent $\Delta\rho$ occurs at 495.0 seconds. At this time, the Macbeth DNBR is greater than 2.0.

15.1.14.1.3 Conclusion

For all of the cases analyzed, sufficient margin to the critical heat flux exists to assure that no fuel damage will occur as a result of the steam line break transient.

15.1.14.1.4 Steam Line Break Accident Subsequent Analyses

15.1.14.1.4.1 Steam Line Rupture Analyses Performed Without Moisture Carryover

The following analyses were performed at the request of the NRC, to determine the most limiting transients assuming no moisture carryover regardless of the break size. The results of these analyses show that the following four transients are limiting with respect to the shutdown margin required.

A. Full Power, 2-loop, nozzle break with AC available

B. Full Power, 2-loop, nozzle break without AC available

C. Zero Power, 2-loop, nozzle break with AC available

D. Zero Power, 2-loop, nozzle break without AC available

The nozzle size break results in the most severe NSSS transient (peak return-to-power) when moisture carryover is not considered.

For both full power and zero power cases parametric analyses were performed to determine the required shutdown margin such that the consequences of the transient were no more severe than the analyses presented in the FSAR with moisture carryover assumed. The full power cases include failures in the main feedwater system for the worst single failure of an active system component. The failure of one condensate pump to trip on MSIS produced the worst consequences for the case with AC power available. The failure of a single main feedwater isolation valve to close on MSIS produced the worst consequences for the case with concurrent loss of AC power. The single failures in the main feedwater system have the effect of (1) increasing the amount of feedwater flow to the steam generator until the main feedwater isolation valves close for the case with failure of one condensate pump to trip, and (2) continuing feedwater flow even after the main feedwater pumps have stopped due to the driving force provided by residual pressure in the heater drain tanks in case of a failure of a main feedwater isolation valve to close. Consequently, each of these failures results in an increased duration of steam generator blowdown.

For the full power, 2-loop, nozzle break cases, the required shutdown CEA worth is -8.6 percent $\Delta\rho$, while for the no load, 2-loop, nozzle break cases, the required shutdown CEA worth is -5.0 percent $\Delta\rho$.

The following analyses were analyzed with these shutdown CEA worths.

A. Full Load, Two-Loop Initial Condition, Nozzle Break, Without Moisture Carryover, Without Loss of AC Power.

B. Full Load, Two-Loop, Initial Condition, Nozzle Break, Without Moisture Carryover, With Loss of AC Power.

C. No Load, Two-Loop, Initial Condition, Nozzle Break, Without Moisture Carryover, Without Loss of AC Power.

D. No Load, Two-Loop, Initial Condition, Nozzle Break, Without Moisture Carryover, With Loss of AC Power.

The NSSS and RPS responses for Case A are presented in Table 15.1.14-14 and Figures 15.1.14-39 through 15.1.14-44. The rapid decrease in secondary pressure resulting from the blowdown through the rupture results in a reactor trip signal due to low steam generator pressure and a MSIS being generated 1.4 seconds into the transient. Flow is terminated from the steam generator connected to the intact steam line at 5.3 seconds into the transient when the Main Steam Isolation Valves (MSIVs) are fully closed.

The core power level decays rapidly with CEA insertion and approaches decay heat levels. However, the continued cooldown of the RCS due to the blowdown through the rupture results in a peak post-trip reactivity of -0.073 percent $\Delta\rho$ occurring at 59.7 seconds and subsequently a peak return to power of 18.3 percent occurring at 60.4 seconds into the transient. The return-to-power transient is terminated when the steam generator connected to the ruptured line empties at 57.0 seconds (this terminates cooldown of the RCS). As a result of the peak return-to-power heat flux of 17.4 percent, which occurs 61.6 seconds into the transient, the minimum Macbeth DNBR for Case A is greater than 2.9.

The NSSS and RPS responses for Case B are presented in Table 15.1.14-15 and Figures 15.1.14-45 through 15.1.14-50. As a result of the loss of AC power, reactor trip occurs on a low DNBR signal at 0.6 seconds into the transient. The rapid decrease in the secondary pressure resulting from the blowdown through the rupture results in an MSIS occurring at 1.5 seconds into the transient thus terminating flow from the steam generator connected to the intact steam line at 5.4 seconds into the transient.

The continued cooldown of the RCS due to the blowdown through the rupture results in a peak post-trip reactivity of +0.023 percent $\Delta\rho$ occurring at 74.0 seconds into the transient and subsequently a peak return-to-power after CEA insertion of 30.8 percent occurring 96.2 seconds into the transient. The return-to-power transient is terminated by the emptying of the steam generator connected to the ruptured steam line which terminates the cooldown of the RCS. For Case B, the peak return-to-power heat flux + 29.9 percent and the resulting minimum Macbeth DNBR of 1.4 occur 99.0 seconds into the transient.

The NSSS and RPS responses for Case C are presented in Table 15.1.14-16 and Figures 15.1.14-51 through 15.1.14-56. As a result of the rapid decrease in secondary pressure resulting from the blowdown through the rupture, a reactor trip signal on low steam generator pressure occurs at 1.9 seconds into the transient. This signal results in the MSIVs being fully closed 5.8 seconds into the transient thus terminated blowdown from the steam generator connected to the intact steam line.

Cooldown of the RCS continues due to the blowdown through the rupture resulting in a peak reactivity of 0.34 percent $\Delta\rho$ occurring at 85 seconds into the transient with a subsequent peak return to power, after CEA insertion, of 21.3 percent occurring at 92.1 seconds into the transient. The resulting peak post trip heat flux of 16.9 percent and resultant minimum Macbeth DNBR of 2.3 occur at 94.2 seconds into the transient in Case C. The return-to-power is terminated by the emptying of the steam generator connected to the ruptured steam line which terminates the cooldown of the RCS, and injection of boron via the HPSI system (one-pump injection assumed).

The NSSS and RPS responses for Case D are presented in Table 15.1.14-17 and Figures 15.1.14-57 through 15.1.14-62. As a result of the rapid decrease in secondary pressure resulting from the blowdown through the rupture, a reactor trip signal on low steam generator pressure occurs at 1.9 seconds into the transient. This signal results in CEA insertion and closure of the MSIVs. The MSIVs are fully closed 5.8 seconds into the transient thus terminating blowdown from the steam generator connected to the intact steam line.

Cooldown of the RCS continues due to blowdown through the rupture resulting in a peak reactivity of 0.43 percent occurring at 66.6 seconds into the transient with a subsequent peak return-to-power, after CEA insertion, of 43.2 percent occurring at 68.3 seconds into the transient. For Case D, the peak post-CEA insertion heat flux of 25.3 percent results in a minimum Macbeth DNBR of 1.4 occurring 105.2 seconds into the transient. The post-CEA

insertion return-to-power is terminated by the emptying of the ruptured steam generator, which terminated cooldown of the RCS, and injection of boron via the HPSI system (one-pump injection assumed).

Although neither an electrical nor a mechanical failure of the main steam isolation valves to close is considered credible, a steam line break analysis was performed for the limiting case with loss of AC power. The results of this analysis were less severe than the results for the main feedwater isolation valve failure. Failure of the main steam isolation valve (MSIV) on the unaffected steam generator to close can result in continued blowdown of steam from that steam generator due to the presence of a steam flow path that is not automatically isolated. The unisolated flow path is the steam line to the tube side of the moisture separators between the high and low pressure turbines. Nominal full power flow for this steam line is 3.5 percent of total full power steam flow from the steam generators. Peak power and peak core heat flux during the post-trip return-to-power were lower for failure of the main steam isolation valve to close than for the main feedwater isolation valve failure. In addition, the return-to-power is of shorter duration than for the main feedwater isolation valve failure.

15.1.14.1.4.2 Cycle 12 Steam Line Break Analysis

The no moisture carryover steam line break post-trip return to power events were reanalyzed for a lower MSIS setpoint, and to bound various plant parameter changes and physics input changes. CESEC-III was used to model the NSSS response, RCP coastdown and natural circulation, and RELAP5 was used to model the feedwater system response for the hot full power (HFP or full load) cases. Prior analysis efforts had utilized CESEC, COAST, and the HFP feedwater system was modeled with simplifying assumptions or the HSTA code. For the hot zero power (HZP or not load) cases, feedwater flow is modeled by matching the energy input by the core at the start of the event.

The analytical basis for the HFP and HZP simulations are discussed below.

A. A double-ended guillotine break (6.14 ft^2) causes the greatest cooldown of the RCS and the most severe degradation of shutdown margin.

B. A break inside the containment building, upstream of the MSIVs and flow measuring venturis causes a non-isolable condition in the affected steam generator. This results in an approach to criticality which is terminated by the dryout of the affected steam generator.

C. A SIAS is actuated when the pressurizer pressure drops below 1400 psia. Time delays associated with the safety injection pump acceleration and valve opening are taken into account. A 40 second HPSI response time was assumed to account for these delays. Additionally, the event was initiated from the highest pressure allowed by the technical specification to delay the effect of the safety injection boron.

D. The cooldown of the RCS is terminated when the affected steam generator blows dry. As the coolant temperature begins increasing, positive reactivity insertion from moderator reactivity feedback decreases. The decrease in moderator reactivity combined with negative reactivity inserted via boron injection cause the total reactivity to become more negative.

E. CESEC-III is used to model the RCP pump coast down on a loss of offsite power. The CPC low DNBR (based on pump speed) trip is credited in this analysis following a loss of offsite power. A CPC low DNBR trip setpoint based on 95% of RCP speed with a 1.0 second response time are assumed.

F. A low steam generator reactor trip setpoint of 620 psia was assumed with a 1.2 second response time.

G. MSIS is actuated on a low steam generator setpoint of 620 psia. The MSIVs, MFIVs and Backup MFIVs all receive an MSIS signal to close. A response time of 4.3 seconds was assumed for the MSIVs. The MFIVs and Back-up MFIVs were assumed to close in 36.4 seconds and 31.8 seconds with a loss of offsite power, and 21.4 seconds and 16.8 seconds with offsite power available, respectively.

The conservative assumptions included in the HZP and HFP simulations are discussed below.

The MTC assumed in the analysis corresponds to the most negative value. This negative MTC results in the greatest positive reactivity addition during the RCS cooldown caused by the steam line break. Since the coefficient of reactivity associated with moderator feedback varies significantly over the range of moderator density covered in the analysis, a curve of reactivity insertion versus moderator density rather than a single value of MTC is assumed in the analysis. The moderator cooldown curve used in the analysis (Figure 15.1.14-109) was conservatively calculated assuming that on reactor trip, the highest worth control element assembly is stuck in the fully withdrawn position. The effect of uneven temperature distribution on the moderator reactivity is accounted for by assuming that the moderator reactivity is a function of the lowest cold leg temperature.

For conservatism, the full steam generator heat transfer surface area is assumed to always be covered by the 2-phase level until a steam generator becomes essentially empty.

The reactivity defect associated with fuel temperature decrease is also based on the most negative Fuel Temperature Coefficient (FTC). Figure 15.1.14-110 represents the FTC curve used in the analysis. This FTC, in conjunction with the decreasing fuel temperatures, causes the greatest positive reactivity insertion during the steam line break event. The delayed neutron fraction assumed is the maximum value including uncertainties for end-of-cycle conditions (total delayed neutron fraction, β, 0.005994). This too maximizes subcritical multiplication and thus increases the potential for return to power.

The minimum CEA worth assumed to be available for shutdown at the time of reactor trip at the maximum allowed power level is -8.25%$\Delta\rho$ with a loss of AC and -8.0% $\Delta\rho$ with AC available. For the HZP cases a shutdown CEA worth of -6.0%$\Delta\rho$ was used. The scram worths used are consistent with the moderator cooldown curve and stuck rod assumed in the analysis. The CEA position versus time of Figure 15.1.0-1C and a 0.6 second holding coil delay time are consistent with the analysis assumption; however, a more conservative normalized reactivity insertion versus CEA position for a +0.3 ASI curve was used.

The EFW system is conservatively modeled to initiate early with both EFW pumps available, this maximizes the potential cooling that could occur. System response times, flows and setpoints are assumed based on increasing the cooling potential of the EFW system.

The analysis assumed that, for the loss of AC power cases one EDG failed to start. The failure of an EDG results in the failure of one HPSI pump and one of the main feedwater isolation valves to close (the faster closing back-up MFIVs were assumed to remain open). For the HFP case with AC available, the failure of the main feedwater pump to trip is the most limiting single failure, therefore, in this case both HPSI pumps are functioning. The single failure of a main feedwater pump was determined to be more limiting than that of a condensate pump utilized in the prior analysis. This was confirmed with the RELAP model. A single failure of a HPSI pump to start was assumed for the HZP case with AC available. The boration from the Safety Injection Tanks was not credited in this analysis.

The key parameters used for the post-trip steam line break analyses are listed in Table 15.1.14-26 for HFP cases and Table 15.1.14-27 for HZP cases. Table 15.1.14-28 through 15.1.14-31 present the sequence of events for the HFP and HZP steam line break cases with and without a concurrent loss of AC. The key transient parameters (core power, core heat flux, RCS pressure, RCS temperatures, steam generator pressure and reactivities) are shown in Figures 15.1.14-85 through 15.1.14-108. The maximum post-trip peak fission powers were negligible and bounded by the analyses presented above.

15.1.14.1.4.3 Cycle 13 Steam Line Break Analysis

The no moisture carryover steam line break post-trip return to power events were reanalyzed to account for a 10 % reduction in the RCS design flow, a small increase in feedwater flow, and address Cycle 13 physics data. CENTS was used to model the NSSS response, RCP coastdown and natural circulation, RELAP5 was used to model the feedwater system response for the hot full power (HFP or full load) cases, HRISE was used to calculate thermal margin on DNBR, and ROCS/HERMITE were used to assess reactivity feedback and peaking.

The analytical basis for the HFP and hot zero power (HZP) simulations are discussed below.

A. A double-ended guillotine break (6.357 ft^2) causes the greatest cooldown of the RCS and the most severe degradation of shutdown margin.

B. A break inside the containment building, upstream of the MSIVs and flow measuring venturis causes a non-isolable condition in the affected steam generator.

C. A SIAS is actuated when the pressurizer pressure drops below 1400 psia. Time delays associated with the safety injection pump acceleration and valve opening are taken into account. A 40-second HPSI response time was assumed to account for these delays. Additionally, the event was initiated from the highest pressure allowed by the technical specifications to delay the effect of the safety injection boron.

D. The cooldown of the RCS is terminated when the affected steam generator blows dry. As the coolant temperatures begin increasing, positive reactivity insertion from moderator reactivity feedback decreases. The decrease in moderator reactivity combined with the negative reactivity inserted via boron injection cause the total reactivity to become more negative.

E. CENTS is used to model the RCP pump coast down on a loss of offsite power. The CPC low DNBR (based on pump speed) trip is credited in this analysis following a loss of offsite power. A CPC low DNBR trip setpoint based on 96.5% of RCP speed with a 1.0 second response time are assumed.

F. A low steam generator pressure reactor trip setpoint of 620 psia was assumed with a 1.3 second response time.

G. MSIS is actuated on a low steam generator pressure setpoint of 620 psia. The MSIVs, MFIVs and Back-up MFIVs all receive an MSIS signal to close. A response time of 4.3 seconds was assumed for the MSIVs. The MFIVs and Back-up MFIVs were assumed to close in 36.4 seconds and 31.8 seconds with a loss of offsite power, and 21.4 seconds and 16.8 seconds with offsite power available, respectively.

H. The HERMITE code was used to calculate the reactivity for the post-trip return to power portion of the analysis. This was done since the HERMITE code, which is a three-dimensional coupled neutronics-open channel thermal hydraulics code can more accurately model the effects of moderator temperature feedback on the power distribution and reactivity for the critical configuration existing during the return to power. The HERMITE results used in the ANO-2 analysis were actually obtained from a parametric study performed for Calvert Cliffs Unit 1 Cycle 7. ANO-2 specific ROCS calculations were used to confirm the applicability of these parametric results to ANO-2.

I. Three-dimensional power distribution peaks (Fq) were determined with the above mentioned ROCS and HERMITE evaluations. Axial profiles consistent with these conservative power distribution peaks were utilized in the analysis.

J. The power produced by the decay of the initial condition delayed neutron precursors and by nominal decay power is distributed according to the nominal power distribution.

K. The thermal margin on DNBR in the reactor core was simulated using the HRISE computer program. The HRISE code is based on the MacBeth CHF correlation described in Reference 48. RCS conditions from CENTS (RCS temperature, pressure, flow, and power) are used in the HRISE thermal margin calculations.

The conservative assumptions included in the HZP and HFP simulations are discussed below.

The MTC assumed in the analysis corresponds to the most negative value. This negative MTC results in the greatest positive reactivity addition during the RCS cooldown caused by the steam line break. Since the coefficient of reactivity associated with moderator feedback varies significantly over the range of moderator density covered in the analysis, a curve of reactivity insertion versus moderator density rather than a single value of MTC is assumed in the analysis. The moderator cooldown curve used in the analysis (Figure 15.1.14-111) was conservatively calculated assuming that on reactor trip, the highest worth control element assembly is stuck in the fully withdrawn position. The effect of uneven temperature distribution on the moderator reactivity is accounted for by assuming that the moderator reactivity is a function of the lowest cold leg temperature.

For conservatism, the full steam generator heat transfer surface area is assumed to always be covered by the 2-phase level until a steam generator becomes essentially empty.

The reactivity defect associated with fuel temperature decrease is also based on the most negative Fuel Temperature Coefficient (FTC). Figure 15.1.14-112 represents the FTC curve used in the analysis. This FTC, in conjunction with the decreasing fuel temperatures, causes

the greatest positive reactivity insertion during the steam line break event. The delayed neutron fraction assumed is the maximum value including uncertainties for end-of-cycle conditions (total delayed neutron fraction, β, 0.005994). This too maximizes subcritical multiplication and thus increases the potential for return to power.

The minimum CEA worth assumed to be available for shutdown at the time of reactor trip at the maximum allowed power level is -7.5144% $\Delta\rho$. For the HZP cases a shutdown CEA worth of -5.0% $\Delta\rho$ was used. The scram worths used are consistent with the moderator cooldown curve and stuck rod assumed in the analysis. The CEA reactivity addition curve of Figure 15.1.0-1D adjusted to a worth of 7.5144 was used in the HFP cases. The HZP cases assumed a CEA drop time consistent with Figure 15.1.0-1C with the 0.6 second holding coil delay time; however, a more conservative normalized reactivity insertion versus CEA position for a +0.6 ASI curve was used.

The EFW system is conservatively modeled to initiate early with both EFW pumps available, this maximizes the potential cooling that could occur. System response times, flows and setpoints are assumed based on increasing the cooling potential of the EFW system.

The analysis assumed that, for the loss of AC power cases one EDG failed to start. The failure of an EDG results in the failure of one HPSI pump and one of the main feedwater isolation valves to close (the faster closing back-up MFIVs were assumed to remain open). For the HFP case with AC available, a bus fast transfer failure is the most limiting single failure as this failure is modeled as the failure of the back-up MFIVs and a HPSI pump. A fast transfer failure would only result in the delayed actuation of the back-up MFIV and HPSI pump. These components would be actuated once the EDG has started. Therefore, the modeling of the fast transfer failure is conservative. This conservative modeling of a fast transfer failure is slightly more limiting than the single failure of a main feedwater pump, which was determined to be more limiting in the prior analysis. A single failure of a HPSI pump to start was assumed for the HZP case with AC available. The boration from the Safety Injection Tanks was not credited in this analysis.

The HFP feedwater addition to the steam generator assumed in this analysis is taken from the Cycle 12 analysis which used a RELAP5 model of the feedwater system. The steam generator pressure profiles and time of MSIS were verified to be consistent with respect to this analysis, thereby allowing the application of the feedwater data generated for Cycle 12. The HFP feedwater data for Cycle 12 was increased by 1% to account for a small expected increase in feedwater flow due to modifications to the high pressure turbine. For the hot zero power (HZP or no load) cases, feedwater flow is modeled by matching the energy input by the core at the start of the event.

The results of the post-trip steam line break analyses demonstrated that there was no calculated fuel failure. Thus the coolable geometry is maintained and the conclusions of Section 15.1.14.1.3 are valid.

15.1.14.1.4.4 Cycle 14 Steam Line Break Analysis

The no moisture carryover steam line break post-trip return to power events were reanalyzed for Cycle 14 because the individual reactivity components were not all bounded by those used in the prior (Cycle 13) analysis. The methodology used was identical to that used for Cycle 13, with the exception that physics uncertainties in the reactivity components are accounted for by a single adjustment to the shutdown worth, rather than the traditional method of adjusting each activity component individually.

The conservative assumptions included in the HZP and HFP simulations that are different from the Cycle 13 assessment are discussed below.

The delayed neutron fraction assumed is the maximum value including uncertainties for end-of-life conditions (total delayed neutron fraction, β, 0.0051594). The minimum CEA worth assumed to be available for shutdown at the time of reactor trip at the maximum allowed power level is -7.1049% Δρ. For the HZP cases a shutdown CEA worth of -4.8400% Δρ was used. The CEA reactivity addition curve was adjusted to a worth of 7.1049% Δρ.

The key parameters used for the post-trip steam line break Cycle 14 analyses are listed in Table 15.1.14-32. Tables 15.1.14-33 through 15.1.14-36 present the sequence of events for the HFP and HZP steam line break cases with and without a concurrent loss of AC power. Minor changes from the Cycle 13 assessment are caused by more realistic modeling adjustments and the cycle specific physics data.

The results of the post-trip steam line break analyses demonstrated that there was no calculated fuel failure. Thus, the coolable geometry is maintained and the conclusions of Section 15.1.14.1.3 are valid.

15.1.14.1.4.5 Cycle 15 at 3026 MWt Main Steam Line Break Analysis

The no moisture carryover steam line break events were reanalyzed to account for replacement steam generators (RSGs) and Power Uprate to a rated power of 3026 MWt. CENTS was used to model the NSSS response, RCP coastdown, and natural circulation. RELAP5/MOD3.1 was used to model the feedwater system response for the HFP (or full load) cases. HRISE was used to calculate the thermal margin on DNBR, which employed the MacBeth correlation. ROCS/HERMITE were used to assess reactivity feedback and peaking.

Input parameters for HFP and HZP from Table 15.1.14-41 and the bounding physics data from Section 15.1.0 have been incorporated in this analysis with the following clarifications:

1. A double-ended guillotine break (6.357 ft^2) causes the greatest cooldown of the RCS and the most severe degradation of SDM. Due to integral flow restrictors, this results in an equivalent break area of less than 2.0 ft^2.

2. A break inside or outside the containment building, upstream of the MSIVs causes a non-isolatable condition in the affected steam generator.

3. An SIAS is actuated when the pressurizer pressure drops below 1400 psia. Time delays associated with the safety injection pump acceleration and valve opening are taken into account. A 40-second HPSI response time was assumed to account for these delays. Additionally, the event was initiated from the highest pressure allowed by the Technical Specifications to delay the effect of the safety injection boron.

4. The cooldown of the RCS is terminated when the affected steam generator blows dry. As the coolant temperatures begin increasing, positive reactivity insertion from moderator reactivity feedback decreases. The decrease in moderator reactivity combined with the negative reactivity inserted via boron injection cause the total reactivity to become more negative.

5. CENTS is used to model the RCP coast down on a loss of offsite power. The CPC low DNBR (based on pump speed) trip is credited in this analysis following a loss of offsite power. The analysis assumed a CPC low DNBR trip setpoint based on 95% of RCP speed with a 1.0-second response time.

6. Due to the reduction of the effective break area, a combination of RPS trips was employed to generate a reactor trip for the offsite power available cases.

   A Low Steam Generator Pressure Trip setpoint of 693 psia for outside containment breaks (normal environment) was assumed with a 1.3-second response time.

   A High Containment Pressure Trip setpoint of 20.7 psia for inside containment breaks (harsh environment) was assumed with a 1.59-second response time.

   For HFP outside containment breaks (normal environment), the CPCs are also available to generate a reactor trip. A CPCs Variable Overpower Trip (VOPT) was assumed with a conservative 1.2-second response time.

7. MSIS is actuated on a low steam generator pressure setpoint of 658 psia for inside containment breaks (harsh environment) and 693 psia for outside containment breaks (normal environment). The MSIVs, MFIVs, and back-up MFIVs all receive an MSIS signal to close. A response time of 4.9 seconds (which includes a 1.4-second MSIS response time) was assumed for the MSIVs. The MFIVs and Back-up MFIVs were assumed to close in 41.4 seconds and 34.9 seconds with a loss of offsite power, and 26.4 seconds and 19.9 seconds with offsite power available, respectively.

8. The HERMITE code (Reference 23) was used to calculate the reactivity for the post-trip return to power portion of the analysis. This was done since the HERMITE code, which is a three-dimensional, coupled neutronics, open channel thermal hydraulics code, can more accurately model the effects of moderator temperature feedback on the power distribution and reactivity for the critical configuration existing during the return to power. The HERMITE results used in the ANO-2 analysis were actually obtained from a parametric study performed for Calvert Cliffs Unit 1 Cycle 7. ANO-2 specific ROCS calculations were used to confirm the applicability of these parametric results to ANO-2.

9. Three-dimensional power distribution peaks (Fq) were determined with the ROCS and HERMITE evaluations mentioned above. Axial profiles consistent with these conservative power distribution peaks were utilized in the analysis.

10. The power produced by the decay of the initial condition delayed neutron precursors and by nominal decay power is distributed according to the nominal power distribution.

11. The thermal margin on DNBR in the reactor core was simulated using the HRISE computer program, which employed the MacBeth CHF correlation and a 1.3 DNBR limit described in Reference 48. RCS conditions from CENTS (RCS temperature, pressure, flow, and power) are used in the HRISE thermal margin calculations.

12. The EOC Doppler curve in Figure 15.1.0-4 was assumed. This was based on the most negative FTC. This FTC, in conjunction with the decreasing fuel temperatures, causes the greatest positive reactivity insertion during the steam line break event.

