ARKANSAS NUCLEAR ONE - UNIT 2

SAR AMENDMENT 26

FACILITY OPERATING LICENSE NUMBER NPF-6

DOCKET NUMBER 50-368

Changes are indicated by beginning the affected information with a revision bar on the right side of the page which stops at the end of the change. Deletions of entire paragraphs or sections have a revision bar to the right of the page where text was deleted. The amendment number is indicated at the bottom of the affected page near the left margin and indicates the latest revision to the information contained on that page. Absence of a revision bar on a replacement page means the page was reprinted for word processing purposes only. However, general formatting changes may have been made to all pages.

ARKANSAS NUCLEAR ONE
Unit 2

SAFETY ANALYSIS REPORT

TABLE OF CONTENTS

Section	Title	Page
1	INTRODUCTION AND GENERAL DESCRIPTION OF PLANT	1.1-1
1.1	INTRODUCTION	1.1-1
1.2	GENERAL PLANT DESCRIPTION	1.2-1
1.2.1	PRINCIPAL SITE CHARACTERISTICS	1.2-1
1.2.2	CONCISE PLANT DESCRIPTION	1.2-1
1.3	COMPARISONS	1.3-1
1.3.1	COMPARISON WITH SIMILAR FACILITY DESIGNS	1.3-1
1.3.2	COMPARISON OF FINAL AND PRELIMINARY INFORMATION	1.3-1
1.3.3	COMPARISON OF PLANT DESIGN WITH REGULATORY GUIDE RECOMMENDATIONS	1.3-1
1.4	IDENTIFICATION OF AGENTS AND CONTRACTORS	1.4-1
1.5	REQUIREMENTS FOR FURTHER TECHNICAL INFORMATION	1.5-1
1.5.1	FRETTING AND VIBRATIONS TESTS OF FUEL ASSEMBLIES	1.5-1
1.5.2	DEPARTURE FROM NUCLEATE BOILING (DNB) TESTING	1.5-1
1.5.3	FUEL ASSEMBLY STRUCTURAL TESTS	1.5-1
1.5.4	FUEL ASSEMBLY FLOW MIXING TESTS	1.5-2
1.5.5	REACTOR FLOW MODEL TESTING AND EVALUATION	1.5-2
1.5.6	FUEL ASSEMBLY FLOW TESTS	1.5-3
1.5.7	CONTROL ELEMENT DRIVE MECHANISM (CEDM) TESTS	1.5-3
1.5.8	SAFETY INJECTION SYSTEM IMPROVEMENT	1.5-3
1.5.9	DNB IMPROVEMENT	1.5-3
1.5.10	LOCA REFILL TESTING	1.5-4
1.5.11	BLOWDOWN HEAT TRANSFER TESTING	1.5-4
1.5.12	STEAM WATER MIXING TEST PROGRAM	1.5-5

TABLE OF CONTENTS (continued)

Section	Title	Page
1.6	MATERIAL INCORPORATED BY REFERENCE	1.6-1
1.6.1	CE TOPICAL REPORTS	1.6-1
1.6.2	BECHTEL TOPICAL REPORTS	1.6-2
1.7	GLOSSARY OF ITEMS	1.7-1
1.7.1	TEXT ABBREVIATIONS	1.7-1
1.7.2	DRAWING INDEX AND SYMBOLS	1.7-1
1.7.3	PIPING IDENTIFICATION	1.7-1
1.7.4	TRADEMARKS	1.7-1
1.8	REFERENCES	1.8-1
1.9	TABLES	1.9-1
2	SITE CHARACTERISTICS	2.1-1
2.1	GEOGRAPHY AND DEMOGRAPHY	2.1-1
2.1.1	SITE LOCATION	2.1-1
2.1.2	SITE DESCRIPTION	2.1-1
2.1.3	POPULATION AND POPULATION DISTRIBUTION	2.1-3
2.1.4	USES OF ADJACENT LANDS AND WATERS	2.1-5
2.2	NEARBY INDUSTRIAL, TRANSPORTATION, AND MILITARY FACILITIES	2.2-1
2.2.1	LOCATIONS, ROUTES, AND DESCRIPTIONS	2.2-1
2.2.2	EVALUATION	2.2-2
2.3	METEOROLOGY	2.3-1
2.3.1	REGIONAL CLIMATOLOGY	2.3-1
2.3.2	LOCAL METEROLOGY	2.3-12
2.3.3	ONSITE METEOROLOGICAL PROGRAM	2.3-21
2.3.4	SHORT-TERM (ACCIDENT) DIFFUSION ESTIMATES	2.3-29

TABLE OF CONTENTS (continued)

Section	Title	Page
2.3.5	LONG-TERM (ROUTINE) DIFFUSION ESTIMATES	2.3-33
2.3.6	ANNUAL RELEASE RATE LIMITS	2.3-33
2.3.7	QUARTERLY RELEASE RATE LIMITS	2.3-34
2.3.8	HOURLY RELEASE RATE LIMITS	2.3-34
2.4	HYDROLOGIC ENGINEERING	2.4-1
2.4.1	HYDROLOGIC DESCRIPTION	2.4-1
2.4.2	FLOODS	2.4-2
2.4.3	PROBABLE MAXIMUM FLOOD ON STREAMS AND RIVERS	2.4-4
2.4.4	POTENTIAL DAM FAILURES (SEISMICALLY INDUCED)	2.4-7
2.4.5	PROBABLE MAXIMUM SURGE AND SEICHE FLOODING	2.4-9
2.4.6	PROBABLE MAXIMUM TSUNAMI FLOODING	2.4-9
2.4.7	ICE FLOODING	2.4-10
2.4.8	COOLING WATER CANALS AND RESERVOIRS	2.4-10
2.4.9	CHANNEL DIVERSIONS	2.4-11
2.4.10	FLOODING PROTECTION REQUIREMENTS	2.4-11
2.4.11	LOW WATER CONSIDERATIONS	2.4-11
2.4.12	ENVIRONMENTAL ACCEPTANCE OF EFFLUENTS	2.4-13
2.4.13	GROUNDWATER	2.4-13
2.4.14	TECHNICAL SPECIFICATION AND EMERGENCY OPERATION REQUIREMENTS	2.4-17
2.5	GEOLOGY AND SEISMOLOGY	2.5-1
2.5.1	BASIC GEOLOGIC AND SEISMIC DATA	2.5-2
2.5.2	VIBRATORY GROUND MOTION	2.5-10
2.5.3	SURFACE FAULTING	2.5-32
2.5.4	STABILITY OF SUBSURFACE MATERIALS	2.5-34

TABLE OF CONTENTS (continued)

Section	Title	Page
2.5.5	SLOPE STABILITY	2.5-39
2.6	REFERENCES	2.6-1
2.7	TABLES	2.7-1
2A	APPENDIX 2A	2.A-1
3	DESIGN OF STRUCTURES, COMPONENTS, EQUIPMENT AND SYSTEMS	3.1-1
3.1	CONFORMANCE WITH AEC GENERAL DESIGN CRITERIA	3.1-1
3.1.1	OVERALL REQUIREMENTS	3.1-1
3.1.2	PROTECTION BY MULTIPLE FISSION PRODUCT BARRIERS	3.1-5
3.1.3	PROTECTION AND REACTIVITY CONTROL SYSTEMS	3.1-12
3.1.4	FLUID SYSTEMS	3.1-16
3.1.5	REACTOR CONTAINMENT	3.1-25
3.1.6	FUEL AND RADIOACTIVITY CONTROL	3.1-29
3.2	CLASSIFICATION OF STRUCTURES, COMPONENTS AND SYSTEMS	3.2-1
3.2.1	SEISMIC CLASSIFICATION	3.2-1
3.2.2	SYSTEM QUALITY GROUP CLASSIFICATION	3.2-2
3.3	WIND AND TORNADO LOADINGS	3.3-1
3.3.1	WIND LOADINGS	3.3-1
3.3.2	TORNADO LOADINGS	3.3-1
3.4	WATER LEVEL (FLOOD) DESIGN	3.4-1
3.4.1	FLOOD ELEVATIONS	3.4-1
3.4.2	PHENOMENA CONSIDERED IN DESIGN LOAD CALCULATIONS	3.4-1
3.4.3	FLOOD FORCE APPLICATION	3.4-1
3.4.4	FLOOD PROTECTION	3.4-2
3.5	MISSILE PROTECTION	3.5-1

TABLE OF CONTENTS (continued)

Section	Title	Page
3.5.1	MISSILE BARRIERS AND LOADINGS	3.5-4
3.5.2	MISSILE SELECTION	3.5-5
3.5.3	SELECTED MISSILES	3.5-13
3.5.4	BARRIER DESIGN PROCEDURES	3.5-13
3.5.5	MISSILE BARRIER FEATURES	3.5-15
3.6	PROTECTION AGAINST DYNAMIC EFFECTS ASSOCIATED WITH THE POSTULATED RUPTURE OF PIPING	3.6-1
3.6.1	SYSTEMS IN WHICH DESIGN BASIS PIPING BREAKS OCCUR	3.6-2
3.6.2	DESIGN BASIS PIPING BREAK CRITERIA	3.6-3
3.6.3	DESIGN LOADING COMBINATIONS	3.6-7
3.6.4	DYNAMIC ANALYSES	3.6-8
3.6.5	PROTECTIVE MEASURES	3.6-38
3.6.6	LEAK-BEFORE-BREAK EVALUATION	3.6-40
3.7	SEISMIC DESIGN	3.7-1
3.7-1	SEISMIC INPUT	3.7-1
3.7.2	SEISMIC SYSTEM ANALYSIS	3.7-5
3.7.3	SEISMIC SUBSYSTEM ANALYSIS	3.7-13
3.7.4	SEISMIC INSTRUMENTATION PROGRAM	3.7-31
3.7.5	SEISMIC DESIGN CONTROL MEASURES	3.7-32
3.7.6	SEISMIC EVALUATION OF CONCRETE MASONRY WALLS	3.7-32
3.8	DESIGN OF CATEGORY 1 STRUCTURES	3.8-1
3.8.1	CONCRETE CONTAINMENT	3.8-1
3.8.2	STEEL CONTAINMENT SYSTEM	3.8-27
3.8.3	CONCRETE AND STRUCTURAL STEEL INTERNAL STRUCTURES OF CONTAINMENT	3.8-28

TABLE OF CONTENTS (continued)

Section	Title	Page
3.8.4	OTHER CATEGORY 1 STRUCTURES	3.8-36
3.8.5	FOUNDATIONS AND CONCRETE SUPPORTS	3.8-50
3.9	MECHANICAL SYSTEMS AND COMPONENTS	3.9-1
3.9.1	DYNAMIC SYSTEM ANALYSIS AND TESTING	3.9-1
3.9.2	ASME CODE CLASS 2 AND 3 COMPONENTS	3.9-17
3.9.3	COMPONENTS NOT COVERED BY ASME CODE	3.9-23
3.10	SEISMIC DESIGN OF CATEGORY 1 INSTRUMENTATION AND ELECTRICAL EQUIPMENT	3.10-1
3.10.1	SEISMIC DESIGN CRITERIA	3.10-1
3.10.2	SEISMIC ANALYSES, TESTING PROCEDURES, AND RESTRAINT MEASURES	3.10-2
3.11	ENVIRONMENTAL DESIGN OF MECHANICAL AND ELECTRICAL EQUIPMENT	3.11-1
3.11.1	EQUIPMENT IDENTIFICATION	3.11-3
3.11.2	QUALIFICATION TESTS AND ANALYSES	3.11-5
3.11.3	QUALIFICATION TEST RESULTS	3.11-6
3.11.4	LOSS OF VENTILATION	3.11-6
3.11.5	CURRENT ENVIRONMENTAL QUALIFICATION PROGRAM	3.11-7

1 INTRODUCTION AND GENERAL DESCRIPTION OF PLANT

1.1 INTRODUCTION

This updated Final Safety Analysis Report (FSAR) is submitted as required by 10 CFR 50.71. Arkansas Nuclear One - Unit 2 is located adjacent to Arkansas Nuclear One - Unit 1 on a peninsula in Dardanelle Reservoir on the Arkansas River in Pope County, Arkansas. The station location is shown on Figure 8.1-2.

Arkansas Nuclear One - Unit 2 began initial operation with core power levels up to 2,815 MWt, which, when contribution from the reactor coolant pumps was included (at 10 MWt), corresponded to an initial net output of approximately 952 MWe. Starting with Cycle 16, all physics and core thermal hydraulics information in this report is based on the rated core power level of 3,026 MWt, which when the maximum contribution from the reactor coolant pumps is added of 18 MWt corresponds to a net electrical output of approximately 1023 MWe. Site parameters, principal structures, engineered safety features, and postulated accidents which could result in a significant release of radioactivity to the environment are evaluated at the expected ultimate core output of 3087 MWt.

The Nuclear Steam Supply System (NSSS) is a Pressurized Water Reactor (PWR) of a type similar to systems now operating or under construction. It uses chemical shim and control rods for reactivity control and produces dry saturated steam in vertical U-tube steam generators. The original NSSS and the design and fabrication of the fuel core have been supplied by Combustion Engineering, Incorporated. The steam generators were replaced in the fall of 2000 prior to Cycle 15 with steam generators supplied by Westinghouse Electric Corporation, LLC.

This unit loaded fuel in August 1978 went critical for the first time in December 1978 and began commercial operation March 1980.

The organization of this report follows closely the "Standard Format and Content of Safety Analysis Reports for Nuclear Power Plants," Revision 1, and the design meets the General Design Criteria as listed in Appendix A to 10CFR50 as described in Section 3.1.

Entergy Operations, Inc., is fully responsible for the safe operation of the plant. The design, construction and aid in the testing and startup of the unit was supplied principally by Bechtel Corporation and Combustion Engineering, Incorporated. Assistance has been and will be rendered by other consultants as required.

On October 23, 1996 (0CNA109617), the NRC issued Amendment No. 177 to the facility operating license to revise the name of the plant's owner from Arkansas Power & Light Company to Entergy Arkansas, Inc. The name "Arkansas Power & Light" or "AP&L" remains in the SAR where the context is historical.

1.2 GENERAL PLANT DESCRIPTION

1.2.1 PRINCIPAL SITE CHARACTERISTICS

Arkansas Nuclear One - Unit 2 is located adjacent to Arkansas Nuclear One - Unit 1 on a peninsula in Dardanelle Reservoir on the Arkansas River in Pope County, Arkansas. The plant is about six miles west-northwest of Russellville, Arkansas, and about two miles southeast of the village of London, Arkansas.

The 1100-acre site allows a minimum exclusion area radius of 0.65 miles from the center of the reactor. Easements have been obtained from the U.S. Army Corps of Engineers for exclusion rights during periods of emergency to portions of the bed and banks of the Dardanelle Reservoir that are within the 0.65-mile radius.

The site is located in a gently rolling valley south of the Boston Mountains and was previously used mostly for pasture land.

The plant grade elevation (near the center of the site) is 353 feet above Mean Sea Level (MSL) while the Dardanelle Reservoir fluctuates between 336 feet (normal pool) and 338 feet (maximum flood control pool) above MSL.

The site is characterized by remoteness from flooding; sound, hard rock for structure foundations; a reliable network for emergency power; and favorable conditions of hydrology, geology, seismology and meteorology.

1.2.2 CONCISE PLANT DESCRIPTION

1.2.2.1 Reactor and Reactor Coolant System

1.2.2.1.1 Reactor

The Pressurized Water Reactor (PWR) is designed for an initial core thermal output of 2815 MWt and an uprate output of 3026 MWt.

The reactor core is fueled with uranium dioxide pellets enclosed in zircaloy, ZIRLO™ OR Optimized ZIRLO™ tubes pressurized with helium and fitted with welded end plugs. The tubes are fabricated into assemblies in which end fittings prevent axial motion and grids prevent lateral motion of the tubes. The Control Element Assemblies (CEAs) consist of Inconel 625 alloy clad boron carbide absorber rods, guided by tubes in the fuel assembly. The initial core consisted of 177 fuel assemblies with several U-235 enrichments in a 3-batch, mixed central zone arrangement.

Fuel rod clad is designed to maintain cladding integrity throughout fuel life. Fission gas release within the rods and other factors affecting design life are considered for the maximum expected exposures.

The reactor and control systems are designed so that any xenon transients will be adequately damped.

The CEAs are capable of holding the core subcritical at hot zero power conditions with margin following a trip, even with the most reactive CEA stuck in the fully withdrawn position.

The combined response of the fuel temperature coefficient, the moderator temperature coefficient, the moderator void coefficient and the moderator pressure coefficient to an increase in reactor thermal power is a decrease in reactivity. In addition, the reactor power transient remains bounded and damped in response to any expected changes in any operating variable.

The reactor is designed to accommodate safely and without fuel damage, the anticipated operational occurrences, backed up by automatic and redundant reactor trips.

See Chapter 4 for further information.

1.2.2.1.2 Reactor Coolant System

The Reactor Coolant System (RCS) is arranged as two closed loops connected in parallel to the reactor vessel. Each loop consists of one 42-inch ID outlet (hot) pipe, one steam generator, two 30-inch ID inlet (cold) pipes and two pumps. An electrically heated pressurizer is connected to one of the loops and a safety injection line is connected to each of the four inlet legs. The RCS is designed to operate at 2,200 psia.

The reactor vessel and its closure head are fabricated from SA-533 Grade B steel clad with stainless steel. Fluence and fracture toughness of the reactor vessel are discussed in Section 4.3.3.3 and Section 5.2.4.

The two steam generators are vertical shell and U-tube units. The steam generated in the shell side of the steam generator flows upward through moisture separators which reduce its moisture content to less than 0.1 percent. All RCS surfaces are either stainless steel or NiCrFe alloy in order to maintain reactor coolant purity.

The reactor coolant is circulated by four electric motor-driven, single-suction centrifugal pumps. The pumps shafts are sealed by mechanical seals. The seal performance is monitored by pressure and temperature sensing devices in the seal system.

The RCS is designed and constructed to maintain its integrity throughout the plant life. Appropriate means of test and inspection are provided.

See Chapter 5 for further information.

1.2.2.2 Engineered Safety Features

The plant design incorporates redundant Engineered Safety Features (ESF). These systems, in conjunction with the containment, insure that the off-site radiological consequences following any Loss of Coolant Accident (LOCA), up to and including a double-ended break of the largest reactor coolant pipe, will not exceed the guidelines of 10 CFR 50.67. The systems ensure that the requirements of 10 CFR 50.46 and Appendix K for Emergency Core Cooling Systems for Light Water Power Reactors are satisfied, based upon analytical methods, assumptions and procedures accepted by the Nuclear Regulatory Commission (NRC). The ESF include: (a) independent systems [Containment Cooling System (CCS) and Containment Spray System (CSS)] to remove heat from and reduce the pressure in the containment in order to maintain containment integrity, (b) a Safety Injection System (SIS) to limit fuel and cladding damage to an amount which will not interfere with adequate emergency core cooling and to limit metal-water reactions to negligible amounts, (c) a containment isolation system to minimize post-LOCA radiological effects off-site, (d) a hydrogen control system to maintain safe post-LOCA hydrogen concentration within the containment, (e) a habitability system to ensure control room

habitability following a LOCA, (f) a penetration room ventilation system to ensure that post-LOCA leakage is collected, filtered, and monitored prior to release to the environment, and (g) a Main Steam Isolation System (MSIS) to protect the reactor and the containment in the event of a main steam line rupture.

See Chapter 6 for further information.

1.2.2.3 Instrumentation and Control

1.2.2.3.1 Control

The Reactor Control System is used for startup and shutdown of the reactor and for adjustment of the reactor power in response to turbine load demand. Normal control is accomplished by manual movement of CEAs or adjustment of boron concentration by the operator in response to a change in reactor coolant temperature. The temperature control program provides a demand temperature which is a function of turbine first stage pressure. This temperature is compared with the existing average reactor coolant temperature. If the temperature is different, operators adjust boron concentration and/or the CEAs until the difference is within the prescribed control band. Regulation of the reactor coolant temperature in accordance with this program maintains the secondary steam pressure within operating limits and matches reactor power to load demand.

Boric acid is used for reactivity changes associated with large but gradual changes in water temperature, xenon concentration and fuel burnup. Additions of boric acid also provide an increased shutdown margin during refueling. The boric acid solution is prepared and stored at a temperature sufficiently high to prevent precipitation.

CEA movement provides changes in reactivity for shutdown or power changes. The CEAs are actuated by control element drive mechanisms mounted on the reactor vessel head. The control element drive mechanisms are designed to permit rapid insertion of the CEAs into the reactor core by gravity.

The Core Operating Limit Supervisory System (COLSS) functions to monitor selected parameters, to provide an on-line calculation of margin to a Limiting Condition for Operation (LCO), and to actuate an alarm when an LCO is reached.

The pressure in the RCS is controlled by regulating the temperature of the coolant in the pressurizer, where steam and water are held in thermal equilibrium. Steam is formed by the pressurizer heaters or condensed by the pressurizer spray to reduce variations caused by expansion and contraction of the reactor coolant due to system temperature changes. Overpressure protection is provided by safety valves connected to the pressurizer and designed in accordance with ASME Code, Section III. The discharge from the pressurizer safety valves is released under water in the quench tank where it is condensed and cooled. When the RCS is below its setpoint (nominally 270 °F), the low temperature overpressure alarm alerts the operator if the low temperature overpressure protection relief isolation valves are not completely open. Overpressure protection for the quench tank is provided by a rupture disc which relieves to the containment.

1.2.2.3.2 Instrumentation

The nuclear instrumentation includes out-of-core and in-core flux detectors. Six independent channels of out-of-core nuclear instrumentation monitor the fission process. Of these channels, the two startup channels are used to monitor the reactor during startup operations. The four safety channels are used to monitor the reactor from routine startup neutron flux levels up to 200 percent power and are used to initiate a reactor shutdown in the event of high linear or logarithmic power. The in-core monitors provide information on neutron flux distribution.

The reactor parameters are maintained within the acceptable limits by the inherent characteristics of the reactor, by the CEAs, by boric acid dissolved in the moderator, and by the operating procedures. In addition, in order to preclude unsafe conditions for plant equipment or personnel, the Reactor Protective System (RPS) initiates reactor shutdown if selected parameters reach their preset limits. Four independent channels normally monitor each of the selected plant parameters. The RPS logic is designed to initiate protective action whenever the signal of any two of four channels reaches the preset limit. Redundancy is provided in all parts of the RPS to assure that no single failure will prevent protective action when it is required.

The process instrumentation monitoring includes those critical channels which are used for protective action. Additional temperature, pressure, flow and liquid level monitoring is provided, as required, to keep the operating personnel informed of plant conditions, and to provide information from which plant processes can be evaluated and/or regulated.

The plant gaseous and liquid effluents are monitored for radioactivity. Activity levels are displayed and off-normal values are annunciated. Area monitoring stations are provided to measure radioactivity at selected locations in the plant.

See Chapter 7 for further information.

1.2.2.4 Electrical System

Unit 2 generates electrical power at 22 kV and is connected to the 500 kV station switchyard through its unit step-up transformer and a single dead-end span of 500 kV overhead transmission line. A bus-tie autotransformer bank interconnects the 500 kV and 161 kV systems in the station switchyard.

Startup Transformer 3 is energized from the 22 kV tertiary winding of the 500 to 161 kV autotransformer while Startup Transformer 2, which is common to both Units 1 and 2, is supplied from the 161 kV ring bus. Thus, either of these two startup transformers, which are fed from different sources, can provide the necessary startup and emergency load requirement of Unit 2. The normal power supply for the unit is the Unit 2 auxiliary transformer.

In the event of loss of normal and preferred auxiliary power sources, the ESF loads can be supplied from the onsite emergency power sources. The emergency onsite power sources consist of two independent and completely segregated emergency diesel generators, each of which has an adequate capacity to meet the loads required for safe shutdown of the reactor.

In the event of loss of normal and preferred auxiliary power sources and the on site emergency power sources (i.e., station blackout), a bus of ESF loads can be supplied from the Alternate AC power source which has adequate capacity to meet the loads required for safe shutdown of the reactor.

The ESF redundant systems have been designed and segregated so that failure of one train will not jeopardize proper functioning of the other train in meeting the shutdown and post-shutdown requirements of the reactor.

Stringent quality assurance standards and programs have been followed in the design, selection, and installation of all Class 1E type equipment and systems. These are discussed in detail under appropriate sections of Chapter 8.

1.2.2.5 Power Conversion

The main turbine is an 1,800 rpm, tandem compound, 4-flow, impulse reaction, condensing unit, having one high pressure and two identical low pressure casings. Combination moisture separator reheaters are employed to dry and superheat the steam between the high and low pressure turbines. The auxiliaries include deaerating surface condensers, condenser vacuum pumps, cooling tower, turbine driven main feedwater pumps, motor driven condensate pumps, and seven stages of feedwater heaters.

The power conversion system removes heat energy from the reactor coolant in two U-tube steam generators, and the turbine-generator converts the steam's heat energy into electrical energy.

Steam produced in the steam generators enters the high pressure turbine through stop valves and governing control valves. From the high pressure turbine the steam flows through the moisture separator reheaters before entering the low pressure turbines.

Each steam line is provided with turbine bypass valves, which discharge to the condenser, and safety and dump valves, which discharge to atmosphere. Steam to the emergency feedwater pump turbine can be taken from either steam line.

The condenser transfers the unusable heat in the cycle to the condenser cooling water. The closed regenerative turbine cycle heats the condensate and returns it to the steam generators.

See Chapter 10 for further information.

1.2.2.6 Fuel Handling and Storage

New fuel is stored dry in vertical racks. Room is provided for 63 new fuel assemblies, with fuel assembly spacing and vault construction sufficient to preclude criticality. New fuel assemblies may also be stored in the spent fuel racks.

The stainless steel lined, reinforced concrete spent fuel pool provides storage for 988 fuel assemblies. Spent fuel assemblies are stored in vertical racks. Adequate spacing is provided to preclude criticality with no credit for the borated pool water.

Cooling and purification equipment is provided for the spent fuel pool cooling water.

Spent fuel cooled initially in the spent fuel pool can be stored in dry storage casks in the ANO ISFSI area.

The fuel handling system provides for the safe handling of fuel assemblies and CEAs and for the required assembly, disassembly and storage of reactor internals. This system includes a refueling machine located inside the containment above the refueling pool, the fuel handling

crane, the fuel transfer carriage, the tilting machines, a CEA handling tool and bridge gantry, new fuel elevator, fuel inspection stand, the fuel transfer tube, a fuel handling machine in the spent fuel storage room, and various devices used for handling and storing the reactor vessel head and internals.

See Section 9.1 for further information.

1.2.2.7 Cooling Water and Other Auxiliary Systems

A Service Water System (SWS) provides required cooling water flows to ESF equipment served by the system, as well as to various non safety-related portions of the plant. That portion of the SWS required for safe shutdown of the plant is designed to meet Seismic Category 1 requirements and the single failure criterion as defined in Chapter 3. Non-safety-related portions are isolated from the SWS during events resulting in ESF actuation. A complete description of the system is found in Section 9.2.1.

A Component Cooling Water (CCW) System removes heat from various reactor auxiliary systems which carry radioactive or potentially radioactive fluids. These systems also require higher water quality than that provided by the SWS. Radiation monitors at the inlet of the component cooling water heat exchangers alarm the control room should radioactivity rise above a preset limit. The CCW System is not required for safe plant shutdown. A complete description of the system is found in Section 9.2.2.

A compressed air system is provided to supply dry, oil-free instrument air for pneumatic controls and valve operators. In addition, a service air system is provided to supply air for pneumatic tools and other air operated equipment. This system is not required for safe shutdown since all pneumatically operated devices in the plant which are essential are designed to assume a fail-safe position upon loss of air supply. This system is described in Section 9.3.1.

A Chemical and Volume Control System (CVCS) controls the purity and chemistry of the reactor coolant as described in Section 9.3.4. Part of the reactor coolant is bypassed through the CVCS via regenerative and letdown heat exchangers, a filter, and ion exchangers before being sprayed into the volume control tank. The charging pumps take suction from this tank and pump the coolant back into its system.

The Shutdown Cooling (SDC) System reduces the temperature of the reactor coolant from less than 275 °F to the refueling temperature, removes decay heat during normal shutdown, and removes heat from the recirculating containment sump water via the shutdown cooling heat exchangers following a LOCA. Section 9.3.6 describes this system.

1.2.2.8 Radioactive Waste Management Systems

The Boron Management System (BMS) and Waste Management Systems (WMS) were designed to provide the means for controlled handling, storage and disposal of liquid, gaseous and solid wastes. As the state of the art of waste management improved, it became economically feasible to utilize vendors to treat liquid and solid waste. The BMS was originally designed to reconcentrate and recover dissolved boron from the liquid effluent for reuse in the plant. This capability of the BMS is currently not used.

Liquid effluent from the RCS first passes through one of the purification filters in the CVCS. When the BMS is used, liquid effluent is processed by successively passing through the vacuum degasifier, filters, and ion exchangers. This operation removes the radioactive material.

As the BMS was originally designed, the liquid could then be processed through the boric acid concentrator; however, the concentrator is currently not in use. Other radioactive liquid wastes can be processed in the WMS for release to the environment or (in the original design) solidification and drumming. The solidification feature is currently not used.

All liquid wastes are sampled prior to release. The waste release rates are as low as practicable and within the guidelines and limits for waste release established by 10 CFR 20 and 10 CFR 50.

All solid wastes are stored in suitable containers for ultimate off-site disposal in accordance with applicable regulations.

Waste gases are filtered and released to the atmosphere via the gas collection header. High activity gases collected in the VCT or the BMS vacuum degasifier are compressed into gas decay tanks. The waste gas held in the gas decay tanks is released to the plant vent after sampling. The tank contents are released at rates well within the limits established by 10 CFR 20 and 10 CFR 50.

See Chapter 11 for further information.

1.2.2.9 General Arrangement of Major Structures and Equipment

Unit 2 is on the same site and is adjacent to Unit 1.

Unit 2's major structures include the containment, turbine building, auxiliary building and a single natural draft cooling tower.

The Unit 2 turbine building is directly north of and abutting the Unit 1 turbine building. The containment is west of the turbine building. The auxiliary building is west of the turbine building adjacent to the containment. The cooling tower is west of and slightly north of the containment. The Unit 2 transformer yard is an extension of the Unit 1 yard and is located east of the turbine building.

The containment houses the NSSS consisting of the reactor, two steam generators, four reactor coolant pumps, the pressurizer, and portions of the RCS auxiliaries and ESF.

The turbine building houses the turbine generator, condenser, condensate and feedwater pumps, low pressure feedwater heaters and various turbine auxiliary equipment.

The auxiliary building houses the fuel handling system, waste processing systems, NSSS auxiliary equipment, high pressure feedwater heaters, vital electrical switchgear and power supplies, the control room and portions of the ESF.

1.2.2.10 Interrelationship With Unit 1

Separate systems and equipment are provided for Unit 2, with few exceptions. Any item or system not specifically identified in the text or on the system diagrams as being shared is used exclusively for Unit 2. The safety of either unit would not be impaired by the failure of the facilities and systems which are shared. A summary of the major shared facilities and equipment follows:

A. Electrical System - Startup Transformer 2 is common to Units 1 and 2 and is available as a standby transformer for the respective unit auxiliary or startup transformers. Its availability as an additional, independent source of power (Section 8.2) to the two sources normally provided for each unit, allows operational flexibility without loss of the redundancy required for the ESF power supply.

B. Control Room - The plant is provided with a central control room located in adjacent areas of the respective auxiliary buildings. The control panels and equipment are physically separated in the control room by a partition wall to eliminate interaction between Unit 1 and Unit 2 systems. Vent louvers above the partition are open to allow the ventilation systems to be shared by both units. The intent of the design is to centralize facility control and yet ensure the safe operational status of each plant, even under accident conditions.

   There are two normal ventilation systems, one for the Unit 1 half and one for the Unit 2 half of the common control room. The air is monitored for radiation and chlorine. Upon receiving a high radiation signal, the entire control room, both Unit 1 and Unit 2 sections, is sealed except for filtered outside air used for pressurization to minimize unfiltered air inleakage. This arrangement assures redundancy in the monitoring system. Air conditioning for both control rooms under isolated control room conditions is maintained by emergency air handling units and condensing units located in Unit 2. The emergency air conditioners are normally powered from vital buses in Unit 2, but one train can be supplied power from a vital bus in Unit 1. Only one emergency air conditioning train is required to operate during and following a shutdown of both units.

C. Emergency Cooling Pond - The cooling pond serves as the source of emergency cooling water for simultaneously shutting down both Units 1 and 2 in the unlikely event of a loss of the Dardanelle Reservoir water inventory. It may also be used as the heat sink for normal plant shutdown in lieu of using the Dardanelle Reservoir, if that is desired. Under controlled conditions, with the Dardanelle Reservoir available, the ECP may provide SW/ACW to Unit 1 with Unit 2 and/or Unit 1 providing makeup to preserve ECP inventory. It is sized to contain sufficient water for dissipating the total combined heat transferred to the Unit 1 and 2 SWS during the design basis LOCA in one unit and a normal plant shutdown of the other unit, while limiting the cooling pond temperature to a maximum of 116 °F. It is also sized to provide adequate fire protection water.

   Separate suction and discharge water lines are used for supplying pond water to the Unit 1 and Unit 2 SWSs. The end of the lines terminating at the cooling pond are housed in seismic Category 1 structures to prevent blockage of the pipe entrance and outlet. A detailed discussion of the pond is contained in Sections 2.5 and 9.2.

D. Waste Disposal System - Certain portions of the waste disposal system are common for Units 1 and 2. These include:

   1. Solid Waste Handling and Storage Facilities;
   2. Laundry Waste System;
   3. Liquid Waste Discharge (circulating water discharge), and
   4. Boric Acid Concentrators (currently not in use).

E. Miscellaneous – The list below contains other common facilities or systems of some significance; it is not intended to list all shared facilities, systems, or components. A functional evaluation of these components is shown in Table 1.2-1. Failure of any of these shared systems will be of no serious consequence since such failure will not prevent the safe shutdown of either unit.

1. Raw Water Storage Tank
2. Diesel Fuel Oil Bulk Storage Tank
3. Communications Systems
4. Clean Chemistry Laboratory and Count Room
5. Fire Water Main, Fire Pumps
6. Fuel Handling Crane (Auxiliary Building)
7. On-Site and Off-Site Environmental Monitoring
8. Sodium Bromide/Sodium Hypochlorite System
9. Turbine Building Crane, Elevator
10. Intake Structure Gantry Crane
11. Startup Boiler
12. Office Buildings
13. Railroad Spur, Access Roads and Parking Facilities
14. Switchyard, Transmission Lines
15. Telemetering and Load Dispatching Equipment
16. Shops (Clean Instrument, Hot Instrument, Hot Machine, Machine, and Welding)
17. Storeroom, Maintenance Facility, Warehouse, and Gas Bottle Storage
18. Reservoir Water Canals
19. Tendon Maintenance Scaffolding (portable)
20. Instrument Air Systems
21. Service Air Compressor
22. Breathing Air System
23. Control Room Kitchen and Sanitary Facilities
24. Oily Water Separator
25. Sewage System
26. Station Security System
27. High Purity Hydrogen System
28. DELETED
29. Liquid Nitrogen Storage Tank
30. Bulk Hydrazine Transfer
31. Post Accident Sampling System (PASS) Building
32. Independent Spent Fuel Storage Installation (ISFSI)
33. Low Level Radwaste Storage Building (LLRWSB)

F. Safety Parameter Display System (SPDS) - The SPDS is a computer-based system designed to monitor and display to the operator a concise set of parameters from which the safety status of the plant can be readily and reliably ascertained. The system functions as the SPDS for both the ANO-1 and ANO-2 Control Rooms and provides plant status information for the Technical Support Center (TSC) and Emergency Operations Facility (EOF).

   See Section 7.6.2.5 for an overall description of the system.

G. Alternate AC (AAC) Power Source - The AAC power source, which consists of a 4400 kW diesel generator (continuous rating) and supporting auxiliaries, is designed to manually pick up the loads on one 4160V ESF bus in either Unit 1 or Unit 2 in the event of a station blackout in either unit. Additionally, it can be connected to a non-1E bus in either unit for performance testing or peaking.