13. The delayed neutron fraction assumed is the maximum value including uncertainties for end-of-cycle conditions (total delayed neutron fraction, β, 0.005994). This too minimizes neutron generation time and thus increases the potential for return to power.

14. EFW is conservatively modeled to actuate early.

15. The SITs were credited in this analysis only for the AC power available cases. The SITs were configured to have the minimum allowed pressure with the maximum volume of water and minimum water temperature. The boron concentration was at the minimum allowed value.

16. A minimum initial RCS flow of 315,560 gpm was assumed for HFP, and a minimum initial RCS flow of 314,682 gpm was assumed for HZP.

17. An initial steam generator pressure of 1001 psia was assumed for HFP, and an initial steam generator pressure of 1065 psia was assumed for HZP.

The conservative assumptions included in the HZP and HFP simulations are discussed below.

The MTC assumed in the analysis corresponds to the most negative value. This negative MTC results in the greatest positive reactivity addition during the RCS cooldown caused by the steam line break. Since the coefficient of reactivity associated with the moderator feedback varies significantly over the range of moderator density covered in the analysis, a curve of reactivity insertion versus moderator density rather than a single value of MTC is assumed in the analysis. The moderator cooldown curve used in the analysis (Figure 15.1.14-113) was conservatively calculated assuming that on reactor trip, the highest worth control element assembly is stuck in the fully withdrawn position. The effect of uneven temperature distribution on the moderator reactivity is accounted for by assuming that the moderator reactivity is a function of the lowest cold leg temperature.

For conservatism, the full steam generator heat transfer surface area is assumed to always be covered by the 2-phase level until a steam generator becomes essentially empty.

The minimum CEA worth assumed to be available for shutdown at the time of reactor trip at the maximum allowed power level is -6.84 %$\Delta\rho$. For the HZP cases a shutdown CEA worth of -4.84 %$\Delta\rho$ was used. The scram worths used are consistent with the moderator cooldown curve and stuck rod assumed in the analysis. The CEA reactivity addition curve of Figure 15.1.0-1D adjusted to a worth of -6.84 %$\Delta\rho$ was used in the HFP cases. The HZP cases assumed a CEA drop time consistent with Figure 15.1.0-1C with the 0.6 second holding coil delay time and a scram worth of -4.84 %$\Delta\rho$; however, a more conservative normalized reactivity insertion versus CEA position for a +0.6 ASI curve was used.

The EFW system is conservatively modeled to initiate early with both EFW pumps available, maximizing the potential cooling that could occur. System response times, flows, and setpoints are assumed based on increasing the cooling potential of the EFW system.

These analyses have considered the worst single failure of an active component. The analysis assumed that, for the loss of AC power cases, one EDG failed to start. The failure of an EDG resulted in the failure of one HPSI pump and one of the MFIVs to close. The faster closing Back-up MFIVs were assumed to remain open. For the HFP case with AC available, a bus fast

transfer failure is the most limiting single failure. This failure was modeled as the failure of the Back-up MFIV and a HPSI pump. A fast transfer failure would only result in the delayed actuation of the Back-up MFIV and HPSI pump. These components would be actuated once the EDG has started. Therefore, the modeling of the fast transfer failure was conservative. This conservative modeling of a fast transfer failure was slightly more limiting than the single failure of a main feedwater pump to trip, which is consistent with the current analysis. A single failure of a HPSI pump to start was assumed for the HZP case with AC available.

The HFP feedwater addition to the steam generators assumed in this analysis was re-generated due to the installation of the RSGs and increase in rated power. The analysis used a RELAP5/MOD3.1 model (Reference 50) to generate the feedwater system response. The steam generator pressure profiles and time of MSIS were verified to be consistent between the CENTS and RELAP5/MOD3.1 results. For the HZP (or no load) cases, feedwater flow is modeled by matching the energy input by the core at the start of the event. An increase in feedwater flow is assumed based on the capacity of the auxiliary feedwater (AFW) pump.

The key parameters used for the post-trip steam line break analyses are listed in Table 15.1.14-41. For the HFP cases, an RCS flow of 315,560 gpm was assumed. For the HZP cases a lower RCS flow of 314,682 gpm was assumed.

Tables 15.1.14-42 through 15.1.14-45 present the sequence of events for the HFP and HZP steam line break cases with and without a concurrent loss of AC power. Only the limiting inside or outside containment case was presented for the HFP and HZP conditions with AC available. Figures 15.1.14-114 through 15.1.14-137 show the transient response for key parameters.

The HFP results of this analysis indicate that a slight return to criticality occurs for the case with loss of AC power. The new maximum post trip reactivity values are 0.0173 %$\Delta\rho$ and -0.0218% $\Delta\rho$ considering a loss of AC and offsite power available, respectively. The peak return to power and minimum DNBR values are 2.76% and 1.70, and 4.26% and 2.72 considering a loss of AC and offsite power available, respectively.

The HERMITE 3-D feedback and 3-D peaking factors are power dependent. The Cycle 15 – 2815 MWt values were more limiting than the Cycle 16 – 3026 MWt values. This input in conjunction with the RSG resulted in a slightly more adverse post-trip return to criticality for the HFP with and without loss of offsite power events (see the sequence of events in Table 15.1.14-42 and Table 15.1.14-43). (The HFP with loss of offsite power event maximum post trip reactivity is 0.0211% $\Delta\rho$, peak return to power is 3.39% of 2815 MWt, and minimum DNBR is 1.38. The HFP with offsite power available event maximum post trip reactivity is -0.02314% $\Delta\rho$, peak return to power is 4.392% of 2815 MWt, and minimum DNBR is 2.48). The times for the sequence of events were within two seconds of the Cycle 16 sequence of events. Since the results for Cycle 15 are valid for only one cycle, they are provided as footnotes to the Cycle 16 sequence of events.

The HZP results of this analysis indicate that a slight return to critical occurs for the case with loss of AC power. The new maximum post trip reactivity values are +0.206% $\Delta\rho$ and -0.545% $\Delta\rho$ considering a loss of AC and offsite power available, respectively. The peak return-to-power and minimum DNBR values are 0.15% and > 10, and zero and > 10 considering a loss of AC and offsite power available, respectively. The Cycle 15 (2815 MWt) results are valid only for one cycle.

As these results indicate acceptable DNBR values, no fuel failure is predicted. The results of the steam line break analyses demonstrated that there were no calculated fuel failures, thus the coolable geometry has been maintained.

A sensitivity study was completed on CEA worth at trip to determine the lowest CEA worth value that would produce either a DNBR of 1.30 (MacBeth) or a peak Linear Heat Rate of 21 KW/ft. The method used was to hold all input parameters, both physics input and plant values, constant and lower the CEA worth at trip until one of the above limits was reached.

The purpose of this sensitivity study was to determine the amount of CEA worth at trip that could be utilized in future reload efforts to offset other physics parameters. Thus, the incremental CEA worth at trip of 0.09 $\%\Delta\rho$ can be credited in future reload efforts. Similarly, an incremental shutdown margin of 1.29 $\%\Delta\rho$ can be credited in future HZP analysis.

15.1.14.1.4.6 Cycle 18 Main Steam Line Break Analysis

The Main Steam Line Break event was evaluated at a higher LOCA Limit of 14.4 KW/ft. The LOCA Limit was used to determine the decay heat 3-D peak.

The methodology was the same as that used in the current analysis in Section 15.1.14.1.4.5. The LOCA Limit value of 14.4 KW/ft was used in place of the previous value of 13.7 KW/ft. No new computer cases were required.

The combination of the radial power distortion and core power that resulted from the current analysis are combined with the higher LOCA Limit value of 14.4 KW/ft to determine the new decay heat 3-D peak for minimum DNBR (mDNBR). The mDNBR was assessed with the new decay heat 3-D peak plus the current fission 3-D peak from the current analysis. Since the fission power 3-D peak was dominant, the increase in decay heat 3-D peak had a negligible impact on the current mDNBR value, which remained above the SAFDL. There was no impact on the current calculated peak LHR value as the current analysis 3-D decay heat radial peak was bounding with respect to the 14.4 KW/ft value. As there were no calculated fuel failures, the radiological dose results are unchanged.

15.1.14.1.4.7 Cycle 21 Main Steam Line Break Analysis

The post-trip Main Steam Line Break (MSLB) event analyses were evaluated to determine the impact of a full core of Next Generation Fuel (NGF). The major impact was the implementation of the NGF pin dimensions and its affect on the calculated MacBeth critical heat flux correlation mDNBR.

The methodology is the same as that used in the current analysis presented in Section 15.1.14.1.4.5. No CENTS computer code cases were run, since input changes due to NGF are small enough such that impact on the results are insignificant and all current input parameters in Table 15.1.14-41 remained unchanged. Of the four post-trip MSLB events analyzed, only the HFP with Loss of AC power (LOAC) was re-evaluated. The remaining three MSLB events, HFP with AC power available, HZP with LOAC, and HZP with AC power available were not reevaluated; as all three of these MSLB events had a minimum MacBeth DNBR value greater than 2.0 and had sufficient margin to the 1.3 MacBeth DNBR limit.

Only the HFP with Loss of AC power (LOAC) case's DNB margin analysis was affected. With the implementation of NGF, the minimum MacBeth DNBR decreased from 1.70 to 1.68. The minimum MacBeth DNBR still remains above the SAFDL of 1.30. Table 15.1.14-42 provides a revised SAR Sequence of Events that includes the new DNBR value. There are no impacts on the MSLB sensitivity study analyses that determine the CEA worth at trip that can be utilized in future reload efforts to offset other physics parameters. Consequently, the conclusions in SAR Section 15.1.14.1.4.5 remain the same.

15.1.14.2 <u>Feedwater Line Break Accident</u>

15.1.14.2.1 <u>Identification of Causes</u>

A feedwater line rupture accident is defined as the failure of a main feedwater system pipe during plant operation. The main feedwater and condensate system on which these analyses are based, are described in Section 10.4.7. A rupture in the main feedwater system rapidly reduces the steam generator inventory causing a partial loss of the main steam heat sink, thereby allowing heatup of the RCS. Depending on initial conditions, break size, break location and steam generator inventory, any of several plant protective system actions may occur. A decrease in the steam generator water level will initiate a reactor trip signal on low steam generator water level. In addition, the decrease in the steam generator pressure may result in a low steam generator pressure trip signal and cause the main steam isolation valves and the main feedwater isolation valves to close. Additional protection against loss of the main steam heat sink is provided by automatic initiation of emergency feedwater to the intact steam generator. The RCS is protected from overpressurization by the high RCS pressurizer pressure trip and the pressurizer safety valves.

If the feedwater line breaks outside of containment or inside containment but upstream of the feedwater line check valves, steam generator blowdown is prevented by the closure of the check valves. The consequences of these feedwater line breaks are the same as the consequences of the loss of normal feedwater flow incidents (Section 15.1.8).

If the feedwater line rupture occurs between the steam generator and the feedwater line check valves, blowdown of the affected steam generator continues until the steam generator pressure equals the containment back pressure. However, termination of the feedwater flow from the intact steam generator as well as the intact lines on the damaged steam generator occurs with closure of the check valves. In addition, the main feedwater isolation valves close on a main steam isolation signal or containment spray actuation signal.

The steam generators are designed to withstand RCS operating pressure on the tube side with atmospheric pressure on the shell side; therefore, the integrity of the RCPB is assured.

15.1.14.2.2 <u>Analysis of Effects and Consequences</u>

15.1.14.2.2.1 <u>Discussion of Cases and Parameters</u>

The analysis of the feedwater line rupture is performed using CESEC, which is a digital simulation of the NSSS, described in Section 15.1.0.6.

Parametric studies were performed to determine the limiting transient with respect to the feedwater line break size. For conservatism the initial steam generator mass and break size were varied in order to obtain the following limiting conditions at the time of trip:

A. Downcomer level, of the steam generator connected to the intact feedwater line, at the low steam generator water level setpoint;

B. Steam generator connected to the ruptured feedwater line empties;

C. Greatest energy content of the RCS without initiating a trip, i.e., RCS pressure 2422 psia; and,

The RCS energy content was maximized through the following set of assumptions:

1. The initial core power was increased to 2,900 MWt (103 percent of design full power).

2. The initial core inlet temperature was increased from 553.7 °F (design) to 556.7 °F.

3. The initial core flow was decreased from 120.8 (design flow) to 116.2 million lbm/hr, which increased the core outlet and hot leg temperatures.

4. The minimum value (BOC, zero burnup) for the fuel gap heat transfer coefficient maximized the stored energy of the fuel.

5. A moderator temperature coefficient of $+0.5 \times 10^{-4} \Delta\rho/°F$ and a 15 percent reduction of the Doppler reactivity feedback maximized the increase of core power prior to trip.

6. Decay heat was maximized by assuming equilibrium core conditions.

7. RCS heatup prior to reactor trip was prolonged by maximizing time to trip. This was accomplished by reducing the initial RCS pressure from 2,250 psia to 2,200 psia and by choosing the combination of a small break with unrealistically high initial steam generator inventories (190,000 lbm).

8. The fluid discharged through the break was assumed to be saturated liquid, although physically the discharge quality must increase as the steam generator liquid is depleted.

9. For the loss of offsite power case, at the time of trip all non-emergency electrical power was assumed to be lost. This minimized heat transfer out of the RCS due to a loss of coolant flow and closure of the turbine and turbine bypass valves.

10. Reactor trip was delayed by not taking credit for a low level trip in the ruptured steam generator.

11. For conservatism, the full heat transfer surface area is available, i.e., the tubes are assumed to always be covered by the 2-phase level, until a steam generator becomes empty.

D. Greatest RCS pressure change with respect to time at the time of trip.

The combination of all of the above conditions existing at the time of trip assures that; 1) the most limiting RCS transient prior to trip has occurred and that 2) a minimum secondary heat sink exists for the subsequent cooldown of the RCS.

As indicated in items "A" through "C" the analyses results in the simultaneous occurrence of the following three trip signals:

A. Steam generator low water level trip signal (steam generator connected to the intact feedwater line);

B. Steam generator low pressure trip signal (steam generator connected to ruptured feedwater line); and,

C. High pressurizer pressure trip signal.

No credit is taken for a low steam generator water level trip in the steam generator connected to the ruptured feedwater line.

Table 15.1.14-18 lists some of the conservative initial assumptions used in the analyses. For the cases analyzed:

A. The variation of reactivity with fuel temperature is included. For conservatism, the absolute value of the slope of the reactivity versus fuel temperature function is decreased 15 percent for both cases.

B. The most reactive CEA is assumed stuck in the fully withdrawn position. The minimum CEA worth available for shutdown when the reactor is tripped is -5.4 percent $\Delta\rho$ for the full load conditions.

C. The emergency feedwater is automatically initiated to the steam generator with the intact feedwater line on a low steam generator water level signal. There is a 65-second delay before this flow reaches the steam generator, if AC power is available, otherwise there is a 112-second delay from the time AC power is lost due to the loading sequence of the diesel generators.

D. The quality of fluid discharged out of the ruptured feedwater line is assumed to be saturated water at the pressure calculated by using the CESEC code. For the limiting transients, a flow rate of 1,300 lbm/sec and an initial steam generator fluid inventory of 190,000 lbm was used. This initial steam generator inventory and break size results in the limiting conditions as discussed above. The initial steam generator inventories assumed are significantly different from the nominal inventories at full power conditions and were used to obtain the most limiting conditions as discussed above. For lower initial steam generator inventories a reactor trip on a low steam generator water level signal in the steam generator connected to the intact feedwater line would occur at an earlier time and subsequently a lower RCS energy content would exist at the time of trip. The combination of the larger initial steam generator inventories and the small blowdown rate through the break allows the pressurizer control systems in the RCS, i.e., pressurizer sprays, etc., to limit the pressure transient to a value below the high pressurizer pressure trip while increasing the energy of the RCS. Increasing the break size will result in either a low steam generator pressure trip in the steam generator connected to the ruptured feedwater line or a high pressurizer pressure trip prior to the occurrence of the limiting conditions listed above.

E. Credit is taken for the closure of the feedwater line swing check valve. Closure of the swing check valve assures isolation of the steam generator connected to the intact feedwater line. Additional isolation of the intact steam generator is provided by closure of the feedwater isolation valves on a MSIS.

F. A conservatively small value of the fuel gap heat transfer coefficient was assumed in the analysis, corresponding to BOC, zero burnup. Doubling the value of the coefficient decreased the peak RCS pressure by 40 psi due to the reduction of fuel temperatures which reduced the Doppler effect and the stored fuel energy.

15.1.14.2.2.2 <u>Results</u>

The NSSS and RPS responses for the feedwater line break cases are presented in Tables 15.1.14-19 through 15.1.14-22 and in Figures 15.1.14-63 through 15.1.14-72.

A. Full Power With AC Available

Tables 15.1.14-19 and 15.1.14-21, and Figures 15.1.14-63 through 15.1.14-67 present the transient for this case.

Concurrently, at 57.6 seconds into the transient the following occur:

1. Affected steam generator empties and low steam generator pressure trip signal is generated;

2. High pressurizer pressure trip signal occurs; and,

3. Low steam generator water level signal occurs in the steam generator connected to the intact feedwater line.

The reduction in the secondary heat sink due to the emptying of the affected steam generator and subsequent closure of the MSIVs results in a peak RCS pressure of 2,576 psia occurring at 62.2 seconds into the transient. Subsequently, the decay in core power level and action of the pressurizer sprays reduce the RCS system pressure until 96.3 seconds into the transient at which time the steam generator connected to the intact feedwater lines empties. As a result of the emptying of this steam generator, the RCS pressure increases to 2,281 psia at 157 seconds into the transient. At this time the effect of the pressurizer sprays and emergency feedwater are sufficient to terminate the RCS pressure rise.

B. Full Power With Loss of AC at Time of Trip.

Tables 15.1.14-20 and 15.1.14-22, and Figures 15.1.14-68 through 15.1.14-72 present the transient for this case.

Prior to trip this case is identical to Case A. At the time of trip, however, the following events are assumed to occur in response to the loss of AC power.

1. Turbine stop valves close instantaneously;

2. Reactor coolant pumps begin to coastdown; and,

3. Pressurizer control systems are lost.

The result of the loss of AC power in addition to the system response in Case A is to cause a higher peak RCS pressure (2,635 psia) to occur at 62.6 seconds into the transient. Subsequently decay in the core power level and the action of the secondary safety valves result in a reduction in the RCS pressure until 91.4 seconds into the transient when the steam generator connected to the intact feedwater line empties. As a result of the emptying of this steam generator, the RCS pressure increases to a peak pressure of 2,508 psia and is maintained below this pressure by the action of the RCS safety valves.

Filling of the pressurizer is prevented by the action of the emergency feedwater, which enters the intact steam generator 175.7 seconds into the transient. At 990 seconds into the transient the effect of the emergency feedwater flow is sufficient to result in a contraction of the RCS and subsequently a decay in the RCS pressures and temperatures, and closure of the pressurizer safety valves.

15.1.14.2.3 Conclusions

As shown by the results of the feedwater line break analysis, no unacceptable consequences occur. The RCS pressure does not exceed 110 percent of the design value and the pressurizer does not fill. Radiological consequences for the feedwater line break transients are no more severe than those presented for the loss of AC power (Section 15.1.9) because the fluid from the steam generator blowdown remains inside the containment.

15.1.14.2.4 Feedwater Line Break Accident Subsequent Analyses

15.1.14.2.4.1 Cycle 3 Feedwater Line Break Analysis

The feedwater line break accident analysis with a loss of AC power was reanalyzed for Cycle 3 using CESEC-III, which is a later version of the method identified above. This analysis was performed essentially consistent with the analysis described above assuming a loss of AC using the inputs from Table 15.1.14-23. The following are some differences from the above identified analysis:

A. The affected steam generator empties, the high pressurizer pressure trip condition occurs, and a low steam generator level trip on the intact steam generator all occur within 2 seconds of each other.

B. A low steam generator pressure trip condition does not occur until minutes after the high pressurizer pressure trip and low steam generator level trip conditions occur.

C. A reactor coolant system pressure of 2300 psia was assumed.

D. Steam generator initial pressure was 949 psia.

E. A moderator temperature coefficient of 0.0×10^{-4} $\Delta\rho$/°F was assumed.

F. A CEA worth at trip of -6.8×10^{-2} $\Delta\rho$ was assumed.

G. A tolerance limit of +1% on the primary side safety valves was accounted for.

H. A core mass flow rate of 115.5×10^{6} lbm/hr was conservatively assumed.

The results indicate that the reduction of the secondary heat sink due to the discharging of saturated water through the feedwater line break and the subsequent emptying of the affected steam generator cause the RCS pressure to increase to 2742 psia. Following reactor trip on high pressurizer pressure, the decay in core power and the action of the primary and secondary safety valves result in a reduction of the RCS pressure.

15.1.14.2.4.2 Cycle 13 Feedwater Line Break Analysis

The feedwater line break accident analysis with a loss of AC power was reanalyzed using CENTS to account for Cycle 13 physics data. This analysis was performed essentially consistent with the analyses described above assuming a loss of AC and using the inputs from Table 15.1.14-24. The analytical bases are discussed below.

A. The feedwater line break analyzed was assumed to occur during full power operation (2900 MWt) with a loss of offsite power at the time trip breakers open. With a loss of offsite power the turbine stop valves are assumed to close, the reactor coolant pumps begin to coast down, and the pressurizer control systems are lost.

B. A CEA insertion curve consistent with the CEA position versus time (including a 0.6 second holding coil delay time) of Figure 15.1.0-1D is used in this analysis; however, a more conservative normalized reactivity insertion versus CEA position for a +0.6 ASI curve was used. The minimum CEA worth assumed available for shutdown, with the most reactive CEA remaining in the fully withdrawn position, when the reactor is tripped is -5.0% $\Delta\rho$.

C. The Doppler curve assumed is consistent with the BOC curve in Figure 15.1.0-4 which already includes a 0.85 multiplier.

D. The initial intact steam generator liquid inventory was assumed to be 168,700 lbm and 93,060 lbm was assumed for the affected unit. These masses were used to ensure the coincidence trip conditions described below.

E. A low steam generator pressure trip does not occur until minutes after the high pressurizer pressure trip and low steam generator level trip conditions occur. This is similar to the Cycle 3 analysis.

F. Only flow from one EFW pump was credited to the steam generator with the intact feedwater line. Flow to this generator is based on a 36.3 second delay after a low steam generator pressure condition exists, which is 225 seconds after a low steam generator level condition occurs. This allows time for the EFW pumps to accelerate and flow to the affected steam generator to be isolated prior to crediting EFW flow to the intact steam generator.

G. A MSIS low steam generator pressure setpoint of 620 psia was assumed with a 1.3 second response time. A 3 second MSIV stroke time (4.3 second response time) and 35 second EFW isolation valve stroke time (36.3 second response time) were also assumed.

H. A conservatively small value for the fuel gap heat transfer coefficient was assumed corresponding to BOC.

I. The lift tolerance for the primary safety valves and secondary safety valves was assumed to be +3% of setpoint.

J. Decay heat was maximized by assuming equilibrium core conditions.

K. The Cycle 13 BOC delayed neutron fraction and EOC neutron lifetime consistent with Section 15.1.0.3 was assumed.

The conservative assumptions included in the feedwater line break simulation are discussed below.

The feedwater line break was assumed to occur during full power operation with concurrent loss of non-emergency AC power at the time of trip. This is limiting from the standpoint of potential RCS pressure increase, since this results in the maximum initial stored energy and minimum steam generator inventory.

A new limiting break size was established by a parametric study as part of this effort. Break size was revisited due to the use of CENTS versus CESEC. The new limiting break size has become that which is sized to pass all feedwater flow but not large enough to cause back flow from the ruptured steam generator. No back flow is modeled until after trip when the feedwater goes away. Feedwater is assumed to go to zero at the start of the event. The break area necessary to pass all feedwater is assumed to be 0.24 ft^2.

The steam generator heat transfer area is conservatively assumed to be fully available down to 19,000 lbm of liquid in the steam generator at which point the area is ramped down to zero at 2000 lbm.

It is conservatively assumed that the blowdown of the affected steam generator is saturated water, when in reality the blowdown would change to “two phase discharge” after the water level dropped below the feedwater ring.

The initial RCS pressure and initial steam generator inventories are selected such that the Low Steam Generator Water Level Trip on the intact steam generator and the High Pressurizer Pressure Trip occur simultaneously with the dryout of the affect steam generator. This results in the maximum peak RCS pressure after trip. A 1.3 second response time has been associated with the low steam generator level trip and a 0.9 second response time with the high pressurizer pressure trip. This difference in response time is reflected in the sequence of event.

The feedwater line break event was initiated at the conditions shown in Table 15.1.14-24. Table 15.1.14-25 presents the sequence of events for this transient. Figures 15.1.14-80 through 15.1.14-84 show the transient response of the key parameters. The results indicate that the reduction of the secondary heat sink and subsequent emptying of the affected steam generator cause the RCS pressure to increase to a maximum of 2730.1 psia. Following reactor trip on high pressurizer pressure/low steam generator (intact) water level, the decay in core power and the action of the PSVs and MSSVs results in a reduction of the RCS and steam generator pressures. The RCS pressure continues to decrease until low steam generator pressure initiates the closure of the MSIVs and MFIVs. The MSIV closure terminates the blowdown of steam from the intact steam generator through the break thus causing the RCS to heat up once more. This heatup is terminated by the opening of the MSSVs and initiation of emergency feedwater to the intact steam generator.

15.1.14.2.4.3 Cycle 15 Feedwater Line Break Analysis

The Feedwater Line Break (FWLB) with a loss of normal AC power event analysis was performed to determine the impact of the Cycle 15 changes including installation of the replacement steam generators.

The methodology used in this analysis has changed slightly from that used in the previous analysis. The previous method determined the limiting FWLB area by combining a simultaneous High Pressurizer Pressure Trip and Low Steam Generator Level Trip on the intact steam generator with a concurrent emptying of the affected steam generator. This required an overly conservative large initial mass difference between the two steam generators. The new method assumes both steam generators are at the same initial mass level. The limiting FWLB area is calculated based on a simultaneous High Pressurizer Pressure Trip and Low Steam Generator Level Trip on the intact steam generator. This is still considered a very conservative approach as no credit is taken for the low level trip in the affected steam generator and the fluid discharge through the break was assumed to be saturated liquid until the affected generator empties.

This analysis has utilized the CENTS computer code for the transient analysis simulation.

Input parameters from Table 15.1.14-46 and the bounding physics data from Section 15.1.0 have been incorporated in this analysis with the following clarifications:

1. The BOC Doppler curve in Figure 15.1.0-4 was assumed.
2. A BOC delayed neutron fraction and neutron lifetime consistent with those defined in Section 15.1.0.3 were assumed.
3. The CEA reactivity insertion curve in Figure 15.1.0-1D was assumed. This curve accounts for a 0.6 second holding coil delay. The curve is consistent with that used in most analyses versus a curve associated with a +0.6 ASI as was used for the Cycle 13 analysis. A CEA worth of -5.0% $\Delta\rho$ was conservatively assumed.
4. The feedwater line break analyzed was assumed to occur during hot full power operation with a loss of offsite power at the time that the trip breakers opened. With a loss of offsite power the turbine stop valves are assumed to close, RCPs begin to coast down, and the pressurizer control systems are lost.
5. The initial steam generator liquid inventory for both steam generators was assumed to be 178,500 lbm.
6. A parametric analysis was performed to determine the FWLB area (0.1798 ft^2) such that a simultaneous trip occurred on High Pressurizer Pressure and Low Steam Generator Level of the intact steam generator. A High Pressurizer Pressure Trip analytical setpoint of 2415 psia with a delay time of 0.65 seconds was assumed. A Low Steam Generator Level Trip analytical setpoint of 6% of narrow range indication with a 1.3 second response time was assumed. This is different than the previous analysis, which assumed a concurrent emptying of the affected steam generator. The analytical trip setpoints for the High Pressurizer Pressure Trip conservatively assumes a harsh environment uncertainty and the Low Steam Generator Level Trip assumes an abnormal environment uncertainty.

7. Only EFW flow from one EFW pump was credited to the steam generator with the intact feedwater line. A conservative EFW flow analytical actuation setpoint of 0% of narrow range indication was assumed with a delay time of 112.4 seconds. The uncertainty associated with the setpoint for EFW flow actuation is based on a harsh environment uncertainty. The time of EFW flow delivery to this generator was based on the maximum of:

   a) the time to receive an EFAS with a delay period that allows the EFW pump to accelerate, or

   b) the time to receive an MSIS with a delay period that allows EFW flow to the affected steam generator to be isolated, or

   c) the time the steam generator ΔP setpoint is reached with a delay period that allows EFW flow to the intact steam generator to be re-initiated.

   Isolation of EFW to the affected steam generator is based on the EFW valve isolation time of 36.4 seconds. EFW flow rate to the intact steam generator is dependent on steam generator pressure.

8. An MSIS analytical setpoint of 658 psia was assumed with a 1.4 second response time, a 3.5 second MSIV closure time, and a 35 second EFW isolation valve stroke time. A high ΔP analytical setpoint of 220 psid was assumed with a 1.4-second response time and a 35-second EFW isolation valve stroke time.

9. A conservatively small value for the fuel gap heat transfer coefficient was assumed corresponding to BOC.

10. An MSSV lift tolerance of +3% and PSV lift tolerance of +3.2% were assumed.

11. An initial core power of 2900 MWt, based on a rated power of 2815 MWt and a 3% uncertainty, was assumed.

12. The BOC MTC of -0.2×10^{-4} $\Delta\rho$/°F was assumed.

13. Assuming equilibrium core conditions maximized decay heat.

14. The analysis considered plugged U-tubes between zero and 10% plugged range per steam generator, with zero percent being conservative.

15. Installation of the RSGs was assumed.

16. A minimum RCS flow of 315,560 gpm was assumed

17. An initial steam generator pressure of 1000 psia was assumed.

18. The PSV flow was adjusted by the Napier correction.

19. Steam generator full heat transfer area is conservatively assumed down to 19,000 lbm (liquid mass). At 19,000 lbm, the steam generator heat transfer is assumed to ramp linearly to zero at 2000 lbm.

The peak RCS and steam generator pressures remained below the respective criteria of 2750 psia and 1210 psia, and the pressurizer did not fill solid with liquid.

The NSSS, RPS, and EFW system responses for the FWLB with loss of AC power on turbine trip event are shown in Table 15.1.14-47 and in Figures 15.1.14-138 through 15.1.14-142.

The combination of the replacement steam generators, an increase in minimum RCS flow, the change in the analytical Low Steam Generator Level Trip and EFAS setpoints, and the change in the analytical MSIS setpoint did not result in the RCS and steam generator pressures exceeding criteria and a pressurizer over-fill did not occur.

15.1.14.2.4.4 <u>Cycle 16 Feedwater Line Break Analysis</u>

The Feedwater Line Break (FWLB) with a loss of normal AC power event analysis was performed to determine the impact of the Cycle 16 changes including a power uprate to a nominal full power of 3026 Mwt.

The methodology used in this analysis has changed slightly from that used in the previous analysis. The previous method determined the limiting FWLB area by combining a simultaneous High Pressurizer Pressure Trip and Low Steam Generator Level Trip on the intact steam generator. The new method assumes that a Low Steam Generator Level Trip on the affected steam generator will occur with 40,000 lbm liquid inventory remaining in the steam generator. The limiting FWLB area is calculated based on a simultaneous High Pressurizer Pressure Trip and Low Steam Generator Level Trip on the affected steam generator at 40,000 lbm. This is still considered a very conservative approach as the fluid discharge through the break was assumed to be saturated liquid until the affected generator empties.

The initial pressurizer pressure which allows simultaneous trips with ruptured steam generator low level, as discussed above, is 2300 psia. This is different from previous analyses where the lowest allowable initial pressurizer pressure, 2000 psia, provided the limiting transient RCS pressure.

This analysis has utilized the CENTS computer code for the transient analysis simulation and NOTRUMP for determining the liquid inventory in the faulted steam generator at the low-level trip setpoint.

Input parameters from Table 15.1.14-48 and the bounding physics data from Section 15.1.0 have been incorporated in this analysis with the following clarifications:

1. The BOC Doppler curve in Figure 15.1.0-4 was assumed.

2. A BOC delayed neutron fraction and neutron lifetime consistent with those defined in Section 15.1.0.3 was assumed.

3. The CEA insertion curve in Figure 15.1.0-1D was assumed. This curve accounts for a 0.6 second holding coil delay. A CEA worth of -5.0% $\Delta\rho$ was conservatively assumed.

4. The feedwater line break analysis was assumed to occur during hot full power operation with a loss of offsite power at the time that the trip breakers opened. With a loss of offsite power the turbine stop valves are assumed to close, RCPs begin to coast down, and the pressurizer control systems are lost.

5. The initial steam generator liquid inventory for both steam generators was assumed to be 164,400 lbm.

6. A parametric analysis was performed to determine the FWLB area (0.1492 ft^2) such that a simultaneous trip occurred on High Pressurizer Pressure and Low Steam Generator Level of the affected steam generator at 40,000 lbm liquid inventory. A High Pressurizer Pressure Trip analytical setpoint of 2415 psia with a delay time of 0.90 seconds was assumed. A Low Steam Generator Level Trip response time of 1.3 seconds was assumed. This is different than the previous analysis, which assumed a Low Steam Generator Level Trip at 6% narrow range level on the intact steam generator. The analytical trip setpoints for the High Pressurizer Pressure Trip conservatively assumes a harsh environment uncertainty.

7. Only EFW flow from one EFW pump was credited to the steam generator with the intact feedwater line. A conservative EFW flow actuation setpoint of 0% of narrow range was assumed with a delay time of 112.4 seconds. The uncertainty assumed on the EFW flow actuation setpoint is based on a harsh environment uncertainty. The time of EFW flow delivery to this generator was based on the maximum of:

   a) the time to receive an EFAS with a delay period that allows the EFW pump to accelerate, or

   b) the time to receive a MSIS with a delay period that allows EFW flow to the affected steam generator to be isolated, or

   c) the time the steam generator $\Delta\rho$ setpoint is reached with a delay period that allows EFW flow to the intact steam generator to be re-initiated. Isolation of EFW to the affected steam generator is based on the EFW valve isolation time of 36.4 seconds. EFW flow rate to the intact steam generator is dependent on steam generator pressure.

8. A MSIS analytical setpoint of 905 psia was assumed with no delay in response time, instantaneous MSIV closure time, and a 35 second EFW isolation valve stroke time. A high $\Delta\rho$ analytical setpoint of 220 psid was assumed with a 1.4-second response time and a 35-second EFW isolation valve stroke time. This is a modification to the previous analysis which assumed a minimum MSIS analytical setpoint pressure of 658 psia and a maximum response time delay and MSIV valve closure time. For the current analysis, a maximum MSIS setpoint minimizes the cooldown of the RCS. In the previous analysis, a minimum setpoint was used to provide maximum depletion of the intact steam generator inventory. For this analysis, intact steam generator inventory depletion is mitigated by the affected steam generator low level trip.

9. A conservatively small value for the fuel gap heat transfer coefficient was assumed corresponding to BOC.

10. A MSSV lift tolerance of +3.5% and PSV lift tolerance of +3.2% were assumed.

11. An initial core power of 3087 MWt was assumed, based on a rated power of 3026 MWt and a 2% uncertainty.

12. The BOC MTC of $-0.2 \times 10^{-4}\ \Delta\rho/°F$ was assumed.

13. Assuming equilibrium core conditions maximized decay heat.

14. The analysis considered plugged U-tubes between zero and 10% plugged range per steam generator, with zero percent being conservative.

15. Installation of the RSGs was assumed.

16. A minimum RCS flow of 315,560 gpm was assumed.

17. An initial steam generator pressure of 999 psia was assumed.

18. The PSV flow was adjusted by the Napier correction.

19. Steam generator full heat transfer area is conservatively assumed down to 19,000 lbm (liquid mass). At 19,000 lbm, the steam generator heat transfer is assumed to ramp linearly to zero at 2000 lbm.

20. An initial pressurizer pressure of 2300 psia was assumed.

The peak RCS and secondary system pressures remained below the respective criteria of 2750 psia and 1210 psia, and the pressurizer did not fill solid with liquid. The NSSS, RPS, and EFW system responses for the FWLB with loss of AC power on turbine trip event are shown in Table 15.1.14-49 and in Figures 15.1.14-143 through 15.1.14-147.

The combination of the increased core power, the change in the analytical Low Steam Generator Level Trip methodology, and the change in the analytical MSIS setpoint and response did not result in the RCS and secondary system pressures exceeding criteria and a pressurizer overfill did not occur.

15.1.14.3 Additional Main Steam Line/Feedwater Line Break Information and Analyses

Additional analyses and information are contained in correspondence to the NRC. These are included in the reference section at the end of this chapter.

15.1.15 INADVERTENT LOADING OF A FUEL ASSEMBLY INTO THE IMPROPER POSITION

15.1.15.1 Identification of Causes

Two accidents are considered in this section: 1) the erroneous loading of fuel pellets or fuel rods of different enrichment in a fuel assembly; and, 2) the erroneous placement or orientation of fuel assemblies.

The likelihood of an error in assembly, fabrication, or core loading is considered to be extremely remote because of the extensive quality control and quality surveillance programs employed during the fabrication process as well as the strict procedural control used during core loading. However, even if the core were to have incorrectly placed fuel rods or assemblies, these would either be detectable from the results of the startup or would lead to a minimal number of rods with excessive power during full power operation.

15.1.15.1.1 Erroneous Loading of Fuel Pellets or Fuel Pins of Different Enrichment in a Fuel Assembly

The probability of manufacturing a fuel assembly with an incorrect enrichment is considered an unlikely event. The extensive quality control and quality surveillance programs in effect during the manufacture of the fuel pellets, in the loading of the fuel rods and in the assembly of the fuel bundles preclude the possibility of manufacturing a fuel bundle with an incorrect enrichment(s).

During the manufacture and assembly of the fuel rods, numerous check points and assay tests ensure that the enrichment is as specified and that the fuel rods and fuel assemblies are properly loaded and assembled. An assay is made of each lot of UO_2 powder to ensure that the enrichment is as required by the fuel specification. During the manufacture of the pellets, each powder lot is isolated during processing. After sintering, an additional enrichment check of the fabricated pellets is made by random sampling. Assembly of the fuel rods is performed by loading the fuel pellets into cladding onto which one end cap has been welded. With the exception of some Batch U fuel rods, the end cap is marked prior to welding, thereby identifying the enrichment to be loaded into the fuel rod. Beginning with Batch U, individual fuel rods will be marked with laser etched bar codes, providing additional means of identifying and tracking each rod.

During assembly of the fuel bundle, the quality control procedures require verification of each fuel rod in the assembly. Each fuel assembly is identified by a serial number which is engraved on the upper assembly plate in a prominent location.

A record of all operations performed on each fuel rod up to and including final assembly into the fuel bundle is recorded by computer. This procedure permits a rapid check at completion of fabrication to ensure that each rod within the fuel assembly has completed all of the required steps within the fabrication process. The computerized recordkeeping system also has the advantage of providing a mechanism by which an accurate record of all fuel rods within a fuel assembly can be defined as well as the enrichment, weight of U^{235} and UO_2, and lot number of the fuel within each fuel rod.

If, however, it is assumed that an assembly is fabricated with some fuel rods made up entirely of the wrong enrichment pellets, then assumptions must be made as to the location and enrichments of these pins.

15.1.15.1.2 Erroneous Placement or Orientation of Fuel Assemblies

The fuel enrichment(s) within a fuel assembly is identified by a coded serial number marked on the exposed surface of the top end plate of the fuel assembly. This serial number is used as a means of positive identification for each assembly in the plant. During the period of core loading, a tag board or computer monitoring system is provided in the control room showing a schematic representation of the reactor core, spent fuel pool and new fuel storage area. The location of each CEA, fuel assembly, and source will be shown on this tag board or computer monitoring system. The tag board or computer monitoring system will be updated in the control room whenever a fuel assembly is moved. The tag board or computer monitoring system operator will be in constant communication with the area where this occurs. Also, a licensed senior reactor operator or senior reactor operator limited to fuel handling will be present in the area to supervise core alterations and ensure that the assemblies are moved to the correct locations. Fuel assemblies will not be moved unless these lines of communication are available. In addition to these precautions, independent inventories of components in the

reactor core and spent fuel storage areas will be made when fuel movement is complete to ensure that the tag board or computer monitoring system is correct. At the completion of core loading, the exposed surfaces of the top end plates are inspected to verify that all assemblies are correctly located. These precautions are included in the core loading procedures which are to be reviewed by appropriate plant personnel.

If, however, in spite of these precautions it is assumed that an assembly is placed in the wrong core position, then many possibilities exist. Probably the worst situation would be the interchange of two assemblies of different reactivities.

15.1.15.2 Analysis of Effects and Consequences

15.1.15.2.1 Erroneous Loading of Fuel Pellets or Fuel Pins of Different Enrichment in a Fuel Assembly

If the enrichment loaded into an assembly is lower than expected or if the misloaded rod or pellet is in an assembly that is not near the peak power density, then the core performance would not be adversely affected.

If the enrichment loaded into an assembly is higher than expected, the magnitude of the local peaking factor increase would depend on several conditions that must be postulated arbitrarily, such as the number of rods replaced by higher enrichment rods and the location of these rods with respect to water holes. At one end of the scale of postulated situations, the increased local peaking would be too small to adversely affect core performance during conditions of normal operation or under accident conditions. These errors may go undetected. Fuel loading errors that cause local power peaking increases large enough to adversely affect core performance under normal or accident conditions will be detectable through the use of in-core instrumentation during startup testing.

15.1.15.2.2 Erroneous Placement or Orientation of Fuel Assemblies

If, in spite of the extreme precautions described above, it is postulated that a fuel assembly is misloaded, several situations may be postulated. The misloading of a fuel assembly may affect the core power distribution only slightly, for example, if assemblies of similar enrichments and reactivities are misloaded. Alternatively, the core power distribution may be affected enough so that core performance would be affected if assemblies having different enrichments or reactivities are misloaded.

In the unlikely event that two assemblies of different enrichments would be interchanged, the misloading would be detected using core power distribution data from the fixed in-core detectors. See Section 4.5 for description of the Core Power Distribution Testing.

The fuel misloading event was considered for power uprate conditions to 3026 MWt. The analysis showed that the ability to detect core misloadings using incore detectors is not degraded due to the power uprate.

The minimum required over-power margin (ROPM) set aside in the setpoint analysis to protect the linear heat generation rate (LHGR) and DNB SAFDLs for the non-LOCA safety analysis AOOs (rod drop, loss of flow, CEAW, etc.) is available to offset the increase in peaking associated with assembly misloadings. Since the maximum increase in peaking associated with the representative assembly misloading (a detectable assembly misloading) is bounded by the minimum ROPM, the LHGR and DNB SAFDLs will not be violated.

15.1.15.2.3 Additional Fuel Misloading Analyses for Reload Cycles

The fuel misloading accident is analyzed for the first cycle and for Power Uprate to 3026 MWt. However, the fuel misloading event is not reanalyzed for reload cycles or reported in the reload licensing submittal. For additional information on fuel misloading, see letter of May 1981 (2CAN058112) regarding analyses done at other CE plants and CE Report CE NPSD-366, "Verification of Control Rod Integrity and Fuel Symmetry."

15.1.16 WASTE GAS DECAY TANK LEAKAGE OR RUPTURE

15.1.16.1 Identification of Causes

The most limiting waste gas accident is an unexpected and uncontrolled release to the atmosphere of the radioactive xenon and krypton fission gases that are stored in one waste gas decay tank. The Gaseous Waste System (GWS) is described in Section 11.3.

Since the waste gas decay tanks are Seismic Category I and Quality Group D, and since they are normally not subjected to pressures greater than 250 psig (design pressure 380 psig), a failure is unlikely. However, a rupture of a waste gas decay tank is analyzed to determine the limiting result from any malfunction in the GWS.

15.1.16.2 Analysis of Events and Consequences

Assumptions and methods used in this analysis are consistent with those of Branch Technical Position ETSB 11-5. The quantity of radioactivity contained in a single tank has been limited to a curie value which will prevent a member of the public at the exclusion area boundary from receiving a total body exposure exceeding 0.5 Rem in a 2-hour period. This is consistent with NUREG-0800, BTP ETSB 11-5, July 1981.

15.1.17 FAILURE OF AIR EJECTOR LINES (BWR)

Unit 2 is a Pressurized Water Reactor (PWR), and this event is not applicable.

15.1.18 STEAM GENERATOR TUBE RUPTURE WITH OR WITHOUT A CONCURRENT LOSS OF AC POWER

15.1.18.1 Identification of Causes

The steam generator tube rupture accident with or without a loss of AC power is a penetration of the barrier between the RCS and the main steam system. Integrity of this barrier is significant from a radiological standpoint, since a leaking steam generator tube would allow transport of reactor coolant into the main steam system. Radioactivity contained in the reactor coolant would mix with shellside water in the affected steam generator. This radioactivity would be transported through the turbine to the condenser, where the noncondensible radioactive materials would be released to the auxiliary building ventilation system via the condenser vacuum pumps.

CE's experience with nuclear steam generators indicates the probability of complete severance of the Inconel vertical U-tubes is remote. No such double-ended rupture has ever occurred in a CE steam generator of this design. The more probable modes of failure result in considerably

smaller penetrations of the pressure barrier. They involve the formation of etch pits or small cracks in the U-tubes or cracks in the welds joining the tubes to the tubesheet.

Diagnosis of the accident is facilitated by radiation monitors in the condenser vacuum pump outlet lines and in the steam generator continuous sample lines. These monitors initiate alarms in the control room to inform the operator of abnormal activity levels.

Behavior of the systems varies depending upon the size of the rupture. For leak rates up to the capacity of the charging pumps, reactor coolant inventory can be maintained and an automatic reactor trip would not occur. The gaseous fission products would be released to the station stack (containment building flutes) through filter units from the secondary system at the condenser vacuum pump discharge.

The amount of radioactivity released increases with the size of the tube failure. For radiological analyses, a leakage area equivalent to a double-ended break of one steam generator tube is assumed. At normal operating conditions the leak rate through the double-ended rupture of one tube would have a maximum flow rate of 52 lb/sec. This exceeds the maximum flow rate available from the charging pumps (18 lb/sec). Therefore, the RCS pressure decreases until a low DNBR trip occurs. Following the reactor trip, the reactor coolant temperature is normally reduced by exhausting steam through the dump and bypass system. The radioactivity exhausted through this system flows to the condenser, where the noncondensible gaseous products are removed via the condenser vacuum pump.

The bypass valves in the dump and bypass system modulate closed to regulate the secondary pressure to the programmed value following the reactor trip. At zero power, the steam bypass controller functions to maintain secondary pressure of 1,000 psia and, in order to cooldown the RCS, the valve must be manually controlled for pressure below 1,000 psia. When the reactor coolant temperature is below 300 °F, the operator can place the shutdown cooling system into operation and terminate RCS heat removal via the steam generators.

For the case with concurrent loss of AC power, the RCS pressure also decreases after the initial pressure transient associated with the loss of AC power. As a result of the loss of AC electrical power would not be available for the station auxiliaries such as the reactor coolant pumps, the steam generator feedwater pumps, and the main circulating water pumps. Under such circumstances, the plant would experience a simultaneous loss of load, feedwater flow, and forced reactor coolant flow.

The loss of all station power is followed by automatic startup of the standby diesel generators, the power output of which is sufficient to supply electrical power to all engineered safety features and to provide the capability of maintaining the plant in a safe shutdown condition.

Subsequent to reactor trip, stored and fission product decay energy must be dissipated by the reactor coolant and steam generator systems. In the absence of forced reactor coolant flow, convective heat transfer into and out of the reactor core is supported by natural circulation reactor coolant flow. Initially, the residual water inventory in the steam generators is used and the resultant steam is released to atmosphere via the self-actuated steam generator safety valves. With the availability of standby power, emergency feedwater is automatically initiated on a low steam generator water level signal and plant cooldown is operator controlled via remotely operated atmosphere dump valves.

The low DNBR trip will prevent the DNB safety limit from being exceeded as a result of this transient. In addition, the pressurizer and secondary safety valves will prevent the RCS pressure and secondary system pressure from exceeding 110 percent of their design values.

15.1.18.2 – 15.1.18.3 REMOVED – HISTORICAL DATA

15.1.18.4 SGTR Subsequent Analyses

15.1.18.4.1 REMOVED – HISTORICAL DATA

15.1.18.4.2 Cycle 15 Steam Generator Tube Rupture With or Without a Concurrent Loss of AC Power

A Steam Generator Tube Rupture with and without a LOAC event evaluation was performed for Cycle 15 to determine the impact of the RSGs. The method used for the evaluation was a comparison of changes in key input parameters between those of the previous analysis versus the new data due to the RSGs.

The major change is the actual steam generator. The RSG consists of the following:

1. A larger secondary side volume of 8172 ft^3 versus 7957 ft^3

2. A larger number of U-tubes per steam generator of 10,637 versus 8411

3. A smaller U-tube inside diameter of 0.608 inches versus 0.654 inches

4. Different U-tube loss coefficients (longer active and inactive U-tube lengths)

5. Higher steam generator operating pressure

An engineering evaluation of changes in key input data was employed to assess the impact on the SGTR events. No computer codes were used. The comparison of key input parameters demonstrated that all values were either the same or conservative for Cycle 15, except for some RSG data. The major driving force is the leak rate from the broken U-tube. The leak rate for the RSG would be lower than for the original steam generator due to the following:

1. The smaller U-tube diameter results in a smaller flow that is directly proportional to the square of the diameter. This alone results in reduction in U-tube leak rates of 13%.

2. The higher secondary side pressure results in a lower pre-trip delta-pressure from primary to secondary system.

3. A comparison of the U-tube flow resistances resulted in a reduction of the U-tube leak rate of at least 5% due to a larger U-tube flow resistance.

Since the U-tube leak rate is less, the primary mass released to the affected steam generator would be less than that documented hence no increase in radiological doses. Due to the bounding nature of the previous analysis, this event was not reanalyzed.

15.1.18.4.3 Power Uprate (Rated Power 3026 MWt) Steam Generator Tube Rupture with a Concurrent Loss of AC Power

15.1.18.4.3.1 Assumptions and Conditions

Subsequent evaluation of a steam generator tube rupture with a concurrent loss of AC power analysis was performed to address Power Uprate to 3026 MWt at Hot Full Power. The CENTS code was used to perform the analysis.

The SGTR with concurrent LOAC event was analyzed to determine the radiological doses for the 2-hour exclusion area boundary (EAB) and the 8-hour low population zone (LPZ) doses. Since the steam releases for this event are directly to the atmosphere via the MSSVs and the intact steam generator atmospheric dump valve, it bounds the radiological doses for the SGTR event with AC power available. Hence, only the SGTR event with concurrent LOAC was analyzed.

Input parameters from Table 15.1.18-5 and the bounding physics data from Section 15.1.0 were incorporated in this analysis with these following clarifications:

A. Installation of the replacement steam generators was assumed.

B. An initial RCS flow of 315,560 gpm was assumed.

C. Core power of 3087 MWt. [3026 MWt plus 2% uncertainty]

D. Emergency Feedwater Actuation Signal setpoint is assumed at 41% narrow range.

E. An initial steam generator pressure of 960 psia was assumed.

F. A SIAS is actuated when the pressurizer pressure drops below 1800 psia. Time delays associated with the safety injection pump acceleration and valve opening are taken into account. A 10 second HPSI response time was assumed to account for these delays.

G. For the analysis, at time zero, when all electrical power is lost to the station auxiliaries, the following is assumed to occur:

   1. The turbine stop valves close and it is assumed that the area of the turbine admission valves is reduced to zero at the minimum closing rate

   2. The steam generator feedwater flow to both steam generators is assumed to go to zero within 10 seconds.

   3. The reactor coolant pumps begin to coastdown and following coastdown the coolant flow necessary to remove residual heat and to cool the reactor core is maintained by natural circulation.