H. Condensate Storage Tank T41B - A safety-grade condensate storage tank, T41B, is shared by Unit 1 and Unit 2. This seismically qualified tank is connected to the Unit 2 EFW system as an available source of EFW.

1.3 COMPARISONS

1.3.1 COMPARISON WITH SIMILAR FACILITY DESIGNS

Table 1.3-1 presents a summary of the characteristics of the Arkansas Nuclear One - Unit 2 plant for Cycle 1 operation. The table includes similar data for Arkansas Nuclear One - Unit 1 (Docket No. 50-313), San Onofre Units 2 and 3 (Docket Nos. 50-361 and 50-362), and Calvert Cliffs Units 1 and 2 (Docket Nos. 50-317 and 50-318), as published for those units. The parameters listed in the ANO-2 Preliminary Safety Analysis Report (PSAR) are shown in parentheses for ease of comparison.

The San Onofre Units 2 and 3 design was selected for comparison because of the basic similarity of the reactor and Nuclear Steam Supply System (NSSS). The Calvert Cliffs Units 1 and 2 design was selected for comparison because of the similarity of the Reactor Coolant System (RCS) and because it was the most recent Combustion Engineering, Inc., (CE) reactor to complete the operating license review by the Directorate of Licensing (DL) and the Advisory Committee on Reactor Safeguards (ACRS). ANO-1 is representative of another supplier's reactor design and was selected since it shares the site with ANO-2 and since it had recently completed the operating license review by DL and ACRS.

Bechtel Power Corporation has served as the Architect/Engineer on all of these plants and has been responsible for the containment design.

1.3.2 COMPARISON OF FINAL AND PRELIMINARY INFORMATION

In the original Final Safety Analysis Report (FSAR) this section provided a discussion of all significant changes that were made in the plant design between the time the PSAR was submitted and the submittal of the original FSAR. Such a comparison is no longer useful in understanding the FSAR. This section was deleted in the update process. It is still available in the original FSAR.

1.3.3 COMPARISON OF PLANT DESIGN WITH REGULATORY GUIDE RECOMMENDATIONS

This section addresses the extent of conformance of plant design with those regulatory guides (or reference sections where such conformance is noted) in effect at the date of issuance of the construction permit, i.e., the applicable guides. In some cases, later revisions of the original guides are addressed if conformance with the later revision is appropriate for Unit 2. The remaining Division 1 Regulatory Guides are not addressed here as they were not included in the design basis of the unit as determined at issuance of the construction permit. However, elsewhere in this SAR, in the description of specific systems, the extent of conformance to specific guides of later issuance may be addressed even though they were not included in the original design basis.

Regulatory Guide 1.1 (12/1/70)

Net Positive Suction Head For Emergency Core Cooling and Containment Heat Removal System Pumps

See Section 6.2.2.2.1.B.1 for the Containment Heat Removal Systems and Section 6.3.2.14 for the Emergency Core Cooling System (ECCS).

<u>Regulatory Guide 1.2</u> (11/2/70)

Thermal Shock to Reactor Pressure Vessels

CE has performed detailed analyses dealing with reactor vessel response to thermal shock and a summary of this work, along with the other considerations of this Regulatory Guide, is contained in Section 6.3.3.13.1. This program is in conformance with Regulatory Guide 1.2.

<u>Regulatory Guide 1.3</u>

Assumptions Used for Evaluating the Potential Radiological Consequences of a LOCA for Boiling Water Reactors

Not Applicable.

<u>Regulatory Guide 1.4</u> (Revision 2, June 1974)

Assumptions Used for Evaluating the Potential Radiological Consequences of a LOCA for Pressurized Water Reactors

Unit 2 conforms to all portions of this guide except C.2.g(3) regarding atmospheric conditions. Site meteorology was used based on a five percentile criterion. Sections 15.1.0.5.2 and 15.1.13.2 provide a more detailed explanation.

<u>Regulatory Guide 1.5</u>

Assumptions Used for Evaluating the Potential Radiological Consequences of a Steam Line Break Accident for Boiling Water Reactors

Not applicable.

<u>Regulatory Guide 1.6</u> (3/10/71)

Independence Between Redundant Standby (Onsite) Power Sources and Between Their Distribution Systems

See Sections 8.3.1.2 and 8.3.2.2.

<u>Regulatory Guide 1.7</u> (3/10/71)

Control of Combustible Gas Concentrations in Containment Following a LOCA

See Section 6.2.5.

<u>Regulatory Guide 1.8</u> (2/10/71)

Personnel Selection and Training

As stated in Section 13.1.2, plant personnel qualification requirements are in compliance with ANSI N18.1 dated March 8, 1971. Personnel training and retraining, described in Section 13.2, are also in compliance with ANSI N18.1 dated March 8, 1971.

<u>Regulatory Guide 1.9</u> (3/10/71)

Selection of Diesel Generator Set Capacity for Standby Power Supplies

See Section 8.3.1.2.

<u>Regulatory Guide 1.10</u> (Revision 1, 1/2/73)

Mechanical (Cadweld) Splices in Reinforcing Bars of Concrete Containments

See Sections 3.8.1.2.4 and 3.8.1.6.2.

<u>Regulatory Guide 1.11</u> (3/10/71)

Instrument Lines Penetrating Primary Reactor Containment

This Regulatory Guide is not applicable to Unit 2 since there are no instrument fluid sensing lines penetrating the containment.

<u>Regulatory Guide 1.12</u> (3/10/71)

Instrumentation For Earthquakes

See Section 3.7.4.1.

<u>Regulatory Guide 1.13</u> (3/10/71)

Fuel Storage Facility Design Basis

The Unit 2 design conforms to all aspects of this guide as described in Section 9.1, based on our position that redundant Seismic Category 1 makeup paths provide adequate cooling capability in the event of a DBE.

<u>Regulatory Guide 1.14</u> (10/27/71)

Reactor Coolant Pump Flywheel Integrity

See Section 5.2.6.1.

<u>Regulatory Guide 1.15</u> (Revision 1, 12/28/72)

Testing of Reinforcing Bars for Category 1 Concrete Structures

See Sections 3.8.1.2.4 and 3.8.1.6.2.

<u>Regulatory Guide 1.16</u> (10/27/71)

Reporting of Operating Information

Conformance with this guide is addressed in the Technical Specifications and Technical Requirements Manual since the guide covers only reporting requirements.

Regulatory Guide 1.17 (June 1973)

Protection of Nuclear Power Plants Against Industrial Sabotage

An Industrial Security Plan has been prepared and submitted (Docket 50-313) which provides the information requested by this guide.

Regulatory Guide 1.18 (Revision 1, 12/28/72)

Structural Acceptance Test for Concrete Primary Reactor Containment

See Sections 3.8.1.2.4 and 3.8.1.7.1.

Regulatory Guide 1.19 (Revision 1, 8/11/72)

Nondestructive Examination of Primary Containment Liner Welds

See Sections 3.8.1.2.4 and 3.8.1.6.3.

Regulatory Guide 1.20 (12/29/71)

Comprehensive Vibration Assessment Program for Reactor Internals During Preoperational and Initial Startup Testing

AP&L implemented a PVMP for Unit 2 in accordance with the requirements of Regulatory Guide 1.20 as it relates to other than prototype units. The basis for this approach and supporting data are contained in Section 3.9.1.4 and in references cited in Section 3.9.

Regulatory Guide 1.21 (12/29/71)

Measuring and Reporting of Effluents from Nuclear Power Plants

The reporting and monitoring recommendations of this guide are covered in the Technical Specifications. The waste management equipment described in detail in Chapter 11 is sufficient to provide the capability for monitoring as recommended in the guide.

Regulatory Guide 1.22 (2/17/72)

Periodic testing of Protective System Actuation Functions

See Sections 7.2.1.1.9 and 7.3.1.1.9.

Regulatory Guide 1.23 (2/17/72)

Onsite Meteorological Programs

The meteorological program described in Section 2.3 complies with the guide except as follows:

A. Temperature difference accuracy is ± 0.3 °C.

B. Dew point temperature accuracy is ± 2.0 °C.

C. Wind speed accuracy.

Regulatory Guide 1.25 (3/23/72)

Assumptions Used for Evaluating the Potential Radiological Consequences of a Fuel Handling Accident in Fuel Handling and Storage Facility for Boiling and Pressurized Water Reactors

See Section 15.1.23.2.2.

Regulatory Guide 1.26 (3/23/72)

Quality Group Classifications and Standards

See Section 3.2.2.

Regulatory Guide 1.27 (Revision 1, March 1974)

Ultimate Heat Sink for Nuclear Power Plants

See Section 9.2.5.3.

Regulatory Guide 1.28 (6/7/72)

Quality Assurance Program Requirements

The quality assurance program described in the Quality Assurance Program Manual (QAPM) complies with Regulatory Guide 1.28 and ANSI N45.2, or describes acceptable alternatives and meets the requirements of 10CFR50, Appendix B. The QAPM describes the revision of Regulatory Guide 1.28 and ANSI N45.2 that is satisfied.

Regulatory Guide 1.29 (6/7/72)

Seismic Design Classification

See Section 3.2.1.2.

Regulatory Guide 1.30 (8/11/72)

Quality Assurance Requirements for the Installation, Inspection, and Testing of Instrumentation and Electric Equipment

This guide is fully complied with as detailed in the Quality Assurance Program Manual.

Regulatory Guide 1.31 (Revision 1, June 1973)

Control of Stainless Steel Welding

See Section 5.2.5.7.

Regulatory Guide 1.32 (8/11/72)

Use of IEEE 308-1971, "Criteria for Class 1E Electric Systems for Nuclear Power Generating Stations"

Full compliance with Regulatory Guide 1.32 has been met as shown in Sections 8.3.2.1.2 and 8.3.2.2.

The battery chargers have been sized to restore the station batteries to a fully charged state while simultaneously supplying all connected loads.

Regulatory Guide 1.33 (11/3/72)

Quality Assurance Program Requirements

The program described in the Quality Assurance Program Manual (QAPM) meets the recommendations of this guide. The QAPM describes the revision of Regulatory Guide 1.33 that is satisfied.

1.4 IDENTIFICATION OF AGENTS AND CONTRACTORS

Arkansas Power & Light Company, as owner, arranged for the purchase of equipment and consulting, engineering and construction services for the installation of Unit 2. Arkansas Power & Light subsequently became Entergy Arkansas, Inc. Entergy Operations, Inc., is responsible for the operation of the unit.

The Bechtel Corporation was retained for engineering, procurement and management of construction services. They also provided assistance in obtaining licenses and permits in pre-operational testing, in quality control, and in initial startup of the project.

Combustion Engineering, Inc., (CE) was contracted to design, manufacture and deliver to the site a complete nuclear steam supply system and fuel. In addition, CE supplied competent technical and professional consultation for erection, initial fuel loading, testing and initial startup of the complete nuclear steam supply system.

The General Electric Company supplied the turbine generator and its auxiliaries.

1.5 REQUIREMENTS FOR FURTHER TECHNICAL INFORMATION

This section provides a description of safety-related technical information relevant to this application.

The Unit 2 reactor incorporates a 16 x 16 fuel assembly with five guide tubes. This design provides an increase in conservatism for LOCA considerations with a minimum change from previous CE fuel designs. The previous designs have undergone extensive testing and operating experience is now being acquired.

The three test programs described in Sections 1.5.1, 1.5.2 and 1.5.3 are considered necessary to confirm the adequacy of the 16 x 16 fuel design. CENPD-87 (Reference 7) and CENPD-184 (Reference 6) present descriptions of development programs aimed at verifying the NSSS design and the anticipated performance characteristics, and at confirming the design margins. Those programs that apply to this plant are identified in Sections 1.5.4 through 1.5.12.

1.5.1 FRETTING AND VIBRATIONS TESTS OF FUEL ASSEMBLIES

A test has been performed using a full sized 16 x 16 fuel assembly. This assembly is identical to the 16 x 16 five guide tube designs used on the Unit 2 reactor. This assembly was subjected to flow testing under reactor operation conditions of temperature, water chemistry, pressure and flow velocity. The results of this test are presented in the Reference Section of Chapter 4.

1.5.2 DEPARTURE FROM NUCLEATE BOILING (DNB) TESTING

Extensive heat transfer testing has been completed with rod bundles representative of the CE 14 x 14 fuel assembly. Analysis of the data using the CE thermal-hydraulic design methods demonstrated the validity of those methods for computing thermal margin and pressure drop for plants using the 14 x 14 fuel assembly. Additionally, the DNB test program has been extended to include DNB tests to confirm the heat transfer capability of the CE 16 x 16 fuel assembly. DNB data were taken for a range of test conditions using electrically heated rod bundles representative of the 16 x 16 fuel assembly. The COSMO/INTHERMIC design codes and the W3 correlation were then employed to predict DNBR under the test conditions. Measured and predicted DNB heat fluxes were then compared for all data in the pressure range of 1,750 to 2,450 psia and with mass velocities less than 3.2×10^6 lb/hr-ft^2. The results of this comparison support the use of the COSMO/INTHERMIC codes and the W3 correlation with a minimum DNBR of 1.3 for computing margin to DNB for the CE 16 x 16 fuel assembly. Additional information on the program and results may be found in Section 4.4.4.2. This supports the analytical methods for computing margin to DNB for Cycle 1 operation. Analytical methods used for later cycles are discussed in Section 4.4.3.4.2.

1.5.3 FUEL ASSEMBLY STRUCTURAL TESTS

The fuel assembly structural testing program was designed to verify the structural adequacy of the CE fuel assembly design under normal handling, normal operation, seismic excitation and LOCA loadings. The test program provides the structural characteristics employed in the fuel assembly structural analyses.

A series of tests were conducted on a CE 14x14 fuel assembly to determine the combined axial and lateral load deflection characteristics of the fuel assembly. Axial compression tests and axial drop tests were performed. Measurements were made of axial loads, axial deflections, lateral deflections of all spacer grids, and strains in the guide tubes and fuel rods.

A series of structural tests on the 16x16 fuel assembly design have also been conducted. A prototype fuel assembly has been subjected to both static and dynamic tests which have determined basic structural characteristics. In addition, several 16 x 16 spacer grids have been subjected to impact tests to determine dynamic load deflection characteristics and damage limits. This test program is summarized in Reference 6 and the results of the tests are presented in the Reference Section of Chapter 4.

1.5.4 FUEL ASSEMBLY FLOW MIXING TESTS

The fuel assembly flow mixing program was designed to determine the magnitude of turbulent interchange in the CE fuel assembly designs. Test data were generated from a two-part series of tests conducted in 1966 and 1968. First, in 1966, a series of single phase tests on coolant mixing through turbulent interchange was run on a model fuel assembly which was geometrically similar to the Palisades assembly. The model enabled determination of vertical subchannel flow rates using pressure instrumentation and the average level of turbulent interchange using dye injection and sampling equipment.

A second series of single phase dye injection mixing tests were conducted on a model of a portion of a CEA type fuel assembly which had sufficient instrumentation to enable measurement (via a data reduction computer program) of the lateral flow across the boundaries of 12 subchannels of the model. These tests, further described in Reference 7, established the effect of turbulent interchange and coolant mixing in CE fuel assemblies and have been completed. Additional information is presented in Section 4.4.4.4.

1.5.5 REACTOR FLOW MODEL TESTING AND EVALUATION

The objective of the reactor flow model test programs is to obtain information on: (1) flow and pressure distributions in various regions of the reactor, (2) pressure loss coefficients, (3) hydraulic loads on vessel internal components, and (4) the detailed flow paths within the reactor vessel. This information is used for establishing or verifying design hydraulic parameters.

Flow model testing, which began in 1966, was designed to obtain those reactor hydraulic design data not amenable to direct calculation. Scale model testing possesses the advantages, relative to actual reactor tests, of: (1) providing the information early in the design stage, (2) being more suitable for extensive instrumentation, and (3) being flexible so that proposed design modifications can be investigated.

The reactor flow models used by CE are approximately one-fifth true scale models, with the exception of the core region which to-date has been simulated by closed tubes, one for each fuel bundle.

By the end of 1972, actual "closed-core" flow model tests had been conducted on four configurations. The conclusions from the tests on the first four configurations are summarized in Reference 7. Additional information on the results of these tests and their applicability to Unit 2 is contained in Section 4.4.3.1.1. These tests are the basis for establishing the flow distribution within the reactor vessel, assigning flow maldistribution factors for thermal margin evaluation, and for predicting component and nozzle-to-nozzle pressure drop.

1.5.6 FUEL ASSEMBLY FLOW TESTS

The purpose of the fuel assembly flow test program was to determine normal fuel assembly distributions and to assess the effect of postulated flow maldistributions on thermal behavior and margin.

The program originated in 1967 with fuel assembly flow distribution testing. Both flow visualization and flow pattern measurements were generated on an overscale model of the lower portion of a Palisades fuel assembly. A second test series was conducted for the CEA type fuel assembly. The second test series was designed to: (1) obtain subchannel flow redistribution data which could be used in developing and validating multi-subchannel thermal and hydraulic analysis methods, (2) determine the effect of various flow obstructions on flow distribution within the fuel assembly, and (3) determine the magnitude of the effect of several of the disturbed flow patterns on the thermal margin within a CEA type reactor.

The information from these tests, described further in Reference 7, has provided subchannel flow redistribution data for confirmation of thermal-hydraulic analysis methods and has established the effect of flow obstructions within the fuel assembly. Additional information on the effects of postulated fuel coolant channel flow blockage is presented in Section 4.4.3.10.

1.5.7 CONTROL ELEMENT DRIVE MECHANISM (CEDM) TESTS

Performance testing of the magnetic jack CEDM is described in Section 4.2.3.4.1 and in Reference 7. The program has confirmed the operability of the drive assembly in normal and misaligned conditions as well as the load-carrying capability and life characteristics.

1.5.8 SAFETY INJECTION SYSTEM IMPROVEMENT

A parametric analysis of Emergency Core Cooling System (ECCS) performance was conducted by calculating the resultant peak clad temperatures for both large and small break Loss of Coolant Accidents (LOCA) for a variety of safety injection tank pressures and water/gas volume fractions. The purpose of this analytical program was to determine if ECCS performance could be improved and accident consequences reduced by optimization of the safety injection tank parameters.

This program, further described in Reference 7, established the effective pressure for safety injection tanks and the required total tank volume and gas/water volume ratio for Unit 2.

1.5.9 DNB IMPROVEMENT

The Departure from Nucleate Boiling (DNB) improvement program was initiated by CE in order to obtain empirical information on the DNB phenomenon and on other thermal and hydraulic characteristics of CE fuel assemblies. Testing has been performed with electrically heated rod bundles which correspond dimensionally to fuel rod configurations under in-reactor temperature pressure and flow conditions to obtain data on DNB, pressure drop, and coolant channel exit temperatures. These data have been employed to verify that the CE thermal hydraulic design methods conservatively predict DNB.

This program is described in References 6 and 7. It is a continuing program providing improvements in the accuracy of CE thermal and hydraulic computer programs for predicting local coolant conditions and pressure drops and confirming the applicability of currently used DNB correlations to the CE fuel design. Additional information on the program and results applicable to Unit 2 are presented in Section 4.4.4.2.

1.5.10 LOCA REFILL TESTING

The objective of this program was to perform preliminary tests to determine the amount of ECCS water injected during blowdown that is retained in the reactor vessel lower plenum.

As a follow-on to the CE/AEC/EPRI steam-water mixing program, CE conducted additional tests on its own to investigate the ECCS bypass problem. The tests were performed on the one-fifth scale model used for the steam-water mixing tests. The cold leg piping was used to bring the ECC water into the downcomer. Steam up-flow in the annulus was developed by flowing the steam directly into the vessel core region. Varying steam flow rates, ECC injection rates and ECC temperatures were investigated.

The preliminary results showed that the amount of water retained in the lower plenum increased as the steam flow decreased and amount of water injected for annulus condensation increased. The test program is summarized in Reference 6. In the approved CE LOCA large break evaluation mode, Reference 2, no credit is taken for ECC injection prior to the end-of-bypass (EOBYP). Under the New Acceptance Criteria, Reference 1, all of the ECC water injected prior to EOBYP must be discarded.

Task C of the CE/AEC/EPRI steam-water mixing program involved annulus penetration tests to investigate the amount of ECCS water injected during blowdown that is retained in the reactor vessel lower plenum. The reactor vessel was one-fifth scale and the cold leg inlet pipe was one-fifth scale diameter and full scale length. A detailed description of the test facility, including the vessel and nozzle mockup, is presented in Reference 12. The experimental test matrix is given in References 11 and 13 and the test results are presented in References 9 and 10. These scoping tests demonstrated that the approved refill model in Reference 2 was conservative.

As a follow-on to the Task C tests, CE performed additional annulus penetration tests. These tests were performed in the same test facility as the Task C tests. The objective of these tests was to investigate a larger range of steam flow rates, ECC injection rates and ECC temperatures than the Task C tests provided. These preliminary results again demonstrated the conservativeness of the refill model in Reference 2. The scoping plenum refill tests were completed in 1974 at CE. Although the test results appeared promising, it appeared that the development of a more realistic, i.e., less conservative, bypass model would require a significant experimental and analytical effort. In addition, the effect of a new bypass model on 16x16 fuel assembly plants, e.g., Arkansas, which are late reflood limited is negligible. Thus, it was decided to terminate further annulus penetration testing. There are no plans to continue the program or to produce a closeout report.

1.5.11 BLOWDOWN HEAT TRANSFER TESTING

A joint CE/EPRI blowdown heat transfer testing program was conducted. The objectives of the test program were:

A. To improve the understanding of transient critical heat flux and post-CHF heat transfer phenomena expected to occur in PWR cores during LOCA blowdown conditions.

B. To experimentally determine the time, location, and distribution of transient CHF and the transient post-CHF heat transfer coefficients in single heated tubes with internal flow and in-rod bundles subjected to conditions representative of large hot and cold leg breaks in PWR's.

Reactor core transient conditions that are predicted to occur during a hypothetical Loss of Coolant Accident (LOCA) were tested. The test program emphasized hydraulic simulation of large cold leg breaks including the double-ended guillotine break. The test program utilized electrically heated rod bundle and single tube test sections. The Single Tube Test Program was performed in CE test laboratories in Windsor, Connecticut, and the Rod Bundle Test Program was performed at Columbia University Heat Transfer Facilities in New York City. The rod bundles consist of 25 heated rods (5 x 5 square array) and have active heated length of 12.5 feet. The rod bundle had a uniform axial heat flux profile and a non-uniform radial power distribution. The non-uniform radial power profile, which simulates a quadrant of a fuel assembly, had a central 9-rod hot region with a 1.070 peak-to-average power distribution and 16 cooler rods with a 0.961 normalized power factor.

The test facility was modified, instrumentation calibrated, and shakedown tests were performed with power on the test sections prior to conducting the planned testing. Single tube and rod bundle blowdown tests with a uniform axial heat flux profile were completed in 1975. The results of these tests are contained in References 4, 5, and 14. The test program is described in Reference 6.

1.5.12 STEAM WATER MIXING TEST PROGRAM

The purpose of the steam water mixing test has been to generate experimental data relating to:

A. The hydraulic resistance to steam flow in both the broken and intact cold legs created by the injection of Emergency Core Cooling (ECC) water.

B. The conditions necessary to establish unrestricted steam passage through the initially water-filled loop seals of the intact cold legs in the presence of ECC injection.

C. The fraction of ECC injection water which may backflow into the loop seals upon initiation of injection.

D. The proportion of ECCS water which is injected during blowdown and goes to the lower plenum of the reactor vessel.

These data are applicable to the latter portion of blowdown and post-blowdown periods of a LOCA. The steam-water mixing program was concluded in early 1974. Additional information on the program is provided in Reference 6.

1.6 MATERIAL INCORPORATED BY REFERENCE

The following list is a tabulation of all Topical Reports which were incorporated by reference as part of the original license application. Other Topical Reports for information purposes, not incorporated by reference, were listed in the individual chapter and section references in the FSAR.

Additional Topical Reports incorporated by reference at later dates are not added to this list but are referenced in the appropriate text.

1.7 GLOSSARY OF ITEMS

This section presents a glossary of abbreviations, symbols, indices, legends and other aids to facilitate understanding of this Safety Analysis Report (SAR). Information was compiled from applicable specifications, drawings, SAR sections and related publications.

1.7.1 TEXT ABBREVIATIONS

The abbreviations of systems, buildings, components and other non-technical information have been alphabetized in Table 1.7-1. Common phrases such as DNB and EFPY are listed along with drawing component and system abbreviations such as SIS and RWT. Standard technical abbreviations are used throughout this SAR. Powers of 10 are usually presented in standard scientific notation, e.g., 5×10^6 or 5E+6 Powers of 10 may also be represented by parentheses; e.g., 5(+6) or 5(6).

1.7.2 DRAWING INDEX AND SYMBOLS

The drawing index scheme combines letters with numbers such that the letter corresponds to the engineering fields (A - Architectural; C - Civil-Structural; E - Electrical and M - Mechanical) and the numbers give sequential ordering. The Piping and Instrumentation Diagrams (P&IDs) are a part of the Mechanical Engineering (M) drawings referenced in Table 1.7-2. Equipment location drawings are also referenced in Table 1.7-2.

The designated Locked Closed (LC) and Locked Open (LO) refer to the position in which certain valves are normally maintained during power operation. Actual valve positions may vary from those shown on the drawings due to different modes of operation, unavailability of certain equipment, etc. Manual valves are normally locked open (or closed) by means of a mechanical lock on the valve stem or hand wheel. Power operated valves are locked open (or closed), with one exception, by means of key-locked hand switches at the control panel. Section 6.3 has more information regarding these particular valves.

1.7.3 PIPING IDENTIFICATION

Piping identification is given in Table 1.7-3 and corresponds to the codes shown on P&IDs.

1.7.4 TRADEMARKS

Optimized ZIRLO, **ZIRLO**, **Low Tin Zirlo**, and **Guardian** are trademarks or registered trademarks of Westinghouse Electric Company LLC, its affiliates and/or its subsidiaries in the United States of America and may be registered in other countries throughout the world. All rights reserved. Unauthorized use is strictly prohibited. Other names may be trademarks of their respective owners.

Table 1.3-1 (continued)

ELECTRICAL SYSTEMS	ANO-2	PSAR***	FSAR Reference Section	Calvert Cliffs* Units 1 & 2	ANO-1	San Onofre* Units 2 & 3
Number of Off-site Circuits	3 – 500		8.2.1.1	2 – 500 kV	2–500 kV	8
Number of Incoming Lines to Start up Transformers	2		8.2.1.3	2	2	2
Number of Startup Transformers	1(+1shared)		8.2.1.3	2	1(+1shared)	4 (Aux)
Number of Main Unit Transformers (Single Phase)	3		F / 8.3.1	4	4	1
Number of 4.16 kV Engineered Safety Features System Buses	2		8.3.1.1.3	4	2	3
Number of 480V Engineered Safety Features System Buses	2		8.3.1.1.4	8	2	3
Number of 120V Vital Buses	4		8.3.1.1.5	8	4	4
Number of Standby Diesel Generators	2		8.3.1.1.7	3	2	2 (+1 shared)
Diesel Generator Rating (KW)	2850		8.3.1.1.7	2500	2750	Criteria: PSAR Section 8.2.3.2.2

---

* The values listed for these plants were taken from public documentation.
** Based on total heat output of the core rather than heat generated in fuel alone.
*** PSAR Data
† Operating Level
‡ This section is not suited for tabular description. SAR section numbers have been included for the location of the detailed description of each system.

(1) Only one is used for engineered safety features systems.
(2) One bus will swing from other two sources; can be connected to only one bus at anytime.
(3) Use of a later ASME Section III code is acceptable, provided the code section(s) used is reconciled.

Table 1.7-3

PIPING IDENTIFICATION

The information in this table is historical in nature and Specification ANO-M-2555 should be referenced for the latest information.

Piping classes are designated by a three-letter code. The first letter indicates the primary valve and flange pressure rating, the second letter the type of material and the third letter the code to which the piping is designated.

The designations are as follows:

First Letter: Pressure Rating[1]

B -	2500 #	J -	125#ANSI B16.1
C -	1500 #	K -	75#WOG[2]Underwriter's Laboratories, Inc.
D -	900 #	L -	250#ANSI B16.1
E -	600 #	M -	200#WOG[2]
F -	400 #	N -	150# ANSI B16.24[3]
G -	300 #	T -	Tubing
H -	150 #		

Second Letter: Material

B -	Carbon Steel	H -	Cast Iron
C -	Stainless Steel	J -	Cast Iron – Cement Lined
D -	Copper, Brass, or Bronze	L -	Carbon Steel – Impact Tested
E -	Note 4	S -	Carpenter 20 Cb-3 Stainless Steel
F -	Note 4	N -	Galvanized Carbon Steel
G -	Note 4	R -	Fiberglass Reinforced

Third Letter: Design Code[5]

A - Nuclear Power Plant Components, ASME B&PV Code, Section III, Class 1
B - Nuclear Power Plant Components, ASME B&PV Code, Section III, Class 2
C - Nuclear Power Plant Components, ASME B&PV Code, Section III, Class 3
D - Power Piping Code, ANSI B31.1.0
F - National Fire Protection Association Codes
J - American Water Works Standards
R - Copper Tubing per ANSI B31.5

Notes

1. All ratings are in accordance with ANSI B16.5 and other ANSI standards as applicable.
2. Water, Oil, or Gas service (not steam service).
3. Not used; listed for historical purposes only.
4. For general use as designated on Piping Class Sheets.
5. Use of a later appropriate ASME Section III code(s) is acceptable provided the section(s) used is reconciled.

2.3-59	MONTHLY, SEASONAL AND ANNUAL EXTREMES OF ABSOLUTE HUMIDITY FOR LITTLE ROCK, ARKANSAS (JANUARY 1956 THROUGH DECEMBER 1962)	2.7-89
2.3-60	SEASONAL AND ANNUAL DIURNAL VARIATION OF MEAN ABSOLUTE HUMIDITY (gm/m³) FOR LITTLE ROCK, ARKANSAS (JANUARY 1956 THROUGH DECEMBER 1962)	2.7-90
2.3-61	MONTHLY, SEASONAL AND ANNUAL DIURNAL VARIATION OF MEAN DEW POINT TEMPERATURE (°F) VARIATIONS FOR LITTLE ROCK, ARKANSAS (JANUARY 1956 THROUGH DECEMBER 1962)	2.7-91
2.3-62	MONTHLY, SEASONAL AND ANNUAL DIURNAL VARIATION OF MEAN RELATIVE HUMIDITY (%) VARIATION FOR LITTLE ROCK, ARKANSAS (JANUARY 1956 THROUGH DECEMBER 1962)	2.7-92
2.3-63	PERCENT FREQUENCY OF OCCURRENCE OF FOG FOR LITTLE ROCK, ARKANSAS (1949-1967)	2.7-93
2.4-1	RAINFALL AND RUNOFF FOR PMF	2.7-94
2.4-2	GROUNDWATER USE IN JOHNSON, LOGAN, POPE, AND YELL COUNTIES - 1970	2.7-95
2.4-3	WELL SURVEY ANO	2.7-96
2.4-4	CHEMICAL ANALYSIS OF GROUND AND SURFACE WATER	2.7-98
2.4-5	JUNE 1974 WELL CANVASS	2.7-99
2.5-1	SUMMARY OF DRILL HOLE DATA	2.7-100

LIST OF TABLES (continued)

Table No.	Title	Page
2.5-2	SUMMARY OF LABORATORY ROCK TESTS	2.7-102
2.5-3	ENGINEERING PROPERTIES FOR SITE SOILS	2.7-104
2.5-4	STATIC ENGINEERING PROPERTIES FOR DESIGN (EMERGENCY COOLING POND)	2.7-105
2.5-5a	LONG-TERM STABILITY EMERGENCY COOLINGWATER POND	2.7-105
2.5-5b	FACTORS OF SAFETY OF EMERGENCY COOLING POND SLOPE	2.7-105
2.5-5c	FACTORS OF SAFETY OF EMERGENCY COOLING POND SLOPE USING PEAK STRENGTH VALUES	2.7-106
2.5-6	RESULTS OF CLASSIFICATION TESTS - 1970	2.7-106
2.5-6a	RESULTS OF LABORATORY TESTS	2.7-107
2.5-6b	PRECONSOLIDATION PRESSURE OF SOIL OVERBURDEN	2.7-110
2.5-7	RESULTS OF CLASSIFICATION TESTS - 1972	2.7-111
2.5-8	MODIFIED MERCALLI INTENSITY SCALE OF 1931 (ABRIDGED)	2.7-112
2.5-9	CHRONOLOGICAL LIST OF EPICENTER LOCATIONS FOR MAP SHOWING SIGNIFICANT EARTHQUAKE EPICENTERS	2.7-113
2.5-10	ANCHOR BAR PULL TESTS	2.7-115
2.5-11	LONG-TERM STABILITY INTAKE AND DISCHARGE CANALS	2.7-115
2.5-12	RESULTS OF CLASSIFICATION TESTS	2.7-116

LIST OF FIGURES

Figure No.	Title
2.1-1	COUNTIES WITHIN A 50-MILE RADIUS
2.1-2	PLOT PLAN AND SITE BOUNDARY
2.1-3	RESTRICTED AREA
2.1-4	LAND USE (PASTURED/CULTIVATED) WITHIN A 50-MILE RADIUS
2.1-5	1970 POPULATION DISTRIBUTION WITHIN 10 MILES
2.1-6	1980 PROJECTED POPULATION DISTRIBUTION WITHIN 10 MILES
2.1-7	1990 PROJECTED POPULATION DISTRIBUTION WITHIN 10 MILES
2.1-8	2000 PROJECTED POPULATION DISTRIBUTION WITHIN 10 MILES
2.1-9	2010 PROJECTED POPULATION DISTRIBUTION WITHIN 10 MILES

2 SITE CHARACTERISTICS

This chapter provides information on the geological, seismological, hydrological, and meteorological characteristics of the site and vicinity in the context of their influence on plant design and operating criteria showing the adequacy of the site characteristics from a safety viewpoint. These are given in conjunction with population distribution, land use, and site activities and controls.

Sections of this chapter that do not describe the facilities at ANO are not encompassed by the FSAR update rule (10 CFR 50.71(e)) and therefore are not required to be updated. This includes such information as projected population densities, lists of industries or facilities, and groundwater users. This information was developed in support of initial licensing and, even if updated, would be unlikely to affect plant operation, the plant design bases, or the conclusions of safety analyses relative to public health and safety.

2.1 GEOGRAPHY AND DEMOGRAPHY

2.1.1 SITE LOCATION

The Arkansas Nuclear One - Unit 2 site is at latitude 35°-18'-42" N and longitude 93°-13'-15" W (Universal Transverse Mercator Coordinates: E478960m; N3907340m).

The site is located in southwestern Pope County, Arkansas, about 57 miles northwest from Little Rock, Arkansas, and 68 miles east of Fort Smith, Arkansas, on a peninsula formed by the Dardanelle Reservoir. The Reservoir is part of the "Multiple-Purpose Improvement Plan for the Arkansas River" and includes the Arkansas River and the former Illinois Bayou. The area of the Reservoir is 36,000 acres; its normal pool elevation (336-338 feet) is controlled downstream by the Dardanelle Lock and Dam No. 10 on the Arkansas River. The town of Russellville is about six miles east-southeast from the site and the village of London is about two miles northwest from the site. The location of counties within a 50-mile radius is shown in Figure 2.1-1. Figure 2.3-3 shows the general geographical and topographical features within a 50-mile radius of the site and Table 2.1-1 provides data for reservoirs and lakes within a 50-mile radius.

2.1.2 SITE DESCRIPTION

Figure 2.1-2 shows the location of significant plant facilities with respect to the property boundary and delineates the area to be considered as the exclusion area. This exclusion area has a minimum radius of 0.65 miles from the center of the reactor and is controlled to the extent necessary by Entergy Operations, Inc. This area includes certain portions of the bed and banks of Dardanelle Reservoir which are owned by the United States. An easement has been obtained from the U.S. Army Corps of Engineers which entitles the Company to exclude all persons from these areas during periods of emergency. A perimeter fence is erected around the immediate station area. A transcript of the easement is included in Appendix 2A.