   4. Charging and letdown flow is reduced to zero. Upon initiation of SIAS, the charging flow instantaneously resumes at maximum capacity.

   5. The steam dump and bypass control system is unavailable for post-trip steam releases.

H. A CPCS low reactor coolant pump shaft speed trip setpoint of 95% and a total delay time of 1.0 second were conservatively assumed. CPCS initiates a reactor trip when the reactor coolant pump shaft speed drops below 95% of its nominal speed.

I. The most negative MTC of -3.8 X 10^{-4} $\Delta\rho$/°F was assumed.

J. The EOC Doppler curve in Figure 15.1.0-4, was assumed.

K. The BOC delayed neutron fraction consistent with those defined in Section 15.1.0.3 was assumed.

L. The CEA insertion curve of Figure 15.1.0-1D was assumed. This curve accounts for a 0.6 second holding coil delay. A CEA worth of -5.0% $\Delta\rho$ was conservatively assumed.

M. An initial maximum core inlet temperature of 556.7 °F was assumed.

N. An initial pressurizer pressure of 2300 psia was assumed.

O. A loss of AC power concurrent with a guillotine rupture of a single U-tube was assumed.

P. Sixty minutes after the tube rupture, the operator has determined which steam generator contains the ruptured tube and isolates the affected steam generator from the main steam system by closing the MSIV.

15.1.18.4.3.2 <u>Results</u>

Figures 15.1.18-17 through 15.1.18-24, and Table 15.1.18-6 presents the transient resulting from a steam generator tube rupture with a concurrent loss of AC power. The steam generator liquid inventory versus time is presented in Figure 15.1.18-23. Figure 15.1.18-24 provides the discharge rate out through the secondary safety valves. During the first 60 minutes following the initiation transient, < 122,500 lbs. of reactor coolant was transported to the main steam system. For this case, radioactivity can only be transported to the surrounding environment by the steam released through the secondary safety valves or atmospheric dump valves. During the first 60 minutes of the transient, 362,000 lbs. of steam were released out the secondary safety valves. The total secondary release within the first 2 hours for the EAB considerations was approximately 635,000 lbm and for the first 8 hours for the LPZ considerations was approximately 1,772,000 lbm.

15.1.18.4.4 <u>AST SGTR Analysis</u>

The analysis input and assumptions used in the calculation of the radiological dose releases for the SGTR event are discussed in Sections 15.1.0.5.5 and 15.1.0.5.6 with the following clarifications:

1. The condenser is assumed unavailable for cooldown. Thus, the entire cooldown was performed by dumping steam to the atmosphere from the intact steam generator.

2. An RCS primary to secondary leakage rate of 150 gpd for the intact steam generator was assumed.

3. Since the SGTR with concurrent loss of AC power event does not result in fuel failure, only the maximum initial RCS activity plus iodine spiking was analyzed.

4. A SG flashing fraction of 0.05 was assumed based on primary fluid and steam generator conditions. No credit for steam generator level recovery and tubes re-submergence, which will occur in approximately 1 hour, has been taken.

5. RCS liquid masses of 454,000 lbm (maximum, to produce largest equilibrium appearance rate) and 432,000 lbm (minimum, to maximize concentrations) are assumed.

Event-generated iodine and preexisting iodine spiking cases were performed for this analysis.

Tables 15.1.18-7 and 15.1.18-8 presents the radioiogical doses associated with this event for the exclusion area (EAB), and the low population zone (LPZ). For these locations the TEDE doses received are shown for the event-generated iodine spiking (GIS) and pre-existing iodine spiking (PIS) conditions.

The radiological releases for a steam generator tube rupture with or without a concurrent loss of AC power are less than the 10 CFR 50.67 guidelines.

15.1.19 FAILURE OF CHARCOAL OR CRYOGENIC SYSTEM (BWR)

Unit 2 utilizes a PWR. This event is not applicable.

15.1.20 CONTROL ELEMENT ASSEMBLY EJECTION

15.1.20.1 Identification of Causes

Rapid ejection of a CEA from the core would require a complete circumferential rupture of the CEDM housing or the CEDM nozzle. The CEDM housing and nozzle are part of the RCPB and are designed and manufactured in compliance with the ASME Code, Section III. Hence, the occurrence of such a failure is considered highly unlikely.

A typical CEA ejection transient behaves in the following manner. After ejection of a CEA from the full power or zero power (critical) initial conditions, the core power rises rapidly for a brief period. The rise is terminated by the Doppler effect. Reactor shutdown is initiated by the high linear power level trip or CPC DNBR trip (based on VOPT), which limit the maximum enthalpy in the fuel during the transient to an acceptable value.

The consequences of the loss of coolant resulting from the RCS rupture are similar to those for small breaks as discussed in Section 6.3.3.

15.1.20.2 Analysis of Effects and Consequences

15.1.20.2.1 Method of Analysis

In the analysis performed to support the operation of Cycle 1, the reactivity forced power transient was simulated by a digital computer program (CHIC-KIN) which simultaneously solves the one velocity neutron point kinetics equations together with the time and space dependent

thermal and hydraulics equations for heat generation and transport within a single channel (Reference 27). The kinetics model incorporates the standard 6-delay group representation along with explicit reactivity contributions from CEA motion, Doppler effect, and moderator density variations. By simulating the core average channel, the CHIC-KIN code computes the total core power generated during the course of the transient.

In the CEA ejection transient, the principal reactivity feedback mechanism affecting the nuclear transient is the Doppler effect. In the point kinetics approach utilized in CHIC-KIN, a spatial Doppler weighting factor accounts for the fact that the Doppler feedback effect is a function of the spatial flux distribution. Although the axial shape does not change significantly during the course of a CEA ejection accident, the radial peak undergoes marked changes. In order to represent the radial Doppler effect, an analysis was performed in which point kinetics calculations were compared with space-time diffusion theory results, for various radial slices, obtained with a CE modified version of the TWIGL code (Reference 45). The radial Doppler weighting factor, W_R, was thus obtained as a function of the ejected CEA worth such that CHIC-KIN and TWIGL results gave the same total core energy release. The values of the radial Doppler weighting factors used in the analysis were obtained from a straight line relationship of Doppler weighting as a function of ejected CEA worth. For conservatism, the straight line was drawn such that the weighting factor was unity for zero ejected CEA worth and was at least 20 percent below all data points.

The results of the space-time analysis have demonstrated that the use of the static, non-Doppler flattened radial fuel rod peaking factors, as obtained from two-dimensional diffusion theory results, in conjunction with the average core energy release as obtained from the point kinetics results, yields hot spot energy releases which are conservative. This results from the lack of consideration of the fact that the Doppler effect during a transient is strongest at the radial peak location, limiting the radial peak to a value below that obtained from the static ejected CEA configuration for the major portion of the transient. The effective transient radial peaking factor is defined as the ratio of the energy rise in the hot fuel rod to the core average energy rise. The ratio of this effective radial peaking factor to the static peaking factor was determined as a function of the ejected CEA worth, and a straight line is used in the analysis to obtain a reduction factor (K) which is used in conjunction with the static radial fuel rod peaking factor and the average core energy release.

The average energy rise in the hottest fuel pellet is obtained from the following relationship:

$$\Delta E_H = [(P/A)_H \times \Delta E_{Ave} \times K] - E_{HT} \qquad \text{Equation 15.1.20-1}$$

where ΔE_{Ave} is the average core energy rise obtained from CHIC-KIN; $(P/A)_H$ (the three-dimensional fuel rod peaking factor) is the ratio of the hot spot power to the average core power obtained from static, non-Doppler flattened diffusion theory calculations; K is the reduction factor defined above; and E_{HT} accounts for heat that is transferred out of the fuel rod during the transient. A conservative calculation of E_{HT} is made by assuming that a post-DNB surface coefficient exists throughout the transient (Reference 10).

The average energy in the hottest fuel pellet at the beginning of the transient is added to the net average energy rise in the hottest fuel pellet as obtained from Equation 15.1.20-1 to determine the total average enthalpy in the hottest fuel spot in the core. A similar procedure is used to compute the total centerline enthalpy in the hottest fuel spot. The initial energy is obtained from the initial local fuel temperature along with an empirical temperature-enthalpy relationship (Reference 11).

The variation of the core local-to-average power ratio with core volume results from the convolution of the axial and radial power distributions for the post-ejection condition, which are based on static core physics calculations. Combining these results with the total average and centerline enthalpies in the hottest fuel spot yields the fractions of fuel with specific total average and centerline enthalpies. The calculated enthalpy values are compared to threshold enthalpy values to determine the amount of fuel experiencing the various degrees of fuel damage. These threshold enthalpy values are as follows (See References 2, 3 and 11):

Clad Damage Threshold:
Total Average Enthalpy = 200 cal/gm

Incipient Centerline Melting Threshold:
Total Centerline Enthalpy = 250 cal/gm

Fully Molten Centerline Threshold:
Total Centerline Enthalpy = 310 cal/gm

The criterion for determining the radioactive fission product release during a CEA ejection is that any fuel rod that exceeds a total average enthalpy of 200 cal/gm releases all of its gap activity.

The CEA ejection is assumed to occur at steady state initial conditions. Four analyses were performed; at BOC and EOC for ultimate full power (2,900 MWt) and zero power (1 MWt.).

These cases represent boundary conditions with respect to reactor operation; the consequences of a CEA ejection incident under other circumstances will be within the range determined from these cases.

For each of the above boundary cases, input parameters for power peaking and ejected CEA worth were selected on the basis of a calculational survey which determined the worst cases. In all cases analyzed, the highest three-dimensional power peak resulted when the maximum reactivity worth CEA was ejected. All calculated ejected CEA worths and three-dimensional peaking factors were increased by 10 percent to account for calculational uncertainties.

The significant independent variables for the full power CEA ejection accident are given in Table 15.1.20-1 and the significant independent variables for the zero power CEA ejection accident are given in Table 15.1.20-2.

Ejected CEA worths and peaking factors for several representative cases at full power are shown in Table 15.1.20-5. Table 15.1.20-6 shows representative cases at zero power. The rod locations corresponding to the lettering scheme used in these tables is shown in Figure 15.1.20-7.

It has been noted that the zero power ejected CEA worth at EOC is less than the worth at BOC. The difference in the worths of the ejected CEA shown in Table 15.1.20-2 between BOC and EOC is accounted for by differences in the reference radial power distributions at hot zero power in combination with the location of the worst ejected CEA. The worst ejected CEA at BOC is in a more important region of the core relative to its location at EOC; hence, it has a greater worth.

The axial power distribution used in this analysis for the fuel enthalpy and DNBR calculations is given in Table 15.1.20-7.

15.1.20.2.2 Results

The transients power generation for the full power BOC and EOC CEA ejection accidents are shown in Figure 15.1.20-1. Significant results for the full power CEA ejection accident are given in Table 15.1.20-3.

The reactivity contributions due to the ejected CEA, insertion of the shutdown CEAs and the feedback effects of fuel and moderator temperature changes for the full power BOC and EOC cases are shown in Figures 15.1.20-3 and 15.1.20-4, respectively. Any changes in the reactivity due to the effects of voids and pressure changes are small compared to the other contributing mechanisms and, therefore, are not included in the analysis.

The transient power generation for zero power BOC and EOC CEA ejection accidents are shown in Figure 15.1.20-2. Significant results for the zero power CEA ejection accident are given in Table 15.1.20-4.

The reactivity contributions due to the CEA ejection, insertion of the shutdown CEAs and the feedback effects of fuel and moderator temperature changes for the zero power EOC and BOC cases are shown in Figures 15.1.20-5 and 15.1.20-6, respectively.

Clad damage may occur during a CEA ejection at zero power for BOC and EOC. The conservative analysis indicates that 2.5 and 4.1 percent of the total number of rods suffer clad damage at zero power for BOC and EOC, respectively. This conservative estimate of clad damage has been made in accordance with the methods described in Section 15.1.20.2.1 and References 2, 3 and 11. The method relies upon comparison of calculate peak rod enthalpy values to the clad damage threshold value of 200 cal/gm. The calculated peak rod enthalpy values are contained in Tables 15.1.20-3 and 15.1.20-4. It is assumed that any rod which exceeds a total average enthalpy of 200 cal/gm experiences cladding damage and releases all of its gap activity. In addition to the above, Regulatory Guide 1.77 recommends that a minimum DNBR of 1.3 be used as the basis for predicting clad failure. CE does not equate a DNBR of 1.3 with the onset of cladding damage. Nevertheless, the fraction of rods below a DNBR of 1.3 is given below:

A. Full Power CEA Ejection Accident Results

	BOC	EOC
Fraction of Rods that Experience DNBR < 1.3	0.0546	0.0568

B. Zero Power CEA Ejection Accident Results

	BOC	EOC
Fraction of Rods that Experience DNBR < 1.3	0.0814	0.1126

The STRIKIN-II code was used to calculate the number of pins that would experience a DNBR < 1.3. For each of the four cases above, parametric hot channel calculations were made using the time dependent average channel power (from CHIC-KIN) multiplied by various radial peaks until a radial peaking factor was determined such that the minimum calculated DNBR during the transient was 1.3. A radial peaking factor versus pin census edit was then used to determine the number of pins with radial peaking factors greater than the above value. This is the value above as the number of fuel pins calculated to experience a DNBR less than 1.3.

In addition to the methods and results explained above, the maximum pressure during the worst zero power CEA ejection accident was conservatively estimated to be less than 2,500 psia. The initial pressurizer level was conservatively chosen to be consistent with full power steady state operating conditions. No credit was taken for heat transfer from the primary to the secondary side of the steam generator. The initial pressurizer and steam generator water level and pressure, as controlled within the operating limit, have an insignificant effect on the number of clad failures.

15.1.20.3 Conclusion

Both full power and zero power CEA ejection accidents have been analyzed and both have been shown to be acceptable at BOC and EOC. No clad damage is predicted for full power at BOC and EOC. Minimal clad damage is predicted for zero power at both BOC and EOC using the initial cycle analysis methodology, but no damage was predicted using the reload cycle methodology. No fully molten centerline condition is indicated for any CEA ejection accident.

15.1.20.4 CEA Ejection Subsequent Analyses

15.1.20.4.1 Cycle 2 CEA Ejection Analysis

The CEA Ejection event was reanalyzed for Cycle 2 to determine the fraction of fuel pins that exceed the criteria for clad damage. The analytical method employed in the reanalysis of this event was the NRC approved Combustion Engineering CEA Ejection method which is described in CENPD-190-A (Reference 49). These methods are similar to those described above with STRIKIN-II being used rather than CHIC-KIN.

The procedure outlined in CENPD-190-A was used to determine the radial average and centerline enthalpies in the hottest axial region of the rod. The calculated enthalpy values were compared to threshold enthalpy values to determine the amount of fuel exceeding these thresholds. These threshold enthalpy values were the same as those used for Cycle 1.

Table 15.1.20-8 lists all the key parameters used in the zero power and full power analyses.

To bound the most adverse conditions during the cycle, the most limiting of either the Beginning of Cycle (BOC) or End of Cycle (EOC) parameter values were used in the analysis. A BOC Doppler defect was used since it produces the least amount of negative reactivity feedback to mitigate the transient. A BOC moderator temperature coefficient of $+ 0.5 \times 10^{-4}$ Δk/k/°F was used because a positive MTC results in positive reactivity feedback and thus increases both coolant temperatures and stored energy. An EOC delayed neutron fraction was used in the analysis to produce the highest power rise during the event.

The power transient produced by a CEA ejection initiated at the maximum allowed power is shown in Figure 15.1.20-8 for the Cycle 2 analysis. Similar results for the zero power case are shown in Figure 15.1.20-9. Both full power and zero power cases are terminated by the high linear power level trip.

The results of the two CEA ejection cases analyzed (Table 15.1.20-9) show that the maximum total energy deposited during the event is less than the criterion for clad damage (i.e., 200 cal/gm). Only a small fraction ($\leq$ 0.005) of the fuel reaches the incipient centerline melting threshold.

15.1.20.4.2 Cycle 10 CEA Ejection Analysis

To address a reduction in the minimum allowable reactor coolant system initial pressure for Cycle 10, the CEA ejection events at HFP and HZP conditions were assessed. Methods consistent with those identified above for the Cycle 2 analysis were employed in this analysis. These analyses were performed based on the parameters in Table 15.1.20-10 and the following input assumptions:

A. A Doppler curve consistent with Figure 15.1.0-3 (BOC) was assumed in both the HFP and HZP analyses.

B. A CEA insertion curve consistent with Figure 15.1.0-1C with a 0.6 second holding coil delay time was assumed for the HFP case. For the HZP case, the CEA position versus time of Figure 15.1.0-1C is consistent with the analysis assumption; however, a more conservative normalized reactivity insertion versus CEA position for a +0.6 ASI curve was used.

C. A high linear power trip setpoint of 128.1 % (of 2815 MWt) with a response time of 0.4 seconds was used in the HFP analysis. The high linear power trip setpoint is increased in this analysis to a value greater than that in Table 15.1.0-1 to include an excore penalty and instrument uncertainty (which accounts for geometry effects of the location of the excore detector in relation to the ejected CEA). A CPC DNBR trip (based on VOPT) setpoint of 54 % (of 2815 MWt) with a response time of 0.59 seconds was assumed in the HZP analysis.

D. The axial power distribution provided in Table 15.1.20-12 was assumed in both cases.

E. A minimum BOC delayed neutron fraction (0.00536) was used in this analysis rather than an EOC value, which is smaller. The EOC value would be overly conservative due to most of the other parameters being based on BOC conditions.

Table 15.1.20-11 presents the average fuel pin and centerline enthalpies that were calculated.

Based on the results, the acceptance criteria are met with no fuel pins calculated to experience cladding damage or a fully molten centerline. Additionally, for the HZP case no pins were predicted to even reach incipient centerline melting and only 0.33 % of the total number of pins reached this limit for the HFP case.

15.1.20.4.3 Cycle 12 CEA Ejection Analysis

For Cycle 12, the CEA ejection events at HFP and HZP conditions were assessed with regards to developing curves of acceptable ejected 3D peak F_q's versus ejected worths. Methods consistent with those identified above for the Cycle 2 analysis were employed in this analysis. These analyses were performed based on the parameters in Table 15.1.20-13 and the following input assumptions:

A. A Doppler curve consistent with Figure 15.1.0-3 (BOC) was assumed in both the HFP and HZP analyses.

B. A CEA insertion curve consistent with Figure 15.1.0-1C with a 0.6 second holding coil delay time was assumed for the HFP case. For the HZP case, the CEA position versus time of Figure 15.1.0-1C is consistent with the analysis assumption; however, a more conservative normalized reactivity insertion versus CEA position for a +0.6 ASI curve was used.

C. A CPC DNBR trip (based on VOPT) setpoint of 55% and 125.5% (of 2815 MWt) with a response time of 0.59 seconds was assumed in the HZP and HFP analyses, respectively.

D. The axial power distribution provided in Table 15.1.20-12 was assumed in both cases.

The objective of this analysis was to ensure the cycle specific physics data was acceptable; hence, a 100 % power case was run rather than the limiting 103 % power limit. Table 15.1.20-14 lists acceptable ejected 3D peak F_q's versus ejected worths that was generated based on the above parameters and the following acceptance criteria:

Total Average Enthalpy ≤ 200 cal/gm

Total Centerline Enthalpy ≤ 250 cal/gm.

The cycle specific physics data is reviewed to ensure these limits are not exceeded.

Based on the above results, no fuel failure is predicted as the acceptance criteria of the total average enthalpy of 200 cal/gm and a total centerline enthalpy of 250 cal/gm were used to determine the allowable ejected 3D peak F_q's versus ejected CEA worth. Ensuring these limits are meet also ensures that the results of the prior analyses remain bounding.

15.1.20.4.4 Cycle 13 CEA Ejection Analysis

The CEA Ejection Event at both HFP and HZP conditions were reanalyzed in Cycle 13 to assess a 10% reduction in the RCS design flow. RCS flow reduction has an adverse effect on the deposited energy during the event. Methods consistent with those identified above for the Cycle 2 analysis were employed in this analysis. These analyses were performed based on the parameters in Table 15.1.20-15 and the following input assumptions.

A. A Doppler curve consistent with Figure 15.1.0-4 (BOC) was assumed in both the HFP and HZP analyses.

B. A CEA insertion curve consistent with Figure 15.1.0-1D with a 0.6 holding coil delay time was assumed for the HFP case. For the HZP case, the CEA position versus time of Figure 15.1.0-1C is consistent with the analysis assumption; however, a more conservative normalized reactivity insertion versus CEA position for a +0.6 ASI curve was used.

C. The axial power distribution provided in Table 15.1.20-16 was assumed in both cases.

D. A CPC DNBR trip (based on VOPT) setpoint of 47% and 134% (of 2815 MWt) with a response time of 0.59 seconds was assumed in the HZP and HFP analyses, respectively.

E. A minimum EOC delayed neutron fraction was assumed.

Table 15.1.20-17 lists the acceptable 3D peak F_q's versus ejected CEA worth that was generated based on the above parameters and the following acceptance criteria.

Total Average Enthalpy ≤ 200 cal/gm

Total Centerline Enthalpy ≤ 310 cal/gm

Cycle specific calculation of the maximum ejected F_q and ejected worth are performed and verified to fall within the limits calculated above.

Based on the above, no fuel failure due to either clad damage or fully molten centerline temperature was predicted. The results of this analysis is bounded by the prior analyses.

15.1.20.4.5 Cycle 14 CEA Ejection Analysis

To address changes in the MTC limits at the 20% and 50% power levels, the CEA Ejection event was reassessed at these power levels. Methods consistent with those identified above for the Cycle 2 analysis were employed to this analysis. The inputs, other than the MTC limit at these power levels, were the same as was used in the Cycle 13 analysis.

Table 15.1.20-18 lists the acceptable 3D peak F_qs versus ejected CEA worth that was generated based on the parameters and acceptance criteria listed in the previous section.

Cycle specific calculation of the maximum ejected F_qs and ejected worth will be performed as part of the cycle specific reload analysis and verified to fall within the limits.

Based on the above, no fuel failure due to either clad damage or fully molten centerline temperature was predicted. The results of this analysis are bounded by the prior analyses.

15.1.20.4.6 Cycle 15 CEA Ejection Analysis

Cycle specific calculation of the maximum ejected F_q's and ejected worth were performed and verified to fall within the limits.

Based on the above, no fuel failure due to either clad damage or fully molten centerline temperature was predicted.

In Cycle 15, the bounding excore decalibration values documented in Table 15.1.20-18 were not verified. The results of the fast-trip CEA ejection cases are not highly sensitive to excore decalibration since the power prompt-jumps above the credible trip setpoint. Due to the limited impact of these parameters on the CEA ejection Fq limits and the significant margin available to those limits in Cycle 15, these parameters were judged to be acceptable for Cycle 15.

The results of the Cycle 15 analysis are bounded by the prior analyses.

15.1.20.4.7 Cycle 16 CEA Ejection Analysis

The CEA Ejection Event at both HZP and HFP conditions were reanalyzed in Cycle 16 to access the impact of uprating the plant power level from 2815 MWt to 3026 MWt. An increase in power level has an adverse effect on the deposited energy during the event. Consistent with

the Cycle 12 analysis, the CEA Ejection Event for Cycle 16 was analyzed with regards to developing curves of acceptable ejected 3D peak Fqs versus ejected worths. Methods consistent with those identified above for the Cycle 2 analyses were employed in this analysis. These analyses were performed based on the parameters in Table 15.1.20-19 and the bounding physics data from Section 15.1.0 with the following clarifications:

A. The BOC Doppler curve in Figure 15.1.0-4 was assumed.

B. An EOC delayed neutron fraction consistent with that defined in Section 15.1.0.3 was assumed.

C. For HFP the CEA insertion curve in Figure 15.1.0-1D was assumed. This curve accounts for a 0.6 second holding coil delay. A CEA worth of -5.0% $\Delta\rho$ was conservatively assumed for HFP.

   For HZP the CEA insertion curve (scram curve) is based on an AS1 of +0.6. A CEA insertion curve consistent with Figure 15.1.0-1E utilizing a 0.6 second holding coil delay was assumed. A CEA worth of -2.0% $\Delta\rho$ was conservatively assumed.

D. For MTC, zero and +0.5 x 10^{-4} $\Delta\rho$/°F were assumed for HFP and HZP conditions, respectively.

E. The variable overpower trip (VOPT) of the core protection calculator system (CPCS) was employed in the analysis. A CPCS trip delay time of 0.60 seconds was assumed. The VOPT assumed an excore uncertainty of 40% from Table 15.1.20-20. For HFP and HZP, conservative VOPT setpoints of 153% and 98% were assumed.

F. For HFP an initial core power of 3087 MWt was assumed based on a rated power of 3026 MWt and a 2% uncertainty. For HZP an initial core power of 30.3 MWt was assumed based on one percent of the rated power value of 3026 MWt.

G. An axial power distribution in Table 15.1.20-16 was assumed.

H. The HFP core inlet temperature of 556.7 was conservatively assumed for HZP.

I. A RCS flow of 315,560 gpm was assumed for HFP and HZP conditions.

Table 15.1.20-20 lists the acceptable 3D peak Fqs versus ejected CEA worth that was generated based on the above-parameters and the following acceptance criteria:

Total Average Enthalpy ≤ 200 cal/gm

Total Centerline Enthalpy ≤ 250 cal/gm

Cycle specific calculation of the maximum ejected F_q and ejected worth are performed and verified to fall within the limits calculated above.

Based on the above, no fuel failure due to either clad damage or incipient melt temperature was predicted to occur. However, to accommodate anticipated predicted fuel failure, radiological dose for up to 14% fuel failure due to clad damage has been considered.