2.1.2.1 Exclusion Area Control

The applicant shall have full control of all activities conducted within the exclusion area, as described above. There are no railroads that traverse the exclusion area other than the plant spur. All the property within this exclusion area is owned by the applicant with the exception of that property owned by the United States. The property owned by the United States, including the waterways therein, shall be controlled under provisions of the easement mentioned above.

Security-Related Information
Text Withheld Under 10 CFR 2.390

The only rights to the property within the exclusion area other than those of the U.S. Department of the Army under Condition 6 of the easement are a right-of-way easement to the Arkansas Natural Gas Corporation in 1959, and to the City of London (with regard to the maintenance of water lines).

A number of tracts had oil and gas leases for 10 years which were executed in 1959 and 1960. These oil and gas leases expired by their own terms and no so-called "delay rentals" were paid to keep the leases in effect. No other property rights or contractual obligations relating to property rights which might be inconsistent with or adversely affect the applicant's ability to exercise complete control of the exclusion area at any necessary or required time exists to the knowledge of the applicant.

As shown in Figure 2.1-2, there are two roads within the exclusion area. In the northeast sector just inside the exclusion area boundary is a short stretch of State Highway 333. Near the exclusion area boundary and encircling the plant site on the east, south, and west is a county road. Agreements with both the Arkansas State Police and the Pope County Sheriff have been made for control of traffic on these roads and all roads giving access to the plant site in the event of an emergency. Further details of the emergency plan specifically related to the use of these roads are given in the Arkansas Nuclear One Emergency Plan.

Also shown in Figure 2.1-2 is a small cemetery south of the plant which is within the exclusion area. The applicant owns all rights to this tract, explicitly including the cemetery rights. Ark. Stat. Ann. K41-3712 prohibits anyone from constructing a fence on property so as to enclose any cemetery unless suitable access by automobile to such cemetery is provided by state or otherwise. However, based on the rights to the cemetery which the applicant has acquired, the applicant could exclude persons from the cemetery if it was deemed necessary. Though the applicant has complete control over activities within the cemetery, continued use of the cemetery for burial purposes is allowed. A count made on October 21, 1975, revealed 206 distinguishable graves in the cemetery. The cemetery is frequented often enough that it is well kept and normally fresh flowers appear on two or three graves. Burial space in the cemetery is very limited and new burials are very infrequent.

2.1.2.2 Boundaries for Establishing Effluent Release Limits

The restricted area for the Arkansas Nuclear One site as defined by 10 CFR 20 is shown on Figure 2.1-3. The boundary of this area is approximately 746 meters from the center line of the containment of Unit 2. Land access to this area will be controlled by posting the area. The intake canal and discharge embayment within this restricted area will be continuously monitored.

The immediate plant area, enclosed by the security fence, will be regularly patrolled by the plant guards as required in the Arkansas Nuclear One Industrial Security Plan. The entire restricted area is easily brought under visual inspection during each patrol.

Distances from plant effluent release points to the exclusion area boundary are given in Table 2.1-2.

2.1.3 POPULATION AND POPULATION DISTRIBUTION

Population and population distributions within a 50-mile radius of the site are discussed in this section. Population data presented is based on the 1970 census data, projected to the year 2010 by decades. The influence of transient populations and the locations of population centers, public facilities, and institutions in the vicinity of the site are also discussed.

2.1.3.1 Population Within 10 Miles

The 1970 population distribution within 10 miles of the site is shown on Figure 2.1-5. This distribution is based on the 1970 census and 1971, photo revised Arkansas State Highway Department County Highway Maps. The population in each sector was determined by counting the rural residential dwellings in each sector and adding this population to the town and city population within each respective sector.

The population projections from 1980 through 2010 in increments of a decade, within 10 miles of the site, are shown in Figures 2.1-6 through 2.1-9. The projected populations for initial plant startup (1976) and end of life (2016) are shown in Figures 2.1-10 and 2.1-11. The projections were calculated using the results of the Arkansas River Region Report, Volume I, Section B, which was prepared by the Industrial Research and Extension Center, College of Business Administration, University of Arkansas for the Arkansas Planning Commission. This report quotes a high and a low estimate for the population growth factors through the time span considered, with the projections shown in this section based on the high estimate.

2.1.3.2 Population Between 10 and 50 Miles

The 1970 population distribution between 10 and 50 miles of the site is shown in Figure 2.1-12. This distribution is based on the 1970 census count and the latest maps showing minor civil division (township) boundaries. Estimates of the population distribution were made using 1970 census tabulations for each individual township, and then calculating the areas of townships in each sector.

The population projections between 10 and 50 miles of the site from 1980 through 2010, in increments of a decade, are shown in Figures 2.1-13 through 2.1-16, respectively. The projected populations for initial plant startup and end of life are shown in Figures 2.1-17 and 2.1-18. The projections were made by assuming a continuation to the year 2016 of the percent change in the population experienced in each county between 1960 and 1970, and calculating the percentage of each sector by counties.

2.1.3.3 Low Population Zone

The low population zone consists of the area outside of the exclusion area (0.65-mile radius from the center of the reactor) but within a 4-mile radius of the site. This distance was selected since it meets the requirements of 10 CFR 100 and allows reasonable protective measures to be taken for residents in this area in case of a serious accident (see Section 13.3). As there are no residents within the 0.65-mile radius exclusion area, the population distributions for the low population zone for the years 1970 to 2010 by decades are the same as those shown in Figures 2.1-5 through 2.1-9, respectively, out to the 4-mile radius line. However, Section 2.1 of the ANO-2 SER, Section 2.1 of Supplement 1 to the ANO-2 SER, and Section 2.1 of Supplement 2 to the ANO-2 SER give a summary of discussions which led to redefining the low population zone radius to meet 10 CFR 100 as 2.6 miles based on projections of the growth of the city of Russellville and its surroundings.

2.1.3.4 Transient Population

The major cause of population influx and shifts occurring within 50 miles of the site is recreational activities that peak during the summer months. Table 2.1-14 lists the state parks, national forests, and recreation areas in Arkansas within 50 miles of the site. This table describes the facilities available, distance and direction from site, and the most recent available attendance records. It should be noted that 70 percent of the Ozark National Forest and 30 percent of the Ouachita National Forest are within 50 miles of the site. Information was not available on the number of people entering the area from outside the 50-mile radius (influx) or the number corresponding to shifts within the 50-mile radius. However, a survey conducted by the Parks Department of Arkansas Polytechnic College determined that 36.6 percent of the visitors to all state parks were from Arkansas and 63.4 percent were from out of state. The survey also determined that in-state visitors rank in order from (1) Little Rock, (2) North Little Rock and (3) Fort Smith. Most of the park facilities are nearer the site than these three major population centers and, therefore, the seasonal population shift would tend to be into the 50-mile radius.

The Dardanelle Reservoir is a major contributing factor to part-time population within the low population zone. Recreational use surveys conducted by the Corps of Engineers at Dardanelle Reservoir indicate that approximately 65 percent of the visitors reside within 50 highway miles of Dardanelle Reservoir. Table 2.1-15 lists the activities offered at Lake Dardanelle on a percentage used basis. Based on a 1969 survey by the Corps of Engineers, 38.8 percent of all visits occur between the months of June and August and 0.99 percent of all visits occur on each weekend day in the same time period. From these data, it is estimated that an average of 2,464 visitors per day are present inside the low population zone from June through August. During the summer weekends, the time of highest utilization, an average of approximately 5,777 visitors per day are inside the low population zone.

2.1.3.5 Population Center

The nearest population center is the city of Hot Springs, Arkansas, with a 1970 population of 35,631 and a near-side distance of 55 miles, south-southeast from the reactor.

It appears from Figure 2.1-11 that during the lifetime of the facility, the city of Russellville can become the new population center. The West Central Arkansas Planning and Development District, Inc. publication, "Preliminary Report Regional Growth and Change, 1975-2000, Demographic and Economic Aspects," indicates a 1975 Russellville population of 16,357, a 40 percent increase above that for 1970.

However, a special 1975 Russellville census indicated a tentative count, as of early December 1975, of 14,000, a 19 percent increase above that for 1970. Page 10 of the referenced publication states "the growth in net residential connections is faster than the regional population increases." AP&L records for the Russellville-Dardanelle-Atkins Control Area show a 24 percent increase in residential connections for 1970 through 1975, far below West Central Arkansas' population projection. The actual percentage increase in population for Russellville for the period 1970-1975 is 49 percent of West Central Arkansas' projection. If the subsequent projections are adjusted on a percentage basis, the Russellville population in 2000 is projected to be 22,420.

Russellville is almost totally confined to three sector segments shown in Figure 2.1-11; 4-5 miles east-southeast, 5-10 miles east-southeast, 5-10 miles east. The total population in these three sector segments projected for 2016 in Fig. 2.1-11 is 20,341. If three additional sector segments (4-5 miles east, 3-4 miles east, 3-4 miles east-southeast), which include very small portions of Russellville and into which Russellville could expand, are added to that total, the projected population for 2016, Figure 2.1-11, is 23,277. This number is conservative in two respects. First it includes an area on the order of three times the current area of Russellville. Second, as stated in Section 2.2.1, the projections in Figure 2.1-11 are based on high estimates of the Arkansas River Region Report.

Based on the above, Russellville will not become a population center during the life of the plant. No other municipality could impact the size of the low population zone. Therefore, a low population zone of 4 miles is acceptable. However, Section 2.1 of the ANO-2 SER, Section 2.1 of Supplement 1 to the ANO-2 SER, and Section 2.1 of Supplement 2 to the ANO-2 SER give a summary of discussions which led to redefining the low population zone radius to meet 10 CFR 100 as 2.6 miles based on projections of the growth of the city of Russellville and its surroundings.

2.1.3.6 Public Facilities and Institutions

Table 2.1-3 lists all the known public facilities within 10 miles of the plant site, the direction and distance of each from the reactor, and their recorded attendance.

2.1.4 USES OF ADJACENT LANDS AND WATERS

2.1.4.1 Recreation

The recreation resources in and around Dardanelle Reservoir are a modern example of variety and multiple use. The recreational choices available to the visitor are a combination of public agency, private, and commercial efforts, resulting in 22 developed areas. Four more areas are planned for the future.

Water-based recreation activities are a focal point of interest, with abundant opportunities for boating and fishing. Some portions of the lake and river are not recommended for body contact activities such as water skiing and swimming, although most bays and inlets such as Piney Bay and the Illinois Bayou are free of unacceptable levels of pollution. Efforts are underway to improve the water quality of Lake Dardanelle and the Arkansas River, as evidenced by a 1969 sanitary survey of the area by the Arkansas Department of Pollution Control and Ecology.

At strategic locations around the shoreline, camping, picnicking, sightseeing, photography, and nature study areas satisfy many thousands of visitors annually. The rich history and folklore of the Ozark region intrigue folk enthusiasts.

In addition to providing visitors with facilities for water-oriented recreation, the Corps of Engineers is trying to maintain a natural balance of nature. This is accomplished by the prevention of erosion, by stocking the streams and lakes with fish, and by the control of lands adjacent to the lake through government ownership. Wildlife habitat is preserved by preventing the removal of timber and other vegetative cover. Maintaining a natural balance of nature retains the beauty of the terrain and thereby prevents shoreline spoilage.

Most of the intensively developed tourist accommodations and attractions are located near the northern and eastern end of Dardanelle Reservoir. More primitive facilities are provided near the southwestern and western shoreline.

For the photographer, steep bluffs along the old river channel upstream from the dam and pine-covered 1,800-foot Mount Nebo provide a photogenic combination of scenery and beauty. An overlook on the Russellville side of the lake provides an excellent view of the dam where one may observe barges passing through the Dardanelle Lock. On the Dardanelle side of the river near the historic Dardanelle Rock, visitors may tour the hydroelectric power plant.

Nearby Arkansas Polytechnic College has leased land parcels on the Illinois Bayou portion of the Reservoir from the Corp of Engineers. These resources constitute an outdoor laboratory for a program in recreation education and research supporting the Institute of Leisure Science at the college. Plans are underway to use the area for demonstrating new concepts in outdoor recreation, conducting research projects, and developing a continuing education program in tourism and leisure services.

Dardanelle Reservoir is strategically located between two national forests and mountain ranges - the Ozark National Forest to the north in the Boston Mountains and the Ouachita National Forest in the Ouachita Mountains to the south. In addition to camping, fishing, and other forest recreation opportunities, Big Piney Creek, Illinois Bayou, and the Mulberry River emanating north of the lake are popular for river floating enthusiasts and float fishermen.

Table 2.1-16 lists diverters of surface waters from Dardanelle Reservoir and the Arkansas River downstream. Table 2.1-16 shows that there are no significant water supply intakes in the Dardanelle Reservoir, or any significant level intakes, that may be contaminated by an accidental release that could affect human exposures indirectly through the food chain. There is only one user of river water for industrial processing from the Dardanelle Reservoir to the Mississippi River. This user is the Arkansas Craft Corporation in Morrilton, Arkansas, about 30 miles downstream of the plant site. River water is used as a coolant and processing medium in the manufacture of brown craft paper for corrugated boxes. These boxes are not used for food wrapping or food-related products, and therefore are not capable of causing exposure through the food chain. The average daily water usage by the manufacturer is 4×10^6 gpd.

In Russellville, Arkansas Polytechnic College offers a series of intercollegiate sports and culture programs. The city operates a parks and recreation system, community theater, and community center. Adequate tourist services are available, including motel, restaurants, and supportive services.

To the south, in the city of Dardanelle, similar services are available. Mount Nebo State Park offers a spectacular view of the Arkansas River Valley from an 1,800-foot developed mesa.

2.1.4.2 Agricultural

Figure 2.1-4 shows the area of land in square miles that is pastured and cultivated within a 50-mile radius of the site. The land use is shown in 16 directional sectors centered on the site and within 5-, 10-, 20-, 30-, 40-, and 50-mile radii.

The land data in Figure 2.1-4 were based on the 1964 United States Census of Agriculture Preliminary Report for Arkansas.

The closest dairy herd is maintained by Arkansas Polytechnic College, approximately five miles from the site. Other cattle closer to this site have been observed, and hypothetical dose calculations were made considering the observed pasture nearest the site.

Tables 2.1-4, 2.1-5, and 2.1-6 provide statistics concerning farming for each county that is completely or partially within a 50-mile radius of the plant site. These include numbers of farm animals and acreage and yields of crops. These statistics were taken from the 1969 Census of Agriculture, published by the United States Department of Commerce, the Social and Economic Statistics Administration, and the Bureau of the Census; the 1971 Agriculture Statistics for Arkansas, released in August 1972, by the Statistical Reporting Service of the United States Department of Agriculture in Little Rock, Arkansas; and 1971 Arkansas Poultry Production, published cooperatively by the Cooperative Extension Service of the University of Arkansas, Division of Agriculture, and the United States Department of Agriculture.

2.1.4.3 Fish and Wildlife

About seven air miles from the lake is Holla Bend National Wildlife Refuge, a 6,300-acre haven which is a wintering refuge for ducks and geese. This refuge serves as a concentration point for waterfowl which then spread out through the surrounding areas, providing ideal hunting as well as enjoyment for the public in waterfowl identification.

The major game animals of the area are squirrel, deer, and rabbit. Quail and dove are also hunted to a lesser extent. In an area about 25 miles south of the plant site, near Lake Nimrod, turkey hunting is very popular and productive. In areas bordering the Arkansas River and near certain lakes (notably Harris Brake Lake, about 35 miles southeast of the plant site), a significant amount of duck hunting is also carried on. Statistics concerning annual kills of these animals are kept only for deer. Table 2.1-7 gives the deer kills for each of the 19 counties totally or partially within 50 miles of the plant site for the 1972-1973 deer season. These figures are those kills that were reported and are estimated to be 75 percent of the actual kill. The figures were obtained by personal conversation with the information office of the Arkansas Game and Fish Commission.

Fish population samples have been made in the Dardanelle Reservoir by the Arkansas Game and Fish Commission for several years. In 1971, the fish population sample point was shifted by the Commission from a point near Piney Bay to a cove in the discharge embayment of Arkansas Nuclear One. The results of the fish population sample conducted in late August 1972 are presented in Table 2.1-8.

The sample was made in a 4-acre cove with an average depth of four feet. Rotenone was used as the collection method. The water temperature was 80 °F. Three hundred feet of block-off net was used on this cove sample.

The predator-nonpredator ratio by weight was 1:6.6, which was essentially the same as the previous year's ratio. There was a good sample of adult largemouth bass, channel catfish and crappie in this sample. The condition factor for the large adult fish was very good, but that for the intermediate and young fish was very poor. There was a good population of forage fish, including both species of shad. An overabundance of the shad were non-forageable except to the larger adult fish. There was an obvious absence of small-size forage fish.

There was a total of 777 predator fish in the sample, weighing a total of 237.4 pounds. These accounted for 2.74 percent of the total sample population and 13.16 percent of the weight.

There was a total of 27,574 forage fish in the sample, weighing a total of 1,566.2 pounds. These accounted for 97.26 percent of the total sample population and 86.84 percent of the weight.

Based on a commercial fishing industry survey conducted from May 1966 to June 1971, the following facts were gathered with regard to commercial fishing on the Arkansas River:

> The commercial fishing industry exhibited a rapid growth in 1970 over previous years. Compared to 1969, a 42 percent increase in the number of regular commercial fisherman was noted, along with a nine percent increase in the amount of gear. The Arkansas River system was the leader in fish production. Mussel fishermen have, for all practical purposes, dropped out of existence. The Arkansas River system showed rapid gains in catfish and buffalo production, with a decrease in other species. The construction of dams along this stream has seemed to concentrate the fish and reduce the current so that gill and trammel nets are very effective in some areas.
>
> In 1970, the commercial fishing along the Arkansas River exhibited the following species and dollar yield:

SPECIES	WEIGHT	$ VALUE
Bowfin	1,000	50
Buffalofish	697,105	125,478
Carp	319,377	15,970
Catfish	1,448,528	506,983
Gar	44,700	2,235
Paddlefish	53,074	9,554
Quillback	19,882	1,989
Drum	108,989	19,618
Sturgeon	- -	- -
Sucker	16,200	810
Food Turtles	10,000	800
Baby Turtles	- -	- -
TOTALS	2,718,855	$683,487

In the spring of 1971, the Arkansas Game and Fish Commission made a 30-day survey of the commercial fishing in the Dardanelle Reservoir. A total of 350 gill nets and 140 trammel nets were observed being raised by fisherman during the 30-day observation period. The total catch of all species of fish is listed in Table 2.1-9.

All told, 6,000 pounds of commercial fish were caught, while only 100 pounds of game fish were caught in the same nets. This leads to the conclusion that commercial fishing is not affecting the game fish population, and that removing many pounds of commercial fish from the lake is aiding the sport fishermen by providing more space and food for the game fish and the chance for better growth.

No creel surveys have been made on the Dardanelle Reservoir, and it is therefore impossible to provide any data on the amount of harvest by sport fishermen.

2.1.4.4 Forestry

Tables 2.1-10 through 2.1-13 present information on the growing stock and area of Arkansas forests, with emphasis on the area subject to impact by Arkansas Nuclear One, including the power distribution system.

The Ouachita Province, including all of its higher "mountain" parts, is in the Ouachita Survey district and has been chosen in Table 2.1-10 to give representative tree diameter distributions. The larger size classes not only explain the importance of sawtimber, but also the conservationist's interest in "old growth" stands of particular aesthetic attractiveness.

In brief, Table 2.1-10 numerically documents the generality that shortleaf pine is the softwood of importance in both the Ozark and Ouachita districts, in contrast with loblolly pine, which becomes more important on the Coastal Plain Province (especially the "Southwest" Forest Survey region). Red cedar is less important in volume, but it attracts aesthetic attention in both the Missouri and Arkansas sections of the Ozark Province, more locally in the Ouachitas and rarely in the Coastal Plain. Bald cypress is restricted to bottomlands, minor in the Ozark and Ouachita regions, almost a "rare" species locally but it attains high importance (502 out of a state total of 912 million board-feet) in the Delta Survey region along the Mississippi River and its tributaries. Hardwood species are far more numerous than softwoods, but constitute slightly less than half of the state's board-foot (sawtimber) volume. Yet, within the Ozark and Ouachita regions and most of the individual counties documented separately in Table 2.1-13, hardwoods are several times as important as the softwoods. Geographic differences among counties are of some importance and are included in the table for an indication of the main groups of forests likely to be disturbed by power line clearing along several routings.

2.2 NEARBY INDUSTRIAL, TRANSPORTATION, AND MILITARY FACILITIES

2.2.1 LOCATIONS, ROUTES, AND DESCRIPTIONS

There are no military bases, missile sites, chemical plants and storage facilities, oil pipelines, or airports within a 5-mile radius of the centerline of the containment of Unit 1 and Unit 2.

There is no major airport with a control tower within 50 miles of the plant site. The closest airports are the Russellville Municipal Airport (8 miles) and Clarksville Municipal Airport (15 miles). There are two low altitude airways nearby, as shown in Figure 2.2-1. This airway, V71, whose centerline is about five miles east of the plant site, has one or two scheduled commercial low altitude turbo-prop flights daily.

The centerline of airway V74N is two miles south of the plant site. This is an alternate route of V74, which is the main route between Fort Smith and Little Rock, 20 miles south of the plant. V74N carries very light, unscheduled traffic only.

The closest high altitude (jet) airway is Route J6-14/279, about 30 miles south of the plant site.

The Missouri-Pacific Railroad passes the plant at a distance of approximately 1.1 miles. The railroad spur into the plant site will handle only materials and equipment necessary for construction and operation of the plant itself. This railroad spur has a manually locked derail device located about 50 yards down the spur from the main line switch. This device would prevent any main line trains from passing this point if they were accidentally switched to this spur.

The Arkansas River is navigable from its mouth to Tulsa, Oklahoma. The river channel passes within approximately 1.4 miles of the reactor building. During 1972, approximately 999,000 tons of cargo were transported past the plant site. The major portion of this cargo was coal, fertilizer and miscellaneous construction equipment. It is predicted that in 1971, approximately 20 to 25 million tons of cargo will be transported on the Arkansas River. The cargo will include iron and steel, petroleum, petroleum products and agricultural products, in addition to that mentioned above.

Figure 2.2-2 shows the location of four industrial facilities. The first three are located about five miles from the plant. The fourth (a gas pipeline) passes within about 600 feet of the Unit 1 reactor building. (The Unit 1 containment sits between the pipeline and the Unit 2 containment). The four facilities are described below:

A. Ward Furniture Manufacturing Company - a manufacturing plant utilizing wood products in the manufacturing process.

B. Thermo Gas Butane Bulk Plant - several large tanks of butane storage are located at this bulk plant.

C. Water Craft Boat Manufacturing Plant - this building is now vacant, but has been used for the manufacturing of fiber glass boats. At the present time, there is no known business interested in locating in the building, but it is a new building and will probably be used for some manufacturing process in the near future.

D. High pressure natural gas line.

The most economically important minerals in the area are stone, such as the Arkansas Cherrystone from quarries in the Hartshorne Sandstone north of Midway, at Altus, and at the Dardanelle Damsite; gravel and sand from Pleistocene deposits such as those 4 miles west of Scranton and from the Arkansas River at Dardanelle; natural methane gas from anticlines in the area; and bituminous coal. The methane gas is tapped by drilling and comes mainly from ocean-deposited sandstones in the lower and middle part of the Atoka formation. Coal is found in the Spadra and Paris shales as a pressurized carbonization of delta-swamp trees and plant debris. Much of it is of coking quality suitable for iron manufacture. Coal strip pits are present north of Russellville, north and west of Clarksville (one seven miles west of Clarksville on U.S. Highway 64 is still working), and near New Spadra. Shaft pits have been abandoned just east of the Dardanelle Dam and are still being worked west and north of Paris. Non-economic minerals of the area include ironstone, manganese minerals, and gypsum.

2.2.2 EVALUATION

2.2.2.1 Natural Gas Pipeline

Security-Related Information
Text Withheld Under 10 CFR 2.390

The crossing has been constructed beneath the water channel with four feet of earth cover. The pipe is 10-3/4 inch O.D. constructed to Type C specification of ASA Code B31.8. The Type C construction extends approximately 600 feet on each side of the crossing.

The worst possible condition with respect to plant safety would be a brittle fracture of the pipeline when operating at its maximum pressure of 500 psig. There are two separate safety considerations:

A. The explosive rupture of the pipeline.

B. Ignition of the gas discharge through the open pipe.

The first consideration when related to TNT equivalent is 0.07 pounds of TNT per foot of pipeline ruptured. During pipeline construction, many times this equivalent is detonated as close as 30 feet to large pipelines in operation without resulting damage. At a distance of several hundred feet from the pipeline, only a few small particles of debris would be expected to fall.

The second consideration is the radiation energy that would be received at the plant resulting from the burning of gas discharged by the pipeline before control valves could be closed.

The computed energy received by one square foot of vertical concrete surface is 21 Btu/ft^2-hour with the pipeline discharging a possible maximum of 48 million cubic feet per day.

The radiation energy is under the maximum of 36 Btu/ft^2-hour that is expected to be received from solar radiation.

Arkansas Power & Light Company's experience has shown no unusual hazards associated with natural gas pipelines in their fossil fuel plants.

The valves in the 10-inch pipeline which would be used to isolate the section of line near the proposed plant would be closed within two hours after a pipeline rupture.

Included in the crossing of the water channel was replacement of that portion of the line constructed in 1928 that extends approximately 600 feet on each side of the water channel. The crossing and replacement pipe meet requirements of Type C construction of USAS Code B31.8, 1968.

The following is an analysis of the consequences of a rapid gas line leak occurring under inversion conditions for the plant site, prepared by Dr. Joseph B. Knox, a consultant:

The purpose of this report is to present the results of an analysis of the consequences of a rapid leak in the natural gas transmission pipeline located 600 feet from the proposed Arkansas Nuclear One reactor. Two different sets of conditions are considered: (A) gas exiting at sonic velocity from the ruptured gas pipe as a buoyant jet oriented either horizontally or vertically, and (B) a hypothetical case is physically unrealistic and constitutes a worst case for the postulated environmental inversion conditions. The input data for the analysis are summarized below:

Gas Line: Diameter 10 inches.
Shortest diameter to the nuclear reactor is 600 feet.
Operating pressure in line is 500 psig.

Atmospheric Conditions: Pasquill F, 1 mps.
Assume an inversion of 9° C in 60 meters.

Combustion Limits: 5% to 15% gas concentration.

A. The Buoyant Jet Case

It is postulated that an instantaneous rupture of the gas pipeline occurs such that the pipe is fully open and oriented vertically. Gas exits at sonic velocity forming a buoyant jet from both pipe openings. Applying the theory of buoyant jets in stratified flows to one of the jets so formed (Fan, 1967, Turbulent Buoyant Jets into Stratified or Flowing Ambient Fluids, University of Michigan Microfilms), the trajectory of the center of the jet and the buoyant force along the jet is calculable, as well as an estimate of the height at which entrainment produces a negligible buoyant force on the air-methane mixture in the plume.

The results indicate that the time required for the jet to pass the height of 60 meters (about the height of the reactor building) is four to six seconds, during which time there is very little transport of the gas towards the building in the 1 mps ambient wind field. With a reasonable value of the entrainment coefficient of 0, i.e. 0.08, the density deficiency of the plume, and hence the buoyant force, becomes negligible at about 2,000 to 3,000 feet. Under stable atmospheric conditions with a surface inversion, there would be no credible way to transport this neutral buoyancy gas down through the inversion to the plant before it diffused to a non-explosive mixture. It is estimated that about 800 seconds would be required for this to be accomplished in the air-gas cloud above the inversion.

The results of this analysis are not materially changed if the analysis is repeated for a horizontal orientation of the ruptured gas pipeline.

B. The Hypothetical Trapped Gas Case

1. Under the postulated inversion conditions, if gas were to be trapped under the inversion, the gas must somehow be diluted with air immediately upon release such that the gas density is greater than that in the overlying temperature inversion.

   For the assumed conditions, the required instantaneous dilution is 13-fold. There is no natural way that such a large instantaneous dilution can be achieved in either stable or unstable atmospheric conditions. At a range of 600 feet (the distance to the plant), about 200 seconds is required for a dilution of a factor of 38 for Pasquill F (1 mps). This dilution rate is more than two orders of magnitude less than that required to keep the gas under the inversion.

2. If one hypothesizes an immediate 13-fold dilution mechanism of some unknown kind necessary to keep the gas under the inversion, and Pasquill F conditions in the environment, then the gas concentration is 0.77 prior to the beginning of its travel downwind. Diffusion under even Pasquill F conditions would be more than sufficient to dilute this gas to a non-explosive mixture prior to traveling 600 feet.

3. If the postulated inversion is less strong than that discussed above, an even larger immediate dilution than 13-fold is required in order to keep the gas under the inversion. Such immediate dilutions are not physically reasonable.

These analyses indicate that the buoyant jet model of the rapid gas leak is physically reasonable, and that explosive gas mixtures will exist only at places removed from the plant. The above analyses have been reviewed by the NRC staff and found acceptable in previous proceedings involving Unit 1 (Docket 50-313) and Unit 2 (Docket 50-368). The conclusions of these reviews are presented in the Safety Evaluation Reports issued at the construction permit and operating license stages of Unit 1 and at the construction permit stage of Unit 2. The following analysis further substantiates the previous conclusions that no adverse consequences from a gas line rupture are foreseen. Since the maximum time between the postulated double-ended rupture of the 10-inch natural gas pipeline and the closing of the isolation valves is two hours, the maximum volume of natural gas which could be released is 13.8 (+6) cubic feet. The volumetric flow rate was calculated to be 5,080 cfs (STP). This was based on the maximum pipe pressure of 500 psig and included the volume between the isolation valves.

As discussed in the buoyant jet analysis above, momentum and buoyancy effects will cause rapid vertical dissipation of the natural gas (96 percent methane) into the atmosphere. Ignition, much less detonation of the gas within the flammable range located on the periphery of the jet, is highly improbable since the turbulence of the jet would inhibit unconfined accumulation of significant quantities of gas in the flammable or detonable range. Normal atmospheric convective and mechanical turbulence efficiently disperses the gas, and only under the most stable atmospheric conditions would it even be feasible to consider this unconfined volume situated on the periphery of the jet potentially detonable. In addition, under surface temperature inversion conditions, potential overpressures resulting from explosions are at a maximum. Thus, the meteorological conditions used for this analysis are based on five percentile meteorology as presented in Section 2.3 and include the same temperature inversion used in the buoyant jet analysis of Dr. Knox.

It should be emphasized that this analysis involves a combination of highly improbable assumptions starting with (1) the double-ended rupture of a Type C section of pipeline (installed in 1969), (2) the existence of an ignition source having a temperature at least as high as 1,200 °F, which is the ignition temperature of the gas, (3) extremely stable atmospheric conditions, (4) a unique, unrealistic detonation of 100 percent of the gas in the detonable range within the jet, (5) the entire volume of gas in the detonable range as a point source at the closest point to the containment, and (6) the detonation rather than deflagration of the unconfined volume of gas. If an ignition event of an unconfined gas-air mixture occurs, deflagration and not detonation will nearly always be the result. Also, the energy requirements for the direct initiation of a detonation in the gas phase appear to be at least four orders of magnitude greater than those for the initiation of a deflagration (Reference 120).

Due to the initial momentum and buoyancy of the release, jet velocity will be much greater than wind speed and the closest point at which the center of a delayed-ignition event could occur will have a vertical coordinate of 200 feet (the height of the containment). Under five percent meteorology, maximum horizontal transport of the centerline would be 10 feet, making 590 feet the distance, d_2, from the centerline of the jet to the containment. Based on a buoyant jet analysis, the estimated quantity of natural gas released in a volume whose vertical midpoint is 200 feet would be a maximum of 71,000 cubic feet. Since this volume is taken to be acting as a point source at the 200-foot level, this neglects the gas more than 400 feet above the ground.

However, the contribution of this gas to the postulated detonation is small due to its relatively great distance from the effective center of the postulated detonation and probable ignition source.

Although the flammable region of this volume of gas is defined as the portion between the lean (five percent) and rich (15 percent) limits, the detonable range of six percent and 14 percent more accurately represents gas concentrations which are capable of contributing to an explosion (Reference 120). Assuming a Gaussian distribution within the buoyant jet, 2.9 percent will fall within the detonable limits. The following relationship may be used to calculate explosive yield (W_2) in terms of equivalent TNT (Reference 12):

$$W_2 = \frac{(\Delta H)(W_{gas})}{2000} = \frac{21{,}500(100\text{lb.})}{2000} = 1075\text{lb. TNT}$$

where

ΔH = 21,500 BTU/lb.

W_{gas} = Weight of natural gas in the detonable range

= (.029) (71,000 ft^3) (.0485 lb/ft^3) = 100 lbs

The blast and resulting overpressure from gaseous explosions most closely relate to nuclear explosion effects (Reference 47). The resulting overpressure from an explosive yield of 1075 lb TNT can be estimated using the surface temperature inversion curve (Figure 3.66 of Reference 33) for a 1 kiloton burst and the following cube root scaling law (Reference 33):

$$d_1 = d_2 \sqrt[3]{\frac{W_1}{W_2}} = 590\text{ft.}\sqrt[3]{\frac{2\text{x}10^6\text{lb}}{1075\text{lb}}} = 7260\text{ft.}$$

where

d_1 = equivalent distance from burst of 1 kiloton TNT

d_2 = distance from centerline of gas jet to containment

W_1 = explosive yield from 1 kiloton TNT

W_2, as defined above (explosive yield of gas in terms of equivalent TNT)

This distance corresponds to a peak overpressure of 1 psi. Peak reflected overpressure can be calculated using the following relationship (Reference 33):

$$P_r = 2P\frac{7P_o + 4P}{7P_o + P} = 2(1)\frac{7(14.73) + 4(1)}{7(14.73) + 1(1)} = 2.06\text{psi}$$

where

P_r = peak reflected overpressure

P = peak overpressure

P_o = atmospheric pressure

This peak reflected overpressure falls well within the limits of the design basis tornado overpressure of 3 psi, and should be considered a maximum based on the extremely conservative assumptions listed above.

Smaller breaks would release gas at a lower mass flow rate and result in a buoyant jet of smaller cross section, a lower total mass of gas in the 0 - 400 foot column. Based on the assumed Gaussian distribution within the jet, the quantity of gas in the detonable range would also be smaller and thus result in a lower value of peak reflected overpressure.

Increased wind speed would coincide with an increase in atmospheric turbulence, thereby further diminishing the already extremely low probability of a detonation.

The analysis and evaluation given here is a conservative one for Unit 2 since it was made for Unit 1, and Unit 1 is located between the pipeline and Unit 2.

As described above, the results of the buoyant jet model are not materially changed for a horizontal break orientation releasing gas towards the plant. The reason for this is that the gas immediately leaving the pipe is momentum dominated due to its release velocity for only a short time (and distance). Thereafter, density deficiency in the ambient air causes buoyant rise to become the dominant mechanism. From a practical standpoint, the orientation of the postulated pipe rupture would have little consequence on the buoyant gas rise. The catastrophic rupture of the buried pipe would likely blow the dirt away from over the pipe. The exiting methane would quickly become buoyancy dominated and would enter the ambient flow nearly vertically. Hence, the gas concentrations expected at the plant would be essentially zero under the reasoning presented in Dr. Knox's analysis. The closest that an ignitable gas concentration center could extend toward the facility is 590 feet, as cited above.

Isothermal gas expansion was assumed for the double-ended pipe rupture. The causes of such a rupture are usually outside forces such as construction activities. However, large brittle pipe fractures (caused by internal forces) can also be reasonably modeled as an isothermal process after the first moments of the rupture. For the slower leak rates through smaller breaks, adiabatic expansion should be assumed. However, such small releases to the atmosphere would be quickly dispersed below hazardous concentrations. The adiabatic and isothermal processes were compared as to their impact on the model results for the large rupture. The adiabatic case shows a gas temperature decrease of 28 °F during the jet expansion. In terms of the buoyant jet model, the adiabatic assumption is only one percent more conservative than the isothermal assumption.