15.1.20.4.8 Cycle 18 CEA Ejection Analysis

The CEA Ejection Event at HFP and HZP power were reanalyzed for Cycle 18 to address the impact of the implementation of ZIRLO^{TM} cladding, Zirconium diboride (ZrB_2) Integrated Fuel Burnable Absorber (IFBA) fuel, and an increase in LOCA linear heat rate (LHR) Limit from 13.7 kW/ft to 14.4 kW/ft.

An increase in the LOCA LHR limit had a small adverse effect on the deposited energy during the event, and then only at the higher initial power levels. The impact of ZrB_2 IFBA fuel and ZIRLO^{TM} cladding had a small effect on the deposited energy and it varied with initial power level. References 54 and 55 discuss the impact of the fuel changes.

Consistent with the Cycle 16 analysis, the CEA Ejection Event for Cycle 18 was analyzed with regards to developing curves of acceptable ejected 3D peaks (Fq's) versus ejected worths. Methods consistent with those identified above for the Cycle 16 analysis were employed in this analysis. These analyses were performed based on the same parameters and same input assumptions used in Cycle 16. The only changes were to the STRIKIN-II code's FATES files that were modified to include the IFBA ZrB_2 fuel and ZIRLO^{TM} fuel cladding, and an increase in the LOCA LHR limit. Table 15.1.20-22 lists the acceptable 3D peaks versus ejected CEA worths that were generated based on the Cycle 18 parameters and the following acceptance criteria:

Total Average Enthalpy < 200 cal/gm

Total Centerline Enthalpy < 250 cal/gm

Cycle specific calculation of the maximum ejected Fq and ejected worth were performed and verified to fall within the limits calculated above.

Based on the above, no fuel failure due to either clad damage or incipient melt temperature was predicted to occur.

15.1.20.4.9 Cycle 20 CEA Ejection Analysis

The CEA Ejection Events at HZP power were reanalyzed for Cycle 20 to address the impact of the implementation of Optimized ZIRLO^{TM} claddingand Next Generation Fuel. The CEA Ejection Events at HFP remained bounded by Cycle 18 analyses.

Implementation of Optimized ZIRLO^{TM} cladding and NGF has a small effect on deposited energy that varies with initial power level. References 56 and 57 discuss the impact of the fuel changes.

Consistent with the Cycle 18 analysis, the CEA Ejection Event for Cycle 20 was analyzed with regards to developing curves of acceptable ejected 3D peaks (Fq's) versus ejected worths. Methods consistent with those identified above for the Cycle 18 analysis were employed in this analysis. These analyses were performed based on the same parameters and same input assumptions used in Cycle 18. The only changes were to the STRIKIN-II code's FATES files that were modified to include the NGF and Optimized ZIRLO^{TM} fuel cladding. Table 15.1.20-23 lists the acceptable 3D peaks versus ejected CEA worths that were generated based on the Cycle 18 parameters and the following acceptance criteria:

Total Average Enthalpy < 200 cal/gm

Total Centerline Enthalpy < 250 cal/gm

Cycle specific calculation of the maximum ejected Fq and ejected worth were performed and verified to fall within the limits calculated above.

Based on the above, no fuel failure due to either clad damage or incipient melt temperature was predicted to occur.

15.1.20.4.10 <u>AST CEA Ejection Analysis</u>

The analysis input and assumptions used in the AST calculation of the radiological dose releases for the CEA ejection event are discussed in Section 15.1.0.5 with the following clarifications:

1. The CEA radiological analyses assume two cases: one in which 100% of the activity released from the fuel is instantaneously and homogeneously mixed in the containment atmosphere and a separate case in which 100% of the activity released from the damaged fuel is completely dissolved in the primary coolant and available for release to the secondary system.

2. The calculations assume 14% failed fuel with fission product gap fractions of 0.10 for noble gases and iodines and 0.12 for alkali metals. A peaking factor of 1.65 is included.

3. The iodine species distribution for the containment release case is 95% particulate, 4.85% elemental and 0.15% organic. For the secondary release case, the distribution is 97% elemental and 3% organic.

4. The primary-secondary release rate is 300 gpd (150 gpd per SG).

5. A flashing fraction of 0.05 is applied to the primary-secondary leakage for the 8-hour duration of the cooldown to entry into shutdown cooling. No credit has been taken for recovery of SG level and re-submergence of the SG tubes, which is expected to occur in approximately one hour following event initiation.

6. No credit has been taken for containment spray or the penetration room ventilation system.

7. A sedimentation coefficient of 0.1/hr, until DF=1000, is assumed. After DF=1000, this coefficient is assumed to be 0.

Table 15.1.20-21 provides the radiological dose results for both CEA ejection cases.

15.1.21 THE SPECTRUM OF ROD DROP ACCIDENTS (BWR)

Unit 2 is a PWR, and this event is not applicable.

15.1.22 BREAK IN INSTRUMENT LINE OR OTHER LINES FROM REACTOR COOLANT PRESSURE BOUNDARY THAT PENETRATE CONTAINMENT

15.1.22.1 Identification of Causes

There are no instrument lines from the RCS which penetrate the containment. Sampling lines are discussed in Section 9.3.2 and containment isolation in Section 6.2.4.

15.1.23 FUEL HANDLING ACCIDENT

15.1.23.1 Identification of Causes

The likelihood of a fuel handling accident is minimized by administrative controls and physical limitations imposed on fuel handling operations. All refueling operations are conducted in accordance with prescribed procedures under direct surveillance of a qualified supervisor. Also, before any refueling operations begin, verification of complete CEA insertion is obtained by tripping each CEA individually to obtain indication of assembly drop and disengagement from the drive shaft. Boron concentration in the coolant is raised to the refueling concentration and is verified by chemical analysis. At the refueling boron concentration, the core would be subcritical, even with all CEAs withdrawn.

After the vessel head is removed, the CEA drive shafts are disconnected from the CEAs. A load cell is used to indicate that the drive shaft is free of the CEA as the lifting force is applied.

The maximum elevation to which the fuel assemblies can be raised is limited by the design of the fuel handling hoists and manipulators to assure that the minimum depth of water above the top of a fuel assembly required for shielding is always present (see Section 9.1.4). This constraint is applied in fuel handling areas inside containment and in the spent fuel pool area.

Supplementing the physical limits on fuel withdrawal, area radiation monitors located at the fuel handling areas would provide both audible and visual warning of high radiation levels in the event of a low water level in the refueling cavity and fuel pool.

The design of the spent fuel storage racks and handling facilities in both the containment and fuel storage area is such that fuel will always be in a subcritical geometrical array, assuming zero boron concentration in the fuel pool water. The spent fuel pool and refueling pool water contains boron at the refueling water boron concentration. Natural convection of the surrounding water provides adequate cooling of fuel during handling and storage. Adequate cooling of the water is provided by forced circulation in the fuel pool system.

Fuel failure during refueling as a result of inadvertent criticality or overheating is not credible. The possibility of damage to a fuel assembly as a consequence of mishandling is minimized by thorough training, detailed procedures, and equipment design. The design of the auxiliary building crane (L3) precludes the handling of heavy objects such as shipping casks over the spent fuel storage racks (See Section 9.1.4.2.10). Movement of heavy loads over the spent fuel storage racks by the new fuel handling crane (2L35) is prevented by administrative controls. Inadvertent disengagement of a fuel assembly from the fuel handling machine is prevented by mechanical interlocks; consequently, the possibility of dropping and damaging a fuel assembly is remote.

Should a fuel assembly be dropped or otherwise damaged during handling, radioactive release could occur in either the containment or the auxiliary building. The ventilation exhaust air from both of these areas is monitored and filtered before release to the atmosphere. The radiation monitors immediately indicate the increased activity level and alarm. The affected area would then be evacuated.

Release of activity through the containment purge system would be prevented by automatic closure of the containment isolation dampers. The containment equipment hatch and the containment personnel hatches would be shut, following personnel evacuation, upon a fuel handling accident inside containment, which would substantially, if not completely reduce the radiological release. Since the auxiliary building cannot be completely isolated, this results in a more limiting activity release to the environment. The ventilation system draws air across the spent fuel pool area; this air is filtered and discharged to the atmosphere through the plant vent.

Since all exterior doors are closed during fuel handling operations, this is the only route for the release of activity to the environment.

Handling of the spent fuel cask is discussed in Section 9.1.4.2.10. The final movement of the spent fuel to storage or in shipping it off-site involves lowering the spent fuel cask through a vertical equipment handling shaft in Unit 1 from the 404-foot level to a railroad car on the 354-foot level. Operational procedures based on safe handling practices and periodic inspections of the fuel handling crane make the possibility of a free-fall drop of the cask occurring in this vertical shaft not credible. Because the crane is designed in accordance with NUREG-0554 and therefore is single failure proof, a postulated cask drop is not a credible event and the structural integrity of the spent fuel pool cask will not be impaired and no safety related components will be impacted. Table 9.1-10 provides site specific information regarding compliance with Ederer's Generic Topical Report for single failure proof cranes. For consideration of ANO-1 systems, structures, and components, see Unit 1 SAR.

15.1.23.2 Analysis of Effects and Consequences

15.1.23.2.1 Method of Analysis

The analysis assumes that a fuel assembly is dropped during fuel handling. Interlocks and procedural and administrative controls make such an event highly unlikely; however, if an assembly were damaged to the extent that one or more fuel rods were broken, the accumulated fission gases and iodines in the fuel rod gaps would be released to the surrounding water. Release of the solid fission products in the fuel would be negligible because of the low fuel temperature during refueling.

The fuel assemblies are stored within the spent fuel rack at the bottom of the spent fuel pool. The top of the rack extends 10 inches above the tops of the stored fuel assemblies. A dropped fuel assembly could not strike more than one fuel assembly in the storage rack (see Figure 9.1-15). Impact could occur only between the ends of the involved fuel assemblies, the bottom end fitting of the dropped fuel assembly impacting against the top end fitting of the stored fuel assembly. The maximum drop distance for this event is 26 inches from the bottom of a fuel assembly residing in the spent fuel handling machine to the top of a fuel assembly in the spent fuel storage racks. For the 26-inch drop the fuel assembly impact velocity is 131 inches per second and the impact stress in the fuel rod cladding is 12,300 psi.

The maximum possible drop distance for a fuel assembly in the spent fuel pool is 202 inches. This is the distance from the bottom of a fuel assembly in the spent fuel handling machine to the spent fuel pool floor. For this worst case drop, the velocity of the fuel assembly at impact with the fuel pool floor is 331 inches per second, and the impact stress in the fuel rod cladding is 31,000 psi.

The analyses of the fuel assembly vertical drops were performed assuming possibly attached appurtenances (CEA, fuel grapple, etc.) were attached and fell with the assembly, consistent with RG 1.183 assumptions. The result of these conservative analyses indicates possible complete failure of both the dropped fuel assembly and the dropped-on fuel assembly. Therefore, the AST dose analyses assume failure of two entire fuel assemblies (472 fuel rods).

The methods used to calculate site boundary doses are described in Section 15.1.0. The RADTRAD code was used to calculate site boundary doses using dose conversion factors from FGR-11 and FGR-12 for the fuel handling accidents in the fuel handling building and in containment.

15.1.23.2.2 <u>Source Term Assumptions</u>

The assumptions related to the release of radioactive material from the fuel and fuel storage facility as a result of a fuel handling accident are given in Regulatory Guide 1.83. Below is a listing of assumptions for the AST analysis.

A. Technical Specifications restrict fuel handling operations until 100 hours after shutdown.

B. The maximum fuel rod pressure 100 hours after a refueling shutdown will be less than 1,500 psig.

C. The spent fuel pool is normally of sufficient depth that the water depth between the top of the damaged fuel rods and the fuel pool surface is no less than 23 feet. A dropped fuel assembly impacting a line load near completion of rotation to a horizontal position will be covered by more than 23 feet of water.

D. All of the gap activity in the damaged rods is released and consists of approximately five percent of the total noble gases other than Kr^{85}, ten percent of the Kr^{85}, five percent of the total radioactive iodine other than I^{131}, and eight percent of the I^{131} in the rods at the time of the accident. This analysis uses ORIGEN-S code to generate the source terms.

E. Rated power for Cycle 16 and beyond is 3026 MWt. The FHA source terms are based on 102% of rated (i.e., 3087 MWt) and a radial peaking factor of 1.70. Each term is then increased by 4% to account for potential future variations in reload core designs.

F. The analysis assumes that the gap inventory is composed of 99.85% inorganic iodine and 0.15% organic iodine.

G. The pool decontamination factors for the inorganic and organic species are 286 and 1, respectively, giving an overall effective decontamination factor of 200. This difference in decontamination factors for inorganic and organic iodine species results in the iodine above the fuel pool being composed of 70 percent inorganic and 30 percent organic species."

H. The analysis assumes a noble gas pool decontamination factor of 1 for noble gases.

I. All releases of fission products to the environment are assumed to occur over a two hour time period.

J. All releases are assumed to be unfiltered and thus, the iodine removal efficiency is 0%.

K. No credit was taken for mixing in the building atmosphere and no credit was taken for an elevated release in this analysis.

L. A site boundary χ/Q of 6.5 x 10^{-4} seconds / cubic meter was assumed. A control room χ/Q of 1.2 x 10^{-3} seconds / cubic meter was used. The control room dispersion factor was calculated using ARCON96 except the spent fuel building exhaust fan location was used. The spent fuel building location dispersion factor was more limiting than the containment, hence was used in this assessment.

M. A breathing rate of 3.5 x 10^{-4} cubic meter / sec was assumed.

The source term assumptions for the shipping cask drop of 50 feet would be as follows:

Fifteen fuel assemblies

Three years operating time

At design power on all assemblies

Cask movement occurs not sooner than 100 days after shutdown

Twenty-five percent of the noble gases are released*

Ten percent of the iodine is released*

Fifty percent of the iodine released plates out**

None of the solid fission products are released from the fuel.

$\frac{X}{Q}$ = 6.5 x 10^{-4} sec/m^3 at site boundary Q

* Based on AEC Division of Reactor Licensing (DRL) staff evaluation of fuel handling accidents.

** Fifty percent plate out of the iodine is a conservative value and is based on the fact that the door at the rail spur access to the plant is shut when the spent fuel cask is lowered. Iodine which escapes the cask resting area after the postulated drop would be plated out on the walls, floors, and ventilation piping.

No credit would be taken for filtration from the auxiliary building ventilation system, since a portion of the ventilation flow path goes through the unfiltered turbine building. Further conservatism would be an assumption of an instantaneous release of the activity vice a "release-rate" approach.

15.1.23.3 Results

Currently, neither unit ships spent fuel offsite and there are no plans to do so. As such, no dropped spent fuel shipping cask accident doses are presented. Dry fuel storage casks are used on site. See the vendor's FSAR for the VSC-24 or the Holtec HI-STORM 100 for further information.

An FHA is assumed to result in failure of two entire fuel assemblies (472 fuel rods) and make their gas gap activities available for release. These activities represent ten percent of total Kr^{85} in the fuel rods, eight percent of total I^{131} in the fuel rods, and five percent of all other noble gases and iodines in the fuel rods. Values of the individual fission product inventories are evaluated assuming operation at 3087 MWt and a maximum radial peaking factor of 1.70. In addition, a 4% margin has been added to accommodate potential reload fuel design variations. FGR-11 and FGR-12 dose conversion factors were used. While certain design features of the plant make the fuel handling accident assumptions listed in Regulatory Guide 1.183 overly conservative for Unit 2, the analysis has been performed using these assumptions.

For bounding FHA, the radionuclides released during the fuel handling accident are assumed to enter the atmosphere directly without filtration. A decay time of 100 hours after shutdown is assumed and 472 fuel rods are assumed to fail with the release modeled as a puff release. Since the release is assumed to be instantaneous without filtration, the analysis is applicable to a fuel handling accident in either the containment or in the spent fuel building (without filtration).

The doses for a fuel handling accident in the auxiliary building with no ventilation or in containment with the personnel airlock open during fuel handling are given in Table 15.1.23-2. These doses are below the acceptable limits of 10 CFR 50.67. In the case of a fuel handling accident in containment, these doses would be further reduced by promptly shutting the personnel airlock, following containment evacuation, in the event of a refueling accident.

15.1.24 SMALL SPILLS OR LEAKS OF RADIOACTIVE MATERIAL OUTSIDE CONTAINMENT

15.1.24.1 Identification of Causes

During normal conditions, all radioactive material is contained within the RCS, the auxiliary systems, or other containers or vessels which are designed to prevent the uncontrolled release of radioactivity to the environment.

Spills, leaks and pipe breaks can occur, however, in a variety of components outside the containment over the lifetime of the plant. Components of greatest concern are those containing fluids with potentially significant radioactive concentrations. The CVCS components contain reactor coolant and are representative of such potentially significant sources. These sources represent a low level of continuous leakage unless repaired.

Any liquid leakage or spills in the auxiliary building have been assumed to reach the site groundwater. Noble gases and iodine releases will be removed by the Auxiliary Building Fuel Handling Floor and Radwaste Area Ventilation Systems. The Auxiliary Building Fuel Handling Floor and Radwaste Area Ventilation Systems are equipped with HEPA and charcoal filters and are continuously monitored for gaseous activity.

15.1.24.2 Analysis of Effects and Consequences

The potential pathway for exposure subsequent to a failure of components outside the containment containing radioactive liquids is assumed to be a release into the groundwater and subsequent transport to a potential receptor.

The site is underlaid by clay and silty clay deposits which overlie shale. Tests performed at the site indicate that these materials exhibit very low permeability. Test results are presented in Chapter 2 of this report. Since both the clay material near the surface and the underlying slate are of such low permeability, radioactive material releases to the groundwater due to an accidental spill would be confined to the immediate vicinity of the site.

The velocity of the groundwater can be calculated by D'Arcy's Law.

V(water) = (P) x (i)/(theta)

where

V(water)	=	the velocity of the groundwater
P	=	permeability of the material = 4.2 x 10^{-6} cm/sec
I	=	hydraulic gradient = 7/2600 ft/ft (assumes maximum groundwater level at the site and minimum power pool - 336 feet - in the reservoir)
theta	=	porosity of the material = 20 percent

15.1.24.3 Conclusion

The nearest potential receptor is conservatively assumed to be at the Dardanelle Reservoir, 2,600 feet from the plant. Using these parameters a transit time of 4.6 x 10^4 years to the nearest receptor was calculated, sufficient to allow for radioactive decay to reduce the radionuclides released to negligible levels. The effects of ion exchange and mechanical dispersion in transit were not considered in the analysis, however both effects would reduce radionuclide concentrations further.

15.1.25 FUEL CLADDING FAILURE COMBINED WITH STEAM GENERATOR LEAK

In analyzing the consequences of transients which result in the release of steam from the secondary system, the specific activity of the released steam is determined from the following assumptions:

A. Continuous operation with a one gpm primary-to-secondary steam generator tube leak;

B. Specific activity of reactor coolant based on continuous operation with one percent failed fuel.

Normal releases resulting from operation with leaking steam generator tubes and defective cladding are discussed in Chapter 11.

15.1.26 CONTROL ROOM UNINHABITABILITY

In order to conform to the requirements of General Design Criterion 19, provisions have been made outside the control room to allow operating personnel, following control room evacuation, to verify that the plant is in a safe hot shutdown condition and to maintain the plant in this condition until such time as the control room is again accessible or additional personnel are available to affect a cold shutdown (see Section 7.4.1.5). Initial conditions and limitations are as follows:

A. The plant is in a normal operating condition (Condition I as defined by ANSI N18.2); concurrent or subsequent accident conditions are not postulated.

B. Concurrent or subsequent natural disasters are not postulated since the probability of such events is small for the time considered.

C. The reactor is tripped by operating personnel prior to evacuation of the control room. The operators inside have 10 minutes in which to reach the remote shutdown panel. The expected maximum time is four minutes.

D. The control room remains intact and all automatic control systems continue to function as designed.

E. Off-site power is not lost. Grid stability studies show that off-site power will not be lost even if Units 1 and 2 are tripped simultaneously.

15.1.26.1 Identification of Causes

Section 9.5.1 describes the fireproof provisions of the control room. Any fire that might start would be limited in size and could be quickly extinguished by one of the control room operators who are always present when the plant is operating. The control room has separate, redundant, self-contained ventilation and air conditioning systems to protect the operators in the event of smoke, noxious gases, or radioactivity in the surrounding areas of the plant. These features are detailed in Sections 9.4 and 12.2. The control room is shielded from both radioactivity and missiles as described in Sections 12.1 and 3.5, respectively.

Since the control room is the only structure other than the containment that can be completely isolated from outside air, it is not credible to postulate control room evacuation due to noxious gases outside the plant. In the event of noxious gas, a small amount of filtered outside air will be used for pressurization of the control room to minimize unfiltered air inleakage. Self-contained air breathing equipment is available inside the control room to allow continued operation in the event of noxious gases. From the above discussion, it is clear that no reasonable basis exists for evacuating the control room. However, such an event is postulated to occur and the effects have been analyzed.

15.1.26.2 Analysis of Effects and Consequences

During a control room evacuation, the operator would trip the reactor. This action results in a turbine trip which is a less severe transient than a loss of load or turbine trip without a RT (see Section 15.1.7 for an analysis of the loss of load accident). Excess steam will be bypassed to the main condenser. No radioactivity will be released to the environment due to control room evacuation.

If control room accessibility is not restored, adequate instrumentation and controls have been provided to maintain the reactor in a safe hot shutdown condition and to bring the reactor to a cold shutdown condition from outside the control room as described in Section 7.4.1.5.

15.1.27 FAILURE OR OVERPRESSURIZATION OF LOW PRESSURE RESIDUAL HEAT REMOVAL SYSTEM

The failure of the shutdown cooling system is discussed in Section 6.3.

15.1.28 LOSS OF CONDENSER VACUUM

15.1.28.1 Identification of Causes

A loss of condenser vacuum due to failure of the circulating water system to supply cooling water, failure of the main condenser evacuation system to remove non-condensable gases, excessive leakage of air through turbine gland packing or any other reasons, results in a turbine generator trip which in turn trips the reactor (unless below approximately 15 percent power). The excess steam generated is dumped into the atmosphere either by the steam dump and bypass system or the main steam safety valves.

15.1.28.2 Analysis of Effects and Consequences

Loss of condenser vacuum is sensed by the turbine emergency trip system, and results in a turbine-generator trip. An analysis of the effects and consequences of a turbine-generator trip is provided in Section 15.1.7. The following analysis describes the functioning of the turbine emergency trip system as condenser vacuum decreases.

Each of the two condenser shells are provided with four pressure switches (total of eight). One switch is used to initiate an alarm should condenser vacuum decrease to approximately 25 inches Hg. The alarm will permit the plant operator to take appropriate corrective actions. Such actions might include starting standby condenser cooling water pump, and/or reducing turbine load to reduce the heat load imposed on the condenser. Should condenser vacuum continue to decrease, two other pressure switches will initiate a turbine trip signal when vacuum decreases to approximately 22 inches Hg. The two switches from each shell are electrically configured to prevent an erroneous turbine trip due to failure of either pressure switch.

The trip signal from the vacuum trip switches de-energizes the two solenoids of the turbine master trip solenoid valve. Two solenoids are provided to prevent a turbine trip upon failure of either solenoid. When de-energized, this valve ports the emergency trip system hydraulic fluid pressure to drain which trips all turbine valves closed. Decrease in the emergency trip system fluid pressure is sensed by two other pressure switches which lock the master trip solenoid in the tripped position until reset by the operator. The latter two pressure switches are provided downstream of a flow orifice to prevent tripping the turbine during short duration pressure changes. The fourth pressure switch provides an interlock with the steam dump and bypass system at approximately 25 inches Hg to prevent or terminate the dumping of steam to the condenser when sufficient vacuum is not available.

15.1.28.3 Conclusion

The turbine protective system incorporates redundant instrumentation which guarantees detection of loss of condenser vacuum. Loss of condenser vacuum will result in a turbine-generator trip. A turbine-generator trip presents no hazard to the integrity of the RCS or the main steam system, as analyzed in Section 15.1.7.

15.1.29 TURBINE TRIP WITH COINCIDENT FAILURE OF TURBINE BYPASS VALVES TO OPEN

This event is described and analyzed in Section 15.1.7.

15.1.30 LOSS OF SERVICE WATER SYSTEM

15.1.30.1 Identification of Causes

The essential portions of the Service Water System (SWS) required to be operated to achieve a safe shutdown of the plant under the postulated accident conditions are designed to meet the requirements of the ASME Code, Section III, Class 3 and Seismic Category 1, including protection from tornado and postulated tornado missiles. Containment penetration piping and the associated isolation valves are designed to meet the requirements of ASME Code, Section III, Class 2 and Seismic Category 1. A program of periodic testing and service rotation of standby equipment is incorporated into the station operating procedures to maintain capability and integrity of the SWS. Starting conditions and assumptions include (1) operational tests, hydrotests and/or visual inspections of the SWS were performed prior to initial startup of the plant to assure system capability and integrity, (2) the emergency cooling pond must contain a sufficient volume of water required for safe shutdown of the plant under the postulated accident conditions, and (3) two loops of the SWS must be in operation prior to plant power generation.

Partial loss of the SWS however, is postulated and can be caused by any one of the following:

A. Electrical power failure:

   The active components of the SWS are powered from the engineered safety features electrical system for two redundant loops. A complete loss of one loop, however, is considered when one of two emergency diesel generators fails.

B. Active failure of components:

   This includes the mechanical failure of sluice gates, service water pumps, and the motor operated valves serving ESF equipment or isolating Seismic Category 1 portions of the SWS.

C. Passive failure of components:

   This includes the failure of equipment and piping in Seismic Category 1 portions.

Operator action is necessary for the following operations:

A. The transfer of service water source from Dardanelle Reservoir to the emergency pond requires operator action from the control room to close the sluice gates at Dardanelle Reservoir and open the ones at the emergency pond. At the same time, SWS discharge must be switched to the pond in order to form a closed loop between the pond, pump compartments and the essential portions of the SWS.

   Valve position failure alarms are provided for the sluice gates, and the service water discharge header valves whose malfunction can lead to a loss of the pond water to the reservoir. Upon actuation of alarm, the associated component and/or the service water loop will be isolated and secured by operator action in the control room.

B. Operator action is also required to isolate and secure the component and/or the service water loop associated with a leak. The components in the SWS can be isolated on an individual basis.

15.1.30.2 <u>Analysis of Effects and Consequences</u>

Based on the single failure analysis presented in Table 9.2-5, no single failure of an active or a passive component of the SWS can lead to a LOCA. The other loop has redundant components and will effect a safe shutdown of the plant. Fluid loss in the essential portions of SWS can be detected as described in Section 9.2.1.3. While the service water pump is running, the actuation of a low pressure alarm energized by a pressure indicating switch located on each main service water supply header can be an indication of a major pipe rupture which could endanger the plant by flooding. In this event, the associated service water pump will be stopped by operator action upon confirmation of the leak.

15.1.31 LOSS OF ONE DC SYSTEM

The DC system has been designed to maintain maximum flexibility for design basis events. Each redundant DC bus has two sources of power: a battery charger (designed as a battery eliminator) and a battery. Additionally, each DC bus has a standby backup charger.

During the transition period between the transfer from off-site power (preferred source) to emergency standby power, control and instrumentation power is provided from the batteries. The battery chargers will be reenergized during the loading sequence of the diesel generator.

15.1.31.1 <u>Identification of Cause</u>

Two abnormal occurrences will cause the loss of a single DC system:

A. bus fault on the 125-volt DC control center; or

B. cable fault between the 125-volt DC control center and the ESF distribution panel.

15.1.31.2 <u>Analysis of Effects and Consequences</u>

The effects of either a bus fault or a cable fault will immediately render that DC system and its associated power train/division inoperable. The bus fault is assumed to cause a secondary plant trip that results in loss of 480 VAC to the faulted train due to loss of control voltage to the offsite switchgear, onsite switchgear, and EDG. Thus, both vital AC inverters on the faulted train de-energize. In the event of the loss of one DC bus, the redundant power train/division will allow a safe shutdown of the plant during emergency conditions.

Monitoring devices and administrative controls ensure that the loss of one DC system during normal operating conditions initiates immediate corrective action.

15.1.32 INADVERTENT OPERATION OF ECCS DURING POWER OPERATION

During power operation, the pressure of the RCS, 2,200 psia, exceeds the shutoff head of the HPSI pumps or the opening pressure of the safety injection tanks. Therefore, a spurious SIAS during power operation will not cause injection of water at refueling boron concentration into the RCS.

15.1.33 TURBINE TRIP WITH FAILURE OF GENERATOR BREAKER TO OPEN

The unit protection system is designed to ensure reliable opening of the 500 kV generator breakers upon a turbine trip. The redundant trip functions are provided by:

A. Sequential trip scheme which trips the generator breakers through position switches on the main stop and intercept valves in series with an anti-motoring relay with a 3 second delay;

B. Electrical anti-motoring relay with a 30 second delay which senses the condition of the machine operating as a motor when the steam supply is lost.

Schemes (A) and (B) use DC power sources derived from redundant batteries. They also act on separate trip coils provided on each 500 kV generator breaker.

15.1.33.1 Identification of Causes

Failure of the generator breakers to isolate the unit on a turbine trip can occur if the 500 kV generator breakers fail to open on a trip command due to a mechanical failure.

15.1.33.2 Analysis of Effects and Consequences

Failure of the 500 kV generator breakers to open against a trip signal will initiate the 500 kV breaker failure relaying scheme provided as part of the switchyard protection scheme. After a preset time delay (approximately 10 cycles), it will trip out all other 500 kV breakers associated with the failed generator breaker.

There are two cases to be considered:

A. Both the 500 kV generator breakers were in service before the turbine trip. Assuming a single failure, one of the generator breakers will open correctly while the second one may fail.

B. Only one of the two generator breakers was in service before the turbine trip. This one breaker fails to open.

In either case, one of two 500 kV bus sections will be completely de-energized. One or both of the two startup transformer (preferred) sources will continue to be available. No system disturbances are anticipated.

15.1.34 LOSS OF INSTRUMENT AIR SYSTEM

15.1.34.1 Identification of Causes

The instrument air system is a non-Seismic Category 1 system, except for the containment penetration piping and associated isolation valves. It is not essential for safe shutdown of the plant. The containment isolation function is discussed in Section 6.2.4.

Failure of the air compressors or their power supplies or the rupture of a component of the system could result in demand exceeding supply with resultant loss of pressure and failure of air operated components to function.

15.1.34.2 Analysis of Effects and Consequences

Pneumatically operated safety-related devices are designed to assume a safe position upon loss of the instrument air supply. Air operated valves which are safety-related are identified in Table 15.1.34-1. Failure modes are also specified in this table.

15.1.34.3 Conclusion

Failure of the instrument air system will not prevent the safe shutdown of the plant and will not allow uncontrolled release of radioactivity to the environment.

15.1.35 MALFUNCTION OF TURBINE GLAND SEALING SYSTEM

15.1.35.1 Identification of Causes and Accident Description

The Turbine Gland Sealing System (TGSS) is discussed in Section 10.4.3. As the discussion shows, in order to guarantee operation of the turbine shaft seals, at least two components, one automatic and one manual, are provided to accomplish major system functions. Therefore, should the automatic component fail to regulate supply steam, unload excess pressure, or maintain necessary vent annuli vacuum, the operator can manually achieve the function. Low steam seal header pressure, high header pressure and low exhauster vacuum conditions are alarmed to alert the operator that the automatic component has failed.

Upon failure of automatic components in the absence of manual control by the operator, steam can escape from the turbine shaft seals into the turbine building, and air may leak into the condenser. The latter condition is considered a loss of condenser vacuum accident, and safe shutdown of the reactor is discussed in Section 15.1.28. The following discussion considers the effects of steam leakage from the shaft seals to the turbine building.

15.1.35.2 Analysis of Effects and Consequences

Failure of the TGSS alone presents no hazard to the safe operation and shutdown of the plant. In the event of primary-to-secondary system leakage from a steam generator tube failure, it is possible for the turbine seal steam to become radioactively contaminated. Radiation monitoring of steam generator blowdown and main condenser vacuum pump discharge will detect this condition. A discussion of the radiological aspects of primary-to-secondary system leakage, including anticipated releases from the TGSS and limiting conditions for operation, are included in Chapter 11. The maximum rate at which steam could be lost through the TGSS is 32,000 lbm/hr. Assuming the uncontrolled release of steam to the turbine building at this rate

for one hour and neglecting iodine plate out within the turbine building, off-site doses would be less than one-fourth of the dose due to a turbine trip with steam dumped for one-half hour (see Section 15.1.7).

15.1.36 TRANSIENTS RESULTING FROM THE INSTANTANEOUS CLOSURE OF A SINGLE MSIV

15.1.36.1 Identification of Causes and Accident Description

The transients resulting from the instantaneous closure of a single Main Steam Isolation Valve (MSIV) are analyzed to determine the CPC Asymmetric Steam Generator Transient Protection (ASGTP) trip setpoint such that in conjunction with the initial margins maintained by the LCOs the DNBR and fuel centerline melt (CTM) design limits are not exceeded.

The event is initiated by the inadvertent closure of a single Main Steam Isolation Valve causing a loss of load to one steam generator. Upon loss of load, pressure and temperature in the affected steam generator increase to the opening pressure of the main steam safety valves. The intact steam generator "picks up" the lost load which causes its temperature and pressure to decrease. The cold leg temperature asymmetry leads to a reactor inlet temperature tilt which produces an azimuthal core power tilt. The most negative moderator temperature coefficient is assumed since this maximizes the power tilt and hot channel radial peaking factor increase. With this assumed sequence of events, the transient results in the greatest asymmetry in core inlet temperature distribution, the greatest increase in hot channel radial peaking factors, and the most limiting DNBR.

15.1.36.2 Analysis of Effects and Consequences

The transient was initiated at the conditions given in Table 15.1.36-1. Table 15.1.36-2 presents the sequence of events for the loss of load to one steam generator. The transient behavior of key NSSS parameters is presented in Figures 15.1.36-1 to 15.1.36-5. A reactor trip is generated by the CPCs low DNBR trip at 2.5 seconds based on high differential temperature between the cold legs associated with the two steam generators. The ASGTP trip setpoint within the CPCs ensures that the acceptable DNBR limit will not be exceeded during the event.

A maximum allowable initial linear heat generation rate of 16.5 kW/ft could exist as an initial condition without exceeding the acceptable fuel to centerline melt of 21.0 kW/ft during this transient. This amount of margin is assured by setting the Linear Heat Rate LCO based on the more limiting of the allowable linear heat rate for LOCA and other transients.

The event initiated from the extremes of the LCO in conjunction with the CPC (ASGT protective) trip will prevent DNBR or centerline fuel temperature from exceeding the design limits.

15.1.36.3 Transients Resulting From the Instantaneous Closure of a Single MSIV Subsequent Analyses

15.1.36.3.1 Cycle 13 Instantaneous Closure of a Single MSIV

The Cycle 13 evaluation of the previously described Asymmetric Steam Generator Transient (ASGT) event has been performed utilizing the same inputs except those described below. In addition to the input modifications, this evaluation has utilized the CENTS computer code described in Section 15.1.0.6.10.

Input parameters from Table 15.1.36-3 and Section 15.1.0 have been incorporated in this subsequent analysis with these following clarifications:

A. The BOC Doppler curve in Figure 15.1.0-4 which includes a 0.85 multiplier is conservatively used.

B. The Cycle 13 delayed neutron fraction and neutron lifetime consistent with Section 15.1.0.3 was assumed.

C. The Cycle 13 CEA insertion curve in Figure 15.1.0-1D was utilized. This curve accounts for a 0.6 second holding coil delay and a CEA worth of 5%.

D. A CPC asymmetric steam generator trip setpoint of 11 °F was assumed. Cold and Hot leg RTD response times of 8 seconds and 13 seconds, respectively, were accounted for along with a CPC trip delay time of 0.59 seconds.

E. The Cycle 13 analysis was performed at 90% power and assumed a nominal RCS pressure of 2250 psia.

A summary of the principal results for the ASGT are given in Table 15.1.36-4. The combined effects of the input modifications and the improved models utilized in the CENTS codes have shown that there are no adverse impacts due to the input modifications. Thus the ASGT trip setpoint incorporated in the CPCs ensures that acceptable DNBR limits will not be exceeded during an ASGT event.

15.1.36.3.2 <u>Cycle 15 at 3026 MWt Instantaneous Closure of a Single MSIV</u>

The Instantaneous Closure of a Single Main Steam Isolation Valve event analysis, previously described as Asymmetric Steam Generator Transient (ASGT) event, was performed to document the impact of the replacement steam generators and a Power Uprate to 3026 MWt at hot full power.

The methodology used in this analysis is the same as that used in the current analysis. This analysis has utilized the CENTS computer code for the transient analysis simulation. The minimum DNBR evaluation was determined using the CETOP code.

Input parameters from Table 15.1.36-5 and the bounding physics data from Section 15.1.0 have been incorporated in this analysis with the following clarifications:

1. The BOC Doppler curve in Figure 15.1.0-4 was assumed.

2. A BOC delayed neutron fraction and neutron lifetime consistent with those defined in Section 15.1.0.3 were assumed.

3. The CEA reactivity insertion curve in Figure 15.1.0-1D was assumed. This curve accounts for a 0.6 second holding coil delay. A CEA worth of -4.5%$\Delta\rho$ was conservatively assumed.

4. A CPC ASGT Trip setpoint of 11 °F was assumed. Cold and hot leg RTD response times of 8 seconds and 13 seconds, respectively, were accounted for along with a CPC trip delay time of 0.60 seconds.

5. The analysis was performed at 90% of rated power and assumed a nominal RCS pressure 2200 psia.

6. An increase in core rated power to 3026 MWt rated was assumed.

7. The most negative MTC of -3.8×10^{-4} $\Delta\rho$/°F was assumed with 10% plugging assumed in the affected steam generator. This results in the largest radial power distortion in the core due to the core temperature asymmetry.

8. Installation of the RSGs was assumed.

9. An RCS flow of 315,560 gpm was assumed.

For the limiting ASGT event, the minimum DNBR is greater than 1.25 and the peak power never increases above its initial value. Although the radial power distortion is large, this in combination with the core power results in a peak LHR that is less than 21 KW/ft. Thus, the SAFDLs are protected.

The NSSS and RPS responses for the ASGT event are shown in Table 15.1.36-6 and in Figures 15.1.36-6 through 15.1.36-10. The combined effects of the input modifications have shown that there are no adverse impacts due to the RSGs, an increase in rated power to 3026 MWT, an increase in RCS flow, and the increase in the most negative MTC (more negative) to -3.8 x 10-4 $\Delta\rho$/°F.

The ASGT Trip setpoint that is incorporated in the CPCs ensures that the acceptable DNB and CTM limits will not be exceeded during an ASGT event. The minimum thermal margin required (reserved) in COLSS for the ASGT event is set equal to or greater than the maximum thermal margin degradation observed during an ASGT event.

15.1.36.3.3 Cycle 18 Instantaneous Closure of a Single MSIV

The instantaneous Closure of a Single Main Isolation Valve event was evaluated at a higher LOCA Limit of 14.4 KW/ft. Only the peak LHR margin was affected. There was no impact on DNB margin.

The methodology was the same as that used in the current analysis presented in Section 15.1.36.3.2. The LOCA Limit value of 14.4 KW/ft was used in place of the previous value of 13.7 KW/ft. No new computer cases were required.

The combination of the radial power distortion and core power results from the current analysis were combined with the higher value of 14.4 KW/ft to determine the new peak LHR value. The newly calculated value remained less than the 21 KW/ft SAFDL.

15.1.36.3.4 Cycle 21 Instantaneous Closure of a Single MSIV

The Instantaneous Closure of a Single Main Steam Isolation Valve (MSIV) event was evaluated for Cycle 21 for Next Generation Fuel (NGF). Only the DNB margin was affected. There was no impact on the LHR margin.

The methodology was the same as that used in the current analysis presented in Section 15.1.36.3.2. The Instantaneous Closure of a Single MSIV event was evaluated for Cycle 21 using the WSSV-T and ABB-NV critical heat flux correlations and the lower DNB SAFDL of 1.23 for the minimum DNBR evaluation. No CENTS cases were repeated, as all other current input parameters in Table 15.1.36-5 remained unchanged.

The Asymmetric Steam Generator Transient Trip setpoint that is incorporated in the CPCs ensures that the acceptable DNB and CTM limits will not be exceeded during an Instantaneous Closure of a Single MSIV event. The minimum thermal margin required (reserved) in COLSS for the Instantaneous Closure of a Single MSIV event is set equal to or greater than the maximum thermal margin degradation observed during the event.

Table 15.1.36-6 provides the revised Sequence of Events for the full core implementation of NGF. The minimum DNBR value remains above the DNB SAFDL value of 1.23. Consequently, the conclusions in SAR Section 15.1.36.3.2 remain the same.

Table 15.1.0-1

**REACTOR PROTECTIVE SYSTEM TRIPS
USED IN THE SAFETY ANALYSES**

	Analysis Setpoint[1]	Trip Delay Time (Sec)
High Logarithmic Power Level[5]	4%	0.4[8]
High Linear Power Level[5]	115.1%[7][10]	0.4[8]
Low DNBR[5]	1.25[6]	0.15[9]
High Local Power Density[5]	21 kw/ft[2]	0.15[9]
High Pressurizer Pressure[5]	2415 psia[11]	0.65[14]
Low Pressurizer Pressure[5]	1400 psia[4]	1.2
Low Steam Generator Water Level[5]	6%[3]	1.3
Low Steam Generator Pressure[5]	693 psia[12]	1.3
High Containment Pressure[5]	20.7 psia	1.2[13]
Manual Reactor Trip	Not Applicable	Not Applicable
High Steam Generator Water Level	Not Applicable	Not Applicable

(1) The analysis setpoints represent the parameter values at which a reactor protective trip is assumed. The actual instrumentation setpoints are set to assure trip at or before the assumed analysis setpoint is reached, taking into account all sensor process delays and uncertainties. Further discussions of the instrumentation setpoints and uncertainties are given in Section 7.2.

(2) Setpoint value is set below the value at which fuel centerline melting would occur, see Section 4.4. This trip may be actuated on several conditions including high local power density Asymmetric Steam Generator Trip (ASGT) and variable over power as discussed in Section 7.2.

(3) Percent of distance between the level nozzles. Upon this trip, the emergency feedwater pumps are automatically started and the emergency feedwater valves are automatically opened. A 9% reactor trip setpoint and Emergency Feedwater analytical actuation is assumed for a Loss of Normal Feedwater. The 6% trip setpoint is assumed in the FWLB analysis. Also in the FWLB analysis, an Emergency Feedwater (EFW) flow analytical actuation setpoint of 0% was assumed.

Table 15.1.0-1 (Continued)

(4) See Section 7.2. An RPS setpoint value of 1400 psia is assumed for the Loss of Coolant Accident (LOCA) analysis. An SIAS setpoint value of 1800 psia is used for the Steam Generator Tube Rupture (SGTR). All other analyses, except SGTR, (Major Secondary System Pipe Break Accident and Excess Heat Removal due to Main Steam System Valve Malfunction) assume an SIAS setpoint of 1400 psia.

(5) The response time testing of these protective system trips is required by Technical Specifications.

(6) The Low DNBR trip is actuated based on the DNBR calculation in the Core Protection Calculator System (CPCS). The CPCS retains the CE-1 CHF correlation and, therefore, the trip setpoint is 1.25. However, the safety analysis uses the TORC and CETOP-D codes, which implement the WSSV-T and ABB-NV CHF correlations for NGF. The DNBR limit for the WSSV-T and ABB-NV CHF correlations is 1.23, which is used in the safety analysis as the SAFDL. The CPCS trip setpoint of 1.25 assures that the DNBR limit or SAFDL of 1.23 for the WSSV-T and ABB-NV CHF correlations will not be violated during normal operation and anticipated operational occurrences to at least a 95/95 probability/confidence level. This trip may be actuated on several conditions including low DNBR, low RCP shaft speed, ASGT, and variable overpower as discussed in Section 7.2.

(7) Additional uncertainties are accounted for in the CEA ejection event, which requires a higher analysis value to account for geometry effects.

(8) The response time of the neutron flux signal portion of the channels is measured from the detector output or the input of the first electronic component in the channel. The neutron detectors themselves are exempt from response time testing.

(9) This is the time from CPC trip generation until trip breaker open. Other delays in generating a CPC trip are discussed in Section 7.2 and individual event descriptions.

The total CPC trip delay, based on changes to the input parameters for the respective trips are:

Low DNBR

a.	Neutron Flux Power from Excore Neutron Detectors	≤ 0.39 seconds*
b.	CEA Positions	≤ 1.09 seconds**
c.	Cold Leg Temperature	≤ 3.79 seconds##
d.	Hot Leg Temperature	≤ 1.54 seconds###
e.	Primary Coolant Pump Shaft Speed	≤ 0.80 seconds#
f.	Reactor Coolant Pressure from Pressurizer	≤ 3.19 seconds

High Local Power Density

a.	Neutron Flux Power from Excore Neutron Detectors	≤ 2.58 seconds*
b.	CEA Positions	≤ 1.58 seconds**

* The response time of the neutron flux signal portion of the channel is measured from detector output or input of first electronic component in channel. The neutron detectors are exempt from response time testing.

Table 15.1.0-1 (Continued)

** Response time is measured from the onset of a single CEA drop.

Response time is measured from the onset of a 2 out of 4 Reactor Coolant Pump coastdown.

Based on an effective resistance temperature detector (RTD) response time of ≤ 8.0 seconds.

Based on an effective RTD response time of ≤ 13.0 seconds.

(10) This value is lower when 1 or more Main Steam Safety Valves (MSSVs) are inoperable.

(11) A setpoint value of 2392 psia is assumed for the Loss of External Load and/or Turbine Trip event and Loss of Condenser Vacuum (LOCV) event.

(12) An RPS trip setpoint of 693 psia is assumed for the Main Steam Line Break (MSLB) outside containment event. A Main Steam Isolation Signal (MSIS) setpoint of 693 psia is assumed for the MSLB outside containment event and the Excess Heat Removal due to Main Steam System Malfunction. An MSIS setpoint of 658 psia is assumed for the MSLB inside containment event. For the Feedwater Line Break (FWLB), a MSIS analytical setpoint of 905 psia was assumed with no delay in response time.

The MSLB assumes a Trip Delay Time of 1.59 seconds. A reduced response time of 1.2 seconds, used for a High Containment Pressure trip, is credited as a back-up to High Pressurizer Pressure, Low Steam Generator Level, and low pressurizer pressure to maintain the containment environment.

(14) The FWLB assumes a Trip Delay of 0.9 seconds.

321.1	CEAs begin to drop, and Maximum power occurs	73.8% of full power
321.2	Maximum heat flux, and Minimum WWSV-T / ABB-NV DNBR*	23.4% of full power > 1.23
324.7	Maximum RCS pressure	< 2750 psia
400	End of transient	--

* For Cycle 21, the WSSV-T / ABB-NV CHF correlations and a DNB SAFDL of 1.23 were applied due to the implementation of a full core of NGF.

Table 15.1.2-1

ASSUMPTIONS FOR THE UNCONTROLLED CEA WITHDRAWAL FROM ONE PERCENT POWER

Parameter	Units	Assumptions
Initial Core Power Level	(MWt)	29.0
Core Inlet Coolant Temperature	(°F)	544.6
Core Mass Flow Rate	($10^6 lb_m/hr$)	116.2
Reactor Coolant System Pressure	(psia)	2200
Steam Generator Pressure	(psia)	978
Total Nuclear Heat Flux Factor	-----	4.2
Moderator Temperature Coefficient	(10^{-4} $\Delta\rho$/°F)	+0.5
Doppler Coefficient Multiplier	-----	0.85
CEA Worth on Trip	(10^{-2} $\Delta\rho$)	-5.0
Steam Bypass System	-----	Manual
Feedwater Regulating System	-----	Manual
Reactivity Addition Rate	(10^{-4} $\Delta\rho$/sec)	1.5
Automatic Withdrawal Prohibit(1)	-----	Inoperative

(1) This function of the RRS has been physically removed.

Table 15.1.2-2

ASSUMPTIONS FOR THE UNCONTROLLED CEA WITHDRAWAL FROM FULL POWER

Parameter	Units	Assumptions
Initial Core Power Level	(MWt)	2900
Core Inlet Coolant Temperature	(°F)	556.7
Core Mass Flow Rate	($10^6 lb_m$/hr)	116.2
Reactor Coolant System Pressure	(psia)	2200
Steam Generator Pressure	(psia)	939
Moderator Temperature Coefficient	($10^{-4}\Delta\rho$/°F)	+0.5
Doppler Coefficient Multiplier	------	0.85
CEA Worth on Trip	($10^{-2}\Delta\rho$)	-5.4
Steam Bypass System	------	Manual
Feedwater Regulating System	------	Automatic
Reactivity Addition Rate	($10^{-4}\Delta\rho$/sec)	0.5

Table 15.1.2-3

**SEQUENCES OF EVENTS
FOR THE UNCONTROLLED CEA WITHDRAWAL
FROM ONE PERCENT POWER, BOC CONDITIONS**

Time (Sec)	Event	Setpoint or Value
0.0	Initiation of Uncontrolled Sequential CEA Withdrawal	-----
25.1	High pressurizer pressure trip condition	2422 psia
26.0	Trip Breakers Open	-----
26.2	Pressurizer Safety Valves Begin to Open	2500 psia
26.3	Shutdown CEAs begin to drop into core	-----
27.6	Peak Core Power Occurs	91% (of 2815 MWt)
28.2	Peak Core Average Heat Flux Occurs	76% (of full power heat flux)
28.2	Minimum DNBR Occurs	≥ 1.25*
28.5	Peak RCS Pressure Occurs	2662 psia

* Based on the CE-1 Correlation, which was used at the time this analysis was performed.

Table 15.1.2-4

**SEQUENCE OF EVENTS FOR THE
UNCONTROLLED CEA WITHDRAWAL FROM FULL POWER**

Time (sec)	Event	Setpoint or Value
0.0	Initiation of Uncontrolled Sequential CEA Withdrawal	--------
14.6	Low DNBR Trip Condition	1.25 (CPC projected)
14.75	Trip Breakers Open	--------
15.05	Shutdown CEAs begin to drop into core	--------
15.15	Peak Core Power Occurs	124% (of 2815 MWt)
15.65	Peak Core Average Heat Flux occurs	120% (of full power)
15.65	Minimum DNBR Occurs	≥ 1.25*
17.6	Peak RCS Pressure Occurs	2425 psia

* Based on the CE-1 Correlation, which was used at the time this analysis was performed.

Table 15.1.2-5

**ASSUMPTIONS FOR THE CYCLE 13
UNCONTROLLED CEA WITHDRAWAL
FROM ONE PERCENT POWER**

Parameter	Units	Assumptions
Initial Core Power	(MWt)	0.002815

ASI	Fr	DNBR
0	3.95	1.31
-0.3	3.52	1.33
-0.6	3.26	1.34
-0.75	2.97	1.34
-0.9	2.90	1.33

Table 15.1.2-8

**ASSUMPTIONS FOR THE CYCLE 16
UNCONTROLLED CEA WITHDRAWAL
FROM HOT ZERO POWER**

Parameter	Units	Conservative Assumptions
Initial Core Power	MWt	0.0003026
RCP Heat	MWt	18
Core Inlet Temperature	°F	552
Pressurizer Pressure(1)	psia	2000
Steam Generator Pressure	psia	1058
Reactor Coolant System Flow	gpm	315,560
Total Nuclear Heat Flux Factor	---	7.7
Moderator Temperature Coefficient	10^{-4} $\Delta\rho$/°F	+0.5
Fuel Temperature Coefficient	---	BOC
CEA Worth on Trip	10^{-2} $\Delta\rho$	-2
CEA Reactivity Addition Rate	10^{-4} $\Delta\rho$/sec	1.8
Steam Bypass System	---	Manual
Feedwater Regulating System	---	Manual
Automatic Withdrawal Prohibit	---	Inoperative

Initial pressures are input as pressurizer pressure. Figures are of RCS pressure. Therefore, the initial values in the Figures are slightly higher by 20 to 30 psi than the value quoted here.