Security-Related Information
Text Withheld Under 10 CFR 2.390

However, five reported explosion incidents have occurred after apparent gas diffusion through the soil. All of these cases occurred in distribution systems near developed areas. In four cases the leaks were induced by construction activities and in one case by corrosion of plastic pipe. In four cases, the ground between the leak and the buildings where ignition occurred was at least partially covered by concrete or asphalt slabs. For these cases, enough gas was diffused a short distance under these slabs to cause ignitable concentrations in adjacent buildings. In one case, the gas was apparently transported 200 feet along existing underground utility lines In these five cases, the gas, leaking in small quantities (compared to a transmission line rupture), was transported along a physical path through the soil for relatively short distances. The gasline crosses a sanitary sewer outlet pipe approximately 700 feet from the closest Unit 2 structure. However, the utility line is approximately three feet below the gas line and ends approximately 60 feet from the crossing. In addition, the sewer line leads to a large sand filter bed through which any gas would escape. It is not a direct connection to any plant structure. Hence, it is not considered as a possible transportation path. There are no other utility lines or man-made pathways between the pipeline and plant structures. It is unlikely that escaping gas from the subject transmission pipeline could find such a transport mechanism through the hard ground. Hence, no appreciable gas buildup in the plant structures is expected.

Considering the effects of onsite meteorological data, including effects of calm conditions or light winds, a methane jet escaping from the gas line would rise rapidly under the force of buoyancy and initial momentum to a height above any low level inversion. Any annual or seasonal increase in frequency of light or calm winds at the site would only enhance the vertical escape of gas vented in the manner postulated in the reference analysis.

Security-Related Information
Text Withheld Under 10 CFR 2.390

In addition to the above, probability studies show that the probability of a rupture of this line and subsequent ignition of the gas is less than 10^{-7} per year. Discussions with members of the NRC staff indicate that conditions favorable for engulfing the upper surfaces of the plant in flammable gas concentrations following rupture of the gas line at its closest approach to the plant have a probability of approximately three percent using the staff's assumptions. The staff has indicated that the length of pipeline in which a similar rupture could bring flammable gas concentrations to the plant was approximately 0.5 km. The rate at which flammable gas may be expected to come into contact with plant building surfaces is therefore of the order of 10^{-6} per year, according to the NRC staff. The NRC analysis considers the overall probability of failure of a gas pipeline, the length of line involved and meteorological conditions conducive to transporting the gas to the plant. However, according to Reference 1, of the pipeline ruptures that have occurred only 46 percent were caused by other than outside forces. Since the segment of pipeline under consideration is wholly on Entergy Operations, Inc. controlled property, damage from outside forces is not credible, and the overall probability of a pipeline rupture should be correspondingly less. Finally, the probability of ignition, given a pipeline rupture, is 0.32 (Reference 87) and thus the overall risk probability is of the order of 10^{-7} per year.

2.2.2.2 Cooling Tower

The cooling tower is located a distance away from the service water piping, diesel fuel piping, and critical structures equal to the height of the tower above grade.

If the cooling tower should fail, and in so doing cause the gas pipeline to rupture, either of two consequences could occur; the gas might be ignited or might escape as a buoyant jet conservatively assumed trapped under an inversion. Both of these cases are treated in Section 2.2.2.1, and the analyses show no adverse effect.

2.2.2.3 This section has been deleted.

2.2.2.4 Other

An accident involving the release of noxious or lethal chemicals in the atmosphere could result in an adverse environment at the plant site. Under these conditions, plant personnel not necessary for a reactor shutdown would be evacuated as promptly as possible. The minimum number of personnel for plant operation would continue operation unless equipment failures occur that would necessitate a shutdown. Portable breathing apparatus will be available to allow adequate access and inspection of areas outside the control room. (The control room is an enclosed area that may be isolated from the outside environment.)

The possibility of explosives being detonated in the waterway and on the highway at distances of 1.05 and 1.4 miles from the plant site, respectively, has also been considered. The potential missiles developed during such a phenomenon would be less severe than those established for tornado design. Ground response at the plant site due to the above phenomenon would be much less than the seismic criteria for Class 1 structures.

For the quantities of chemicals dissolved into the Dardanelle Reservoir, the dilution thereof would be such that no adverse effects upon plant equipment would result. Provisions on the design of the intake structure prevent the entry of debris and foreign objects due to shipping accidents. In the unlikely event that the intake structure became inoperative, the plant could be safely shut down using the emergency pond.

Consideration was given to the possibility of a loaded barge entering the plant site area during a maximum flood. Upon notification of a flood warning, Entergy Operations, Inc. can obtain information on barge traffic in the area of the plant site and would check any such barges to ensure that they are either under the control of a tug or securely fastened to a pier. During this flood condition, Entergy Operations, Inc. would maintain communications with the U.S. Corps of Engineers and the U.S. Coast Guard in order to be informed of any such barge traffic on the Dardanelle Reservoir. The U.S. Army Corps of Engineers requires that barge traffic on the Arkansas River be halted if the flow in the river is greater than 350,000 cfs, which is much less than the 900,000 cfs for which the reservoir system is designated. Since adequate notification of a pending flood of this magnitude is available (approximately four to five days advanced warning will be had), it is considered to be a very remote possibility that a barge would become a floating hazard. Further, as one can see by examining Figure 2.1-3, Round Mountain provides a natural barrier to prevent or divert a barge (or other object) from being carried into the plant site area by the current. There is also a substantial tree line separating the plant site from the cove north of Round Mountain. This tree line extends up to an elevation of 383 feet and ranges between 100 to 400 feet in depth, thereby providing a natural barrier against any barges which might enter this cove, which is highly unlikely. It is therefore concluded that a large floating object could not enter the plant site area, even under the conditions of maximum flood.

Normally, Dardanelle Reservoir will fluctuate between elevations of 336 and 338 feet MSL at the dam, as necessary to re-regulate inflows to the lake for the generation of hydroelectric power. Operational studies indicated that under certain combinations of flow and power loads, the pool may be lowered as low as Elevation 335 at the dam and stay below Elevation 336 for brief periods of less than 1-day duration.

The only conceivable reasons for lowering the pool below an elevation where a source of service water and makeup water supply to the circulating water system would be lost are emergency pool lowering because of indicated damage to a gate, causing loss of the pool and planned temporary lowering of the pool to permit necessary repairs which cannot be performed otherwise. The probability of this severe a drawdown is extremely remote, but if it happened, the plant could be safely shut down by using the emergency pond.

2.3 METEOROLOGY

2.3.1 REGIONAL CLIMATOLOGY

Figure 2.3-1 shows the relative locations of the site and the climatological stations used in the preparation of this section.

2.3.1.2 General Climate

Because it has homogeneous climatic conditions, the boundaries of the state of Arkansas may be used to delineate the general climatic region of the plant site.

Arkansas experiences a continental type climate with large diurnal and seasonal variations in temperature. Yet, because of proximity to the Gulf of Mexico, there are occasional intrusions of maritime tropical air masses during all seasons, but more frequently in the summer. During fall, winter and spring, the weather conditions in Arkansas exhibit frequent wide variations due to synoptic scale events, such as cold frontal passages from the north and northwest, and the development of warm frontal activity or extra tropical cyclones in the Gulf of Mexico and the southern states. In the summer season, most of the weather variations are due to local showers and storms rather than to synoptic scale events. Tropical hurricanes moving north out of the Gulf of Mexico occasionally cause widespread rain in late summer or fall, but hurricane wind conditions are ameliorated before reaching the region.

The Arkansas Nuclear One Station is on a peninsula in Dardanelle Reservoir, an impoundment on that portion of the Arkansas River lying between the Boston Mountains to the north and the Ouachita Mountains to the south, as illustrated in Figure 2.3-3. Although these mountains generally reach to about 2,000 feet--and occasionally 3,000 feet--above sea level, they provide

some shelter from polar and arctic air masses, resulting in less snowfall and fewer extremes of cold weather than are experienced by locations to the east or west of the mountains. These mountain ranges and the river between them also combine their influences to increase the frequency of winds with significant components from the east or west.

Mean annual temperatures show a uniform gradient toward lower values across the state from south to north, whereas summer mean temperatures are quite uniform throughout. In the winter, normal daily minimum temperatures drop to 37°F in the southeast corner of the state and to 25 °F in the northwest, with normal minimum temperatures at the site averaging near freezing in December and January. Temperatures at 90°F or higher occur more than 90 days per year in central and southern Arkansas, falling off to about 60 days per year in the northern part of the state. (Data sources 2.3.1-A, B)

Annual average rainfall is quite uniform throughout the state, varying from 56 inches per year in some of the mountain regions, to about 52 inches at the plant site, and to 46 inches along the northern borders of the state. The precipitation is also quite uniform throughout the year with monthly average values varying from a little less than three inches per month in some sectors of the region to nearly six inches per month in other sectors. In the winter seasons only, there is a gradient of rainfall intensity from higher values in the south to lower values in the north. Mean annual total snowfall varies from 12 inches in the north to two inches in the south. (Data source 2.3.1-B)

The mean percentage of possible sunshine experienced in the state varies from about 50 percent in the winter to 75 percent in the summer season (Data source 2.3.1-B).

2.3.1.3 Severe Weather

Except for high air pollution and drought, most of the severe weather in the Arkansas region is usually associated with thunderstorms which occur about 60 days per year (Data source 2.3.1-A), with the most frequent activity in May, June, and July (Data source 2.3.1-C.) Hail is observed two to four days per year (Data source 2.3.1-A) in most locations; the average number of tornadoes reported in the state approaches 20 per year.

2.3.1.3.1 Precipitation

Estimated point rainfall maxima (inches) for the region are:

	Return Period (Years)						
Duration	1	2	5	10	25	50	100
30 min	1.25	1.45	1.85	2.10	2.40	2.70	3.00
1 hour	1.55	1.80	2.30	2.65	3.10	3.45	3.75
2 hours	1.90	2.25	2.75	3.25	3.75	4.20	4.65
3 hours	2.10	2.40	3.20	3.60	4.20	4.65	5.15
6 hours	2.50	2.95	3.75	4.45	5.00	5.60	6.20
12 hours	3.00	3.60	4.55	5.25	6.20	6.70	7.40
24 hours	3.50	4.10	5.30	6.10	7.10	7.90	8.70

(Data source 2.3.1-E)

The above values are comparable to the extreme rainfall amounts (inches) which have occurred in a 60-year period at Forth Smith and Little Rock:

Duration	Fort Smith (1901-1961)	Little Rock (1900-1961)
5 min.	0.58	0.63
10 min.	1.15	1.01
15 min.	1.54	1.35
30 min.	2.25	2.07
60 min.	2.47	3.00
2 hr.	4.34	4.60
3 hr.	4.67	6.82
6 hr.	5.13	7.68
12 hr.	6.15	8.19
24 hr.	8.58	9.58

(Data source 2.3.1-F)

The "probable maximum precipitation" estimate of extreme rainfall is used to provide complete safety-design criteria in situations where structural failure might be disastrous. It may be defined as the critical depth-duration-area rainfall relations for a particular area that would result if conditions during an actual storm in the region were increased to represent the most critical meteorological conditions that are considered probable. The probable maximum precipitation values have been estimated for a 10-square-mile area in the vicinity of the site as:

Duration	Inches
6 hr.	30.0
12 hr.	36.0
24 hr.	39.0
48 hr.	42.0

(Data source 2.3.1-G)

Extreme snowfalls (inches) for representative stations in the area are:

Period	Fort Smith (49 yrs, 1921-69)	Little Rock (77 yrs, 1893-1969)
24 hours	17.5	13.0
Calendar Month	18.3	19.4

Period	Fort Smith (29 yrs, 1946-74)	Little Rock (33 yrs, 1942-74)
January	6.3	12.0
February	11.5	9.6
March	5.3	7.0
April	T	T
May	0	0
June	0	0
July	0	0
August	0	0
September	0	0
October	0	0
November	3.9	4.8
December	5.0	9.8
Season	11.5	12.0

(Data source 2.3.1-C)

Extremes of snowfall (inches) for the state of Arkansas are:

24 Hours:	25.0 Corning 1/22/18	(79 years, 1892-1970)
Single Storm:	25.0 Corning 1/22/18	(79 years, 1892-1970)
Calendar Month:	48.0 Calico Rock 1/18	(67 years, 1904-1970)
Season:	61.0 Hardy 1917-18	(74 years, 1897-1970)

(Data source 2.3.1-H)

2.3.1.3.2 Hail

The most commonly reported hailstones are 1/2- to 3/4-inch in diameter and cause little or no property damage. However, much larger stones are associated with the more severe thunderstorms. Hard hail that does not shatter on impact, 1-inch diameter and larger, will cause heavy damage to roofs, pit thin steel surfaces such as automobiles, and may break windows. Larger hail breaks window panes, occasionally shatters automobile windshields, and has been known to puncture automobile roofs.

All of Arkansas is subject to damaging hail. In the 1 degree latitude-longitude square including Russellville, hail 3/4 inches or more in diameter has been reported about once a year. Due to their infrequency, there is no specific hailstorm season, but the peak frequency for the state occurs during April (Data sources 2.3.1-A, N).

2.3.1.3.3 Ice Storms

Glaze and ice storms, attributed to precipitation in the form of freezing rain, although infrequent, are at times severe. It is estimated that one or two short periods of freezing rain will be experienced each year; however, these usually result in such a slight accumulation of glaze ice that little or no damage is done other than slight inconveniences to traffic. Moderate to heavy ice storms are estimated to occur about once every four years and can be very damaging to utility lines and trees, as well as being a serious traffic hazard. The ice coating, resulting from moderate to heavy ice storms in the central United States, seldom endures more than seven days and usually endures less than three days (Data sources 2.3.1-C, M).

2.3.1.3.4 Thunderstorms

In this area, the maximum frequency of thunderstorms occurs in late spring and the summer months, with a wintertime minimum in December and January.

The annual distributions of thunderstorms for Fort Smith and Little Rock are:

Mean Number of Thunderstorm – Days per Month

Month	Fort Smith (24 yrs, 1946-69)	Little Rock (27 yrs, 1943-69)
January	1	2
February	2	2
March	4	5
April	7	7
May	9	7
June	7	7
July	8	9
August	6	6
September	4	4
October	3	2
November	2	3
December	1	1

(Data source 2.3.1-C)

The monthly and seasonal lightning events for Arkansas are given in Table 2.3-57. These lightning data are derived from lightning events in which deaths or serious injuries took place. Therefore, they are not representative of the total lightning occurrences expected. Furthermore, the monthly distribution may not be representative because the number of deaths or injuries would increase as the amount of outside activity increases; and people become more exposed to lightning strokes.

NASA has developed a method of estimating the number of cloud-to-ground lightning strokes from observations of thunderstorms days. This procedure is presented in data source 2.3.1-U.

The factor of 0.23 is multiplied by the number of days per year in which thunder is heard to obtain an estimate of the number of lightning strokes reaching the earth per square mile. This method was developed for the Cape Kennedy area and may be applied to give a rough estimate of the number of lightning strokes.

2.3.1.3.5 Tornadoes

From 1953 through 1962 a total of 19 tornadoes occurred in a 1° square centered near the site. This gives an annual frequency of 1.9 (Data source 2.3.1-I). From 1955 through 1967, a total of 23 tornadoes occurred in the same 1° square. This gives an annual frequency of 1.8 (Data source 2.3.1-N). The probability of a tornado hitting a point is:

$$P = 2.8209\ t/A$$

where A is the area in square miles of 1° square centered on the point, and t is the mean annual frequency of tornadoes in the area (Data source 2.3.1-I). For the plant site, t is 1.9 and A is approximately 3,900 square miles.

$$\text{Thus, } P = (2.8209)\ 1.9/3900 = .00137$$

The return period, the reciprocal of P, is 1/P = 1/.00137 = 730 years.

Therefore, the probability of a tornado hitting the site in any given year is .00137 with a return frequency of once every 730 years.

Table 2.3-56 provides the monthly and seasonal distribution of tornado occurrence for Arkansas.

2.3.1.3.6 Hurricanes

Tropical cyclones, including hurricanes, lose strength as they move inland, and the greatest concern is possible damage from winds or flooding due to excessive rainfall. The extremes for winds and rainfall presented elsewhere include hurricane effects. The chronology of tropical cyclones that affected Arkansas, 1936-60, follows:

Year	Cyclone's Life	Force
1931	Jul 11-17	T
1932	Aug 26 - Sep 3	T
1932	Sep 18-21	T
1932	Oct 7-18	T
1933	Jul 21-27	T
1934	Jun 4-21	T
1937	Aug 24 - Sep 2	T
1937	Sep 29 - Oct 3	T
1939	Aug 7-2	T
1940	Aug 2-10	T
1940	Sep 19-24	T
1941	Sep 16-25	T
1942	Aug 17-22	T
1943	Sep 15-19	T
1947	Aug 18-27	T
1948	Jul 7-11	T
1948	Sep 1-6	T
1949	Sep 3-5	T
1949	Sep 27 - Oct 6	T
1950	Aug 20 - Sep 1	T
1950	Sep 1-9	T
1953	Sep 14-20	T
1955	Jul 31 - Aug 2	T
1955	Aug 23-29	T
1956	Jun 11-14	T
1957	Jun 25-28	T
1957	Aug 8-11	T
1957	Sep 16-19	T
1959	May 28 - June 2	T
1959	Jul 22-27	T
1960	Jun 22-28	T

* T indicates less than hurricane force winds in Arkansas (Data source 2.3.1-J).

2.3.1.3.7 Extreme Winds

Estimated extreme winds at 30 feet above ground for the general area are:

Return Period (Years)	Faster Mile* (miles per hour)
1000	93
200	79
100	74
50	69
20	63
10	59
5	55
2	49

(Data source 2.3.1-K)

In the one degree latitude-longitude square including Russellville, wind storms with wind speeds 50 knots or greater have been reported about once a year (Data source 2.3.1-N).

* The fastest mile is highest wind speed lasting for any time interval during which a length of air one mile long passes a wind instrument.

2.3.1.3.8 Air Pollution Potential

In January 1972, Holzworth published a study (Data source 2.3.1-L) on mixing heights, wind speeds, and potential for urban air pollution throughout the contiguous United States. Surface and upper air data from the National Weather Service Station at Little Rock, Arkansas were included in the analyses made for this study. The data covered the 5-year period 1960 through 1964.

The mixing height (or depth), as used in the study, is defined as the height above the surface through which relatively vigorous vertical mixing occurs. The morning mixing height was calculated as that existing around the morning commuter rush hours. The afternoon mixing height may be considered to coincide approximately with the usual mid-afternoon minimum concentration of slow-reacting urban pollutants.

Wind speeds for both morning and afternoon were computed as arithmetic averages of speeds observed at the surface and aloft within the mixing layer.

The following table shows mean mixing heights and wind speeds as calculated for Little Rock, Arkansas:

	Morning		Afternoon	
Season	Mixing Height (Meters)	Wind Speed (mps)	Mixing Height (Meters)	Wind Speed (mps)
Winter	541	5.2	1101	6.6
Spring	544	5.7	1612	7.0
Summer	375	3.7	1851	4.9
Autumn	342	3.8	1401	5.2
Annual	450	4.6	1491	5.9

The above data show that, on the average, the greatest air pollution potential (lowest mixing height and lowest wind speed) occurs on summer and autumn mornings.

In his study, Holzworth also used a mathematical model to compute the average normalized concentration ($\overline{X}/\overline{Q}$) (i.e., the concentration ($\overline{X}$) averaged over a city and normalized for uniform average area emission rate ($\overline{Q}$), as a function of mixing height (H), wind speed (U), and a long-wind distance (S) across the city. The assumptions used in his model are not applicable to point source emissions, but the model can be used to determine concentrations resulting from many widely spaced sources when the average emission rate per unit is known. It should be noted that ($\overline{Q}$) refers to average emission rate per unit area, and that ($\overline{X}/\overline{Q}$) has dimensions of seconds meter^{-1}. This is in contrast to ($\overline{X}/\overline{Q}$) used in Section 2.3.4, which has dimensions of seconds meter^{-3}.

Some of Holzworth's results are shown below as a qualitative indication of the diffusion characteristics of the central Arkansas region:

$\overline{X}/\overline{Q}$ VALUES FOR 10 KM* CITY AS
CALCULATED FOR LITTLE ROCK, ARKANSAS

	Median		Upper Decile	
Season	Morning (Sec m^{-1})	Afternoon (Sec m^{-1})	Morning (Sec m^{-1})	Afternoon (Sec m^{-1})
Winter	10	10	48	11
Spring	10	9	47	10
Summer	14	10	53	11
Autumn	19	10	61	11
Annual	12	10	54	11

* Refers to along-wind distance across the city.

East of the Rocky Mountains the annual median concentrations for 10 km cities varies between only 9 and 13 sec m^{-1} in the morning. Annually, the median afternoon X/Q values for a 10 km city are, for the most part, not much smaller than the values for morning, and they are practically uniform, being either 9 or 10 sec m^{-1}.

The persistence of high meteorological potential for air pollution is indicated by parameters called episodes and episode-days by Holzworth. An episode occurs if a mixing depth of 2,000 meters or less, combined with wind speed six meters per second or less, persists without precipitation for at least two days (five consecutive computations at morning and afternoon). Holzworth determined the frequency of 2-day and 5-day (11 consecutive computations) episodes at several intensities, where intensity is greater at slower winds and shallower mixing depths. Episode-days are the total number of days included in the episodes.

Below are tabulated the numbers of episodes and episode-days in five years at Little Rock. Also shown is the season having the largest number of episode-days.

EPISODES AND EPISODE-DAYS IN 5 YEARS
AT LITTLE ROCK, ARKANSAS FOR EPISODES
LASTING AT LEAST 2 DAYS

Mixing Height (Meters)	(Parameters)	Wind Speed (Meters per second) ≤ 2	≤ 4	≤ 6
≤ 500	Episodes	0	1	2
	Episode – days	0	3	5
	Season*	-	W	W
≤ 1000	Episodes	0	9	30
	Episode – days	0	23	83
	Season	-	W&A	W
≤ 1500	Episodes	0	23	68
	Episode – days	0	59	202
	Season	-	A	A
≤ 2000	Episodes	0	39	126
	Episode – days	0	105	388
	Season	-	A	A

*W - Winter
SP - Spring
SU - Summer
A - Autumn

EPISODES AND EPISODE-DAYS IN 5 YEARS
AT LITTLE ROCK, ARKANSAS, FOR EPISODES
LASTING AT LEAST 5 DAYS

2.3.2 LOCAL METEOROLOGY

2.3.2.1 Data Sources

Sources used in the preparation of the local meteorology include:

2.3.2-A "Wind Distribution by Pasquill Stability Classes (5), Seasonal and Annual, Little Rock, Arkansas." U.S. Department of Commerce, NOAA, Environmental Data Service, National Climatic Center, Asheville, N.C., September 1971.

2.3.2-B "Local Climatological Data" for Little Rock and Fort Smith, Arkansas," U.S. Dept. of Commerce, ESSA, Environmental Data Service, Government Printing Office, Washington, D.C., 1969.

2.3.2-C "Climatic Summary of the United States - Supplement for 1951 through 1960 - Arkansas." U.S. Department of Commerce, Weather Bureau, Washington, D.C., 1965.

2.3.2-D "Climatic Summary of the United States - Supplement for 1951 through 1960 - Arkansas." U.S. Department of Commerce, Weather Bureau, Washington, D.C., 1965.

2.3.2-E Personal Communication with Mr. Carl Landers, National Weather Service Office, Little Rock, Arkansas, August 16, 1973.

2.3.2-F "Climatic Summary of the United States, Section 59 -Arkansas North of the Arkansas River." U.S. Department of Agriculture, Weather Bureau, Washington, D.C., 1933.

2.3.2-G "Climatic Summary of the United States, Section 60 -Arkansas South of the Arkansas River." U.S. Department of Agriculture, Weather Bureau, Washington, D.C., 1933.

2.3.2-H American National Standards Institute, "Requirements for Minimum Design Loads in Buildings and Other Structures," ANSI A58.1-1972.

2.3.2-I Personal Communication with Mr. Beckerwerth, National Climatic Center, Asheville, North Carolina, May 16, 1974.

2.3.2-J Thom, H.C.S., "Distribution of Maximum Annual Water Equivalent of Snow on the Ground." Monthly Weather Review, Volume 94, No. 4, April 1966.

2.3.2-K "Snow Load Studies," Housing Research Paper 19. Housing and Home Finance Agency, Division of Housing Research, Washington, D.C., 1952.

2.3.2-L "Uniform Summary of Surface Weather Observations Part E - Psychrometric Summary" for January 1956 - December 1962, Jacksonville, Arkansas/Little Rock AFB.

2.3.2-M "Uniform Summary of Surface Weather Observations, Parts A-F" for January 1949 to April 1967, Jacksonville, Arkansas/Little Rock AFB.

2.3.2.2 Normal and Extreme Values of Meteorological Parameters

At present, only limited meteorological observational data exist for the plant site and only temperature and precipitation data exist for the Russellville-Dardanelle area. Therefore, data from proximal locations have been used to estimate or indicate normals and extremes that may be expected at the site.

2.3.2.2.1 Winds

Tables 2.3-1 through 2.3-13 show percentage frequencies of the 40-foot above grade wind from each wind sector (22.5°) on an annual and monthly basis at the site. These tables were prepared from data collected from February 7, 1972 through February 7, 1973.

The annual summary, Table 2.3-1, shows the prevailing direction to be from the east, with a secondary maximum, almost as large, from the east-northeast. The annual mean speed is 5.86 mph and the percentage of calms is 1.6 percent.

The "Fastest Miles" on record at Little Rock and Fort Smith are as follows, (mph) (Fastest Mile is defined in Section 2.3.1.3.7):

Month	Little Rock (32 Years, 1942-1974)	Fort Smith (29 Years, 1946-1974)
January	S 44	W 42
February	SW 57	W 56
March	SE 56	SW 41
April	NW 65	W 45
May	NW 61	NW 57
June	NE 60	N 58
July	NW 56	NE 44
August	NW 54	NE 44
September	NW 50	NE 52
October	SSW 58	W 54
November	SW 49	W 56
December	SW 48	SW 45

(Data Source 2.3.2-B)

2.3.2.2.2 Temperatures

The estimated monthly average daily maximum and minimum temperatures and extreme maximum and minimum values are as follows:

	DEGREES FAHRENHEIT			
Month	Average Daily Maximum	Extreme Maximum	Average Daily Minimum	Extreme Minimum
January	51.2	82	29.8	-11
February	53.6	87	31.3	-15
March	64.1	95	40.2	7
April	74.0	96	49.7	25
May	81.7	100	58.1	32
June	89.3	107	66.5	37
July	93.2	113	66.5	49
August	92.7	113	68.5	46
September	86.6	110	61.2	32
October	75.9	98	48.5	23
November	62.7	88	37.7	12
December	52.5	86	31.7	0
ANNUAL	73.1	113	49.4	-15

The above values are based on 48-49 years of record at Dardanelle (1909-1958) and 43-48 years of record at Russellville (1887-1909 and 1936-1950) (Data source 2.3.2-C).

The absolute maximum (113 °F) occurred at Russellville in July and at Dardanelle in August. The absolute minimum (-15 °F) occurred at Russellville in February.

Table 2.3-58 provides monthly, seasonal and annual diurnal mean air temperature variations for Little Rock.

2.3.2.2.3 Humidity

Estimated average relative humidity (%) for four different times of day at the site are:

Month	HOUR (CST) 00	06	12	18
January	76	80	60	63
February	74	79	57	57
March	69	76	53	52
April	75	81	56	56
May	82	86	57	58
June	82	87	56	57
July	85	88	58	62
August	83	88	58	62
September	86	90	59	66
October	81	85	49	62
November	78	82	57	64
December	76	80	61	65
Annual	79	84	57	60

The above values are estimated from five years of record at Fort Smith (1965-1969) and nine years of record at Little Rock (1961-1969) (Data source 2.3.2-B).

To estimate the extreme values that occurred, the combination of observed dry and wet bulb temperature that yields the largest and smallest possible value of absolute humidity was determined. The resultant values of extreme, both low and high, absolute humidity for each month, season and annually are presented in Table 2.3-59. Values of relative humidity associated with these extreme absolute humidities give an indication of the expected extremes. Relative humidities of 100 percent can be expected during each month of the year. The extreme low relative humidities of about 10 percent can also be expected throughout all months of the year.

Monthly average dewpoints for the site were estimated based on monthly average temperatures and monthly average relative humidities which were obtained from the above tables. The dewpoint values (°F) are as follows:

January	31.4	July	72.1
February	32.1	August	70.6
March	39.8	September	65.5
April	50.7	October	52.1
May	60.3	November	41.0
June	67.4	December	33.1

Table 2.3-60 presents the seasonal and annual diurnal variations of mean absolute humidity. Table 2.3-61 and 2.3-62 give the expected monthly, seasonal, and annual diurnal variations of dewpoint temperature and relative humidity, respectively.

2.3.2.2.4 Precipitation

Estimated monthly precipitation normals and mean number of days with precipitation equal to or greater than 0.5 inch at the site are presented below:

Month	Normal (Inches) (a)	No. of Days 0.5 In. (b)
January	3.99	2
February	3.86	3
March	4.76	3
April	4.87	4
May	5.70	3
June	4.25	3
July	4.06	3
August	3.55	2
September	3.63	2
October	3.11	2
November	3.98	3
December	3.40	2
Annual	49.16	32

(a) Based on 45 to 50 years of record at Russellville (1887-1909 and 1936-1960).
(b) Based on 9 to 10 years of record at Russellville (1951-1960).

(Data source 2.3.2-C)

Monthly extremes of precipitation on record at Russellville, Little Rock, and Fort Smith are (in inches):

Month	Russellville (24 years, 1937-60)	Little Rock (44 years, 1931-74)	Fort Smith (44 years, 1931-74)
January	12.81	18.04	11.33
February	10.20	11.02	9.21
March	16.05	9.49	13.03
April	12.45	14.20	10.32
May	11.34	12.74	14.71
June	8.97	7.82	15.02
July	9.62	7.76	10.41
August	12.58	14.46	8.71
September	8.01	9.09	10.49
October	11.13	9.68	12.05
November	10.94	9.54	14.01
December	7.52	9.14	10.09

(Data sources 2.3.2-B, C, D)

The snow and sleet season in the area runs from November through March with a trace (T) reported in April. The average monthly totals for Russellville for the period of record (1927 - 1960) are given below (in inches):

January	2.2	July	0
February	2.2	August	0
March	0.3	September	0
April	0	October	0
May	0	November	0.3
June	0	December	0.9
Annual	5.7		

(Data source 2.3.2-C)

Examination of the weather records for Russellville and Dardanelle shows that the maximum snow and ice accumulation occurred during January 10 to January 24, 1918. In this time, 19.7 inches of snow fell and the temperature did not rise above freezing, so the snow fall probably accumulated through the period. A scan of the records back to 1892 indicates no other comparable period occurred. (Data source 2.3.2-E)

The 100-year return period, antecedent snow and ice pack for the area in which the plant is located, in terms of snow load and water equivalent is listed below (Data source 2.3.2-H):

Snow load = 9.0 lbs/ft^2

Water Equivalent = 1.728 inches

The water equivalent of new-fallen frozen precipitation is not measured routinely by the National Weather Service (NWS). Since 1952, the NWS has made one daily measurement of the water equivalent of snow on the ground. The water equivalent of new-fallen frozen precipitation would be very difficult to estimate from these data since this parameter is influenced significantly by the promptness and frequency of the observation during or after the storm. Therefore, any statistical study relevant to estimating the probable maximum water equivalent of frozen precipitation from a single winter storm would be hampered by a relatively poor data base.

The record snowfall for the state of Arkansas was 25.0 inches occurring at Corning, which is located in the northeastern corner of the state (Data source 2.3.1-H). Thom (1966) has indicated there is a very poor relationship between snow depth and snow density (Data source 2.3.2-J). Values of water equivalent for several years were obtained from climatological records at Fort Smith and Little Rock (Data source 2.3.2-I). From these data, a conservative value of snow density for new-fallen snow was estimated as 0.20 inch of water per inch of snow.

The maximum probable water equivalent of frozen precipitation from a single winter storm was determined from the record snowfall of 25.0 inches and the conservative value of 0.20 for snow density. The snow load and water equivalent are listed below:

Snow load = 26.04 lbs/ft^2

Water Equivalent = 5.0 inches

A study conducted by the U.S. Weather Bureau in 1952 estimated the maximum probable snow load from a single storm in this area to be 20.0 lbs/ft^2 (Data source 2.3.2-K). Based on this figure, the estimate of 26.04 lbs/ft^2 is quite conservative.

2.3.2.2.5 Fog

Heavy fog is defined as that fog which reduces visibility to 1/4 mile or less. No fog data are available for the site area. Heavy fog frequencies for Little Rock and Fort Smith area:

	Number of Days	
Month	Little Rock	Fort Smith
January	3	2
February	2	1
March	1	1
April	1	*
May	1	1
June	*	1
July	1	1
August	1	1
September	1	1
October	2	2
November	2	1
December	2	2
Annual	16	16

* Less than ½ day. (Based on 32 years (1943-1974) of record at Little Rock and 29 years (1946-1974) of record at Fort Smith) (Data source 2.3.2-B).

The occurrence of fog is greatly influenced by topography and varies significantly over short distances. Therefore, to ascertain the expected and extreme duration of fogs, analysis of hourly or 3-hourly observations from a nearby representative location with a long period record is required. The closest station to the plant site with an adequate fog record is Little Rock. These data may not be representative of the site because of the influences of terrain and the Dardanelle Reservoir. Table 2.3-63 presents the percent frequency of occurrence of fog for Little Rock. The fog frequencies presented in this table are for visibility reductions of six miles or less and, therefore, are not restricted to heavy fogs. Seasonal and annual diurnal variations can be determined from this table.

The frequency of smog has not been estimated. Smog occurrences at the urban locations of Little Rock and Fort Smith, for which adequate climatological records exist, are not representative of the rural environment at Arkansas Nuclear One. No smog or fog records exist at Russellville.

2.3.2.2.6 Atmospheric Stability

In this section, wind direction and speed data are presented in relative frequency distributions by stability classes for each season and annually for Little Rock, Arkansas. Stability classes used are based on Pasquill's class structure (See Journal of Applied Meteorology, February 1964), as follows:

Pasquill Stability Class	Identified In Tables As	Definition
1	A	Extremely Unstable
2	B	Unstable
3	C	Slightly Unstable
4	D	Neutral
5,6,7	E	Slightly Stable to Extremely Stable

Tables 2.3-14 through 2.3-38 contain the wind/stability data. They give the frequency of occurrence of surface winds by direction, speed, and stability class. The data in these tables were developed from observations taken from January 1966 through December 1970. The tables are self-explanatory, except that the calm values have been distributed in the 0-3 speed category, based on the number of observations in speed categories 0-3 and 4-6 (Data source 2.3.2-A).

2.3.2.3 Potential Influence of the Plant and Its Facilities on Local Meteorology

It must be recognized that while data in the previous section are considered representative of local meteorology, the stations from which the data are derived are, in some cases, as much as 75 miles distant from the site. Consequently, departures from the normal and extreme values given above are expected.

Potential modifications of the local meteorology of the plant site resulting from the existence and operations of Unit 2 are recognized, but believed to be minimal. The buildings and ancillary structures, especially the natural draft cooling tower, are expected to have some small influence on the local flow of air; specifically, mechanical turbulence is expected downwind of the plant in the lower layers. Also expected to be of minor influence is a modification of the radiative properties of the site area.

The cooling tower plume is expected to enhance or reinforce naturally occurring low cloud coverage by a small percentage, depending on the position of the observer.

Since temperature and humidity measurements are routinely made near the ground in the levels where man normally lives, it is expected that the cooling tower plume will have little effect on the normals and extremes derived from these measurements. The possibility of the plume surfacing is remote, due to the buoyancy of the plume caused by its sensible heat content.