Table 15.1.2-9

SEQUENCE OF EVENTS FOR THE CYCLE 16 UNCONTROLLED CEA WITHDRAWAL FROM HOT ZERO POWER

Time, seconds	Event	Setpoint or Value
0.0	Initiation of CEA bank withdrawal	--
22.4	CPCS VOPT trip conditions occurs	36% of full power
23.0	Trip breakers open, and Rod withdrawal stops	--
23.2	Maximum power occurs	75.5% of full power
23.6	CEAs begin to drop	--
23.7	Maximum heat flux occurs, and Minimum WSSV-T / ABB-NV DNBR*	38% of full power > 1.23
27.4	Maximum RCS pressure occurs (includes pump head)	< 2750 psia

* For Cycle 21, the WSSV-T / ABB-NV CHF correlations and a DNB SAFDL of 1.23 were applied due to the implementation of a full core of NGF.

Table 15.1.2-10

ASSUMPTIONS FOR THE CYCLE 16 UNCONTROLLED CEA WITHDRAWAL AT HOT FULL POWER

Parameter	Units	Conservative Assumptions
Initial Core Power Level	MWt	3087
RCP Heat	MWt	18
Core Inlet Temperature	°F	556.7
Pressurizer Pressure(1)	psai	2000
Steam Generator Pressure	psia	1044
Reactor Coolant System Flow	gpm	315,560
Moderator Temperature Coefficient	10^{-4} $\Delta\rho$/°F	0.0
Fuel Temperature Coefficient	---	BOC
CEA Reactivity Addition Rate	10^{-4} $\Delta\rho$/sec	1.0
CEA Worth on Trip	10^{-2} $\Delta\rho$	-5.0
Steam Bypass System	---	Manual

(1) Initial pressures are input as pressurizer pressure. Figures are of RCS pressure. Therefore, the initial values in the Figures are slightly higher by 20 to 30 psi than the value quoted here.

Table 15.1.2-11

SEQUENCE OF EVENTS FOR THE CYCLE 16 UNCONTROLLED CEA WITHDRAWAL AT HOT FULL POWER

Time, seconds	Event	Setpoint or Value
0.0	Initiation of CEA bank withdrawal	--
6.5	CPCS VOPT trip conditions occurs	112.4% of full power
7.1	Trip breakers open	--
7.7	Maximum power occurs, and CEAs begin to drop	114% of full power
8.1	Maximum heat flux occurs, and Minimum WSSV-T / ABB-NV DNBR*	111% of full power > 1.23
9.7	Maximum RCS pressure occurs (includes RCP pump head)	< 2750 psia

* For Cycle 21, the WSSV-T / ABB-NV CHF correlations and a DNB SAFDL of 1.23 were applied due to the implementation of a full core of NGF.

Table 15.1.3-1

ASSUMPTIONS FOR THE FULL LENGTH CEA DROP

Parameter	Units	Conservative Assumptions
Initial Core Power Level	MWt	2900
Core Inlet Coolant Temperature	(°F)	556.7
Core Mass Flow Rate	(10^6 lbm/hr)	116.2
Reactor Coolant System Pressure	(psia)	2250
Steam Generator Pressure	(psia)	923
Axial Shape Index(1)	(asiu)	(2)
Initial Total Nuclear Heat Flux Factor	--	2.35
Dropped CEA Reactivity Worth	(10^{-2} $\Delta\rho$)	(2)
Ratio of After-Drop to Before-Drop Rod Radial Peak	--	(2)
Time for Dropped CEA to be fully inserted	(sec)	1.0
Moderator Temperature Coefficient	($10^{-2}\Delta\rho$/°F)	-3.5
Doppler Coefficient Multiplier	--	1.15
CEA Worth on Trip	(10^{-2} $\Delta\rho$)	-5.3
Reactor Regulating System	--	Automatic(3)
Steam Bypass System	--	Automatic
Feedwater Regulating System	--	Automatic

(1) Axial Shape Index = $\frac{\text{Power in Lower Half of Core – Power in Upper Half of Core}}{\text{Total Core Power}}$

(2) See Table 15.1.3 for cases at two initial axial shape indices

(3) The RRS automatic mode has been physically removed; however, this assumption is retained in the analyses for the purpose of conservatism.

Table 15.1.3-2

RESULTS OF FULL LENGTH CEA DROP

Axial Shape Index	Reactivity Insertion	Initial DNBR	Final 3-D Peak	Initial[1] 3-D Peak	Time[2] of Trip	Peak Hot Channel Heat Flux Value/Time	Min. DNBR Value/Time
+0.19	-0.10% $\Delta\rho$	1.68		1.27	0.6 sec	103.6/2 sec	1.3/2.0 sec
+0.19	-0.10% $\Delta\rho$	2.25		1.27	2.3 sec	110.1/3 sec	1.3/3.5 sec
-0.27	-0.10% $\Delta\rho$	1.39		1.27	0.6 sec	101.8/1.3 sec	1.3/1.3 sec
-0.27	-0.10% $\Delta\rho$	1.55		1.27	1.7 sec	105.6/2.2 sec	1.3/2.2 sec

(1) The 27 percent increase in radial peaking factor during the transient is 10 percent greater than the calculated increase in peaking factor which is 24 percent. This uncertainty is in addition to the 10 percent uncertainty applied to the initial radial peak.

(2) Time of trip refers to the time a low DNBR Trip Signal is generated. The scram rods begin to fall into the core 0.45 seconds later.

Table 15.1.13-1

ASSUMPTIONS FOR DESIGN BASIS LOSS OF COOLANT-ACCIDENT

Parameter/Assumption	Assumed Value
Reactor Power	3086.52 MWt (102% Rated Power)
Percent of Core Noble Gases Released	100%
Percent of Core Iodine Released	40%
Iodine Species Distribution	4.85% Elemental 95% Particulate 0.15% Organic
Containment Free Volume	1.78 E6 ft^3
Sump Water Volume	62898 ft^3
Sprayed Volume	1.388 E6 ft^3
Unsprayed Volume	3.92 E5 ft^3
Mixing Rates Between Sprayed and Unsprayed Regions	11880 CFM
Spray Removal Rates	
Elemental Iodine	20/hour prior to recirculation 0/hour during first 11 min of recirculation 10/hour up to Decontamination Factor (DF) of 200 0/hour after DF = 200
Particulate Iodine	3.97/hour prior to recirculation 4.24/hour during recirculation up to DF of 50 0.424/hour until DF=1000 DF = 1000 0/hour after DF = 1000
Organic Iodine	No Removal
Containment Leak Rate	0.1%/day from 0 to 24 hours 0.05%/day after 24 hours
Release Point	Ground Level
Dose Conversion Factors	From FGR 11 & 12
Percent of Released Iodine in Sump During Recirculation (for ESF leakage calculation)	100%

ADDITIONAL CONTROL ROOM DOSE ASSUMPTIONS

Dispersion Coefficients, χ/Q	
0 to 2 hours	9.77 E-4 sec/m^3
2 to 8 hours	5.76 E-4 sec/m^3
8 to 24 hours	2.56 E-4 sec/m^3
1 to 4 days	1.69 E-4 sec/m^3
4 to 30 days	1.28 E-4 sec/m^3
Control Room Volume	40,000 ft^3
Control Room Unfiltered Inleakage	250 CFM
Control Room Filtered Inflow	333 CFM*
Control Room Recirculation Flow	1667 CFM*
Intake Filter Efficiency	99%
Recirculation Filter Efficiency	
Elemental & Organic	95%
Particulate	99%
Occupancy Factors	
0 to 24 hours	1.0
1 to 4 days	0.6
4 to 30 days	0.4
Breathing Rate	3.5 E-4 m^3/sec

* Limiting case is VSF-9 in operation with 333 cfm outside air.

Table 15.1.13-2

LOSS OF COOLANT ACCIDENT DOSES

Location/Dose Component	Dose (Rem TEDE)
2 Hour Exclusion Area Boundary Doses	
Containment Release	9.350
ESF Leakage	0.174
Total	9.524
30 Day Low Population Zone Doses	
Containment Release	0.654
ESF Leakage	0.055
Total	0.709
Control Room Doses	
Containment Release	1.708
ESF Leakage	0.274
Cloud Shine	0.006
Containment Shine	0.106
Total	2.094

Table 15.1.13-3

RELEASE FRACTIONS AND TIMING

Phase	Timing	Fraction
Gap Release	30 sec – 0.5 hrs	0.05 for noble gases 0.05 for halogens 0.05 for alkali metals
Early In-Vessel Release	0.5 – 1.8 hrs	0.95 noble gases 0.35 halogens 0.25 alkali metals 0.05 tellurium metals 0.02 strontium and barium 0.0025 noble metals 0.0005 cerium group 0.0002 lanthanides

Table 15.1.14-1

AVERAGE MOISTURE CARRYOVER FOR VARIOUS STEAM GENERATOR CONDITIONS

Initial Condition	Effective Break Area	Average Moisture Carryover Fraction Ruptured Steam Generator	Average Moisture Carryover Fraction Intact Steam Generator
Full Load	6.3 ft^2	0.65	0.41
	2.0 ft^2	0.0	0.0
No Load	6.3 ft^2	0.77	0.41
	1.0 ft^2	0.0	0.0
No Load (Outside Containment)	2.49 ft^2	0.64	0.41

Table 15.1.14-2

ASSUMPTIONS FOR STEAM LINE BREAK ANALYSIS

	Conservative Assumptions	
Parameter	Full Load 2-Loop/1-Loop	No Load 2-Loop/1-Loop
Initial Core Power Level, Mwt	2900/1277	1.0
Core Inlet Coolant Temperature, °F	556.7/559.4	547.6
Core Flow Rate 10^6lbm/hr	116.2/53.7	116.2/53.7

KEY PARAMETERS ASSUMED IN THE CYCLE 2 CEA EJECTION ANALYSES

Parameter		
Full Power	Units	Cycle 2
Core Power Level	MWt	2900
Core Average Linear Heat Generation Rate at 2815 MWt	KW/ft	5.54
Moderator Temperature Coefficient	10^{-4} $\Delta\rho$/°F	+0.5
Ejected CEA Worth	%$\Delta\rho$	0.30
Delayed Neutron Fraction, β	--	0.00482
Maximum Post-Ejected Radial Power Peak	--	2.94
Axial Power Peak	--	1.75
CEA Bank Worth at Trip	%$\Delta\rho$	-5.4
Fuel Temperature Coefficient	--	0.85
CEA Ejection Time	sec	0.05
Zero Power		
Core Power Level	MWt	1.0
Ejected CEA Worth	%$\Delta\rho$	0.82
Post-Ejected Radial Power Peak	--	8.23
Axial Power Peak	--	2.50
CEA Bank Worth at Trip	%$\Delta\rho$	-2.4
Fuel Temperature Coefficient Multiplier	--	0.85
CEA Ejection Time	sec	0.05

Table 15.1.20-9

CYCLE 2 CEA EJECTION EVENT RESULTS

Full Power	Cycle 2
Total Average Enthalpy of Hottest Fuel Pellet (cal/gm)	156
Total Centerline Enthalpy of Hottest Fuel Pellet (cal/gm)	267
Fraction of Rods that Suffer Clad Damage (average Enthalpy ≥ 200 cal/gm)	0
Fraction of Fuel Having at Least Incipient Centerline Melting (Centerline Enthalpy ≥ 250 cal/gm)	≤ 0.005
Fraction of Fuel Having a Fully Molten Centerline Condition (Centerline Enthalpy ≥ 310 cal/gm)	0

Zero Power	Cycle 2
Total Average Enthalpy of Hottest Fuel Pellet (cal/gm)	164
Total Centerline Enthalpy of Hottest Fuel Pellet (cal/gm)	296
Fraction of Rods that Suffer Clad Damage (Average Enthalpy ≥ 200 cal/gm)	0
Fraction of Fuel Having at Least Incipient Centerline Melting (Centerline Enthalpy ≥ 250 cal/gm)	≤ 0.005
Fraction of Fuel Having a Fully Molten Centerline Condition (Centerline Enthalpy ≥ 310 cal/gm)	0

Auxiliary building with no ventilation or containment with open personnel airlock	4.01	0.19	1.19

Table 15.1.34-1

IDENTIFICATION OF SAFETY-RELATED AIR OPERATED VALVES AND THEIR FAILURE MODES

Valve No.	Valve Description	SAR Figure No.	Failure Mode	Comments and Consequences
2CV-6207-2	Nitrogen Supply to Safety Injection Tanks Isolation Valve	3.2-5	Fail Closed	Valves close on CIAS or SIAS. Nitrogen supply is not required for shutdown.
2CV-6213-2	Nitrogen Supply to Containment Isolation Valve	3.2-5	Fail Closed	
2CV-4823-2	CVCS Letdown Flow Valve	9.3-4	Fail Closed	Valve closes on CIAS. Letdown flow is not required for safe shutdown.
2CV-4847-2	Reactor Coolant Pump Bleed-off Valve	9.3-4	Fail Closed	Valve closes on CIAS or SIAS. Bleed-off is not required following containment isolation.
2CV-2061-2	Containment Sump to Auxiliary Building Sump Isolation Valve	11.2-1	Fail Closed	Valves close on CIAS or SIAS. Closed position isolates Containment.
2CV-2201-2	Reactor Drain Pump Suction Isolation Valve	11.2-1	Fail Closed	

Table 15.1.34-1 (continued)

Valve No.	Valve Description	SAR Figure No.	Failure Mode	Comments and Consequences
2CV-1016-1 2CV-1066-1	Steam Generator Blowdown Tank Valves	10.2-3	Fail Closed	Valves close on MSIS. Closed position prevents blowdown of steam generator via this path.
2CV-1010-1 2CV-1060-2	Main Steam Isolation Valves	10.2-3	Fail Closed	Valves close on loss of air supply. Pressure in secondary system will build up but overpressure is prevented by main steam safety valves. Accumulator T-091 provides air supply to prevent fast closing of valves if normal air supply air line break occurs.
2CV-8283-1 2CV-8284-2 2CV-8285-1 2CV-8286-2	Containment Purge System Isolation Valves	9.4-4	Fail Closed	Valves close on CIAS or SIAS. Valve closing isolates containment.
2CV-8471-1 2CV-8472-1 2CV-8474-2 2CV-8475-2 2CV-8497-2 2CV-8498-2	ESF Pump Room Ventilation Isolation Valves	N.A. (M-2262)	Fail Closed	Valves close on SIAS. Closed position isolates the ESF pump rooms. Emergency cooling is provided in each room.

Table 15.1.34-1 (continued)

Valve No.	Valve Description	SAR Figure No.	Failure Mode	Comments and Consequences
2UCD-8683	Control Room Isolation Damper	9.4-1	Fail Closed	Failure of air supply or electric power isolates the control room.
2PCD-8685	Control Room Isolation Damper	9.4-1	Fail Closed	
2UCD-8609	2VSF-9 Shutoff Damper	9.4-1	Fail Open	Open position ensures availability of flow path to control room emergency filters.
2PCD-8607-A 2PCD-8607-B	2VSF-9 Return Air Damper 2VSF-9 Outside Air Damper	9.4-1 9.4-1	Fail Open Fail Open	
2CV-3852-1 2CV-3851-1	Chilled Water Containment Isolation Valves	3.2-4	Fail Closed	Valves close on CIAS. Chilled water is not required for plant safety.
2CV-0714-1	EFW 2P-7A/B Flushing Control Valve	10.2-4	Fail Closed	Verified closed by EFAS.
2CV-0798-1	EFW 2P-7A/B Recirc. Flush Line Control Valve	10.2-4	Fail Closed	Closed by EFAS, but not credited for isolation. 2EFW-11B & C are credited for isolation.
2CV-5091	Shutdown Cooling Bypass Valve	6.3-2	Fail Open	Open during power operation with key removed from handswitch.

Table 15.1.34-1 (continued)

Valve No.	Valve Description	SAR Figure No.	Failure Mode	Comments and Consequences
2CV-5093	Shutdown Cooling Modulating Valve	6.3-2	Fail Closed	Closed during power operation.
2CV-5637-1	RWT to SFP Purification Isolation Valve	9.1-1	Fail Closed	Closed by SIAS.
2CV-5638-2	RWT to SFP Purification Isolation Valve	9.1-1	Fail Closed	Closed by SIAS

16 TECHNICAL SPECIFICATIONS

The final Technical Specifications (TSs) were issued with the Operating License, and have been updated periodically through various license amendments. The Technical Specifications currently exist as updated in a separate binder/volume.

16.1 MODE 4 TS END STATES

NRC Safety Evaluation Report (SER) (2CNA031502, ML15068A319) approved a Mode 4 end state for several ANO-2 TSs. Provided risk is appropriately managed, the shutdown statements within the subject TSs no longer require placing the unit in Mode 5.

16.1.1 MODE 4 TS END STATE IMPLEMENTATION AND RISK ASSESSMENT

The aforementioned SER is associated with ANO-2 TS Amendment 301, which adopted TSTF-422, "Change in Technical Specifications End States (CE NPSD-1186)." The NRC approved the Mode 4 end states for TSs specified in the SER provided the following implementation guidance is implemented:

- Entergy will follow the guidance established in Section 11 of NUMARC 93-01, "Industry Guidance for Monitoring the Effectiveness of Maintenance at Nuclear Power Plants," Nuclear Management and Resource Council, Revision 4A, April 2011.

- Entergy will follow the guidance established in WCAP-16364-NP, Revision 2, "Implementation Guidance for Risk Informed Modification to Selected Required Action End States at Combustion Engineering NSSS Plants (TSTF-422)," dated May 2010, with the exception that Section 11 of NUMARC 93-01, Revision 4A, will be utilized to meet 10 CFR 50.65(a)(4) requirements in lieu of NUMARC 93-01, Revision 3.

The implementation guidance of WCAP-16364-NP has been implemented into a common Operations directive. The directive, along with procedures associated with risk assessments, were also updated to ensure risk assessments would be performed in accordance with NUMARC 93-01, Revision 4A, Section 11.

17 QUALITY ASSURANCE

17.1 QUALITY ASSURANCE DURING OPERATIONS

NRC accepted Arkansas Power and Light Company's (AP&L's) Topical Report, AP&L-TOP-1A, "Quality Assurance Manual Operations" by letter dated May 5, 1980. This report describes the quality assurance (QA) program which AP&L applies to those operational phase activities involving safety-related structures, systems and components for ANO.

With the acceptance of AP&L-TOP-1A, the chapter section "Quality Assurance During Design and Construction," was deleted due to lack of applicability.

As of June 10, 1986, the Quality Assurance Manual Operations was reclassified as a quality program description in lieu of a Topical Report. This change did not reduce AP&L's quality commitments previously accepted by the NRC on May 5, 1980. Annual revisions to the Quality Assurance Manual Operations, which do not reduce commitments, shall be submitted in conjunction with ANO-1 Safety Analysis Report submittals.

As of April 30, 1999, the ANO QA Manual Operations was deleted and replaced with the EOI QA Program Manual (QAPM).

18 AGING MANAGEMENT PROGRAMS AND ACTIVITIES

The integrated plant assessment for license renewal identified aging management programs necessary to provide reasonable assurance that systems, structures, and components within the scope of license renewal will continue to perform their intended functions consistent with the current licensing basis (CLB) for the period of extended operation. This section describes the aging management programs and activities that will be required during the period of extended operation. "The Quality Assurance Program implements the requirements of 10 CFR 50, Appendix B. The Quality Assurance Program includes the elements of corrective action, confirmation process, and administrative controls and is applicable to all aging management programs credited for license renewal including programs for safety-related and non-safety related structures, systems and components."

18.1 PROGRAMS AND ACTIVITIES

18.1.1 ALLOY 600 AGING MANAGEMENT PROGRAM

This program will manage aging effects of alloy 600/690 items and alloy 52/152 and 82/182 welds in the reactor coolant system that are not addressed by the Reactor Vessel Head Penetration Inspection Program, Section 18.1.21, and the Steam Generator Integrity Program, Section 18.1.26. This program will detect primary water stress corrosion cracking (PWSCC) by using the examination and inspection requirements of ASME Section XI, as augmented by commitments in NRC correspondence. During development of the ANO-2 Alloy 600 Aging Management Program, guidance developed by the EPRI MRP for selection, inspection, and evaluation of nickel-based alloy items will be considered. The Alloy 600 Aging Management Program will be initiated prior to the period of extended operation.

18.1.2 BOLTING AND TORQUING ACTIVITIES

The Bolting and Torquing Activities Program manages the loss of mechanical closure integrity for bolted connections and bolted closures in high temperature systems and in applications subject to significant vibration. The program relies on recommendations for a comprehensive bolting integrity program, as delineated in the Electric Power Research Institute EPRI NP-5067, Good Bolting Practices. This program also relies on industry recommendations for comprehensive bolting maintenance, as delineated in the EPRI TR-104213, Bolted Joint Maintenance and Applications Guide.

18.1.3 BORIC ACID CORROSION PREVENTION PROGRAM

The Boric Acid Corrosion Prevention Program relies on implementation of recommendations of NRC Generic Letter (GL) 88-05 to monitor the condition of ferritic steel and electrical components on which borated water may leak. The program will detect borated water leakage by periodic visual inspection of borated water containing systems for deposits of boric acid crystals and the presence of moisture. This program will manage loss of material, loss of mechanical closure integrity, and corrosion of connector surfaces.

18.1.4 BURIED PIPING INSPECTION PROGRAM

The Buried Piping Inspection Program will include preventive measures to mitigate corrosion and periodic inspection to manage the effects of corrosion on buried carbon steel piping. Preventive measures will be in accordance with standard industry practice for maintaining

external coatings and wrappings. Buried pipes will be inspected when they are excavated during maintenance. The Buried Piping Inspection Program will be initiated prior to the period of extended operation.

18.1.5 CAST AUSTENITIC STAINLESS STEEL (CASS) EVALUATION PROGRAM

The Cast Austenitic Stainless Steel (CASS) Evaluation Program will augment the inspection of reactor coolant system components in accordance with the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code, Section XI. The CASS Evaluation Program will manage the effects of loss of fracture toughness in reactor coolant system CASS components susceptible to thermal aging embrittlement using additional inspections and a component-specific flaw tolerance evaluation. This program will not include reactor vessel internals CASS components which are evaluated and inspected as part of the PWR Vessel Internals Program (Section 18.1.23 and Section 18.1.24). The CASS Evaluation Program will be initiated prior to the period of extended operation.

18.1.6 CONTAINMENT LEAK RATE PROGRAM

As described in 10 CFR Part 50, Appendix J, containment leak rate tests are required to assure that (a) leakage through the primary reactor containment and systems and components penetrating primary containment do not exceed allowable values and (b) periodic surveillance of reactor containment penetrations and isolation valves is performed so that proper maintenance and repairs are made during the service life of the containment. This program manages loss of material and cracking for equipment constituting the containment pressure boundary.

18.1.7 DIESEL FUEL MONITORING PROGRAM

The Diesel Fuel Monitoring Program ensures that adequate diesel fuel quality is maintained to prevent plugging of filters, fouling of injectors, and corrosion of fuel systems. This program manages aging effects on the internal surfaces of diesel fuel tanks and piping within the scope of license renewal. The program monitors fuel oil quality and the levels of water and microbiological organisms in the fuel oil. Visual inspections of tanks drained for cleaning ensures that significant degradation is not occurring. This program manages the loss of material and cracking for fuel oil system components.

18.1.8 ENVIRONMENTAL QUALIFICATION (EQ) OF ELECTRIC COMPONENTS PROGRAM

The EQ Program manages component thermal, radiation, and cyclical aging of electrical equipment important to safety as required by 10 CFR 50.49. The EQ Program manages aging effects through the use of aging evaluations based on 10 CFR 50.49(f) qualification methods. As required by 10 CFR 50.49, EQ components not qualified for the license term are to be refurbished, replaced, or have their qualification extended prior to reaching aging limits.

18.1.9 FATIGUE MONITORING PROGRAM

The Fatigue Monitoring Program tracks the number of critical thermal and pressure transients for selected reactor coolant system (RCS) components in order not to exceed the design limit on fatigue usage. The program ensures the validity of analyses containing explicit cycle count assumptions. The components managed by this program are those shown to be acceptable by analyses that explicitly addressed thermal and pressure fatigue transient limits.

18.1.10 FIRE PROTECTION PROGRAM

The Fire Protection Program includes fire barrier inspections and a diesel-driven fire pump inspection. The fire barrier inspections entail periodic visual inspection of fire barrier penetration seals, fire barrier walls, ceilings, and floors, and periodic visual inspection and functional tests of fire rated doors. The diesel-driven fire pump inspection requires that the pump be periodically tested to ensure that the fuel supply line can perform its intended function.

18.1.11 FIRE WATER SYSTEM PROGRAM

The Fire Water System Program applies to water-based fire protection systems that consist of sprinklers, nozzles, fittings, valves, hydrants, hose stations, standpipes, water storage tanks, and aboveground and underground piping and components that are tested in accordance with the applicable National Fire Protection Association (NFPA) codes and standards. Such testing assures the minimum functionality of the systems. These systems are normally maintained at required operating pressure and monitored such that leakage resulting in loss of system pressure is immediately detected and corrective actions initiated. A sample of sprinkler heads will be inspected using the guidance of NFPA 25.

18.1.12 FLOW-ACCELERATED CORROSION PROGRAM

The Flow-Accelerated Corrosion Program manages loss of material due to flow-accelerated corrosion. This program includes (a) an analysis to determine critical locations, (b) limited baseline inspections to determine the extent of thinning at these locations, and (c) follow-up inspections to confirm the predictions, or component repair or replacement as necessary.