Drizzle from the natural draft cooling tower plume is largely confined to the site or a few hundred meters beyond. It is expected to occur principally during those times when naturally occurring fog is likely. The maximum rate of precipitation is expected to be less than a thousandth of an inch per hour and will not significantly affect precipitation normals and extremes.

Local fog frequency could be slightly enhanced by the cooling tower plume, first by the surfacing of the plume, and second by the evaporation and condensation of the warm drift during its fall to the ground. As mentioned above, surfacing of the plume is a remote possibility. The second mechanism is effective only during periods of high humidity when natural ground fog is likely to occur, and is expected to be confined within a 0.5-mile radius of the tower.

2.3.2.4 Topographical Description

Figures 2.3-2 and 2.3-3 are maps showing detailed topographic features within radii of five miles and 50 miles of the plant, respectively. Figures 2.3-4 through -7 show topographic cross sections in the 16 compass point sectors radiating from the plant. The topography within five miles of the plant can be described as gently rolling and is not expected to have any adverse effects on either short-term or long-term diffusion conditions, as discussed in the following paragraphs.

These maps and cross sections suggest that two features of the terrain should be examined for possible influences on the dilution qualities of the site and on the mathematical models which are used in the numerical analysis of the hazards due to accidental releases of radionuclides. These features are the Dardanelle Reservoir, plus other adjacent water surfaces, and the ridge-valley configurations within five miles of the reactor building, which might cause channeling of winds under stable conditions.

To assess the influence of the reservoir, the frequency of stable conditions during trajectories from over-water, from limited over-water, and from fully overland directions were examined, as shown in the following table:

Trajectory From	Wind Directions	of Pasquill Classes		
		A-D	E	F&G
Over-Water	E-S-SSW-SW-WSW-W	66.2	20.6	13.2
Limited Over-Water	ENE-ESE-SE-SSE	56.8	27.1	16.1
Overland	WNW-NW-NNW-N-NNW-NE	47.9	28.5	23.6

It is apparent that over-water trajectories tend to have a lower frequency of stable conditions. Further, the trajectories which are overland in approaching the meteorological tower will become over-water trajectories since they must continue across the Dardanelle Reservoir or the Illinois Bayou. Consequently, trajectories from the reactor reaching the far side of these water surfaces should have fewer stable conditions than the meteorological tower data indicate.

The prevailing wind is easterly and this direction preference may be enhanced by the low terrain in the east sector (see Tables 2.3-40 and 2.3-41). Downwind from the plant, this easterly wind, under stable conditions, might be channeled into the west-northwest or into the west-southwest sectors, since topography in these sectors is lower than in the west sector. However, Pasquill F and G conditions prevail only 12 percent of the time during east winds. Further, as already has been shown, these 12 percent Pasquill F and G conditions will be subject to the influence of the Dardanelle Reservoir in reducing the stability of the ground layers. It is concluded that the standard Gaussian dispersion model using Pasquill classes defined by vertical thermal stability will provide an appropriately conservative evaluation of the dilution climate of the plant site.

The top of the natural draft cooling tower will extend above all terrain within three miles of the plant, and the rise of the tower plume should normally carry it above all other terrain in the vicinity.

2.3.3 ONSITE METEOROLOGICAL PROGRAM

2.3.3.1 Preoperational Program

The preoperational meteorological program was designed to measure the parameters needed to evaluate the dispersion characteristics of the site for the evaluation of the consequences of routine operations and of hypothetical accidental releases of radionuclides to the atmosphere.

2.3.3.1.1 Instrumentation and Recording System

The meteorological onsite data acquisition program was begun in September 1967, and data have been collected almost continuously since that date. Initially, wind speed and wind range were observed on a 30-foot pole. In June 1969, a 190-foot tower was erected onsite with wind data observed at approximately 34 feet and at 180 feet and temperature differences observed between approximately 34 and 180 feet. In December 1985, a new 197-foot tower was erected to replace the existing tower with instrument levels at approximately 33 and 187 feet. The tower is at a position 0.51 mile due east of the Unit 1 reactor building, as shown in Figures 2.1-2 and 2.1-3. It is 800 feet southeast of the early 30-foot pole site, and at a ground elevation of about 360 feet above mean sea level. This location for the tower is far enough from the reactor buildings and other buildings at the site to provide relatively undisturbed weather data; yet its exposure in terms of the terrain of the site is quite similar to that of the reactor buildings. It is a suitable site, therefore, for both preoperational and operational purposes. The recording system is located at the foot of the tower.

It is useful to define the extent to which the data collected at the top of the meteorological tower, 190 feet above grade, is representative of atmospheric conditions which may occur at the cooling tower exit at 475 feet above grade, particularly as these conditions affect the characteristics and behavior of the natural draft cooling tower plumes. These plumes have been extensively investigated to develop mathematical models which predict variations in the plume as the ambient atmospheric conditions vary. It is only necessary, therefore, to evaluate the effects on mathematically predicted plume characteristics of the changes in atmospheric conditions anticipated between 190- and 475-foot elevations. Specifically, model predictions of visible plume height and length and surface fogging and icing conditions depend upon wind speed, temperature and dewpoint of the ambient atmosphere, together with the characteristics of the plume at the tower exit point (Data sources 2.3.1-0 and 2.3.1-P for plume height plus data source 2.3.1-Q for plume length, fogging, and icing).

Data taken on a 900-foot radial tower in Philadelphia, Pennsylvania, were investigated to determine the change of temperature and wind speed with height, as determined by hourly observations at four levels over a 14-month period (Data Source 2.3-1-R). The terrain in the vicinity of Philadelphia tower is fairly rough with a river and a variety of building shapes and sizes nearby. At the site, terrain is hilly, with a river and a few buildings in the vicinity. Temperature decreased with height on the Philadelphia tower at about one-half the adiabatic lapse rate. The average difference between 190 feet and 475 feet was 9.75 °F. Wind speed increased logarithmically with height, with an average difference between speeds at 190 feet (9.2 mph) and at 475 feet (12.0 mph) of 2.8 mph. Data were not taken to measure humidity on this tower, but dewpoint generally decreases with height because moisture sources are near the surface, i.e. surface water evaporation and vegetative evapo-transpiration.

The plume characteristics of rise above tower exit point, visible length, and plume ground level icing and fogging were evaluated by means of the mathematical models referenced above,

using a data set at 30 and 190 feet and another data set at 30 and 475 feet above grade. In these two data sets, the atmospheric conditions were assumed to vary between 190 and 475 feet in accordance with the relationship observed on the Philadelphia tower and using the assumption that relative humidity is constant above 190 feet. The following table compares plume characteristics predicted from the 30- to 190-foot data set with those from the 30- to 475-foot data set.

Atmospheric Variable	Plume Rise	Length of Visible Plume	Ground Level Fogging	Ground Level Icing
Temperature difference	-	-	-	-
Wind Speed (Upper)	±	±	±	±
Wind Direction (Upper)	o	-	-	-
Temperature (Upper)	o	o	o	o
Dewpoint (Upper)	o	o	o	o
Moisture Deficit (Upper)	o	-	-	-

Legend of Effects:
- \- Slightly conservative
- o Negligible or no effect
- ± Random and very small

A remaining uncertainty in this evaluation concerns the possibility that orographic effects at the plant site would make 190-foot data less representative of conditions at 475 feet than is the normal case.

The closest terrain at the height of the 190-foot sensors is at one mile to the north-northwest; except in the north-northwest through northeast sectors, such terrain heights are more than two miles away, as shown in Figure 2.3-2. Further, terrain as high as the cooling tower exit is no closer than three miles in any sector, or five miles in sectors other than west and north-northwest. It is unlikely, therefore, that orographic effects on wind flow would influence the representativeness of 190-foot data for characterizing those atmospheric conditions at 475 feet which influence plume characteristics.

It may be concluded that data collected at the 190-foot tower is reasonably representative of atmospheric conditions at the height of the cooling tower exit, particularly as these conditions influence natural draft cooling tower plume characteristics and behavior.

In July of 1971 the elevations of some of the instruments on the meteorological tower were adjusted to conform with changes in accepted meteorological practice. Temperature differences from 30 feet to the higher levels and winds at 40 feet and 190 feet were recorded

after that data. Because of malfunction of the lower level wind instrument, a redundant instrument was installed at this level on February 7, 1972 to insure continuity of data.

The important specifications for the tower weather instruments used in the pre-operational program are as follows:

Weather Element	Tower Elevation (ft)	Make & Model	Threshold Mph	Distance Constant (ft)	Damping Ratio	Accuracy
Wind Speed	40 and 90	Litton 511S-4	0.6	5(1)	NA	± 1% or 0.13 knots, whichever is greater
Wind Direction	40 and 90	Litton 510D-2	0.81	4(1)	0.4	± 3%
Temp Diff.	30 – 85 30 – 190	Litton				< 0.25 °F
Wind Speed	40 1071	MRI	0.75	18(1)		± 2%
Wind Dir.	40	MRI 1071	0.75	4(2)	0.5 to 0.6	± 1% full scale

(1) 63% Recovery
(2) 50% Recovery

The data which is incorporated in the following analysis of onsite diffusion conditions at the site were collected between February 7, 1972, and February 7, 1973. This annual meteorological record had a data recovery of nearly 96 percent, thereby providing assurance that a bias did not inadvertently occur because of instrument outages (see Table 2.3-39 for listing of periods of sustained invalid observations). The meteorological record from July 1971 to July 1972, which required power law reduction from 190 feet to determine low level winds for part of the year, was evaluated in the amendments to the PSAR and is fully consistent with the record reported herein. In achieving the 95+ percent data recovery, recourse was made to the redundant wind speed and wind direction sensor for the February 7 to July 29, 1972 period.

2.3.3.1.2 Equipment Maintenance and Calibration

The weather instruments on the tower were checked and calibrated in May and November of 1972. The temperature difference system was found to be within instrument specifications. In May of 1972, the 33- and 190-foot sensors used for assigning Pasquill stability classes were set at the same reference level and the recorders showed zero differential. The wind direction and speed sensors and recorders were also found to be within specifications in November of 1972. In May of 1972 one of the Litton instruments had a bad bearing, and the data presented herein are from the MRI 1071 sensor between February and July 1972.

The MRI instrument was returned to Meteorological Research, Inc. for a calibration check after July 29, 1972, to insure its accuracy during the period February 7 to July 29, 1972, a period when it provided the primary wind record for the site. The calibration check record shows that it

was within specified tolerances when received at the MRI factory. There is reasonable assurance, therefore, that the data incorporated in the analyses and summaries in Sections 2.3.3, 2.3.4 and 2.3.5 were from instruments which were within specifications.

2.3.3.1.3 Data Reduction and Analysis

All data were initially recorded on strip charts and were reduced by Dames & Moore, professional meteorologists, or by trained technicians under their direct supervision. Hourly average values of wind speed, direction and temperature differences were read off the charts in the form of sequential values of the concurrently occurring weather elements. These were keypunched and entered into a computer for analysis. The computer programs used for analysis of the data are standard Dames & Moore programs, previously used for Safety Analysis Report preparation at other sites.

The temperature difference values from 33 to 190 feet on the tower were used to define Pasquill class stability conditions at the site in accordance with the following table:

Stability Classification	Pasquill Category	Temperature Change with Height (°C/100m)
Extremely Unstable	A	< -1.9
Moderately Unstable	B	-1.9 to -1.7
Slightly Unstable	C	-1.7 to -1.5
Neutral	D	-1.5 to -0.5
Slightly Stable	E	-0.5 to 1.5
Moderately Stable	F	1.5 to 4.0
Extremely Stable	G	> 4.0

2.3.3.2 Wind Roses by Pasquill Stability Categories

Joint frequency distributions of wind speed and wind direction recorded at 40 feet above grade and of Pasquill stability categories for the period February 7, 1972 through February 7, 1973 are given in Tables 2.3-40 and 2.3-41. Together with the sequential listing of hourly data, these provided the weather data which are necessary and sufficient for the analyses in the following sections which describe the diffusion qualities of the site.

To evaluate the representativeness of the February 7, 1972 to February 7, 1973 period, as compared to long-term conditions in central Arkansas, comparisons of seasonal and annual stability and wind speed distributions (%) for Little Rock, Arkansas are shown here:

Season	Stability	Period 1966-70	Period 2/7/72 2/7/73
	A	0	0
	B	1.33	1.10
DJF	C	9.25	8.38
	D	59.31	60.03
	E(F&G)	30.11	14.01
	F(G)	--	16.48
	A	0.90	0.82
	B	6.39	6.79
MAM	C	10.93	11.01

	F(G)	--	22.28
	A	2.15	1.90
	B	12.47	14.27
JJA	C	18.18	16.03
	D	26.71	27.31
	E(F&G)	40.49	10.33
	F(G)	--	30.16
	A	0.41	0.14
	B	5.52	5.22
SON	C	13.35	10.99
	D	36.81	46.57
	E(F&G)	43.90	10.16
	F(G)	--	26.92
	A	0.87	0.72
	B	6.46	6.86
ANNUAL	C	12.95	11.61
	D	43.02	44.36
	E(F&G)	36.71	12.47
	F(G)	--	23.98

Season	Speed (Knots)	Period 1966-70	Period 2/7/72 2/7/73
	0 - 3	7.65	9.75
	4 - 6	31.31	25.55
	7 - 10	39.69	39.29
DJF	11 - 16	19.78	22.16
	17 - 21	1.56	3.02
	J 21	0.11	0.27
	Calms	3.63	5.22
	0 - 3	7.72	11.28
	4 - 6	29.08	32.07
	7 - 10	41.26	34.24
MAM	11 - 16	19.71	21.33
	17 - 21	2.15	1.09
	J 21	0.08	0
	Calms	3.78	5.98
	0 - 3	13.67	17.39
	4 - 6	45.62	42.26
	7 - 10	33.53	33.97
JJA	11 - 16	6.87	6.11
	17 - 21	0.27	0.14
	J 21	0.03	0.14
	Calms	6.36	9.10
	0 - 3	12.55	17.99
	4 - 6	41.68	37.64
	7 - 10	33.57	32.69
SON	11 - 16	11.54	11.26
	17 - 21	0.66	0.41
	J 21	0	0
	Calms	6.02	10.44
	0 - 3	10.38	14.11
	4 - 6	36.94	34.39
	7 - 10	37.01	35.04
ANNUAL	11 - 16	14.45	15.20
	17 - 21	1.16	1.16
	J 21	0.05	0.10
	Calms	4.95	7.68

The annual stability distributions are quite similar. The annual distribution of wind speeds shows that the February 7, 1972 to February 7, 1973 period had a greater percentage of calms and winds in the 0 - 3 knot class.

The above data were obtained from STAR program computer runs (Jobs #13029 and #01772) done by the National Climatic Center, Asheville, North Carolina.

2.3.3.3 Wind Persistence

The stability-independent wind persistence over the period of record is summarized in Table 2.3-42. Persistence counts were carried through calms if persistences longer than eight hours were quite rare. The longest persistence was 15 hours, in one case from west-northwest, in the other, from east-northeast; one 14-hour persistence from west-northwest was observed.

The stability-dependent persistences are summarized in Tables 2.3-43 through 2.3-49. In this case, changes in direction or stability class terminated a persistence count. Counts were continued through calms if direction and stability class were maintained by the observation subsequent to the calms. Maximum persistences in the unstable classes (A, B and C) were four hours or less. Persistences longer than six hours under D and E stability were rare, although one 10 and one 11-hour persistence and one 13-hour persistence were observed under D and E stability, respectively. Maximum persistence length for F and G stability was eight and four hours, respectively.

2.3.3.4 Operational Program

During operation of the nuclear station, the meteorological program will be continued for the following purposes:

A. To provide real-time meteorological information in the control room to be used for decisions concerning routine station operations.

B. To provide the meteorological summaries from which the concentrations of radionuclides due to atmospheric releases during normal station operations can be estimated.

C. To provide real-time meteorological data in the control room from which initial estimates of the radiological consequences of an accidental release of radioactive material into the atmosphere can be made.

To satisfy the need by the plant operators for real-time weather information, as described in Regulatory Guide 1.23, all data observed in the tower installation will be recorded on strip chart recorders located in the reactor control room and stored electronically. These data will be summarized and analyzed seasonally to permit assessment of the concentrations of radionuclides in the surrounding region resulting from routine plant operations, in accordance with the requirements of Regulatory Guide 1.21 (12/29/71).

The parameters are recorded at a maximum of 1-minute intervals and averaged over a 1-hour period by the program. The average is made by summing the valid observations within that hour and dividing by the number of valid observations in that hour. When the volume of data unavailable from the magnetic tape is large enough, the data may be reduced from the strip charts.

The quality and reliability of available weather instrumentation has improved since the inception of the preoperational program. The tower, instruments and recording systems have, therefore, been replaced with modern equipment for the operational program.

Historical data on the original tower removed - To review the exact wording please refer to Section 2.3.3.4 of the FSAR.

Instrument inspection and maintenance procedures have been developed for the new tower instruments and recorders to ensure that data recovery will continue to exceed 90 percent. Testing will be performed on frequencies commensurate with the importance of the instrumentation.

In March 1986, the original 190-foot high instrumented meteorological tower, primary sensors, signal conditioners, and control room recorders were replaced by an upgraded meteorological system. This system consists of a 197-foot high meteorological tower with sensors at 10 meters and 57 meters, lightning protection (for the tower, sensor input signal lines, signal conditioning AC power, and the data lines between the tower site and the control room), signal conditioning electronics, a 2.5 KVA liquid propane fueled backup generator with auto start/auto transfer capability, a dedicated line FSK transmitter/receiver pair, new control room recorders and data acquisition system.

The 197-foot high tower is located at approximately the same location as the original 190-foot high tower and is serviced by the same tower site building. Mounted on the tower is an electric winch driven sensor elevator which provides for automatically raising and/or lowering of the sensor carriage assemblies to ground level for servicing of the sensors. Parameters measured at each tower level are: (a) wind direction (0° to 540°), (b) wind speed (0 to 100 mph), (c) ambient temperature (-50 °C to +50 °C), and (d) dew point (-50 °C to +50 °C).

The signal conditioning electronics are comprised of signal conditioners for: (a) each level wind direction, (b) each level wind speed, (c) each level dew point, (d) lower level reference ambient temperature, (e) delta temperature between levels, and (f) standard deviation of upper level wind direction (sigma theta). Liquid crystal displays of each of these parameters in engineering units were provided and are located along with the signal conditioners and FSK transmitter at the tower site building. The signals from the signal conditioners are digitized, multiplexed, and transmitted back to the Unit 1 control room where they are de-multiplexed and converted back to analog signals to be sent to the recorders, as well as RDACS via the SPDS.

The sensors, signal converter electronics, FSK transmitter, and data acquisition system, are all on the backup power system. The fuel supply sizing has been selected to provide at least eight (8) hours of continuous use in the event of loss of off-site power. The existing uninterruptible power supply is used in conjunction with the generator to provide for battery backup power during the transition from off-site to generator power. Indication of transfer to backup power is provided on the front panel of the meteorological cabinet located in the Unit 1 control room.

The data acquisition system, provides for transfer of the meteorological data to a remote location for data reduction. Data validation is also provided.

In 2008, meteorological data storage was moved to the Plant Data Server (PDS). Data validation is performed using data from the PDS system.

2.3.4 SHORT-TERM (ACCIDENT) DIFFUSION ESTIMATES

2.3.4.1 Eight Hours or Less Dilution Factors

The atmospheric diffusion evaluations for the Arkansas Nuclear One station are based upon an assumed ground level release, i.e. no advantage is realized from effluent emissions from elevated released points. The effluent plume is assumed to spread, during downwind transports, according to a Gaussian dispersion model. The equation representing this mode (see NRC Regulatory Guide 1.4) is:

$$\frac{X}{Q} = \frac{1}{\bar{u}\left(\pi \sigma y(p,D) \sigma z(p,D) + cA\right)} \qquad 2.3.4-A$$

where

X/Q = dilution factor (seconds/meter^3)

p = Pasquill stability class index

σy(p,D) = horizontal dispersion coefficient of the plume (meters) per Pasquill class, at distance D

σz(p,D) = vertical dispersion coefficient of the plume (meters) per Pasquill class, at distance D

cA = Building wake term = 0.5(2206). The effect on X/Q of the term cA is limited to a factor of 3 or less.

$\bar{u}$ = hourly average wind speed (meters/second)

D = distance from reactor containment structure to exclusion zone, actual site boundary or low-population zone (meters)

Ground reflection is assumed at all points; this doubles the concentrations which are to be expected in the free atmosphere.

The diffusion climatology of a site is defined by the frequency distribution of the dilution factors. This distribution is dependent upon concurrent values of $\bar{u}$, the diffusion parameters σy and σz, upon downwind distances and building wake effects. The diffusion parameters depend, in turn, upon values of vertical temperature gradient (Δt) at the site. Wind speed and direction and Δt have been recorded at the site, and hourly values of each have been reduced from strip charts.

Both σy and σz are functions of downwind distance from the effluent source (the reactor containment structure) and the Pasquill stability class. The minimum distance from the reactor containment structure to the exclusion zone boundary for each of the 16 wind direction sectors is tabulated in Table 2.3-50.

2.3.4.2 Longer than Eight Hour Dilution Factors

After the first eight hours, the dilution factors are best represented by an equation that accounts for changes in wind direction and the resultant meandering of the plume, as shown below:

$$X/Q(i.n) = \frac{2.032}{nD} \sum_{j=1}^{n} \left[\frac{k}{\overline{u}(j) \left[\sigma_z^2(j) + \frac{cv^2}{\pi} \right]^{1/2}} \right] \qquad 2.3.4\text{-}B$$

where

X/Q (i,n) = average dilution factor (seconds/meters^3) over n hours in section i at the LPZ distance

σ_z (j) = vertical dispersion coefficient for hour j (dependent on Pasquill class) at the LPZ distance

$\overline{u}$ (j) = average windspeed (meter/second) for hour j

D = distance of LPZ from site (meters)

v = height of reactor building (meters)

c = building wake shape factor (0.5)

K = wind direction dependent variable:
1 if wind blowing to sector i
0 if wind not blowing to sector i

The effect on X/Q of the term cv^2/π is limited to a factor of $\sqrt{3}$ or less. This equation, which recognizes the influence of building wake effects at shorter radius distances, is derived from Equation 3.142 on Page 112 of Meteorology and Atomic Energy, and it has recently become accepted meteorological practice to use it in place of the sector spread equation given in Regulatory Guide 1.4.

Step by step details of the accident diffusion analysis are given in Table 2.3-51.

2.3.4.3 Estimated Values of Hourly Dilution Factors

The concurrent hourly values of Δt, wind direction and speed have been accumulated and used with a minimum distance of 1,046 meters from the reactor building to the minimum exclusion zone boundary, and a wake factor cA of 1,103 square meters, to develop frequency distributions of 1-hour dilution factors. Dilution factors for the actual exclusion zone boundary have also been computed.

Two cumulative frequency distributions of hourly dilution factors, which describe the diffusion climatology of the site, have been developed using Equation 2.3.4-A with wind speeds and Pasquill classes from the onsite data (see Figure 2.3-8). One distribution shows values for the minimum exclusion zone boundary (minimum EZB); the other shows values for the closest point

in each sector for the actual exclusion zone boundary (actual EZB). The dilution factor which is exceeded five percent of the time, a significant feature of the site diffusion climatology, is 6.5(-4) seconds/meter^3 for the minimum EZB. This value is equivalent to dilution qualities associated with Pasquill F and a wind speed of 0.5 meter per second. It should be noted that calm conditions are included in the distribution using the instrument threshold as the upper boundary of the class of wind speeds included in "calm". The 5-percentile and 50-percentile values at both the minimum and actual EZB are given in the following table:

	Percentile	
0 – 2 Hours	5%	50%
Minimum Exclusion Zone Boundary	6.5(-4)	5.0(-5)
Actual Exclusion Zone Boundary	5.5(-4)	4.5(-5)

Hourly Dilution Values, Relative Concentrations, Seconds/meter^3.

2.3.4.4 Estimated Values of Dilution Factors for Periods up to 30 Days

The average dilution factors for the outer boundary of the Low Population Zone (LPZ) at 4 miles (6,436 meters) have been calculated for 0-8 hours, 8-24 hours, 1-4 days, and 4-30 days for each sector. Calm conditions were included in the calculations by assigning them a wind speed of 0.3 (1/2 the threshold value; see Section 2.3.3.1.1) and distributing them among the 16 direction sectors in proportion to the directional frequencies of the lowest speed class interval.

The centerline Equation 2.3.4-A was used for the 0-8 hour period, and the sector spread Equation 2.3.4-B was used for longer duration periods. All dilution factor averages at each duration were placed in cumulative frequency distributions for each sector. The worst case, the five and 50 percentile averages, in the worst sector were selected from these frequency distributions for each duration interval, as shown in the following table; the nature of these worst sector frequency distributions is illustrated in Figures 2.3-9 to 2.3-12.

Duration of Averages	Percentile of All Averages	Worst Sector Relative Concentration Seconds/meter^3	Sector Affected
8 Hours	Worst	1.29(-4)	W
	5%	2.30(-5)	WSW
	50%	3.00(-7)	W
16 Hours	Worst	7.63(-6)	W
	5%	2.60(-6)	WSW
	50%	2.80(-7)	WSW
3 Days	Worst	2.75(-6)	WSW
	5%	1.50(-6)	WSW
	50%	4.50(-7)	WSW
26 Days	Worst	1.23(-6)	W
	5%	9.40(-7)	WSW, SW
	50%	5.90(-7)	WSW

For most direction sectors, the 50 percentile of the frequency distribution of 8-hour average relative concentrations is zero, i.e. for more than 50 percent of the 8-hour periods the wind did not affect the sector once. This is also true of half of the 16-hour sectors. Except for the 26-day averages, all frequency distribution of all sectors include some averages with a value of zero, because the wind skipped the sector for entire averaging periods. It is useful to know, therefore, the five and 50 percentiles of the frequency distributions from which the zero values have been arbitrarily omitted. The following tables show these distributions:

		Worst Sector		
Duration of Averages	Percentile of the Non-Zero Averages	Frequency of Non-Zero Sector Averages	Relative Concentrates Seconds/meter^3	Sector Affected
8 Hours	5%	55.6%	3.3(-5)	WSW
	50%	38.2%	3.5(-6)	SW
16 Hours	5%	76.4%	3.8(-6)	WSW
	50%	58.3%	5.2(-7)	SW
3 Days	5%	99.4%	1.5(-6)	WSW
	50%	99.4%	4.5(-7)	WSW
26 Days	5%	100%	9.4(-7)	WSW, SW
	50%	100%	5.9(-7)	WSW

It may be noted that for the 26-day averages, the values in this and the preceding table are the same.

The details of the diffusion climatology of the site for longer duration accident evaluations are provided in the following tables (Tables 2.3-52 and 2.3-53). This shows for each sector and each averaging period, the highest relative concentration experienced, the five and 50 percentile of all non-zero averages, and the frequency of non-zero averages in the sector.

Relative concentrations falling at the five percentile level in the worst sector of the annual onsite data provided a conservative basis for evaluations of the consequences of an accidental release of radionuclides into the atmosphere. Using this criteria, the dilution factors to be used for accident evaluations are compared with the tentative recommendations provided in Regulatory Guide 1.4, as follows:

Duration of Accidental Release	Recommended for Arkansas Nuclear One	Regulatory Guide 1.4
0 - 8 Hours	2.3(-5)	4.2(-5)
8 - 24 Hours	2.8(-6)	8.3(-6)
1 - 4 Days	1.5(-6)	2.8(-6)
4 - 30 Days	9.4(-7)	6.0(-7)

Section 2.1 of the ANO-2 SER, Section 2.1 of Supplement 1 to the ANO-2 SER, and Section 2.1 of Supplement 2 to the ANO-2 SER give a summary of discussions which led to redefining the low population zone radius to meet 10 CFR 100 as 2.6 miles based on projections of the growth of the city of Russellville and its surroundings. The atmospheric dilution factors used in the analysis of the environmental consequences of accidents at the LPZ given in Table 15.1.0-5 are based on this 2.6 mile (4,184 meters) radius, using the methodology described above.

2.3.5 LONG-TERM (ROUTINE) DIFFUSION ESTIMATES

2.3.5.1 General

The onsite meteorological data has been analyzed to determine the average annual dilution factors which are applicable to routine venting or other routine gaseous effluent releases, using Equation 2.3.4-B.

D = varied in increments out to 80 kilometers
N = numbered of hourly observations in the year.

Calm conditions were included as described in Section 2.3.4.4. Because releases of effluents are assumed to be at the ground, and the terrain is expected to exhibit little or no channeling effects (see Section 2.3.2.4), the choice of the standard finite cloud parameter, with sector widths equal to $\pi/8$ radians is justified. To further insure conservative results, a limitation was placed on the maximum value of the vertical dispersion coefficient. This value was the annual average mixing depth for this region of 925 meters (Data source 2.3.1-L).

2.3.5.2 Calculations

Details of the routine release diffusion analysis are given in Table 2.3.51. Annual average dilution factors at the minimum site boundary and various other distances are given in Table 2.3-54. The maximum value is 8.0(-6) seconds/meter^3 at 1,046 meters in the west-southwest sector. The average value at the actual site boundary is 2.8(-6) seconds/meters^3. Annual average dilution factors at other distances are shown in Table 2.3-55. Long-term diffusion estimates for distances out to five miles are shown in Figure 2.3-13 and to 50 miles in Figure 2.3-14.

2.3.6 ANNUAL RELEASE RATE LIMITS

The design objective in the ODCM relating to the average annual release rate of noble gases and other radioactive isotopes discharged from the plant (except I-131 and particulate radioisotopes with half-lives greater than eight days) provides that the resulting annual dose at the site boundary should be less than 10 mrem to the whole body or any organ of an individual.

Using the methodology of Regulatory Guide 1.111, the highest annual average X/Q value for a ground level release is 2.0 x 10^{-5} sec/m^3 in the west-southwest sector at a distance of 0.65 miles. This dispersion factor (X/Q) will be used to calculate the annual dose at the site boundary. Dose calculations are based on the dose models in the Standard Radiological Technical Specifications (NUREG-0472).

2.3.7 QUARTERLY RELEASE RATE LIMITS

The maximum allowable quarterly release rate of gross gaseous activity may not exceed eight times the maximum allowable release rate averaged over any 1-hour period.

This method of calculating the maximum allowable quarterly release rate is based on the highest annual average X/Q value of 2.0 x 10^{-5} sec/m^3 and the dose models in NUREG-0472.

2.3.8 HOURLY RELEASE RATE LIMITS

The ODCM limit the release rate of radioactive materials and gaseous wastes (except I-131 and particulate radioisotopes with half-lives greater than eight days) when averaged over any 1-hour period to that rate which would result in an off-site concentration equal to the maximum permissible concentration, as defined in Section 2.5.5.2.1, Table II, Column 1, 10 CFR 20. These calculations will be based on the highest annual average X/Q value of 2.0 x 10^{-5} sec/m^3, consistent with the X/Q value used in calculating annual and quarterly limits.

2.4 HYDROLOGIC ENGINEERING

2.4.1 HYDROLOGIC DESCRIPTION

2.4.1.1 Site and Facilities

Security-Related Information
Text Withheld Under 10 CFR 2.390

As shown on Figure 2.5-13, the construction of Unit 2 has not significantly altered the natural drainage. The emergency cooling pond collects much of the surface runoff in its vicinity, but it has a spillway which conducts the excess runoff to its natural destination. Likewise, the intake canal alters the path of surface runoff, but not its destination.

2.4.1.2 Hydrosphere

The plant site is located on a peninsula on the left bank of Dardanelle Reservoir on the Arkansas River about seven river-miles upstream from the dam. The downstream side of the peninsula is formed by the flooded valley of Illinois Bayou, a left bank tributary. See Figure 2.1-2.

Dardanelle Reservoir is part of the Arkansas River navigation project. The project provides a minimum 9-foot navigation depth from the mouth of the Arkansas River at the Mississippi River to Catoosa, Oklahoma, near Tulsa, on the Verdigris River, a distance of more than 500 miles. There are 17 locks and dams in the system. Thirteen of these are simple locks and dams, providing navigation lifts of 30 feet or less. Dardanelle, Ozark, Robert S. Kerr, and Webbers Falls Dams (in order from downstream to upstream) are higher, with lifts up to 54 feet, and include some storage for hydropower generation.

Upstream from the head of navigation, there are seven large multi-purpose reservoirs. These reservoirs control the flow from about 140,000 square miles of drainage area with about 12,000,000 acre-feet of storage of which about 6,000,000 acre-feet are reserved for flood control.

Dardanelle Reservoir is 259 miles upstream from the mouth and has a drainage area of 153,703 square miles. A navigation lift of 54 feet raises shipping to the top of the power pool at Elevation 338 feet. The minimum navigation pool elevation is 336 feet, providing a normal two feet of storage in the reservoir for power generation. Power generation is on the basis of mean daily inflow equaling mean daily outflow, within the 336-338 feet limits. Total storage in the reservoir is 486,200 acre-feet at Elevation 336 feet.

2.4.2 FLOODS

2.4.2.1 Flood History

Since the minimum power pool level, 336 feet, was first reached in January 1965, the maximum level of the reservoir was 338.45 feet on June 5, 1974.

The U.S. Geological Survey has operated a gauging station on the Arkansas River at Dardanelle, two miles downstream from the dam, since July 1937. The maximum discharge at this station was 683,000 cfs in May 1943. A flood in April 1927 was somewhat lower than the 1943 flood. Another gauging station at Van Buren, 95 river-miles upstream from Dardanelle Dam, has been in operation since 1927. The drainage area at the Van Buren station is about two percent less than that at the dam. At this station, the 1943 flood, with a discharge of 850,000 cfs, was the greatest flood since at least 1833.

The gauging station at Little Rock, in operation since 1927, is about 90 river-miles downstream from Dardanelle Dam and has a drainage area about three percent larger. The 1833 flood at Little Rock was about 4.5 feet higher than that of 1943. The 1943 peak discharge at Little Rock was 536,000 cfs.

Daily streamflow records for the period January 1923 to September 1957 for the Dardanelle gauging station just below the dam, have been adjusted by the Corp of Engineers to reproduce flows as they would have been regulated by the complete system of dams upstream. The maximum regulated daily discharge during this 34-year period was 480,000 cfs. See Sections 2.4.4, 2.4.5, 2.4.6 and 2.4.7 for history of dam failures, seiches, tsunami and ice jams, respectively.

2.4.2.2 Flood Design Consideration

All safety-related plant facilities, including structures, systems and equipment, are either designed to withstand or are protected against the PMF level, as discussed in Section 3.4.1 The elevations of two different hypothetical flood conditions were analyzed.

2.4.2.2.1 Probable Maximum Flood Combined With Wind Wave Action

Security-Related Information
Text Withheld Under 10 CFR 2.390

2.4.2.2.2 Probable Maximum Flood Combined With Ozark Dam Failure

Security-Related Information
Text Withheld Under 10 CFR 2.390

2.4.2.3 Effects of Local Intense Precipitation

The 24-hour Probable Maximum Precipitation (PMP) is tabulated in Section 2.4.3.1 and was determined in accordance with procedures outlined in Reference 117. The ½-hour incremental distribution of the 6-hour PMP was obtained as per current NRC practice. Reference 11 was used to determine the intensities of storms with durations shorter than 30 minutes. They are as follows:

Duration (Min.)	Accumulated PMP (in.)
5	3.1
10	4.8
15	6.0
30	8.3
60	11.7

All safety-related equipment in Seismic Category 1 structures is protected by measures discussed in Section 3.4.4. As these structures are designed to withstand a maximum water level resulting from the PMF, and as this level exceeds that resulting from the PMP (see Section 3.4.1), a failure of yard drainage facilities to carry off the PMP would not affect operation of safety-related equipment. Drainage facilities for Seismic Category 1 structure roofs are designed to handle the effects of the local PMP without causing damage to the roof support structure. Even if drains from the Auxiliary Building roof are fouled, water ponding from a PMP event would not cause the Emergency Diesel Generators (EDGs) to become inoperable due to water ingress via the EDG room air inlet louvers.

The emergency cooling pond is excavated in natural soil; therefore, erosion is limited by the natural topography of the site. The cooling pond will continue to be functional even if this limited amount of erosion occurred during the PMF. The emergency cooling pond spillway is designed to accommodate one-half the PMP. For the PMP, the spillway and adjacent embankment are protected by providing riprap upstream and sod downstream.

Because of the usual light snowfall and the slow rate of snowmelt as compared with the contribution from high-intensity short-duration storms critical to the design of drainage systems, snowmelt contribution is considered not significant for the design of drainage systems in the Unit 2 area.

The all-season PMP has the greatest probability of occurrence in July. However, it is possible to have a seasonal PMP of lesser intensity occurring during the winter or in early spring when there is an appreciable amount of snow or ice accumulation on the roofs of safety-related structures.

The monthly snowfall records for the period of 1951-72 at Russellville, some six miles to the southeast of the ANO-2 site, were examined (References 112 and 113). Daily snowfall records as well as snow-on-ground information at Little Rock and Fort Smith for the period of 1956-72 we also reviewed (References 114 and 115). It was concluded that because of the moderate winter temperature in this area, snow or ice accumulation extending for a period of more than two weeks is a very unlikely event even during January, the coldest month of the year. The records also revealed that about 75 percent of the annual snowfall occurs in the month of January and February with about equal amounts fallen in each of these months. Due to the lack of snow-on-ground information in the site area, the monthly snowfalls recorded at Russellville

were assumed to be equivalent to the snow accumulation in the Unit 2 area at the end of the month in question. The snow accumulation frequency analysis was carried out using the maximum of the snowfall recorded in the months of January and February. For safety analysis, a 100-year snow accumulation coincide with a 48-hour PMP was used. It was found that a February PMP (27.0 inches) coincides with a snow accumulation of 1.7 inches (water equivalent) and is the most critical, yielding an equivalent 48-hour water depth of 28.7 inches. To prevent this amount of water from accumulating on the roofs of safety-related structures, in the event drains are clogged, scuppers have been provided in parapet walls at selected locations.

2.4.5 PROBABLE MAXIMUM SURGE AND SEICHE FLOODING

Dardanelle Reservoir is not of sufficient size to be affected by surge or seiche flooding.

An analysis of landslide potential has been made for the slopes adjacent to Dardanelle Reservoir between Hartman, Arkansas and Dardanelle Lock and Dam No. 10. Most of the slopes adjacent to the reservoir range from less than 1° up to 12°. These slopes are not sufficiently steep to develop landslides capable of affecting the elevation of the reservoir pool.

An arm of the reservoir connected to the main body of the reservoir by Piney Creek (upstream of the plant site) has adjacent slopes up to 65° on the eastern flanks of Bee Bluff and Perry Bluff. Potential landslides in this area are no hazard to the site, however, because Piney Creek averages only 400 feet wide and is several miles in length between the two bodies. This long, narrow connection would severely dampen any flood or surge before it reached the main body of the reservoir.

Maximum slopes up to 36° occur adjacent to the main body of the reservoir, approximately two miles upstream of Dardanelle Lock and Dam No. 10. These steeper slopes decrease to less than 6° within 500 feet from the reservoir. The velocity of any landslide developing in these slopes would be very low and would create no surge hazard to the site. It is extremely doubtful that a slide in this area could be large enough to affect the flow through the reservoir to the spillway or outlet works. In any case, there would be ample time to remove, if necessary, any slide material, before water levels upstreams would be significantly affected. The U.S. Corps of Engineers is of course obligated to insure that free flow through the reservoir is maintained.

2.4.6 PROBABLE MAXIMUM TSUNAMI FLOODING

Due to its inland location and the presence of several downstream dams, tsunamis cannot reach the site.

2.4.7 ICE FLOODING

Ice formation in this portion of the Arkansas basin is light and infrequent and will not cause flooding problems. The general climate in the area surrounding the Dardanelle Reservoir is not conducive to significant ice formation. Historically, ice formation has been so negligible that the Corps of Engineers does not maintain records of ice formation. In addition, the flow of the river during periods of freezing temperatures is sufficiently large that ice formation is not probable in the main stream. During extended periods of sub-freezing temperatures, minimal icing has been experienced along the banks of sloughs and inlets where the water is slow moving or stagnant. However, no problems with ice flooding are anticipated.

Any surface ice formation in the vicinity of the intake structure will not affect the operation of the intake structure. As shown on Figure 2.4-5, the water entrances and sluice gates from both the intake canal and the emergency cooling pond are well below water level and subsequently will not be affected by surface ice formation.

2.4.8 COOLING WATER CANALS AND RESERVOIRS

2.4.8.1 Canals

The canals which carry the reservoir water to and from Unit 1 for once-through cooling will also be used to supply cooling tower makeup water and service water from Unit 2. The intake canal conveys water from the Illinois Bayou portion of Dardanelle Reservoir to the intake structure. It is approximately 4,000 feet long and, at normal pool level of 338 feet, the width varies from 80 feet at the mouth to 135 feet at the intake structure, with an average depth of 14 feet. As can be seen in Figure 2.4-6, the intake canal deepens and widens before reaching the intake structure. This feature results in debris entrained in the lake water dropping out of suspension and collecting in this area. This prevents excessive amounts of silt from entering the service water system. The discharge canal returns the cooling water to the reservoir. It is approximately 600 feet long and has an average width of 165 feet with an average depth of 11 feet at normal pool elevation of 338 feet. Both canals are completely excavated and contain no sections formed by dikes or in fill. Bank slopes are planted with grass or protected by rip-rap to prevent erosion.

As there is virtually no runoff into the canals nor are there any stream crossings, a PMF could only occur as a result of Arkansas River runoff as discussed in previous sections. The canals would not be destroyed or seriously damaged by floods of any magnitude or by wind effects in Dardanelle Reservoir. For plans, profiles and sections of the intake and discharge canals, see Figures 2.4-6 and 2.4-7. These figures reflect the as-built condition of the canals at the end of plant construction. As a result of normal plant operation they may not reflect the current configuration.

2.4.8.2 Reservoirs

The emergency cooling pond is discussed in Section 9.2.5. The design is discussed in Section 9.2.5.1; hydrology in Section 9.2.5.2.1.1; and hydraulics in Section 9.2.5.2.1.2. For plans and sections of the pond, see Figures 2.5-21 and 9.2-10.

The only other reservoir involved is Dardanelle Reservoir. Dardanelle Dam was designed and built by the Corps of Engineers to withstand the PMF and associated wind effects.

2.4.9 CHANNEL DIVERSIONS

In the unlikely event of upstream diversion or natural damming of the Arkansas River by landslide, ice blockage, or other causes, there would be sufficient storage in Dardanelle Reservoir to permit normal plant shutdown.

2.4.10 FLOODING PROTECTION REQUIREMENTS

All safety-related facilities were designed to withstand the effects of hydrostatic pressures, buoyancy and wave action under the PMF conditions. The design bases required to assure that these structures are adequate for the design flood are discussed in Sections 2.4.2 through 2.4.4 and in Section 3.4.

The specific provisions for flood protection and their implementations are discussed in Section 3.4.4.

A comparison with the Regulatory Guide 1.59 position listed under C.2 shows that the design basis floods considered in the design meet the intent of the Regulatory Guide. A more conservative approach than that presented in Section 2.4.4 was used. A simultaneous occurrence of the PMF and an earthquake capable of failing the upstream Ozark dam was considered in developing the design flood elevation (see Section 2.4.2.2.2). Hence, the wind generated wave action was considered superimposed only on the PMF static water level (see Section 2.4.2.2.1).

Additional conservatism was gained by considering a 45 mph wind velocity in establishing the wind generated wave action in lieu of the 40 mph wind suggested in Regulatory Guide 1.59.

2.4.11 LOW WATER CONSIDERATIONS

2.4.11.1 <u>Low Flow in Rivers and Streams</u>

According to information obtained from the Little Rock District of the U.S. Army Corps of Engineers, it is possible for the inflow to the reservoir to be zero under very exceptional circumstances, but these conditions would exist for only a few hours, during which time there would be more than enough water in storage in the reservoir to supply the consumptive use of the plant.

2.4.11.2 <u>Low Water Resulting from Surges, Seiches, or Tsunamis</u>

Although Dardanelle Reservoir is not subject to surges, seiches, or tsunamis, a study was made of the effect of the probable maximum wind of 93 mph (see Section 2.3.1.3.7) on the minimum navigation pool of 336 feet. With the PMW from the west-southwest, the longest fetch is 3.2 miles. The maximum setdown at the intake in the Illinois Bayou estuary under these conditions is 0.7 foot, or a reservoir level of 335.3 feet.

2.4.11.3 <u>Historical Low Water</u>

Since initial filling to an elevation of 336 feet, the bottom of the power pool in January 1965, the minimum level of Dardanelle Reservoir was 335.88 feet in October 1967. The minimum discharge since 1937 at the USGS gauging station two miles downstream from Dardanelle Dam was 416 cfs in October 1956. The USGS gauging station on the Arkansas River at Van Buren measures the flow from about 98 percent of the drainage area above Dardanelle Dam. The minimum flow at this station since 1927 was 300 cfs in October 1956.

The 1923-57 streamflow record for Dardanelle Dam, adjusted by the Corps of Engineers to stimulate regulated conditions, had a minimum daily discharge of 400 cfs.

2.4.11.4 Future Control

Since the Dardanelle Reservoir is an essential element in the overall Arkansas River navigation project, any future upstream control can only serve to further firm up the low flows of the river rather than to reduce flows to the extent of endangering the water supply for the plant.

2.4.11.5 Plant Requirement

The descriptive information concerning the Service Water (SW) pump compartment elevation and required and available submergence for the SW pump is given in Section 9.2.1. Based on the minimum allowable water level of 335 feet in the Dardanelle Reservoir, the required submergence of eight feet, zero inches is exceeded, and therefore, the SW pump will deliver the flows shown on drawing M-2250.

Unit 2 shares the intake and discharge canals with Unit 1. The canals are discussed in Section 2.4.8.1. The discharge of the SWS is used as a makeup source for the Circulating Water System (CWS). Site water withdrawal and consumption rates for Lake Dardanelle are specified in a contract with the U.S. Army Corp of Engineers. The CWS is described in Section 10.4.5.

2.4.11.6 Heat Sink Dependability Requirements

The station can obtain the required minimum cooling water from the Dardanelle Reservoir through the canals based on the low water level of 336 feet and the extreme lower water level of 335 feet in the Reservoir. At any water level below 335 feet in the intake canal, the station cannot be assured of obtaining sufficient cooling water for continuous rated power operation. At a water level of 335 feet, the plant will be shut down and the water source shifted to the emergency cooling pond.

Three redundant level indicating switches are located in the intake structure and actuate low water level alarms in the main control room when water level drops below 335 feet in the intake structure.

The emergency cooling pond is the alternate heat sink for the Reservoir. Its design bases are discussed in Section 9.2.5.

The SWS source of water supply will be switched over to the emergency cooling pond by remote manual operation of the control switches of the intake structure sluice gates and the system discharge header valves as described in Section 9.2.1.2.3.7.

Firewater requirements, including source of water supply and the relation to the heat sinks, are described in Section 9.5.1.

2.4.12 ENVIRONMENTAL ACCEPTANCE OF EFFLUENTS

The hydrologic features of the site and site area, together with related plant design features, enable the environment to accept normal, inadvertent or accidental releases of radioactive liquid effluents without undue risk to the general public. The locations and users of surface and groundwater are given in Sections 2.4.1.2 and 2.4.13.2. Section 2.4.13 describes the groundwater conditions in the vicinity of the site and describes the ability of the groundwater to withstand the effects of accidental spills of radiation liquids.

The design bases for those systems which release radioactive nuclides to the environment are described in Chapter 11. The liquid radwaste systems are described in Section 11.2; gaseous radwaste systems in Section 11.3; and solid radwaste systems in Section 11.5. These systems are enclosed in the Seismic Category 1 auxiliary building and the bulk of the liquids are stored below the finish plant grade. The gaseous radwastes are stored below grade in the Category 1 auxiliary building.

In the event an accidental spill of liquids containing radioactive material occurs in the plant, all of the liquids will be contained in the Category 1 auxiliary building. If the spill of liquid is directly to the ground, groundwater contamination is extremely unlikely due to the impervious nature of the soil in the area of the plant.

Section 11.2.9 describes the normal release of plant liquid effluents for potential exposure pathways.

Section 9.2.5 describes the ultimate heat sink and its design bases. During normal shutdown and accident conditions, the Dardanelle Reservoir is the primary heat sink. As described in Section 10.4.5, the bulk of normal plant cooling is supplied by the closed loop CWS. Meteorological effects of the natural draft cooling tower are discussed in Section 2.3. The Service Water System (SWS) is described in Section 9.2.1. Heat loads are small in relation to Unit 1. Historically, the environmental impact of Unit 1 was analyzed in the Unit 1 Environmental Report (Docket Number 50-313). Thermal and chemical pollution to Dardanelle Reservoir is regulated by the Arkansas Department of Environmental Quality. Authorization to discharge is addressed in the approved site NPDES permit.

2.4.13 GROUNDWATER

Investigation of regional and local conditions indicates that the nuclear plant and appurtenant facilities will have no adverse effects on groundwater resources in the vicinity of the site. If an accidental radioactive spill occurs, it would not affect off-site groundwater supplies.

2.4.13.1 <u>Description and Onsite Use</u>

The principal groundwater resources in the vicinity of the site are in fractured indurated rocks of Paleozoic age and in alluvial sands and gravel along parts of the Arkansas River. The alluvial sands and gravels are not present at the site. The indurated rocks are poor aquifers. Groundwater is not a source of water for plant construction or operation.

2.4.13.1.1 Regional Groundwater Conditions

The site is in the Arkansas Valley section of the South-Central Paleozoic Groundwater Province defined by Meinzer (1923). Conditions in this province are generally unsatisfactory for developing good water wells because of the low permeabilities of the rocks. The principal source of groundwater are sandstones and limestones of Paleozoic age which are widespread in the region. Groundwater in these rocks is meager or of poor quality in much of the province. Good supplies are available from glacial or alluvial deposits, but they are restricted to valleys adjacent to major streams. The principal bedrock aquifer of the Arkansas Valley section is the Atoka Formation of Pennsylvanian age. The most productive wells in the Atoka Formation are in fractured shale rather than the sandstone (McGuinness, 1963). The Atoka Formation crops out two miles north, four miles east, and four miles south of the site and is over 600 feet below land surface at the site. The site is separated from the Atoka Formation by clay as well as by the relatively impermeable shales and sandstones of the McAlester Formation and the Hartshorne sandstone.

The most consistently productive aquifer in the region is the alluvium along the Arkansas River (Bedinger and other, 1963). The alluvial deposits are not present at the site; the nearest exposure of alluvium is about four miles southeast of the site, below Dardanelle Dam.

The quality of groundwater in the region is generally good. However, nearly all of the water is hard and some of it contains excessive iron (McGuinness, 1963).

2.4.13.1.2 Groundwater Conditions at the Site

The site is on a peninsula along the northern shore of Dardanelle Reservoir. The peninsula is about two miles long and about two miles wide at the widest point. The land surface at the site is relatively flat at about an elevation of 353 feet, which is 15 feet higher than normal pool elevation of 338. The tops of several hills on the peninsula range from an elevation of 460 to an elevation of 500 feet.

The site is underlain by unconsolidated clay and silty clay deposits that mantle dense indurated rocks. The thickness of the clay ranges from about eight to 30 feet in the vicinity of the site. The clay is nearly impermeable. The uppermost bedrock unit is the McAlester Formation of Pennsylvanian age. The McAlester Formation at the site includes shale and sandstone, which is exposed on the hills near the site. The porosity of the McAlester Formation is very low. The uppermost few feet of bedrock at the site is slightly more permeable than most of the shale and sandstone sequence, but this zone is relatively impermeable. Limited quantities of groundwater can be pumped from fractures and joints in the McAlester formation.

Groundwater at the site is derived from precipitation on the adjacent hills. The water infiltrates the surface and percolates through fractures in the bedrock toward Dardanelle Reservoir, as shown by water levels in Figures 2.4-1 and 2.4-2. Groundwater in the bedrock at the site is confined by the clay mantle.

The emergency cooling pond, located about 1,200 feet northwest of the plant site, is about 500 feet east of an embayment in Dardanelle Reservoir. Design of the pond is based on the consideration that seepage will build a groundwater mound to the height of water level in the pond at an elevation of 347 feet. However, the impermeable nature of the foundation material at the cooling pond indicates the amount of water lost by seepage will be negligible. Any seepage to the northeast, north or northwest will be intercepted by a drainage pipe underlying

the clay blanket before it could infiltrate the shale bedrock. The drainage pipe will divert the seepage into the spillway and consequently westward into Dardanelle Reservoir. To the south and southwest the pond is excavated in impermeable clay. Any seepage not being intercepted by the drainage pipe will migrate southwestward toward Dardanelle Reservoir. This is the shortest path with the steepest gradient. Even with a maximum groundwater level at the pond pool elevation of 347 feet, the potential for groundwater to move southeastward toward the plant is precluded by the longer flow path and the much smaller gradient. A conservatively high value for seepage has been calculated and is included in Section 2.5.5.2.2. This number is so small as to be negligible for ECP thermal performance calculations; however, it is included in the current ECP post-accident inventory analysis (section 9.2.5.3).

2.4.13.1.3 Onsite Use of Groundwater

Groundwater does not supply any of the water required for construction or operation of Arkansas Nuclear One. The soil and rocks at and adjacent to the site are incapable of supplying a significant quantity of groundwater for plant requirements.

2.4.13.2 Sources

Most of the groundwater developed in the vicinity of the site is utilized for rural domestic use. Groundwater discharges into Dardanelle Reservoir about one-half mile southwest of the site. Groundwater is not utilized between the site and the groundwater discharge area.

2.4.13.2.1 Regional Use of Groundwater

Estimated groundwater used during 1970 in the four counties of Arkansas that are within 15 miles of the site was about 9.6 million gallons per day (Halberg, 1972). Groundwater use by county and by use are presented on Table 2.4-2. Wells capable of yielding more than 10 gpm are nearly all extracting water from sands and gravels of the alluvium along the Arkansas River and its larger tributaries. Small wells that provide rural domestic and livestock supplies are distributed throughout the area.

The largest groundwater users within the four counties are the municipalities of Atkins, 16 miles southeast of the site, and Dardanelle, six miles southeast of the site. Other municipal groundwater users along the Arkansas River between Little Rock and Fort Smith are Morrilton, about 30 miles southeast and Ozark, about 30 miles northwest of the site (Bedinger, et al., 1963).

2.4.13.2.2 Use of Groundwater in the Vicinity of the Site

The only use of groundwater in the vicinity of the site is for local domestic purposes. Good groundwater bearing zones are not present in the overburden material at or near the site. Limited supplies are pumped from joint systems in the shale and sandstone bedrock aquifers. Most wells are less than 150 feet in depth. These wells are capable of only relatively low yields and a "good" well may produce up to 50 gpm.

Wells within a 3-mile radius of the site were canvassed in September 1971. Two hundred and eighty-four wells were located in the canvas. Total production from these wells is estimated to be about 100,000 gallons per day. A summary of well data is presented in Table 2.4-3. The area canvassed is shown on Figure 2.4-3. In June 1974 an updated canvass was made of wells in the immediate vicinity of the site west, east, and south between the site and the reservoir as shown in Figure 2.4-4. Data from these wells is given in Table 2.4-5. Location with respect to piezometric gradient relative to the site may be judged from Figures 2.4-1 and 2.4-2.

2.4.13.2.3 Projected Future Use of Groundwater

Future groundwater development in the site vicinity is expected to be small. The low permeability of the aquifer precludes the possibility of developing wells with sufficient production for irrigation or industry. Therefore, future groundwater development in the area will continue to be primarily for rural domestic and livestock use. The location of any future wells drilled near the plant site will be limited because of the property on which the plant is built occupies most of the peninsula. An increase in groundwater use in other areas in the vicinity will be at about the same rate as the increase in rural population. The rural population in the area is not expected to increase significantly during the next several decades.

2.4.13.2.4 Water Levels and Groundwater Movement

The water table generally conforms to the topography in the vicinity of the site. Figure 2.4-1 shows the water levels in wells within one and one-half miles of the site.

At the site, the water table slopes about 24 feet per mile southwestward toward Dardanelle Reservoir as shown on Figure 2.4-2.

2.4.13.2.5 Reversibility of Groundwater Flow

The existing southwestward direction of flow at the site could be reversed only by sustained pumping between the site and the hills approximately one mile to the north and east. The region cannot be significantly affected by future development.

2.4.13.2.6 Water Quality

Samples of group water, of Dardanelle Reservoir water and of Arkansas River water from downstream of the dam (located about nine miles southeast of the site) were chemically analyzed. Table 2.4-4 presents the results of the analyses. Locations of sampling points, except No. 13, are shown on Figure 2.4-1. Sampling point No. 13 is from the Arkansas River below Dardanelle Dam and is beyond the area shown on Figure 2.4-1.

Portions of the above mentioned surface water samples were analyzed by Tracerlab of Richmond, California for gross beta analyses. Values varied from 18.0 to 27.9 picocuries per liter, indicating normal surface water background radioactivity.

Surface water samples had an average pH value of 7.4 and average total dissolved solids of 432 ppm (parts per million). The groundwater from the sampled wells, all from the bedrock confined system, ranges in quality from slightly acidic to alkaline, from a high bicarbonate content of 444 ppm to a low of 5 ppm, and from a high total dissolved solids content of 1,559 ppm to a low of 34 ppm. Total hardness ranges between 830 and 4 ppm.

A preliminary evaluation of the quality of the sampled wells indicates that a zone extending between water wells No. 6 and 3, north and east of the plant site, produces the best quality water. The average total dissolved solids of the samples from this zone is 245 ppm (excluding the low 34 ppm analysis). However, two wells within this zone have some undesirable constituents. Well No. 2 has an iron (Fe) content of 1.3 ppm which is above the U.S. Public Health Service recommended maximum of 0.3 ppm. Wells No. 4 and 5 have manganese (Mn) contents of 0.3 and 4.0 ppm which are above the recommended drinking water maximum of 0.05 ppm. Also it should noted that wells No. 8 and 9, located about 2,500 feet west of the site area, are undesirable either due to nitrate (NO_3) or due to amount of total dissolved solids.

The two wells sampled in the vicinity of the site (No. 1 and 7) produce alkaline bicarbonate water with total dissolved solids of 773 and 635, respectively, as compared with the recommended maximum of 500 ppm. In all other respects this water is chemically satisfactory for human consumption.

2.4.13.3 Accident Effects

Operating a nuclear plant at this site will not jeopardize the groundwater resources of the site or the region even if radioactive liquids were accidentally spilled at the site. The site area is covered with eight to 30 feet of compact clayey soil which is essentially impermeable to the flow of water downward to the bedrock fracture system.

In the unlikely event that radioactive material percolated through the nearly impermeable clay that underlines the site, the contaminated water would flow slowly southwestward toward Dardanelle Reservoir. The bedrock is characterized by low permeability as indicated by low yields to wells; therefore, groundwater velocity through these rocks is low. Arkansas Power and Light Company property extends nearly to the reservoir shore and the only wells that lie along possible groundwater flow lines are the site groundwater monitoring wells, which have an above grade surface completion that prevents any surface drainage from entering the well. Groundwater development, for reasons presented in Section 2.4.13.2.3, is not expected to change the flow pattern. It is concluded that groundwater resources will not be jeopardized in the future by the plant.

2.4.13.4 Monitoring and Safeguard Requirements

Groundwater monitoring is not needed during plant operation to protect regional or local groundwater systems.

2.4.13.5 Design Bases for Subsurface Hydrostatic Loadings

Text Withheld Under 10 CFR 2.390

2.4.14 TECHNICAL SPECIFICATION AND EMERGENCY OPERATION REQUIREMENTS

Arkansas Nuclear One - Unit 2 has been designed such that no credible hydrological event can affect its ability to achieve and maintain a safe shutdown condition.

As discussed in Section 9.2.5, the emergency cooling pond is designed to provide sufficient heat dissipation capability to enable simultaneous safe shutdown of both Units 1 and 2 in the event of a loss of Dardanelle Reservoir inventory due to dam failure.

Procedures adopted at Arkansas Nuclear One require initiation of shutdown of both units with the necessary lead time to achieve safe shutdown before the flood level reaches an elevation of 354 feet, the elevation at which turbine building flooding would begin.

As outlined in Section 8.2, it will be necessary to install temporary connections over the 161 kV switchyard to connect Startup Transformer 2 directly to the 161 kV Pleasant Hill transmission line in the event that the flood level exceeds elevation 356 feet, six inches so as to maintain one source of off-site power to the plant. Since the plant will be shut down before the flood reaches an elevation of 354 feet, these temporary connections are not necessary to safely shut down the plant.

Security-Related Information
Text Withheld Under 10 CFR 2.390

As discussed in Chapter 3, flood levels approaching an elevation of 354 feet would be an extremely unusual occurrence and, based upon historical data would take from two days to several weeks to develop. This would allow more than sufficient lead time for the emergency procedures outlined above to be performed.

Since flood levels necessitating plant shutdown are extremely unlikely, this situation will be covered by the abnormal operating procedures for natural emergencies rather than by Technical Specifications.

2.5 GEOLOGY AND SEISMOLOGY

In accordance with the criteria provided in Appendix A, "Seismic and Geologic Siting Criteria for Nuclear Power Plants," of 10 CFR 100, and the NRC Standard Format, this section describes and evaluates the geologic and seismologic conditions for the region around the Arkansas Nuclear One plant site. Foundation conditions for Unit 2 are evaluated, and the foundation design is described. The seismic history of the region is examined and suitable criteria for seismic design are developed. Field and laboratory test data which provide the basis for the engineering analyses and conclusions presented in this report are summarized on Tables 2.5-1 through 2.5-7.

The purpose of this section is to present the results of the evaluation of regional and site geology. That evaluation was made in sufficient detail to ensure the safe design of the nuclear power facility. Results of the literature study, field studies, foundation exploration, and laboratory test programs are presented. Static and dynamic properties of the foundation materials are described, and design criteria are outlined. Groundwater factors affecting plant construction and operation are discussed. (Groundwater conditions are presented in detail in Section 2.4.13).

The site is located in Pope County, Arkansas, about six miles northwest from Russellville. It is about one and one-quarter miles south of Interstate 40 and two miles from the small town of London. The plant is situated on a peninsula formed by the Corps of Engineers' Dardanelle Reservoir.

The site is underlain by eight to 30 feet of stiff clay which overlies essentially horizontally bedded shale with interbedded sandstone and siltstone of Pennsylvanian age. The rock surface has low relief and slopes gently to the southwest. No evidence of faulting at the site was found during the investigation program. Laboratory testing of numerous rock samples show that the rock has a bearing capacity well above the maximum loads to be imposed by the structures.

A search of published and unpublished literature was made to determine geologic history, stratigraphy and structure of the region around the site. State and federal agencies were contacted to obtain and examine pertinent documents and to discuss geologic and groundwater conditions of the site and region. A list of references is provided at the end of this section.

The scope of investigations was to define site foundation conditions and regional and site geologic, geohydrologic, and seismological conditions. The purpose of the investigation was to determine the characteristics of the foundation materials, especially in regard to their suitability for supporting the structures, to determine the depth and configuration of the groundwater table, to determine the characteristics of the soil and rock materials with respect to their effect on the migration of radioactive solutions should such solutions come in contact with them, and to evaluate the seismicity of the area so that appropriate parameters for seismic design could be selected. Consultants in geology and seismology were retained to evaluate independently the results of the geologic and seismologic investigations.

A geophysical survey was performed by Boyles Bros. Drilling Co., of Auburn, California, to measure P-wave velocities and to calculate the dynamic modulus of elasticity of the foundation rock. Drilling and sampling was done by Grubbs Consulting Engineers, Inc., of Little Rock, Arkansas, under the direction of Bechtel Corporation. Soil tests were designated by Bechtel Corporation and done by Grubbs Engineers, Inc. Selected rock core samples from the drill holes were tested by Bechtel Corporation in their laboratory in San Francisco.

As a result of the investigations performed, it is concluded that geologic, seismologic, and foundation conditions at the Arkansas Nuclear One site are adequate in all respects for a nuclear power plant.

2.5.1 BASIC GEOLOGIC AND SEISMIC DATA

2.5.1.1 Regional Geology

The region around the plant site is underlain by a synclinorium called the Arkansas Valley. The uppermost bedrock unit in the site area is the McAlester formation of Pennsylvanian age. It consists of black, dense, horizontally bedded shale and interbedded sandstone and shale. Some faulting has occurred in the region, but the faults are related to the folding and all are pre-Cretaceous in age.

2.5.1.1.1 Regional Physiography

The site is situated in the center of the Arkansas Valley section of the Ouachita province (see Figure 2.5-1). The Arkansas Valley is a gently undulating east-west trending plain or lowland 25 to 35 miles wide that extends from near Searcy westward beyond Fort Smith. Many long, sharp ridges and several broad-topped hills rise above the general level of the valley. In most parts of the valley the topography is an expression of the east-west trending structure. Broad, open synclines are expressed by high, flat-topped mountains; steeply tilted limbs of anticlines and synclines are generally expressed by sharp ridges, some of which are miles long.

2.5.1.1.2 Regional Geologic History

The Arkansas Valley is essentially a Paleozoic basin which had its most significant development during the Mississippian and Pennsylvanian. The greatest accumulations occurred during the Lower (Morrowan) and Lower Middle (Atokan) Pennsylvanian. Deformation of the Ouachitas occurred during Mid-Pennsylvanian time (Croneis, 1930). During this time, the Ouachitas were strongly folded, with some thrust faulting, especially in Oklahoma. The Arkansas Valley section lies between the essentially flat-lying rocks of the Boston Mountains on the north and complexly folded strata of the Ouachita Mountains on the south. Its structure, therefore, has some of the characteristics of both its bounding regions, but is generally a region of broad, gentle folds which trend east-west and are only moderately faulted. Faulting is related to the folding and is pre-Cretaceous in age (see Section 2.5.1.1.3).

Since Cretaceous (and probably late Paleozoic) time, erosion has been the primary agent in the development of land forms in the region. No sediments younger than Pennsylvanian are found in the region, except for Quaternary terrace and alluvial deposits along the stream valleys (Figure 2.5-2). In a few places, intrusive rocks, mapped by Croneis (1930) as mid-Cretaceous cut the Paleozoic sediments. In the Arkansas Valley, these rocks consist of scattered dikes and sills of varying composition. None occur at the plant site.

2.5.1.1.3 Regional Geologic Structure

The Arkansas Valley section is a trough both structurally and topographically. Near the northern border of the Arkansas Valley the faulting is normal, the folds are gentle, and most of the dips south of the anticlinal crests are steeper than those north of them. Near the southern border of the province thrust faulting is common, the folds are pronounced, and the dips north of the axes of the anticlines are steeper than those south of them. The true intermediate structural

character of the central part of the Arkansas Valley is shown by the occurrence of both normal and thrust faults in close proximity, by the increase in the number of symmetrical folds, and by the character of the folding itself which is intermediate between the close folding on the south and the gently open folding on the north. The Arkansas Valley section, unlike the Ouachita section, has been folded down to form a synclinorium (Figure 2.5-3).

The nature of the structural features of the Arkansas Valley and their relation to the structure of the adjacent Ouachita and Boston Mountains show that the dominant force in the production of those features was horizontal pressure exerted from the south. The folding and thrust faulting developed in post-Paleozoic, pre-Cretaceous time due to the subsidence of a land mass to the south (Croneis, 1930). The normal faults were also connected with this episode of deformation and are believed to have formed either contemporaneously with folding, or as a result of tension developed after the period of folding (Croneis, 1930 and Hendricks, 1950). Some normal faults are also believed to have formed during deposition and subsidence of the Pennsylvanian sediments. In the Arkansas Valley the southward-dipping faults terminate against northward dipping normal faults (Haley, 1968). The folds and faults of the Arkansas Valley cannot be precisely dated (Caplan, 1957), but it is known that they are very old geologic structures and probably were formed before Cretaceous time (Croneis, 1930).

East-west trending folds are mapped in the area of the site (Figure 2.5-2). From about three miles north to three miles south of the site there are two anticlines and one syncline (Figure 2.5-4). From north to south these structures are as follows: London anticline, Scranton syncline, and the Prairie View anticline. The plant site is located on the Scranton syncline in which the maximum dip rarely exceeds 10 degrees, except locally where contorted beds may dip as steeply as 20 degrees.

The London anticline extends from about four and one-half miles northwest of the town of London, east to about three miles northwest of the site. This anticline may continue east to connect with the anticline mapped about three miles northeast of the site (Figure 2.5-2). The south limb of the London anticline is steeper than the north limb (Merewether and Haley, 1961).

The Scranton syncline, also known as the Ouita syncline, extends from northeast of Russellville, westward to a point about five miles northwest of Scranton, where it is presumably terminated by the Dublin fault (Haley, 1968). On the western part of the Scranton syncline the south limb is steeper than the north limb. However, on the eastern portion of the syncline the north limb is steeper than the south limb (Merewether and Haley, 1961).

The Prairie View anticline is mapped from a point three miles southwest of the town of Scranton, east to at least as far as Russellville. This nearly symmetrical anticline is broken by northward-dipping normal faults (Haley, 1968).

There are a number of inactive faults mapped in the vicinity of the Arkansas River, particularly to the northwest and west of the site. These are primarily east-west-trending faults. Of these, the London and Prairie View faults are the closest to the site (Figure 2.5-4). The London fault and accompanying unnamed small branch fault trend east-west about four miles north of the site. A small fault which branches from the unnamed fault lies about two and one-half miles northeast of the site. The London fault is a high-angle south-dipping normal fault. It is best exposed about eight miles northwest of the site at Big Piney Creek where the eastern part of the fault ends. At this locality, the fault plane dips 58 degrees south and has an apparent displacement of about 20 feet. The fault is also exposed to the east along Flat Rock Creek and in a drainage ditch along a country road about eight miles from the site. An unnamed east-west-trending fault

lies about one mile south of the London fault. The trend of this unnamed fault changes toward the east to generally southeast. It intersects the London fault in the vicinity of the north fork of Mill Creek (Haley, 1961).

The Prairie View fault is exposed about 12 miles west of the site, and has been projected to within six miles of the site by Merewether and Haley (1961). The Prairie View fault extends to the west as far as three miles northwest of the town of Subiaco. It is an east-west-trending high angle normal fault with the north side downthrown. The maximum displacement along the fault is 350 feet, and occurs about two miles west of the town of Prairie View (Haley, 1968). The fault plane dips 65 degrees northward at the western end and has a displacement of about 170 feet.

Both the London and Prairie View faults, and other similar east-west-trending faults in the Arkansas Valley are associated with the folding which occurred between late Paleozoic and Cretaceous time. These faults have formed either contemporaneously with folding, or as a result of tension developed after the folding (Croneis, 1930 and Hendricks, 1950). Some normal faulting also occurred during deposition and subsidence of the Pennsylvanian sediments.

In summary, the only faults within five miles of the site are the Prairie View fault, and the London fault and its branch faults. The closest fault is only a small branch fault and approaches within about two and one-half miles of the site. The last movement of these faults occurred prior to Cretaceous time, or over 135 million years ago.

2.5.1.1.4 <u>Regional Stratigraphy</u>

The Arkansas Valley lies within the area of outcrop of Paleozoic rocks which occupy essentially the northwestern half of the state. The rocks of the Arkansas Valley are nearly all of sedimentary origin; they include only a few bodies of igneous rock (Figure 2.5-2). The beds in the valley consist chiefly of non-fossilferous shale and sandstone, and little calcareous material is present.

Mississippian and older rocks occur at depths in excess of 7,000 feet at the site, and are therefore not treated in detail. They consist primarily of sandstone and shale with some thin limestone horizons.