18.1.13 HEAT EXCHANGER MONITORING PROGRAM

The Heat Exchanger Monitoring Program will manage loss of material and cracking, as applicable, on heat exchangers in various systems. The Heat Exchanger Monitoring Program will inspect heat exchangers for degradation using non-destructive examinations, such as eddy-current inspections and visual inspections. If degradation is found, then an evaluation will be performed to determine its effects on the heat exchanger's design functions. The Heat Exchanger Monitoring Program will be initiated prior to the period of extended operation.

18.1.14 INSERVICE INSPECTION – CONTAINMENT INSERVICE INSPECTION PROGRAM

The Containment Inservice Inspection Program implements the applicable requirements of ASME Section XI, Subsections IWE and IWL as modified by 10 CFR 50.55a. Every 10 years the containment inservice inspection program for ANO-2 is updated to the latest ASME Section XI code edition and addendum approved by the Nuclear Regulatory Commission in 10 CFR 50.

18.1.15 INSERVICE INSPECTION –INSERVICE INSPECTION PROGRAM

The Inservice Inspection Program implements the applicable requirements of ASME Section XI, Subsections IWB, IWC, IWD and IWF, and other requirements specified in 10 CFR 50.55a with approved NRC alternatives and relief requests. Every 10 years the Inservice Inspection Program for ANO-2 is updated to the latest ASME Section XI code edition and addendum approved by the Nuclear Regulatory Commission in 10 CFR 50.

18.1.16 NON-EQ INACCESSIBLE MEDIUM-VOLTAGE CABLE PROGRAM

The Non-EQ Inaccessible Medium-voltage Cable Program will apply to inaccessible (e.g., in conduit or direct buried) medium-voltage cables within the scope of license renewal that are exposed to significant moisture simultaneously with applied voltage. In this aging management program, periodic actions will be taken to prevent cables from being exposed to significant moisture. In-scope medium-voltage cables exposed to significant moisture and voltage will be tested to provide an indication of the condition of the conductor insulation. The specific type of test performed will be determined prior to the initial test. The Non-EQ Inaccessible Medium-voltage Cable Program will be initiated prior to the period of extended operation.

18.1.17 NON-EQ INSULATED CABLES AND CONNECTIONS PROGRAM

The Non-EQ Insulated Cables and Connections Program will apply to accessible (i.e., able to be approached and viewed easily) insulated cables and connections installed in structures within the scope of license renewal and prone to adverse localized environments. An adverse localized environment is significantly more severe than the specified service condition for the insulated cable or connection. The program will visually inspect a representative sample of accessible insulated cables and connections for cable and connection jacket surface anomalies. The Non-EQ Insulated Cables and Connections Program will be initiated prior to the period of extended operation.

18.1.18 OIL ANALYSIS PROGRAM

The Oil Analysis Program ensures the oil environment in mechanical systems in the scope of license renewal is maintained to the required quality. By monitoring oil quality, the Oil Analysis Program maintains oil systems free of contaminants (primarily water and particulates) thereby preserving an environment that is not conducive to loss of material, cracking or fouling.

18.1.19 PERIODIC SURVEILLANCE AND PREVENTIVE MAINTENANCE PROGRAM

The Periodic Surveillance and Preventive Maintenance Program consists of periodic inspections and tests that are relied on to manage aging effects that are not managed by other aging management programs. Preventive maintenance and surveillance testing activities provide for periodic component inspections and testing to detect various aging effects applicable to those components included in the program for license renewal.

18.1.20 PRESSURIZER EXAMINATIONS PROGRAM

The Pressurizer Examinations Program will use volumetric examinations required by ASME Section XI to manage cracking of the stainless steel and nickel-based alloy cladding and attachment welds to the cladding which may propagate into the underlying ferritic steel. Volumetric examination of the circumferential shell to head weld and the weld metal between the surge nozzle and the vessel lower head will be performed each inspection interval. The Pressurizer Examinations Program is an existing program.

18.1.21 REACTOR VESSEL HEAD PENETRATION PROGRAM

The Reactor Vessel Head Penetration Program manages cracking of nickel based alloy reactor vessel head penetrations exposed to borated water to assure that the pressure boundary function is maintained. The program consists of both visual and volumetric examinations in

accordance with ASME Code requirements as reflected in the approved ISI Plan. The program will be modified as appropriate to implement evolving commitments in response to industry experience and regulatory requirements. The Inservice Inspection (Section 18.1.15) and Water Chemistry Control Programs (Section 18.1.33) are used in conjunction with this program to manage cracking of the reactor vessel head penetrations.

18.1.22 REACTOR VESSEL INTEGRITY PROGRAM

The Reactor Vessel Integrity Program manages reduction of fracture toughness of reactor vessel beltline materials to assure that the pressure boundary function of the reactor vessel is maintained. The program is based on ASTM E-185-82, “Standard Recommended Practice for Surveillance Tests for Nuclear Reactor Vessels,” and includes an evaluation of radiation damage based on pre-irradiation and post irradiation testing of Charpy V-notch and tensile specimens. Through the Reactor Vessel Integrity Program, reports are submitted as required by 10 CFR Part 50 Appendix H.

18.1.23 REACTOR VESSEL INTERNALS CAST AUSTENITIC STAINLESS STEEL (CASS) PROGRAM

The PWR Vessel Internals Program will manage aging effects of cast austenitic stainless steel reactor vessel internals components. This program will supplement the reactor vessel internals inspections required by the ASME Section XI Inservice Inspection Program. The program will manage cracking, reduction of fracture toughness, and dimensional changes using inspections of applicable components which will be determined based on the neutron fluence and thermal embrittlement susceptibility of the component. The PWR Vessel Internals Program will be initiated prior to the period of extended operation.

18.1.24 REACTOR VESSEL INTERNALS STAINLESS STEEL PLATES, FORGINGS, WELDS, AND BOLTING PROGRAM

The PWR Vessel Internals Program will manage aging effects of reactor vessel internals plates, forgings, welds, and bolting. This program will supplement the reactor vessel internals inspections required by the ASME Section XI Inservice Inspection Program. This program will manage the effects of crack initiation and growth due to stress corrosion cracking or irradiation assisted stress corrosion cracking, loss of fracture toughness due to neutron irradiation embrittlement, and distortion due to void swelling. This program will provide visual inspections and non-destructive examinations of reactor vessel internals. The PWR Vessel Internals Program will be initiated prior to the period of extended operation.

18.1.25 SERVICE WATER INTEGRITY PROGRAM

The Service Water Integrity Program relies on implementation of the recommendations of NRC Generic Letter (GL) 89-13 to ensure that the effects of aging on the service water (SW) system will be managed. The program includes surveillance and control techniques to manage aging effects in the SW system or structures and components serviced by the SW system.

18.1.26 STEAM GENERATOR INTEGRITY PROGRAM

In the industry, steam generator tubes have experienced degradation related to corrosion phenomena, such as primary water stress corrosion cracking, outside diameter stress corrosion cracking, intergranular attack, pitting, and wastage, along with other mechanically induced

phenomena, such as denting, wear, impingement damage, and fatigue. Using NEI 97-06 as a guideline, the Steam Generator Integrity Program uses nondestructive examination techniques to identify tubes that are defective and need to be removed from service or repaired in accordance with the guidelines of the Technical Specifications. In addition, the Steam Generator Integrity Program uses nondestructive examination techniques to manage the effect of aging on secondary side internals needed to maintain tubing integrity.

18.1.27 STRUCTURES MONITORING – MASONRY WALL PROGRAM

The Masonry Wall Program will manage cracking of masonry walls within the scope of license renewal. Masonry walls are visually inspected as part of the Structures Monitoring Program conducted for the maintenance rule, 10 CFR 50.65.

18.1.28 STRUCTURES MONITORING – STRUCTURES MONITORING PROGRAM

Structures monitoring as required by 10 CFR 50.65 (the maintenance rule) is based on the guidance in NRC Regulatory Guide (RG) 1.160, Rev. 2, and NUMARC 9301, Revision 2. These two documents provide guidance for development of licensee-specific programs to monitor the condition of structures and structural components within the scope of the maintenance rule and the scope of license renewal, such that there is no loss of structure or structural component intended function.

18.1.29 SYSTEM WALKDOWN PROGRAM

The System Walkdown Program will conduct inspections to manage loss of material, loss of mechanical closure integrity and cracking, as applicable, for systems and components within the scope of license renewal. The program will use general visual inspections of readily accessible system and component surfaces during system walkdowns.

18.1.30 WALL THINNING MONITORING PROGRAM

The Wall Thinning Monitoring Program will manage loss of material from components, as applicable, within the scope of license renewal. Inspections will be performed to ensure wall thickness is above the minimum required in order to avoid failures. The Wall Thinning Monitoring Program will be initiated prior to the period of extended operation.

18.1.31 WATER CHEMISTRY CONTROL – AUXILIARY SYSTEMS WATER CHEMISTRY CONTROL PROGRAM

The Auxiliary Systems Water Chemistry Control program manages loss of material, cracking, and fouling, as applicable, of components in the scope of license renewal. The program monitors and controls the relevant chemistry conditions for components exposed to treated water environments. The following Industry guidance was used in development of the Auxiliary Systems Water Chemistry Control Program.

- EPRI TR-107396
- EPRI NP-5569
- CE-NPSD-448
- B&W Water Chemistry Manual
- EPRI TR-105504
- Technical Manual for Alternate AC (AAC) Diesel Generator System

18.1.32 WATER CHEMISTRY CONTROL – CLOSED COOLING WATER CHEMISTRY CONTROL PROGRAM

The Closed Cooling Water Chemistry Control Program includes preventive measures that manage loss of material, cracking, and fouling, as applicable, for component cooling water system components. These chemistry activities provide for monitoring and controlling component cooling water chemistry using procedures and processes based on EPRI TR-107396, "Closed Cooling Water Chemistry Guidelines."

18.1.33 WATER CHEMISTRY CONTROL – PRIMARY AND SECONDARY WATER CHEMISTRY CONTROL PROGRAM

The Primary and Secondary Water Chemistry Control Program manages loss of material, cracking, and fouling, as applicable, by control of contaminants. This water chemistry program relies on monitoring and control of water chemistry based on EPRI guidelines, TR-105714 and TR-102134, for primary water chemistry and for secondary water chemistry.

18.1.34 ONE-TIME INSPECTION

The One-Time Inspection Program confirms that aging effects are being adequately managed for components in raw or untreated water. This program will perform destructive or nondestructive inspections on internal surfaces of a sample of components in the following systems.

- Auxiliary building heating and ventilation
- Auxiliary building sump
- Drain collection header
- Liquid radwaste management
- Post-accident sampling
- Resin transfer
- Regenerative waste
- Spent resin

The One-Time Inspection Program will be initiated prior to the period of extended operation.

18.2 TIME-LIMITED AGING ANALYSES (TLAAs)

18.2.1 REACTOR VESSEL NEUTRON EMBRITTLEMENT

Three analyses that address the effects of neutron irradiation embrittlement of the reactor vessel have been identified as TLAAs. These analyses address:

- Charpy upper-shelf energy,
- Pressurized thermal shock, and
- Pressure-temperature (P-T) limits.

The analyses were updated to 48 effective full power years (EFPY) which represents the approximate end of the period of extended operation (60 years) assuming a capacity factor of 80%. The Reactor Vessel Integrity Program described in Section 18.1.22 will ensure that the time-dependent parameters used in these TLAAs remain valid through the period of extended operation. The reactor vessel neutron embrittlement TLAAs are projected to the end of the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii).

18.2.1.1 Charpy Upper Shelf Energy

Appendix G of 10 CFR 50 requires that reactor vessel beltline materials maintain a Charpy upper shelf energy (C_VUSE) of no less than 50 ft-lb throughout the life of the vessel. The C_VUSE values were calculated using Regulatory Guide 1.99, Revision 2, Positions 1 and 2. The C_VUSE is maintained above 50 ft-lb for all base metal (plates and forgings) and welds at 48 EFPY. Therefore, the analysis of upper shelf energy has been projected to the end of the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii).

18.2.1.2 Pressurized Thermal Shock

10 CFR 50.61(b)(1) provides rules for the protection of pressurized water reactors against pressurized thermal shock. The projected values of reference temperature for pressurized thermal shock, RT_{PTS}, are required to be assessed upon request for a change in the expiration date for the facility operating license.

10 CFR 50.61(b)(2) establishes screening criteria for RT_{PTS}: 270 °F for plates, forgings, and axial welds and 300 °F for circumferential welds. Projected values for RT_{PTS} at 48 EFPY for ANO-2 were calculated using 10 CFR 50.61 and are all within the established screening criteria for 48 EFPY. Therefore, calculations for RT_{PTS} have been projected to the end of the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii).

18.2.1.3 Pressure-Temperature Limits

Appendix G of 10 CFR 50 requires operation of the reactor pressure vessel within established pressure-temperature (P-T) limits. ANO-2 submitted, and the NRC approved, a license amendment request for reactor coolant system pressure-temperature curves for 32 EFPY (References 6, 7, 17, and 18). The curves specify limits on RCS pressure and temperature for up to 32 effective full power years with a 7.5% power uprate. These P-T curves are based on a fluence analysis methodology that complies with Regulatory Guide 1.190 and utilize ASME Code Cases N-640 and N-588. The ANO-2 P-T limit analyses have been extended to 48 EFPY and the operating window at 48 EFPY is sufficient to conduct normal heatup and cooldown operations. Therefore, pressure-temperature limits for ANO-2 have been projected to the end of the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii).

18.2.2 METAL FATIGUE

The design analysis of metal fatigue is a TLAA for Class 1 and selected non-Class 1 mechanical components within the scope of license renewal. Industry experience and new research have found additional fatigue issues, such as thermal stratification and environmentally-assisted fatigue, which were not considered in the original plant design.

18.2.2.1 Class 1 Metal Fatigue

Fatigue evaluations performed in the design of the Class 1 RCS components were based on a number of design cycles assumed for the life of the plant. The RCS design transients used in the fatigue evaluations for the Class 1 components were reviewed for ANO-2. The numbers of actual RCS design transients from plant operating history were extrapolated to 60 years of operation. In all instances, the number of RCS design transients assumed in the original design was greater than the extrapolated number for 60 years of operation. Therefore, the fatigue evaluations for the Class 1 components remain valid for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i). The RCS design transients are monitored through the Fatigue Monitoring Program, which is discussed in Section 18.1.9.

18.2.2.2 Non-Class 1 Metal Fatigue

Piping components that may have normal or upset condition operating temperature in excess of 220 °F for carbon steel, or 270 °F for austenitic stainless steel, were evaluated for fatigue. The piping components were evaluated for their potential in 60 years of plant operation to exceed the limiting number of equivalent full temperature cycles used for the original design. Fatigue considerations for the original piping and component design are valid for the period of extended operation.

18.2.2.3 Environmentally-Assisted Fatigue

Recent test data indicate that certain environmental effects (such as temperature, oxygen, and stress) in the primary systems of light water reactors (LWR) could result in greater susceptibility to fatigue than would be predicted by fatigue analyses based on the ASME Section III design fatigue curves. The NRC has concluded that although not safety significant through the end of the initial license term, the environmental effects associated with fatigue life should be addressed for license renewal.

The effects of environmentally-assisted thermal fatigue for the limiting locations identified in NUREG-6260 were evaluated for ANO-2 in accordance with 10 CFR 54.21c(1)(i and ii) and all locations are acceptable for the period of extended operation with the exception of the charging nozzle, shutdown cooling line, and pressurizer surge line. The approach for addressing environmental fatigue for the above locations will include one or more of the following:

(1) Further refinement of the fatigue analysis to lower the CUFs to below 1.0, or

(2) Repair of the affected locations, or

(3) Replacement of the affected locations, or

(4) Managing the effects of fatigue of the locations by an inspection program that has been reviewed and approved by the NRC (for example, periodic nondestructive examination of the affected locations at inspection intervals to be determined by a method accepted by the NRC). The inspections are expected to be able to detect cracking due to thermal fatigue prior to loss of function. Replacement or repair will then be implemented such that the intended function will be maintained for the period of extended operation, or

(5) Monitoring ASME Code activities to use the environmental fatigue methodology approved by the code committee and NRC.

Should ANO-2 select Option 4 (inspection) to manage environmentally-assisted fatigue during the period of extended operation, details such as scope, qualification, method, and frequency will be provided to the NRC prior to entering the period of extended operation.

The effects of environmental-assisted thermal fatigue for the limiting locations identified in NUREG-6260 have been evaluated for ANO-2 in accordance with 10 CFR 54.21(c)(1)(i) and 10 CFR 54.21(c)(1)(ii) and all locations are acceptable for the period of extended operation with the exception of the charging nozzle, shutdown cooling line, and pressurizer surge line. Cracking by environmentally-assisted fatigue of these locations is addressed using one of the five approaches previously discussed in accordance with 10 CFR 54.21(c)(1).

18.2.2.4 Thermal Stresses in Piping Connected to Reactor Coolant System

ANO-2 provided responses to NRC Bulletin 88-08, Thermal Stresses in Piping Connected to Reactor Coolant Systems, in References 8 and 9. A review of 39 reactor coolant system (RCS) connected systems determined that none of these lines were determined to be subject to temperature distributions which would result in unacceptable thermal stresses. Supplement 3 to NRC Bulletin 88-08 was addressed for ANO-2 via a Combustion Engineering Owners Group (CEOG) task which revealed that only 3 piping systems (safety injection, shutdown cooling, and hot leg injection) could possibly be subject to excessive stresses due to outleakage from the RCS. Additional evaluations of these 3 systems determined that due to ANO-2's specific configuration and existing instrumentation, these systems will either not be subject to the outleakage type stratification as described in Supplement 3, or there is sufficient instrumentation and precautions in place to detect outleakage.

Subsequently, commitments regarding inspections at ANO-2 in response to NRC Bulletin 88-08 have been superseded by the ANO-2 risk-informed inspection (RIISI) of ASME Class 1 piping, as approved by the NRC (References 10, 11, 12, and 13). Aging effects due to thermal stratification as described in Bulletin 88-08 will be managed in accordance with 10 CFR 54.21(c)(1)(iii) by maintaining associated thermal fatigue calculations and augmented inspections (as part of RIISI) through the period of extended operation.

18.2.2.5 Pressurizer Surge Line Thermal Stratification

The ANO-2 response to NRC Bulletin 88-11, Pressurizer Surge Line Thermal Stratification (References 14 and 15), included analyses by the CEOG that demonstrated that the bounding surge line and nozzles for Combustion Engineering plants met the ASME Code stress and fatigue requirements for a 40-year design life considering thermal stratification and thermal striping. ANO-2 verified the applicability of the CEOG report and the plant-specific stress and fatigue analysis was completed as required by NRC Bulletin 88-11. Visual inspections of the pressurizer surge line were also performed.

Subsequently, commitments regarding inspections at ANO-2 in response to NRC Bulletin 88-11 have been superseded by the ANO-2 risk-informed inspection (RIISI) of ASME Class 1 piping, as approved by the NRC (References 10, 11, 12, and 13). The RIISI program meets the requirements of 10 CFR 54.21(c)(1)(iii). Aging effects due to thermal stratification as described in Bulletin 88-11 will be managed by maintaining associated thermal fatigue calculations and augmented inspections (as part of RIISI) through the period of extended operation.

18.2.3 ENVIRONMENTAL QUALIFICATION OF ELECTRICAL COMPONENTS

The ANO-2 Environmental Qualification (EQ) of Electrical Components Program, discussed in Section 18.1.8, manages component thermal, radiation and cyclical aging, as applicable, through the use of aging evaluations based on the qualification methods of 10 CFR 50.49(f). Aging evaluations for EQ components that specify a qualification of at least 40 years are considered TLAAs for license renewal. The EQ Program ensures that the qualification of these EQ components will be maintained. The effects of aging will thus be managed in accordance with 10 CFR 54.21(c)(1)(iii).

18.2.4 CONCRETE CONTAINMENT TENDON PRESTRESS

The analysis of loss of prestress in the containment building post-tensioning system is a time-limited aging analysis. Loss of tendon prestress in the containment building post-tensioning system will be managed for license renewal in accordance with 10 CFR 54.21(c)(1)(iii), by the Containment ISI Program. This program, discussed in Section 18.1.14, includes tendon surveillance testing. Prior to the period of extended operation, trend lines for ANO-2 tendon prestressing forces will be developed using regression analysis in accordance with guidance provided in NRC IN 99-10. If prestressing force trend lines indicate that existing prestressing forces in the containment would go below the minimum required values (MRVs) prior to the next scheduled inspection (Reference 10 CFR 50.55a(b)(2)(ix)(B) or 10 CFR 50.55a(b)(2)(viii)(B)), then systematic retensioning of tendons, a reanalysis of the containment or a reanalysis of the post tensioning system is warranted to ensure the design adequacy of containment.

18.2.5 CONTAINMENT LINER PLATE AND PENETRATION FATIGUE ANALYSES

The interior surface of the containment is lined with welded carbon steel plate to provide an essentially leak tight barrier. At the penetrations, the containment liner plate is thickened to reduce stress concentrations. The criteria in SAR Sections 3.8.1.3.4 and 3.8.1.6.3 were applied to the containment design to ensure that the integrity of the liner plate is not exceeded under design basis accident conditions. The evaluation of this issue for license renewal is based on an analytical assessment of the containment liner and penetrations as described in SAR Section 3.8.1.4.2 and the results of recently completed containment liner plate evaluations for ANO-2. TLAAs for the ANO-2 reactor containment structure include containment liner and containment penetration fatigue analyses.

Mechanical penetrations are leak-tight, welded assemblies. As described in SAR Section 3.8.1.4.2, containment penetrations are designed to meet the requirements of ASME Section III. The evaluation for mechanical penetrations covers the penetration assembly and the weld to the process piping, but does not include the process piping within the penetration. The closure of the pipe to the liner plate is accomplished with special heads welded to the pipe and the liner plate reinforcement. Penetration anchorage to the containment wall is designed to resist pipe rupture, seismic and thermal loads.

Liner plate stress analyses indicate a conservative maximum stress of approximately 30 ksi for worst case (DBA) conditions. Stresses from normal operating cycles such as heatup and cooldown are less than 30 ksi. Using ASME section III, Division 1 design fatigue curve, at 30 ksi the maximum cycles for the liner would be approximately 25,000. The number of normal operating cycles for the liner plate will be well below this value. On this basis, the liner plate and penetrations are suitable for the cyclic loads of normal operating conditions throughout the period of extended operation.

For license renewal, containment liner plate and penetration fatigue analyses remain valid for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

18.2.6 OTHER PLANT-SPECIFIC TIME-LIMITED AGING ANALYSES

Other ANO-2-specific TLAAs include leak-before-break (LBB) analyses, fracture mechanics evaluation of the RCP casing, steam generator flow-induced vibration analysis, alloy 600 nozzle repairs and fatigue evaluations for high energy line break analyses.

18.2.6.1 RCS Piping Leak-Before-Break

The leak-before-break analyses reported in CEN-367-A (Reference 16) are TLAAs since they are based on the 40-year design limits for reactor coolant system fatigue transient cycles. As described for Class 1 metal fatigue in Section 18.2.2.1, the assumed number of RCS design transients are acceptable for 60 years so these analyses will remain valid during the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

18.2.6.2 RCP Code Case N-481

Compliance of the primary loop pump casings to ASME Code Case N-481 was evaluated for ANO-2. The evaluation is based on the 40-year design limits for reactor coolant system fatigue transient cycles, and is therefore a TLAA. As described for Class 1 metal fatigue in Section 18.2.2.1, the assumed number of RCS design transients are acceptable for 60 years so the Code Case N-481 evaluation will remain valid during the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

18.2.6.3 Steam Generator Tubes – Flow-Induced Vibration

The TLAA applicable to the steam generators is the analysis of steam generator tube flow induced vibration (FIV). The time dependent assumptions made within the FIV calculation are based on a forty-year design life of the steam generators. The ANO-2 replacement generators were installed in 2000 and their design life, which extends to 2040, surpasses the period of extended operation. Therefore, the steam generator FIV analysis remains valid for the period of extended operation.

18.2.6.4 Alloy 600 Nozzle Repairs

In 2000, repairs were made to a number of pressurizer heater penetrations, and resistance temperature detector (RTD) and pressure measurement nozzle penetrations on the RCS hot leg. The repair for the pressurizer heater penetration replaced the pressure boundary weld on the inside surface of the pressurizer nozzle with a weld on the outside of the pressurizer. The hot leg piping penetration modification consisted of removing a portion of the old RTD/pressure tap by cutting it near the outer wall of the RCS piping and replacing it with a new nozzle welded on the outside surface of the RCS piping.

A fracture mechanics evaluation was performed to evaluate the potential for a crack in the remaining pressurizer and RCS hot leg penetration welds to propagate in the pressurizer vessel or hot leg pipe wall. The crack growth evaluations utilized operating transient cycles which were assumed over a 40 year plant lifetime. The replacement nozzles and attachment welds were qualified for structural adequacy in accordance with ASME code criteria. This analysis included a simplified fatigue evaluation which considered cyclic loads due to pressure, thermal gradients, and mechanical loads. As described for Class 1 metal fatigue in Section 18.2.2.1, the 40-year design limits for reactor coolant system transients are acceptable for 60 years. The fatigue crack growth analysis for the repairs will remain valid during the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i). Similarly, the fatigue analysis for the replacement nozzles and attachment welds remains valid for the period of extended operation.

18.2.6.5 High Energy Line Break Analyses

For the high energy line break analyses, the selection of break locations for ASME Section III Class 1 piping was in part based on piping fatigue analyses. These fatigue evaluations, and thus the high energy line break analyses, are TLAAs since they are based on the 40-year design transients limits. As described for Class 1 metal fatigue in Section 18.2.2.1, the assumed number of RCS design transients are acceptable for 60 years so these analyses will remain valid during the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

18.2.6.6 RCP Motor Flywheel

The flaw growth analysis associated with the reactor coolant pump motor flywheel is conservatively treated as a time-limited aging analysis. The analysis addresses the growth of pre-existing cracks subjected to 4,000 reactor coolant pump motor startup or shutdown cycles, which exceeds by a factor of eight the number of RCP cycles projected through the period of extended operation. Therefore, the flaw growth analysis remains valid for the period of extended operation.