The Pennsylvanian sequence is divided into three main groups in this area. They are the Morrow series of the Lower Pennsylvanian, and the Atoke and Des Moines series of the Middle Pennsylvanian (Figure 2.5-5). The Morrow series consists of the Hale formation and the overlying Bloyd shale. The Hale formation is further divided into the Cane Hill and Prairie Grove members. The Gulf Oil Corp., No. 1 W.H. Tackett well (about six miles from the site) terminated in the Cane Hill at a depth of 7,525 feet after penetrating 129 feet of the Cane Hill. That part of the Cane Hill penetrated consisted of shale, very finely sandy siltstone, and well cemented, very silty, very fine-grained sandstone. The Prairie Grove member of the Cane Hill formation and the Bloyd shale are very similar, and consist of shale, slightly silty to silty shale, siltstone, very fine to coarse grained sandstone and limy sandstone, and very fine to medium grained sandy fossiliferous limestone (Merewether and Haley, 1961).

The Atoka series is represented in Arkansas by the Atoka formation, which rests unconformably on the rocks of the Morrow series. The Atoka formation consists of dark gray to grayish black shale, dark gray slightly silty to very silty shale, medium to dark gray siltstone, light to dark gray very fine grained sandy siltstone, light to medium gray slightly silty to very silty very fine-grained sandstone, some light to medium gray slightly limy to limy fine to medium grained sandstone,

and, in the upper part, a few coal beds and one zone containing thin beds of very silty limestone (Merewether and Haley, 1961). The Atoka formation is from 6,700 to about 7,800 feet thick in the region around the site.

The Des Moines series is represented in this region by rocks of the Krebs Group; the Hartshorne sandstone, the McAlester formation, and the Savannah formation. The Savannah formation is absent over most of the area, and is not present at the site. The Hartshorne sandstone rests unconformably on the Atoka sequence and was defined by Hendricks and Parks (1950) as the first continuous sandstone underlying the lower Hartshorne coal bed. In general, the Hartshorne is grayish white to light gray, very fine to medium grained, slightly silty sandstone. Its thickness ranges from 80 to about 160 feet in the project area.

The McAlester formation conformably overlies the Hartshorne sandstone, and is the uppermost bedrock unit in the site area. The McAlester is up to 800 feet thick in this area and consists of shale, silty shale, siltstone, silty very fine grained sandstone, and three or more coal beds (Merewether and Haley, 1961). At the site the McAlester formation is about 160 feet thick and contains no coal horizons. The Savannah formation overlies the McAlester formation but does not occur at the site. It consists of 18 feet of siltstone and silty very fine grained sandstone where observed in the area.

Terrace deposits and alluvium of Quaternary age occur along the Arkansas River valley and the valleys of major tributaries. At least two terrace levels exist along the Arkansas River, with the highest about 50 feet above river level. Alluvium along the Arkansas River and most of the major tributaries is largely covered by the waters of the Dardanelle Reservoir. Soil at the site consists of from eight to 30 feet of clay and silty clay.

2.5.1.1.5 <u>Tectonic Structures</u>

The site is located on the axis of the Scranton-Ouita syncline in the Arkansas Valley synclinorium (Figure 2.5-4). The synclinorium lies between the essentially flat-lying rocks of the Boston Mountains on the north and the complexly folded strata of the Ouachita Mountains to the south. Its structure, therefore, has some of the characteristics of both its bounding regions, but is generally a region of broad, gentle folds which trend east-west and are only moderately faulted (Figure 2.5-6). Faulting is related to the folding and is pre-Cretaceous in age.

The folds in the vicinity of the site trend generally east-west. Dips along the flanks are rarely in excess of 15 degrees, and usually less than 10 degrees. A detailed description of the folds and faults in the area around the site is presented in Section 2.5.1.1.3, Geologic Structure. Sections 2.5.2.2 and 2.5.4.1 also discuss regional geologic and tectonic structure.

2.5.1.1.6 <u>Potential Subsidence, Collapse, or Uplift</u>

The rocks in the region around the site are primarily well indurated sandstone and shale with only thin limestone beds, to a depth of at least 7,000 feet. No natural cavernous or karstic terrain exists in the region. The carbonate rocks are buried at great depth and are not subject to solutioning. Thin coal seams occur in the area, but do not occur beneath the site. No mining has occurred in the subsurface within three miles of the site. Oil extraction does not occur in the Arkansas Valley. Natural gas production occurs in the area, but production is from well indurated rocks and subsidence is not a problem. A crustal movement map showing probable vertical movements of the earth's surface was issued by the U.S. Commerce Department in August, 1972. The map does not show any movement within 150 miles of the site; however, it

states that the blank areas simply mean that there is not enough data to determine if they are being uplifted or subsiding. On the same map, the area of indicated movement closest to the site shows only slight regional uplift (1 - 5 mm per year).

The site is located on a gently rolling plain adjacent to the Dardanelle Reservoir. Natural slopes in the vicinity of the site are gentle and no high ridges occur within at least two miles of the site. Potential landslides are not a problem at the plant site. Additional data on stability of subsurface materials is presented in Section 2.5.4.

2.5.1.1.7 Regional Groundwater Conditions

The site is in the Arkansas Valley section of the South-Central Paleozoic Groundwater Province defined by Meinzer (1923). Conditions in this province are generally unsatisfactory for developing good water wells because of the low permeabilities of the rocks. The principal sources of groundwater in the region are sandstones and limestones of Paleozoic age. Although groundwater in these rocks is usually meager or of poor quality, many wells produce small quantities for domestic and farm use. Some large supplies are available from glacial or alluvial deposits, but they are restricted to major stream valleys.

The principal bedrock aquifer of the region is fractured shale of the Atoka Formation. Neither the alluvial deposits, nor the Atoka Formation is available at the site for groundwater. Regional groundwater conditions are more fully described in Section 2.4.13.

2.5.1.2 Site Geology

The site is about six miles northwest from Russellville, and about two miles from the small town of London. The plant is situated on a peninsula formed by the Corps of Engineers' Dardanelle Reservoir. As shown on Figure 2.5-7, a subsurface investigation program, including soil and rock borings, observation wells, and a geophysical survey, was completed at the site to obtain data on geologic, soil, and foundation conditions. Results of the drill holes are summarized in Table 2.5-1, and graphic logs of holes are presented in Figures 2.5-8 through 2.5-12. Samples of soil and rock materials were tested in the laboratory to determine their static and dynamic properties. The results of the testing program are presented in Section 2.5.1.2.5.1.

2.5.1.2.1 Site Physiography

The plant is located on a broad, nearly flat bench adjacent to the floodplain of the Arkansas River. This bench is at about Elevation 353 feet, at the lower of the two Pleistocene terrace levels described by Merewether and Haley (1961). Soil on the terrace consists of clay and silty clay, and is from eight to 30 feet thick at the site. The broad floodplain of the Arkansas River is now covered with the waters of the Dardanelle Reservoir in the vicinity of the site. The low hills adjacent to the site (Figure 2.5-13) are formed by the gently upturned strata along the flanks of the Scranton-Ouita syncline. Relief within the limits of the site area is less than 10 feet.

2.5.1.2.2 Site Stratigraphy

The regional stratigraphy is presented in Section 2.5.1.1.4 and shown on the geologic column, Figure 2.5-5. Rocks of the Hartshorne formation of Des Moinesian age (upper mid-Pennsylvanian) were penetrated by the drill holes, which reached a maximum depth of 165 feet in hole 201. Rock at the site probably represents the lower 70 to 80 percent of the McAlester formation since coal beds occur in the upper part of the formation and none were encountered

at the site. Rock penetrated from depth 159.5 to 165 feet in Hole 201 consisted of gray, dense, fine grained, well cemented, horizontally bedded sandstone. Above this sandstone horizon, a zone of shale with thin sandstone interbeds was penetrated. This zone, approximately 60 feet thick, is primarily light to dark gray, hard shale with minor sandstone interbeds. The uppermost bedrock unit at the site consists of 70 to 90 feet of hard black shale. The upper four to eight feet of bedrock is weathered to a soft gray shale which grades to hard, tan clay at the top.

Soils at the site consist of eight to 30 feet of tan clay and silty clay. Some of this material was deposited by the Arkansas River as alluvium and has since been isolated by further downcutting of the river channel.

2.5.1.2.3 Structural Geology of the Site

The site is located directly over the axis of the gently folded Scranton-Ouita syncline. Rock core recovered during exploration, and site foundation inspection during construction show bedding to be horizontal or dipping gently at the site. The axis of the syncline trends generally east-west, and the rock rises along the flanks of the structure at angles of from four to 15 degrees. The rock is only moderately jointed, with joints inclined from 40 degrees to vertical but predominantly from 50 degrees to 70 degrees. The bedrock surface has low relief and slopes gently to the southwest (Figure 2.5-14). The structural geology of the region around the site is presented in Section 2.5.1.1.3.

2.5.1.2.4 Geologic History of the Site

The geologic history of the region is presented in Section 2.5.1.1.2 and summarized here. The site is in the Arkansas Valley, a Paleozoic basin which had its greatest development in Mississippian and Pennsylvanian time. During late Paleozoic, probably mid-Pennsylvanian, the sediments in the basin were folded and faulted. In the vicinity of the site, both folding and faulting were moderate. Dips of from five to 15 degrees are common on the flanks of the folds. Faulting and significant structural warping occurred in the area before the Cretaceous (Croneis, 1930). Erosion has probably been continuous in the area since the Cretaceous, and no deposits younger than mid-Pennsylvanian are encountered near the site, except for Pleistocene terrace deposits and recent alluvium along the Arkansas River and its major tributaries. The site is located on a terrace of the Arkansas River, adjacent to the Corps of Engineers' Dardanelle Reservoir.

2.5.1.2.5 Site Geologic and Foundation Conditions

The site is underlain by eight to 30 feet of moderate to stiff, plastic, red and tan clay with occasional zones of silty clay, which overlies black, dense, horizontally bedded shale and interbedded shale and sandstone of the McAlester formation. The rock is only moderately jointed with the joints varying in dip from 40 degrees to vertical, but dipping predominantly between 50 degrees and 70 degrees. The joints are tight and essentially impervious. Drill water was lost only at the weathered shale contact, and in all holes the return was nearly 100 percent while coring in shale; indicating few joints and tight, dense rock. Fresh shale cores showed a tendency to part along bedding planes and to expand slightly upon removal and exposure to air. The data from 93 drill holes indicates the bedrock surface has low relief and slopes gently to the southwest (Figure 2.5-14).

The deepest hole, DH-201, penetrated interbedded shale and sandstone at a depth of 97.0 feet and dense fine-grained sandstone at 159.5 feet (Figure 2.5-15). This sandstone was also found in DH-1 at 149.0 feet and crops out near lake level 3,200 feet east of the site. No evidence of faulting or offset of any of the beds was found during these investigations. The nearest mapped fault is two and one-half miles northeast of the site.

Overlying the unweathered shale is four to eight feet of highly weathered shale which grades downward from hard stratified tan clay to very soft, light gray weathered shale. Standard penetration tests in the top of this zone typically required 50 or more blows to penetrate one foot.

During excavation of the foundation for Unit 2 at the Arkansas Nuclear One site, the specifications required that after foundation grade was reached, all rock surfaces would be cleaned and coated with gunite within 24 hours after their exposure. This procedure was followed to prevent slaking of the shale during construction. The rock exposed was dense shale, silty shale and siltstone and no zones with undesirable or unstable mineralogy were encountered. These provisions were successful.

2.5.1.2.5.1 <u>Physical Properties of Site Materials</u>

All Category 1 structures except the Emergency Cooling Pond (ECP) inlet and outlet structures, electrical manholes and the Condensate Storage Tank T41B pipe trenches are founded on competent unweathered bedrock of the McAlester Formation of Pennsylvanian age. The bedrock consists primarily of hard dark gray shale with some thin sandstone and siltstone interbeds. Samples of rock core from the exploratory drilling were tested in the Bechtel Geologic Laboratory in San Francisco. Standard test procedures were followed. The results of these tests are shown in Table 2.5-1. The lowest and highest unconfined compressive strength of the 45 samples tested are 2,420 psi (167 TSF) and 4,690 psi (338 TSF). The average is 3,460 psi or 249 TSF.

Testing showed the specific gravity of the rock to be in the range of 2.51 to 2.67 with about 2.57 the average. Porosity varies from 2.0 percent to 7.81 percent with 5.9 percent about the average. Absorption ranges from 1.13 percent to 3.1 percent with an average of around 2.4 percent. The site seismic survey indicated P-wave velocities in the fresh rock to be from 10,000 to 14,500 fps indicating dense, competent rock. Results of this survey are shown on Figure 2.5-16. S-wave velocities were not measured in situ since the structures are founded on rock, but a value of 5,350 fps was calculated using a P-wave velocity of 10,000 fps and a Poisson's ratio of 0.30. The dynamic modulus of elasticity ranges from 2.8 (+6) psi to over 5 (+6) psi (See Section 1.7 for an explanation of symbols).

Figure 2.5-17 is a site plan showing the arrangement of major plant structures. Plant excavations are shown on Figures 2.5-18 and 2.5-19. Backfill is shown on Figure 2.5-20.

Soil borings were done by Grubbs Consulting Engineers, Inc. and soil tests were performed in their Little Rock laboratory. Engineering properties of site soil materials are listed in Tables 2.5-3, 2.5-4, 2.5-5, and 2.5-6. An additional program of field investigation was initiated in July, 1972 in the ECP area to evaluate the properties of weathered shale and prospective borrow materials. Eight test pits were made in the three proposed borrow areas to evaluate the engineering properties of the soil proposed to be used for the clay blanket and the embankment fill. Two borrow areas south of the intake canal shown on Figure 2.5-31, Section 2.5.5.2.1 were recommended for use. Four plate load tests were made on weathered shale within the pond

area to develop its shear strength parameters for use in the embankment stability analysis. For location of test pits and detailed soil properties, refer to the Soil Report by Grubbs Consulting Engineers, Inc. in Section 2.5.5.2.1.

The clay soil at this site is not a sensitive soil. The consolidated drained direct shear tests on undisturbed samples of overburden soils in boreholes 224, 228, 232 and 234 presented in Section 2.5.5.3.1, Figures 2.5-56, -58, -60 and -62 show that the ratio between the peak and residual shear strength varies between 1.10 to 1.90 which indicates low sensitivity.

Moreover, test results from boreholes 101 through 131 in Table 2.5-6a and that of boreholes 223, 224, 225, 228, 230, 232, 234 and 236 in Section 2.5.5.3.1, Table 2.5-12 show that the in situ moisture content of the soil is close to the plastic limit, therefore the liquidity index is close to zero. The average undrained shear strength, C, of the soil is approximately 1.14 TSF (Table 2.5-6a). From the relation between $c/\overline{p}$ ratio and plasticity index established by Skempton (Reference 95, p. 117) the preconsolidation pressure and the present soil overburden pressures are computed and presented in Table 2.5-6b.

The basis for the assumed properties of weathered shale and filter materials are as below:

<u>Unit weight of weathered shale</u> The insitu density of shale as determined in some boreholes are abstracted below from Table 2.5-6a:

Borehole No.	Depth (ft)	Type of Material	Insitu Density (γm), PCF
126	28.0	Weathered Shale	149
127	22.0	Shaley Clay/Shale	141
Average			145

<u>Filter materials properties:</u> For well graded, clean sand used as filter material, the moist density at optimum moisture varies between 128 - 142 pcf and the effective angle of internal friction is of the order of about 38° (Reference 26, Table 9-1, P7-9-2), hence the assumptions of 135 pcf as the unit weight and 35° as the angle of internal friction for saturated sand are quite reasonable.

There are no shears or zones of crushed material in the rock which underlies the plant structures. The bedrock contains some joints and fractures, as does all rock to some degree. Some joints were encountered in the borings, and noted during site foundation inspection, but these were tight and are not significant to the site foundation conditions. Some crenulation of the bedding occurred when the rocks were folded at the end of Paleozoic time. These crenulations occur in localized zones, and do not affect site foundation conditions.

Rock at the site has been exposed at or near the surface since the Cretaceous, over 135 million years ago, and shows no evidence of deformation since that time. Therefore, no significant unrelieved residual stresses should be expected to exist in the foundation rock and no evidence of unrelieved residual stress was observed during the exploration or excavation.

The foundation rocks consist of shale, silty shale and siltstone, and no zone with undesirable or unstable mineralogy were observed during exploration or excavation. Seismic velocities of 11,000 to 14,500 fps (Vp) were recorded, and unconfined compressive strengths ranged from 3,140 psi for the samples tested. A swell test was conducted on a crushed gray shale sample with a nominal surcharge of 200 psf. The recorded maximum swell was 0.30 percent. Obviously, the shale is a competent, well indurated rock, and significant swelling or heave

should not be anticipated. The rock at foundation grade was protected from air slaking and moisture absorption by the application of gunite to exposed surfaces within 24 hours after final excavation. No swelling or heave of the foundation rock was noted prior to placement of concrete.

2.5.1.2.5.2 Behavior of Site Materials During Prior Earthquakes

The behavior of the surficial geologic materials at the site during prior earthquakes was evaluated by studying existing ground conditions, and by comparing the known effects of Intensity VI-VII earthquakes (the maximum the site has experienced historically) on soil and rock similar in strength, density, water content, etc. to those underlying the plant.

There is no evidence at or near the site of any ground failure, such as fissuring, lurching, subsidence or landsliding during recent earthquakes. In view of the intensities which the site has experienced in historic times (discussed in Section 2.5.2.5) and the dense, strong condition of the rock and soil, it is virtually certain that ground failure has not occurred near the site during historic earthquakes.

2.5.1.2.5.3 Properties of Embankment Materials for all Category 1 Structures

The only Category 1 embankment required at this site is in connection with some portions of the emergency cooling pond (Figure 2.5-21). For the soil fill consisting of overconsolidated, highly plastic clay, evaluation of dynamic engineering properties of the embankment material was not required, as such materials will not liquify. The static engineering properties are summarized in Table 2.5-3. Design properties for stability analysis are given in Table 2.5-4 and Figure 2.5-22. A more detailed treatment of the static soil properties is given in Sections 2.5.5.2.1 and 2.5.5.3.1 and for design properties in Section 2.5.5.2.1. The computed factor of safety of the embankment slope was found to be higher than the required factor of safety under all conditions, including earthquake condition as summarized in Tables 2.5-5a and 2.5-5b. For further discussions and details on factor of safety of pond slope stability, refer to Section 2.5.5.

2.5.1.2.5.4 Site Groundwater Conditions

Limited quantities of groundwater can be pumped from fractures and joints in the McAlester and Hartshorne formations. Groundwater in these rocks is confined below the nearly impermeable clay at the site. Groundwater at the site is derived from precipitation on the hills near the site. Water infiltrates the surface and percolates through fractures in the bedrock toward Dardanelle Reservoir as shown by water levels in Figures 2.4-1 and 2.4-2. The water table at the plant site is about 10 feet below ground surface at Elevation 342. Detailed discussion of groundwater conditions at the site are included in Section 2.4.13.

2.5.2 VIBRATORY GROUND MOTION

The pertinent literature regarding the seismology and geology for the general area was studied; the seismic history, geology and foundation conditions at the site were evaluated. Included in this report are summaries of the regional geology and site geology, a description of the earthquake history of the area and a general evaluation of the seismicity of the site and region around it.

The geologic conditions and seismic history are used in determining the Operating Basis Earthquake (OBE) (the greatest earthquake likely to affect the site within the lifetime of the facility) and the Design Basis Earthquake (DBE) (a hypothetical earthquake which exceeds in intensity any earthquake expected to be felt at the site). Taking into account all the seismic information for the site location, conservative values of 0.10 g for the OBE and 0.20 g for the DBE were used.

2.5.2.1 Geologic Conditions of the Site

Detailed descriptions of the geologic conditions at and in the vicinity of the site are presented in Section 2.5.1. However, summaries of the regional and site geology are also presented here.

2.5.2.1.1 Regional Geology

Physiographically, the site is situated in the center of the Arkansas Valley section of the Ouachita province. The Arkansas Valley is a gently undulating east-west-trending plain or lowland, 25 to 35 miles wide, that extends generally from Searcy westward to Fort Smith. Many long, sharp ridges and several broad-topped hills rise above the general level of the valley. In most parts of the valley the topography is an expression of the east-west-trending structure. Broad, open synclines are expressed by high, flat-topped mountains, steeply tilted limbs of anticlines and synclines are generally expressed by sharp ridges, some of which are miles long.

The Arkansas Valley lies within the area of outcrop of Paleozoic rocks which occupy essentially the northwestern half of the state. The rocks of the Arkansas Valley are nearly all of sedimentary origin; they include only a few bodies of igneous rock. The beds in the valley consist chiefly of shale and sandstone, all of Carboniferous age, and most of them belonging to the lower part of the Pennsylvanian series. The rocks are generally highly carbonaceous and in some places are coal bearing. They contain little or no calcareous material.

2.5.2.1.2 Site Geology

The site is located in an area where clay and silty clay overlay bedrock, consisting of Pennsylvanian McAlester formation shale. Thickness of the clayey overburden varies from about eight to 30 feet in the vicinity of the site and may be described as moderate to stiff, plastic, red and tan clay with occasional zones of silty clay. The McAlester formation consists of black, dense, horizontally bedded shale and sandstone. This bedrock sequence forms the trough of the east-west-trending Scranton syncline. Hard, fine-grained sandstone of the Hartshorne formation occurs at a depth of about 150 feet beneath the site.

2.5.2.2 Underlying Tectonic Structures

The Arkansas Valley section, which is a trough both structurally and topographically, lies between the essentially flat-lying rocks of the Boston Mountains on the north and the complexly folded strata of the Ouachita Mountains on the south. Its structure, therefore, has some of the characteristics of both its bounding regions. Near the northern border of the Arkansas Valley the faulting is normal, the folds are gentle, and most of the dips south of the anticlinal crests are steeper than those north of them. Near the southern border of the province, thrust faulting is common, the folds are pronounced, and the dips north of the axes of the anticlines are steeper than those south of them. The true intermediate structural character of the central part of the Arkansas Valley is shown by the occurrence of both normal and thrust faults in close proximity, by the increase in the number of symmetrical folds, and by the character of the folding itself

which is intermediate between the close folding on the south and the gentle open folding on the north. The Arkansas Valley section, unlike the Ouachita section, has been folded down to form a synclinorium.

The nature of the structural features of the Arkansas Valley and their relation to the structure of the adjacent Ouachita and Boston Mountains show that the dominant force in the production of those features was horizontal pressure exerted from the south. Croneis (1930) believed that the folding and thrust faulting, which developed in post-Paleozoic but pre-Cretaceous time, may be related to the subsidence of a large land mass to the south; the normal faults were also connected with this episode of deformation. These are believed to have formed either contemporaneously with folding, before folding, or as a result of tension developed after a period of folding (Croneis, 1930 and Hendricks, 1950). Some normal faults are also believed to have formed during deposition and subsidence of the Pennsylvanian sediments. In the Arkansas Valley the southward-dipping faults terminate against northward dipping normal faults (Haley, 1968). The precise dating of the folds and faults of the Arkansas Valley cannot be done with assurance (Caplan, 1954), but it is known that they are very old geologic structures and probably were formed before Cretaceous time (Croneis, 1930).

East-west trending folds are mapped in the area of the site. Within three miles north to three miles south of the site are two anticlines and one syncline. From north to south these structures are as follows: London anticline, Scranton syncline, and Prairie View anticline.

There are a number of old faults mapped in the vicinity of the Arkansas River, particularly to the northwest and west of the site. These are in the main, east-west-trending faults. The only faults within five miles of the site are the Prairie View fault, and the London fault and its branch faults. The closest fault is only a small branch fault and approaches within about two and one-half miles of the site. The last movement of these faults is believed to have occurred prior to the Cretaceous.

A personal interview was conducted with Mr. Boyd R. Haley of the U. S. Geological Survey. During this interview the age of the London and Prairie View faults and their physical characteristics as seen in the field were discussed in detail. The age determination of these faults, as made by Messsrs. Haley and Merewether of the U. S. Geological Survey is based on two facts. First, similar, normal faults extend into eastern Arkansas. These faults can be traced under the Cretaceous sediments of the Mississippi embayment and the faults do not cut the Cretaceous materials. Secondly, Mr. Haley has stated (verbal communication) that from well log data, the U.S.G.S. has determined that many of the Arkansas normal faults appear to be "growth faults" - that is faults which developed continuously during deposition. They have determined that displacements along these faults are often greater with depth, and in some cases the faults don't cut the Mesozoic strata. Mr. Haley believes that the London fault is in part this type of fault, and that the Prairie View fault has had a significant growth type displacement. Mr. Haley also stated that neither he nor Mr. Merewether had found any evidence of recent movement on the London or Prairie View faults.

Using the State of Arkansas Information Circulars and the geologic maps of the area (work completed by E. A. Merewether and B. R. Haley), the fault traces and exposures were located and studied.

London Fault. Merewether notes three exposures of the London fault in the Delaware quadrangle. Two of these exposures were located and examined.

In the State of Arkansas Information Circular 20-A, Mr. Merewether states:

> The London fault extends into the Delaware quadrangle from the east and probably ends a few hundred yards west of Big Piney Creek. The fault is a high-angle south-dipping normal fault with the downthrown block on the south side. The fault plane is best exposed on the west side of Big Piney Creek in the NW-¼ NW-¼ NW-¼ sec. 15, T. 8 N., R. 22 W. At this locality, the fault plane dips 58° south and the fault has an apparent displacement of about 20 feet.

On the bank at Piney Creek, approximately 6-½ miles northwest of the site, the plane mapped by Mr. Merewether as the fault strikes approximately N 30 E and dips 58° to the southeast. At this location the rock formation consists of the massively bedded, generally fine-grained sandstone of the Hartshorne formation. The sandstone dips gently to the south, but is cross-bedded on a relatively large scale creating apparent local reversals in dip.

At the exposure where Mr. Merewether mapped the fault plane, a sudden steepening of the dip on the south side of the plane could be interpreted as dragging. The dip resumes the gentle southerly trend a few feet south of the plane. No slickensides or crushing were noted along the plane.

At the rock-overburden contact, no offset of the bedrock or soil occurs. This shows that sufficient time has elapsed since the last fault movement for erosion to remove any evidence of a fault-related scarp.

Because of the similarities in the appearance of the bedrock across the fault, correlation of individual units within the sandstone could not be made and actual offset could not be determined.

The other exposure noted by Mr. Merewether that was found, was only described by Mr. Merewether as to its location "...and in a drainage ditch along the county road between secs. 10 and 11, T. 8 N., R. 22 W...." At this location, the fault was difficult to discern. A road cut here exposes very weathered rock. Closely spaced fractures apparently delineate the fault trace as mapped by Mr. Merewether. No slickensides or crushing were noted. The Hartshorne sandstone crops out in the road ditch. The rock's surface is smooth across the fault. The fractures have the appearance of tension cracks along the axis of a small anticline which are vaguely visible in the weathered road cut. No definite fault trace was actually found.

Two other possible exposures were noted a short distance southwest of the Piney Creek exposure. One which is located in an abandoned quarry appears to be fractures along an anticlinal axis. The axis appears to be the line along which relatively undisturbed Hartshorne sandstone beds become folded, jointed and fractured. The axial zone is more disturbed than the surrounding formation. The individual sandstone units appear continuous across the fractured zone although definite correlation is very difficult because of the massive nature of the geologic formation.

The other exposure, which is in an I-40 road cut, strikes roughly N 30 E and dips ± 30° to the southwest. This is about two feet wide and is easily identified by broken and disoriented rock fragments. No slickensides were observed; however, it was noted that a vague correlation of a geologic unit could possibly be made across the trace. If the correlation is correct, the displacement is less than 10 feet.

Only two of the exposures of the fault plane have been mapped by B. R. Haley in the Russellville west quadrangle. One of these exposures was undoubtedly obliterated by recent road work. The other could not be located, although the area was carefully examined.

The main trace of the London fault and its branches often follows rather deep stream valleys, the bottoms of which are usually filled with Quaternary alluvium. The fault does not cut these sediments. Rocks older than the Quaternary and younger than the Pennsylvanian have been eroded making a more accurate relative age determination on the basis of offset units impossible.

The valleys along which the faults are traced, do not appear to be fault produced. When the amount of movement and the length of time since the last movement are considered, the valleys appear to be much too wide and deep to be fault produced. Where the fault is exposed at its western end, no valleys exist.

Mr. Haley stated (verbal communication) that the indicated location of the fault's trace is generally based on the positions and the measured stratigraphic thickness of the geologic units. He agreed that it is very difficult to recognize or locate the faults in the field. At the eastern fault exposure noted by Mr. Haley (not found by field investigation), the geologic units on both sides of the fault appear identical but are mapped as Hartshorne on the south side and Atoka on the north. Mr. Haley stated (verbal communication) that the units are difficult to distinguish but with sufficient field work, they can be shown to be different geologic units. Investigation of the surface indicated by Merewether and Haley disclosed no suggestion of recent fault movement.

<u>Prairie View Fault</u>. In the Information Circular 20-A, Mr. Merewether also states: "The Prairie View fault, the outcrop of which is concealed by alluvium in the Delaware quadrangle, has been extended into the mapped area from the west. Where exposed (west of the Delaware quadrangle), the Prairie View fault is a high-angle north-dipping normal fault with the downthrown block on the north side."

A. J. Collier shows the fault extending westward from the Delaware quadrangle across the New Blain quadrangle and terminating in the Scranton quadrangle. Its nearest approach to the site is 6-½ miles. No exposures of this fault could be found by field investigation. The land surface is undulating because of a series of parallel anticlinal ridges. The limbs of these folds form dip slopes. Along the crest of the Prairie View anticline where this fault is indicated by Collier (1906), the ground surface is irregular and there are no outcrops. A rather broad valley runs along the folds crust. No definite evidence of faulting could be determined in this area.

After the field investigation of the indicated fault traces and the discussion with Mr. Haley, it was concluded that there is no available evidence that these features have experienced recent movement. It is likely that they have not moved since the Cretaceous. They are not considered to present a risk to the site.

2.5.2.3 <u>Behavior During Prior Earthquakes</u>

There is no physical evidence of any fissuring, landsliding, lurching, or caving of banks to indicate that past earthquakes have disturbed either the surficial deposits or the substrata beneath the site. The New Madrid Earthquakes of 1811-1812 (described in detail in Section 2.5.2.5.3) produced areas of earth disturbances in eastern Arkansas; however, these areas were at least 90 miles from the site.

2.5.2.4 Engineering Properties of Materials Underlying the Site

All Category 1 structures except the ECP inlet and outlet structures, electrical manholes, and the Condensate Storage Tank (T41B) pipe trenches are founded on competent unweathered bedrock. The properties of the bedrock materials are summarized in Table 2.5-2.

Seismic velocities of the shale bedrock range from 11,000 to 14,500 fps. The rock has a dynamic modulus of elasticity ranging from a minimum of 2.8 (+6) psi to over 5 (+6) psi, indicating good foundation rock. It has good strength properties and will cause no amplification of ground motion from an earthquake. Additional information on foundation properties of the rock under Category 1 structures is provided in Section 2.5.1.2.5.1.

2.5.2.5 Earthquake History

Historical and instrumental data show that seismic events in the southeastern part of the United States, with the exceptions of those in the New Madrid, Missouri Areas, and the Charleston, South Carolina area, are relatively infrequent and characterized by fairly low intensities and magnitudes.

The site is located in the center of the Arkansas Valley section of the Ouachita province, in an area which appears to be seismically quiet since no significant earthquakes have been reported closer than 48 miles to the site.

The following paragraphs include information on the epicenter map for the area within 200 miles of the site, earthquakes felt in the vicinity of the site, the New Madrid Earthquakes, and the Seismic Risk map of the United States prepared by Dr. S.T. Algermissen of the U.S. Coast and Geodetic Survey.

2.5.2.5.1 Epicenter Map

Figure 2.5-23 shows the locations of the significant historical earthquakes which have occurred within a 200-mile radius of the site--the area bounded by latitudes 32 to 38.5 degrees north, and longitudes 89 to 97 degrees west. The earthquakes plotted within this area are those of Intensity IV-V and greater. All intensities in this report are based on the Modified Mercalli Intensity scale of 1931 unless otherwise stated (see Table 2.5-8 for this scale). Each earthquake is shown on Figure 2.5-23 by a Roman numeral at the epicenter. The Roman numeral indicates the greatest reported intensity for that quake. A list of the epicenters shown on this map is given in Table 2.5-9. Most of the epicenters are listed and located in the references by latitude and longitude. These locations may denote either field epicenters, or instrumentally located epicenters. Many of the older locations are field epicenters; that is, an epicenter was placed at the locality or center of the area receiving the greatest effects from that quake.

References used for this study are shown on Figure 2.5-23 and are also listed in the Reference Section. The first historical quake in the central United States is listed in the references as occurring in 1699, so all quakes on this map have occurred since then. The references for this map have been checked for earthquakes occurring through October 1972.

2.5.2.5.2 Earthquakes Felt in Arkansas

The closest epicenter to the site is 48 miles. This earthquake occurred on October 22, 1882 and had a maximum intensity of VI-VII. The U.S. Coast and Geodetic Survey has approximated the location of this epicenter. They state, however, that it was difficult to accurately locate it because of insufficient reports from the region most affected. Some investigators place this epicenter near El Reno, Oklahoma.

The earthquake of October 22, 1882 is described as follows in the 1973 edition of "Earthquake History of the U.S." (U.S. Dept. of Commerce Publication 41-1, J.L. Coffman and C.A. von Hake, editors).

> 1882, October 22, Arkansas. This shock was felt in northern Texas, Oklahoma, western Arkansas, and eastern Kansas. It extended from Greenville and Paris, Texas to Wichita and Leavenworth, Kansas, a distance of 450 miles, and to Warrenton, Mo. At Sherman, Texas, heavy machinery vibrated, bricks were thrown from chimneys, and movable objects overturned. Houses were shaken at Fort Smith, Arkansas. It was difficult to obtain the probable epicenter because of insufficient reports from the region most affected.

Authorities listed for the above description are the following three reports:

A. Rockwood, C.G., "American Earthquakes," Am. Jour. of Sci. and Arts, 3rd Series, Vol. 25. 1883.

   Oct. 22 About 4.15 P.M. an earthquake was felt in northern Texas, western Arkansas and eastern Kansas, and presumably in the intervening portions of the Indian Territory. The region affected extended from Greenville and Paris, Tex., and Little Rock, Ark., northwesterly to Wichita and Leavenworth, Kan., a distance of some 300 miles. The shock was reported from numerous places within these boundaries, and also, as a light shock, from Warrenton, MO, which is farther eastward. The most definite report of time was from Wichita, Kan., which gave 4:19, Jefferson City, Mo., time. In many places two or three pulsations were noticed, having a duration of about 30 seconds in all. Reports of direction are too various to be classified. No damage was done other than overturning movable articles and knocking bricks from chimney-tops.

B. Merriams, D.F., "History of Earthquakes in Kansas," Bull. Seis Soc. Am., Vol. 46, No. 2, April 1956.

   1882, October 22 - (35° N, 94° W; VII-VIII.) (M.M.) The epicenter was in Arkansas but the earthquake was felt over an area of 135,000 square miles, including eastern Kansas, about 4:15 PM. (3 and 6) (The numbers 3 and 6 indicate numbered references in Merriam's publication. Number 3 refers to an early (1947) edition of "Earthquake History of the U.S.", and Number 6 refers to a publication by R.R. Heinrich, in which Heinrich rates the 1882 earthquake as maximum Modified Mercalli Intensity VI).

C. Monthly Weather Review - October 1882, U. S. Weather Bureau.

   The shock of the 22d was felt at various points in the states of Arkansas, Kansas, Missouri and Texas. Concerning this shock, the following reports have been received:

Mount Ida, Arkansas, 22d: At 4:15 p.m., a distinct shock, accompanied by a rumbling sound, was felt at various places in this (Montgomery) county.

Fort Smith, Arkansas, 22d: At 4:15 p.m., three distinct shocks, all occurring within about 30 seconds were felt at this place. The vibrations were east and west. Houses were shaken so that furniture and crockery rattled; bells were rung, and in a few instances bricks were shaken from chimneys.

Little Rock, Arkansas, 22d: Two light shocks of earthquake were felt between 4:00 and 5:00 p.m. The shocks were separated by an interval of two seconds, and the vibration was from southeast to northwest.

Rogers, Arkansas, 22d: A slight earthquake shock, continuing about 30 seconds was felt here at 4:12 p.m. Reports from Seligman, Missouri, state that it was also plainly felt at that place.

Fayetteville, Arkansas, 22d: An earthquake shock was felt here at 4:15 p.m. The vibration was from north to south, and lasted eight seconds. It was sufficiently violent to throw bottles from shelves.

Wichita, Kansas, 22d: An earthquake shock occurred at this place at 4:19 p.m. (Jefferson City, Missouri, mean time.) Its duration was about five seconds. There were three pulsations, the first being the strongest. Windows were rattled, the walls of buildings swayed, and furniture moved in houses.

Wellington, Kansas, 22d: A shock of earthquake was distinctly felt here about 4:00 p.m. The pulsation seemed to be east and west, and continued for several seconds.

Leavenworth, Kansas 22d: A slight earthquake shock was felt here at 3:54 p.m. A tremulous movement of the earth was first noticed, which continued with even intensity from 20 to 40 seconds, when a heavier shock followed, lasting about 15 seconds. The disturbance then became less perceptible for about a minute and 30 seconds, when the most distinct shock occurred, which was sufficient to rattle windows and shake chandeliers.

Warrenton, Missouri 22d: About 4:25 p.m., an earthquake shock was felt at this place. The vibration was north and south. The shock was sufficient to cause windows, etc., to rattle.

Sherman, Texas, 22d: An earthquake shock was felt at this place about 4:00 p.m. At the Eagle mills, which were shut down at the time, the machinery was seen to vibrate, and the belts creaked as if the engine was being started. At Compress, the shock was so violent as to ring the call-bell on the engine, and cotton bales standing on end were seen to sway. McKenny, Greenville, Bonham, and Paris, all in northern Texas, report having experienced the shock. At Paris, a clock was thrown from the side of a wall, and at Bonham, loose bricks were shaken from the top of a wall.

Three other sources contain descriptions of this earthquake.

A. Heinrich, R.R., "A Contribution to the Seismic History of Missouri," Bull. Seis. Soc. Am., Vol. 31, No. 3, July 1941. Earthquake shock in eastern Kansas and western Missouri at 4:15 p.m. Articles were moved and bricks were shaken from chimneytops. Am. Jour. Sci., 3d ser., 25:359. (VI) (M.M.)

B. Reid, H.F., Reid Earthquake Catalog. Collection of earthquake and volcano data on 3x5 cards, and augmented by newspaper clippings of principal earthquakes. Available on microfilm from N.O.A.A., Boulder, Colorado.

Local Date:	4.15 p.m. 22 Oct. 1882
Locality:	Indian Ter., Texas, Arkansas, Kansas
Intensity:	VII (R.F.)
Authorities:	Am. Jr., Sc., 1883, Vol. 25, p. 359. Felt over an area of 135,000 sq. miles in northern Texas, western Arkansas, eastern Kansas, and presumably in the intervening portions of the Indian Territory.

The region affected extended from Greenville and Paris (Texas), Little Rock (Ark.), and N.W. to Wichita and Leavenworth (Kansas). Also reported from Warrenton, Missouri.

C. "Earthquake History of Arkansas," U.S. Dept. of Commerce Earthquake Information Bulletin, Vol. 2, No. 4, 1970.

Although the historical record for the central United States can be traced to about 1800, the first shock listed for Arkansas occurred in October 1882. Since few reports were received from the region most affected, the epicenter of this shock is not well known, and several investigators have placed the origin near El Reno, Oklahoma, instead of western Arkansas. The shock threw bricks from chimneys at Sherman, Texas, and shook houses strongly at Fort Smith, Arkansas, Texas, and Missouri, about 135,000 square miles (VII M.M).

J. Docekal ("Earthquakes of the Stable Interior, with Emphasis on the mid-Continent," 1970, Doctoral thesis - University of Nebraska) has re-evaluated the effects and characteristics of this earthquake. Based on this re-evaluation, he has relocated the epicenter of the 1882 earthquake 175 km. to the south-southwest of coordinates listed in "Earthquake History of the U.S.", in the vicinity of Bonham, Texas, almost 200 miles from the ANO-2 site. He rates this event as epicentral Intensity VII (M.M.).

Docekal's recent investigations probably provide the most complete data available for this earthquake at this time. Therefore, the earthquake is of less significance than thought previously.

In 1969, an earthquake occurred 50 miles from the site. "Seismological Notes" in the Bulletin of the Seismological Society of America rates this shock as epicentral Intensity V. More recent references (U.S. Earthquakes, 1969, and Abstracts of Earthquake Reports for the U.S.) list this shock as having an epicentral intensity of VI. Abstracts of Earthquake Reports for U.S. states that this earthquake was not felt at Russellville.

No other significant earthquakes have occurred within 50 miles of the site during historic times. Other earthquakes probably felt at the site are listed below.

1811-1812 - Described in Section 2.5.2.5.3.

1867, April 24 - 39.5N, 96.7W, Maximum Intensity VII (MM). Shock at Lawrence, Kansas, where objects were thrown from shelves and plaster was cracked. Walls were cracked in Manhattan, Kansas; felt in Arkansas, Illinois, Indiana, Missouri, Nebraska and Kentucky.

1895, October 31 - 37.ON, 89.4W, Maximum Intensity VIII (MM). Heaviest near Charleston, Missouri, where land sunk. At Cairo, Illinois chimneys were demolished. Felt from Canada to Mississippi and from Georgia to Kansas.

1903, November 4 - 38.5N, 90.3W, Maximum Intensity VI-VII (MM). St. Louis. Felt in southern Illinois, Kentucky, Mississippi, Arkansas, Missouri, and Tennessee.

1909, September 27 - 39.ON, 87.7W, Maximum Intensity VII (MM). Indiana. Felt area included southwest half of Indiana, all of Illinois, eastern Iowa and Missouri, west half of Kentucky and Arkansas.

1909, October 23 - 37.ON, 89.5W, Maximum Intensity V (MM). Center in southeastern Missouri. Felt in Missouri, Arkansas, Mississippi, Tennessee, Kentucky, Illinois and Indiana.

1915, December 7 - 36.7N, 89.1W, Maximum Intensity V-VI (MM). A sharp earthquake near mouth of the Ohio River. It was felt in Illinois, Kentucky, Tennessee, Arkansas, Mississippi and Missouri.

1917, April 9 - 38.1N, 90.6W, Maximum Intensity VI (MM). Epicentral region between St. Louis and New Madrid, Missouri, where windows were broken and plaster cracked. Felt in Kansas to Ohio and from Wisconsin to Mississippi.

1927, May 7 - 36.5N, 89.OW, Maximum Intensity VII (MM). Arkansas and adjacent states. Strongest at North Jonesboro, Arkansas where brick chimneys were tumbled down. Although it was felt strongly in Arkansas, the area over which it was felt indicates that the epicenter was further to the east near the position listed.

1940, November 23 - 38.2N, 90.1W, Maximum Intensity VI (MM). Felt throughout Illinois, Kentucky, Tennessee, Missouri, and Arkansas.

1952, April 9 - 35.4N, 97.8W, Maximum Intensity VII (MM). Center near El Reno, Oklahoma, where chimneys fell and walls were cracked. Felt in western Arkansas (I-III) at Clarksville and Dardanelle which are within 20 miles of the site.

1962, July 23 - 36.1N, 89.8W, Maximum Intensity VI (MM). Plaster cracked in Dyersburg, Tennessee. Site area just on edge of felt area according to map but not reported felt by towns near the site area.

1965, October 20 - 37.51'N, 91.05'W, Maximum Intensity VI (MM). Centered in east central Missouri, VI at St. Louis. Not reported felt in towns near site area which lies at the limit of perceptibility.

1968, November 9 - 38.0N, 88.5W, Maximum Intensity VII (MM). Southern Illinois. It was reported not felt at Russellville even though it was felt at Dardanelle. It was reported felt with Intensity V in the extreme northeast part of Arkansas and Intensities I-III as far south as Murfreesboro 90 miles southwest of the site.

1971, October 1 - Jonesboro, Arkansas. According to "Seismiological Notes" in the Bulletin of the Seismological Society of America, Vol. 62, No. 3, "Walls shook and teeth rattled at Trumann, Arkansas. Small objects fell from shelves. Many older homes cracked and groaned during the shock. Citizens emerged from their homes to find the cause of the disturbance (Press)."

> "Felt in 75 communities. A maximum intensity of V was reported for Sedgwick (135 miles from Russellville) with cracking of concrete floor, Lake City (155 miles from Russellville) which reported cracked buildings, shifting of objects ("Strongest earthquake ever felt; loudest by far"); Bay where many were frightened and earthquake noise was reported as thunderous; Black Oak (160 miles from Russellville), Brookland (140 miles), Delaplane (150 miles) and Trumann (150 miles) (where slight damage occurred to concrete blocks). Scattered felt reports from Missouri (9 communities), Texas (1), Kentucky (6), Mississippi (1), Alabama (2), Indiana (1), Tennessee (10), and Illinois (5), (Questionnaire canvass),"
>
> This shock may have been felt lightly in the vicinity of the site, but probably was not and certainly not with an intensity greater than about II.

Earthquakes have occurred in Arkansas on November 17, 1970, February 1, 1972 and October 2, 1973 but were not felt in the plant site area.

2.5.2.5.3 The New Madrid Earthquakes

The earthquakes which have most significantly affected Arkansas and all adjoining states in the Mississippi Valley region occurred near New Madrid, Missouri in 1811 and 1812. These earthquakes consisted of a succession of shocks of varying intensities, beginning December 16, 1811 and lasting throughout the years 1812 and 1813. The maximum intensity of these shocks was estimated to be XII, with a probable magnitude of 8 (Richter). Nuttli (1973) estimates the surface-wave magnitude of the Dec. 16, 1811 shock as 6.9. Shocks on Jan. 23, 1812 and Feb. 7, 1812 had estimated surface-wave magnitudes of 6.8 and 7.1, respectively.

The nearest points at which systematic attempts were made to record the shocks from the New Madrid earthquake were at Louisville, Kentucky and Cincinnati, Ohio. At Louisville, 250 miles from the epicenter, 1,764 shocks were recorded between Dec. 16, 1811 and May 6, 1812 at which time the recording of shocks ceased. At Cincinnati, 340 miles from the epicenter, 41 periods of shocks were recorded, eight of which occurred between May 5, 1812 and Dec. 12, 1813. The available data indicate that there were at least 1,882 earthquake shocks.

A good description of the area affected is given by Myron L. Fuller in his 1912 paper, "The New Madrid Earthquake."

> The area affected by the New Madrid Earthquake may be subdivided into an area of marked earth disturbances, an area of slight earth disturbances, and an area of tremors only. In the first is included the territory characterized by pronounced earthquake phenomena, such as domes and sunk lands, fissures, sinks, sand blows, large landslides, etc. This district included the New Madrid region, originally considered a relatively small

> area, including the villages of New Madrid and Little Prairie (Caruthersville). It is now known, however, to be somewhat larger, extending from a point west of Cairo on the north to the latitude of Memphis on the south, a distance of more than 100 miles, and from Crowley Ridge on the west to Chickasaw Bluffs on the east, a distance of over 50 miles. The total area characterized by disturbance of the type mentioned is from 30,000 to 50,000 square miles.
>
> In the area of slight earth disturbances will be included districts in which such minor features as the caving of banks, etc., took place. We have records in the narratives of Latrobe (1836) and others of the occurrence of such phenomena along the Mississippi and Ohio, while Bradbury (1904) records similar disturbances as far down the Mississippi as the mouth of the St. Francis, near Helena. The disappearance of Island 94 near Vicksburg has been described by August Warner. In fact, there is little doubt that such phenomena as caving were prominent northward nearly to Herculaneum, north-eastward to a point beyond the Wabash and southward at least to the mouth of the Arkansas. Although no records from the White River region have been seen, it was probably included in the area of slight disturbance. It is also possible that the lower Arkansas was affected to some extent.
>
> The area of tremors was naturally far more extensive. On the north they are reported to have been felt in "upper Canada", on the northwest they are reported to have been felt by the Indians in the region of the upper portions of the Missouri country, and in the region between the headwaters of the Arkansas and the Missouri, a distance of more than 500 miles from New Madrid. Southwestward the shocks were felt in the Red River settlements and on the Washita River, an equal distance from the center of disturbance. To the south the shock was felt at New Orleans, also 500 miles distant; to the northeast at Detroit, 600 miles away; and to the east at Washington, over 700 miles and at Boston, 1,100 miles distant. A total area of over 1,000,000 square miles, or half that of the entire United States, was so disturbed that the vibrations could be felt without the aid of instruments.

Figure 2.5-24 lists some of the effects of the New Madrid earthquake, as described by Fuller and other investigators. The references are listed on the figure.

2.5.2.5.4 Seismic Risk Map

Figure 2.5-25 is the seismic risk map showing areas of the conterminous United States most vulnerable to earthquakes. The map was made by a group of research geophysicists headed by Dr. S.T. Algermissen of the U.S. Coast and Geodetic Survey and issued in January, 1969.

The map divides the conterminous United States into the following four zones:

- Zone 0: Areas where there is thought to be no reasonable expectancy of earthquake damage.
- Zone 1: Areas of expected minor damage.
- Zone 2: Areas where moderate damage could be expected.
- Zone 3: Areas where major destructive earthquakes may occur.

The zones are based principally on the known distribution of damaging earthquakes, their intensities, and geological considerations.

The site lies well within Zone 1 where minor damage should be expected. According to this map, minor damage corresponds to Intensities V and VI on the Modified Mercalli Intensity Scale.

2.5.2.6 Correlation of Epicenters With Geologic Structures

With the exception of earthquakes associated with the New Madrid area, very few shocks have occurred within a 200-mile radius of the Unit 2 site; and the shocks which have occurred have not been definitely correlated with geologic structures.

Much seismic activity has been associated with the New Madrid and Ste. Genevieve fault zones. The large pattern of earthquake epicenters of the 1811-12 New Madrid earthquake series was elongated northeastward along the New Madrid fault zone into Illinois and Kentucky. A branching lobe of epicenters also extended northwestward up the Ste. Genevieve system nearly to St. Louis (Heyl, et al., 1965).

A second line of seismic activity is the northwestern part of the Ste. Genevieve fault, near St. Louis, Missouri. Earthquake epicenters have been scattered along this fault zone and along the possible southeast extension of this zone into northwestern Tennessee (Heyl, et al., 1965).

Earthquake generation along the fault zones appears to be partly related to domal activity of the ends of the fault zones (Heyl and Brock, 1961).

2.5.2.7 Identification and Description of Active Faults

The New Madrid Fault Zone - In southwest Kentucky, southern Illinois, and Missouri, is the upper part of the Mississippi embayment, a basin in which Paleozoic rocks have been progressively downwarped since mid-Cretaceous time and in which clastic strata of upper Cretaceous, Paleocene, Eocene, Pliocene, Pleistocene, and Holocene ages have been deposited. This gently warped cratonic region is characterized by large gentle domes, basins, and folds. Complex fault systems connect and cross the larger structures at the head of the embayment (Heyl, et al., 1965).

The buried Precambrian surface underlying the region is broad and undulating, a result of warping younger than the Precambrian. This surface is sharply bent and broken along the major fault zones. The larger faults of the area are probably surface expressions of ancient Precambrian lineaments (Heyl, et al., 1965), which have been inferred from geologic and gravity data (McGinnis, et al., 1972).

The larger faults and fault zones include the following (Heyl, et al., 1965).

A. The Shawneetown-Rough Creek fault zone, traceable from the collapsed Jessamine Dome in central Kentucky to the New Madrid fault zone near Shawneetown, Illinois, where it curves southwestward around the northwest end of the Hicks Dome and joins the northwest side of the New Madrid fault zone.

B. The Ste. Genevieve fault zone, a high angle thrust fault beginning southwest of St. Louis and extending southeastward into Illinois with an extension into northwestern Tennessee.

C. The Cottage Grove Fault zone, trending westward across southern Illinois to the Mississippi river, where it may end against the Ste. Genevieve system. Faults of a similar westward nature are traceable further west through southeast Missouri.

D. The New Madrid fault zone, a broad belt of northeast trending faults extending from near Vincinnes, Indiana, southwestward through and beyond New Madrid, Missouri.

As mentioned, earthquake generation along the fault zones appears to be partly related to domal activity at the ends of the fault zones. The development of the Hicks Dome, in southern Illinois, was probably the result of the intrusion of magma deep within the Precambrain basement at the intersection of several basement (Precambrian) fault lineaments (Heyl and Brock, 1961). Tension faults first appeared during uplift in the Permian. Later, the dome was faulted by the New Madrid system along basement lineaments, followed by cooling of the magma and partial collapse of the dome (Heyl, et al., 1965). This action was combined with compressive forces acting along the Rough Creek-Shawneetown fault zone, which compressed and rotated the north end of the anticlinal dome in a counter-clockwise direction, developing the numerous northeast-trending fault blocks. During the late Cretaceous, the Mississippi embayment was formed by downwarping of the block south of the intersection of the New Madrid and Ste. Genevieve fault zones (Heyl and Brock, 1961).

Movement along one fault zone in the region is apparently related to movement along a connected fault zone. The main Rough Creek-Shawneetown system is a zone of sheared and faulted rock considered to be a wrench-fault system. Both strike-slip and reverse faulting has occurred along southward-dipping fault planes. The strike-slip component of movement was left lateral, from the eastern end of the fault zone at its western end. The New Madrid zone apparently acted as a shear-relief feature for the Shawneetown-Rough Creek system (Heyl, et al., 1965).

The New Madrid fault zone is characterized by many narrow fault blocks and wedges that are elongated to the northeast. Vertical displacements between 700 and 800 feet are exhibited along one that follows the course of the Mississippi River (Bond, et al., 1971). The fault follows the trend of faults developed previously in both Paleozoic and Cretaceous strata (Lammlein, et al., 1971). This particular fault has the downthrown side on the west and according to Bond was probably responsible for the New Madrid earthquakes of 1811-12. Another fault, further to the west in Missouri, parallels the Mississippi River fault and is downthrown on the east, so that a graben is formed within the western part of the Mississippi River floodplain (Bond, et al., 1971).

Bond, et al., (1971) state in the section of their article dealing with the northern Mississippi Embayment, under the heading "Faults", as follows (p. 1216):

> Because of the sparse subsurface control, only the major displacements can be plotted in the embayment area. A fault that trends northeast is downthrown on the west, has 700 to 800 feet (210 to 240 m) of displacement, and follows the course of the Mississippi River. Movement along this fault probably was responsible for the New Madrid earthquakes in 1811 and 1812, the largest tremor ever recorded in North America.

The article goes on to point out other faults that have been inferred to exist in the Paleozoic rocks beneath the embayment (see Figure 45 of Bond, et al. for locations of these faults), but the only fault shown by Bond, et al. to offset the surface of the Palezoic-Cretaceous unconformity is the northeast trending fault described in the foregoing quotation. Subsurface contours on the datum defined by the Paleozoic-Cretaceous unconformity and the location of the inferred offset of this surface are shown in Figure 46 of Bond, et al. Deep test control data for the northern Mississippi Embayment are listed in Table 4, p. 51 of Illinois State Geological Survey's 1971 publication, Illinois Petroleum 96. However, Bond, et al. offer no further data or rationale for correlating the particular fault described in the foregoing quotation with the New Madrid earthquakes of 1811-1812.

The northern and southern limits of the New Madrid system have not been definitely established in the literature. According to Heyl, et al., (1965), the zone extends northeastward from the Mississippi River embayment, past New Madrid and across the Wabash River, where it becomes synonomous with the Wabash River fault zone.

The southern end of the New Madrid fault zone was placed in extreme northeastern Arkansas by Heyl and Brock, 1961. King, 1965, extended the zone to about 25 miles south of the northeastern Arkansas-southeastern Missouri border. Based on the location of epicenters of earthquakes having intensities greater than V, McGinnis (1963) placed the southern limit of the zone just north of the Arkansas-Missouri border south of New Madrid. The above limits were determined by the locations of subsurface and surface faults, earthquake epicenters, and basement lineaments.

Recent work by Kisslinger and others (1971) and Followill (1972) indicates that earthquakes occurring in the New Madrid fault zone since 1970 may delineate the southern end of the New Madrid system more accurately. The epicenters of these earthquakes are distributed along a northeast-southwest trend west of New Madrid that is parallel to, but not coincident with previously mapped or inferred faults. The southern end of this trend, as defined by Kisslinger, is marked by a 4.5-magnitude event occurring on Nov. 17, 1970, 10 miles south of the southwest Missouri-northeast Arkansas border, almost 200 miles northeast of the site. This event coincides with the southern limits of the fault zone determined by Heyl and Brock, 1961, based on faulting evidence. Focal depth of this event was about 19 kilometers, indicating a possible basement origin for the earthquake.

One other earthquake, farther south than the 1970 event, may be associated with movement within the New Madrid fault zone. The 1955 event in northeastern Arkansas occurred along the trend established by Kisslinger and others, 1971. This maximum Intensity IV event is the southernmost of any event occurring along the trend of the New Madrid fault zone as established by Kisslinger.

Followill, in 1972, includes both the 1955 Arkansas event and the 1843 Memphis event within the limits of the New Madrid fault zone. This places the fault zone at about 180 miles from the Unit 2 site area. The isolated 1843 Memphis earthquake occurred over 50 miles east of the trend of the New Madrid fault zone as defined by Kisslinger.

Bond, in his 1971 report concerning potential petroleum production in the Northern Mississippi embayment, discusses the regional stratigraphic and structural geology as jointly interpreted by representatives of the Illinois, Indiana, Kentucky, and Tennessee Geological Surveys, Vanderbilt University, and Marathon Oil Company. The data presented in this report are based on numerous petroleum exploration programs. A detailed description of the major regional

faulting provides evidence for the terminus of the New Madrid zone in west-central Tennessee and northeastern Arkansas. Offset along the northeast-southwest trending fault thought by Bond responsible for the 1811-1812 series of earthquakes can be traced in the subsurface to about 90 miles north of Memphis. This fault bisects a much larger (in displacement) east-west-trending fault near its southern end.

There is no reflection of major faulting of the Paleozoic surface found in the Mississippi embayment south of the Pascola arch to and beyond the Ouachita tectonic front. Numerous data points (based on petroleum wells) have been utilized to construct contours on top of Paleozoic strata. In the northern embayment area, the contours reflect the influence of the Mississippi structural trough with its V-shaped contours pointing northeasterly. Continuing south, the gradual trend of the contours changes to an east-west direction. Considering the number of data points, a fault of major proportions similar to the New Madrid zone would be reflected by the structural contours. No major fault is shown to exist.

The basic data from which Bond, et al., (1971) and Schwalb (1971) published subsurface structural interpretations are given in Table 4, p. 51 of Illinois Geological Survey's 1971 publication Illinois Petroleum 96. Additional data points and datum contours are given in Cushing, Boswell and Hosman (1964).

The spacing of the data points, though sparse, is such that major structural displacements on the order of several hundred feet can at least be reasonably postulated. The only fault indicated by the above-referenced sources to involve strata as young as Cretaceous is one which is shown displacing the surface of the unconformity on top of Paleozoic basement, extending for about 100 miles in a north-northeast direction parallel to the axis of the embayment from western Dyer County (Tennessee) to the Illinois-Kentucky border. Displacement along the fault attains a magnitude of 700 to 800 feet, but no displacement of the surface of the Paleozoic-Cretaceous unconformity is shown extending south of the Pascola arch.

Other major faults offsetting Paleozoic strata but not Cretaceous or younger strata are shown by Schwalb (1971, Fig. 1). A very large fault trending slightly south of east for about 90 miles from Dunklin County, Missouri to Henderson County, Tennessee and having an estimated 4,000 feet of displacement, downthrown to the south, appears effectively to define the southern edge of the Pascola arch, as located by Bond, et al., (1971) and by Bristol and Buschbach (1971). However, since this major east-west fault is not shown offsetting the Paleozoic-Cretaceous erosion surface, it must therefore have not experienced movement since prior to Cretaceous time, over 135 million years ago, and so would not be expected to be related to present-day seismic activity in the New Madrid earthquake zone. No major faulting is indicated by any of these above referenced sources for the Paleozoic surface south of the Pascola arch. No significant indications of major faulting can be interpreted from regional Mesozoic structural maps.

No major active faulting has been established in the Cenozoic strata of the Mississippi embayment south of Memphis. The Big Creek fault zone is discussed in Fisk's report and a later report by Krinitsky. Boring data in the latter report are interpreted to indicate minor faulting in the Tertiary strata along the Big Creek escarpment near Helena, Arkansas. However, evidence is inconclusive and does not justify the presence of a major structure. Boring programs initiated by the Corps of Engineers at various river structures (locks and dams) on the Ouachita River encountered no faulting associated with Fisk's topographic lineaments. The Catahoula Lake and Ouachita River fault zones of Fisk were investigated and no faulting associated with these lineaments is evident.

Cushing, 1964, included in his report on the Mississippi embayment, an east-west cross section through the embayment tangential to the northern limit of the Ouachita tectonic front. The borings used to construct the section terminate in either Cretaceous or Paleozoic rock so that a complete record of the Cenozoic history in that part of the embayment is presented. Other than the normal basinal cross-sectional configuration, no major faults or other unusual anomalies are evident.

Caplan in 1954, in describing the subsurface geology of northeastern Arkansas, presented evidence, based on numerous petroleum wells, which suggest the lack of major faulting of Paleozoic and post-Paleozoic strata. The cross-sections are perpendicular to and cross the axis of the Mississippi structural trough north of the Ouachita front.

Geophysical, seismological, physiographic, and structural geologic evidence suggests that the New Madrid seismic zone is restricted to a relatively narrow, elongated belt within the Mississippi embayment paralleling the Mississippi River from Memphis northward to southermost Illinois.

Physiographic effects of the 1811-1812 New Madrid earthquakes documented by Fuller (1912) were confined to this belt. Its width as delineated by the major surface effects of the 1811-1812 events is about 50 miles and extends from Crowley's Ridge in Arkansas to the Loess Hills in western Tennessee (Fuller, 1912, pl. 1). The closest approach of such a zone to the site would be at least 150 miles. If certain raised areas occurring near and on either side of the Mississippi River, such as the Blytheville and Tiptonville "domes", had been differentially elevated by earthquake action, then they furnish proof that earthquakes occurred there prior to the New Madrid events (Fuller, pp. 12-13, 63-64). Summarizing the evidence indicating likely areas of earthquake disturbance in the embayment, Caplan (1954) states (p. 37):

> Faulting, slumping and general evidence of crustal displacement may be expected in those portions of the embayment affected by the New Madrid earthquake of 1811-1812. According to Fuller (1912) the epicenter of this earth movement was in northeastern Arkansas and southeastern Missouri, between Crowley's Ridge and the Mississippi River. Evidence examined by Fuller indicated the existence of a fault or fault system trending northeast-southwest across the general area affected, but actual area placement of the fault or fault system could not be made with the information available. The maximum expression of faulting and related adjustments attributable to the New Madrid earthquake in Arkansas is likely to be found in the region between Crowley's Ridge and the Mississippi River, from the general vicinity west of Memphis, Tennessee, to the Missouri line. The fault system postulated might extend from Memphis to the head of the embayment at Cairo, Illinois.

The area which experiences secondary surface displacement due to violent ground motion should be considerably greater than the area in which occur faults or fault zones capable of causing the ground motion. There is appreciable structural geologic evidence that the area of the embayment within which such a capable fault or fault zone is most likely to occur is located close to the axis of the embayment. Stearns and Marcher (1962), in reconstructing the post-Cretaceous tectonic history of the Mississippi embayment, show (p. 1391, fig. 4) that only the central, axial region has been differentially downflexed. They conclude (p. 1393):

> The Mississippi Embayment syncline has not been uniformly bent. Rather, the east and west limbs individually have a uniform slope and bending has occurred within a narrow zone trending along the Mississippi River. This fact may be significant tectonically because

> the valley of the Mississippi River in this area has been the locus of many earthquakes, and numerous faults have displaced the Pleistocene valley fill. These structural movements have taken place where the sharp syncline is super-imposed on the crest of the Late Cretaceous dome, i.e. the Pascola arch.

Although many major faults have been postulated by numerous authors to occur in the Paleozoic rocks beneath much of the Mississippi embayment (Bond, et al., 1971; Phelan, 1969; Schwalb, 1971; Tikriti, 1968), it seems highly significant that only one major fault has been demonstrated to offset Cretaceous and younger sediments of the embayment (Bond, et al., 1971; Mateker and others, 1968 (cited in Lammlein and others, 1971); Tikrity, 1968, pl. 14 and p. 91). This fault coincides with the zone of maximum downwarp of the embayment syncline depicted by Stearns and Marcher (1962) and is the one which Bond, et al., (1971) declare was responsible for the 1811-1812 New Madrid earthquakes.

Subsurface stratigraphic evidence of lesser displacements on the order of 100 feet or less is generally lacking in the embayment due to the relatively wide spacing of control points. Boswell, et al., (1965, plate 1) show an offset in Cretaceous rocks of about 100 feet near Cairo in western Carlisle County, Kentucky, and another of about the same magnitude in the Cretaceous in central Crittenden County, Arkansas. A northeast-trending normal fault of about 100 feet of throw is shown by Moore (1965) cutting near-surface strata as young as Pleistocene and Recent in Lake and western Obion Counties, Tennessee, near Reelfoot Lake.

These three faults are in approximate alignment; if they were to be connected, they would form a single fault whose alignment and position would correspond to that of the larger fault displacement shown by Bond, et al., (1971) at the base of the Cretaceous along the axis of the embayment.

The occurrence of major regional fault zones in the embayment was proposed by Fisk (1944) on the basis of his interpretation of aerial photographic lineaments and topographic features. In Arkansas, he shows the "Ozark escarpment fault zone" trending northeast along the Ozark escarpment at the western edge of embayment, the "Big Creek fault zone" extending from Cairo, Illinois to Memphis and southwestward, the "Arkansas River fault zone" extending southeast from Little Rock, Arkansas to Greenville, Mississippi and beyond, and the "White River fault zone", extending from Jackson and Independence Counties, Arkansas, southeast past Helena, Arkansas, and into Mississippi. However, a subsequent publication by Caplan (1954) presents a series of geologic sections across the embayment in Arkansas intersecting Fisk's proposed fault trends, and fails to show any fault offsets in the embayment sediments. Since Caplan's sections were based on rather extensive subsurface data from wells, it appears that the idea of northeast and southwest trending sets of major zones in the embayment as proposed by Fisk (1944) is thus far contradicted by available subsurface data in Arkansas. Tikrity (1968) concludes (p. 93) that a major fault does not occur along the Ozark escarpment north of Batesville, Arkansas. In Tennessee, no faults are shown in the Tertiary by Criner and others (1964) for the Memphis area (Shelby County) in spite of the greater density of control points there. A recent section compiled by Bicker (1974) across the embayment in northern Mississippi shows no fault offsets in the embayment sediments, though many faults are shown in the underlying Paleozoic rocks. If the section by Bicker (1974) and the Section B-B' by Caplan (1954) were combined, they would illustrate the absence of major faulting across the entire Mississippi embayment south of Memphis.

Subsurface structural geologic data therefore indicate that the most likely location for a major fault correlative with the New Madrid events is parallel with, and at or close to, the axis of the Mississippi embayment north of Memphis.

Geophysical investigations show the occurrence of rather localized but prominent Bouguer gravity anomalies of up to 50 milligals near the axis of the northern Mississippi embayment (Phelan, 1969, pl.2). Although there is no direct evidence to relate these anomalies (the Bloomfield, Malden and Covington anomalies) to tectonic or seismic activity, if they are assumed to be related, they would suggest that the origin of tectonic and seismic disturbances in the embayment is confined to a north-south linear zone near the axis of the embayment.

The pattern of earthquake epicenters estimated from intensities reported since 1811 (Figure 2.5-23) reveals a marked concentration centered along the Mississippi River from southern Illinois to Memphis and effectively defines the New Madrid seismic zone. Epicenters of Intensities IV-V and greater belonging to this seismic zone do not appear to be located west of Jonesboro, Arkansas, nor south of Memphis, Tennessee. A microearthquake study conducted in 1968 by Lammlein and others (1971) demonstrates considerable microseismic activity in northwesternmost Tennessee, opposite the "Boot Heel" of Missouri, some stations indicating an average of as many as five microseismic events per day. This area also corresponds to the area of greatest density of macroseismic activity in the New Madrid seismic zone as shown in Figure 2.5-23.

Focal mechanism (nodal plane) solutions determined from the sense of motion of first and second P-wave arrivals and from surface studies (Street and others, in press) indicate high angle normal (tensional) faulting along a north-south structure from Memphis north to about latitude 36.3°N, and high angle thrusting (compression) north of that point to about latitude 38.5°N. Hypocenters occur at depths of 0 to 30 kilometers (0 to 18 miles). Thus along the eastern edge of Arkansas a tensional stress field seems to be operating which would tend to generate north-south normal faulting. The importance of this finding for the Unit 2 site is that it would appear to rule out the existence of seismically active trends that could extend westward toward the site at right angles to the relatively narrow, north-south elongated New Madrid seismic zone.

It is therefore concluded on the basis of all available geophysical, seismological, physiographic and structural geologic evidence that the New Madrid seismic zone is restricted to a relatively narrow, north-south oriented belt centered along the Mississippi River, extending from Memphis north to Illinois and westward as far as Crowley's Ridge in Arkansas. This western limit also corresponds to the approximate western extent of recorded macroseismic activity and of the most severe effects of the 1811-1812 New Madrid earthquakes as documented by Fuller (1912).

The aforementioned evidence leads to the conclusion that future large intensity seismic events are likely to be limited to the region north of Memphis and generally within the northern Mississippi embayment. The cause of major seismic events is attributed to the known major faults in that area such as the New Madrid, Rough Creek, and Ste. Genevieve fault zones. The seismic history of the area, as defined in a recent TVA report and the seismic study for the Unit 2 site, suggests that high intensity earthquakes occur within the limits of the buried Pascola Arch. All available surface and subsurface geologic data indicate that the major faults are not continuous southward beyond central-western Tennessee.

2.5.2.8 Maximum Earthquake

The historical seismicity data indicates that Arkansas is not an area of earthquake centers; however, the effects of distant shocks should be considered, in particular those which occurred over 150 years ago along the Mississippi River north and south of New Madrid, Missouri.

From Myron L. Fuller's publication, "The New Madrid Earthquake" (U.S.G.S. Bull. 494), it may be estimated that St. Louis, Missouri experienced an intensity of VII during the New Madrid shocks. St. Louis is about 60 miles closer to New Madrid than the site and is founded, in part, on thick alluvial deposits overlying shale and limestone, unweathered shale bedrock. Consequently, Fuller's data indicates that the intensities at the Unit 2 site due to the New Madrid shocks were probably less than VII.

Dr. Perry Byerly, in a letter dated August 5, 1970 (see Appendix 2A of the FSAR), has stated:

> A study of the earthquake history of the area indicates that the greatest shaking in the area of the site was from the New Madrid earthquakes of 1811 and 1812.
>
> I am impressed by the good foundation at the site, seismic speeds 11,000 to 14,500 ft/sec. I would estimate that the greatest intensity that could be expected at the site would be a high VI or low VII, corresponding to 0.1g (I doubt if that great an intensity has been attained in historic time).

Otto W. Nuttli, in his publication "The Mississippi Valley Earthquakes of 1811 and 1812: Intensities, Ground Motion and Magnitudes." (1973) states "Although the 1811-1812 earthquakes often are called the New Madrid earthquakes or earthquake, there is sufficient evidence to place the epicenter of the first earthquake (Dec. 16, 1811) to the southwest, probably in northeast Arkansas near the southern end of the lake formed by the St. Francis River...". Dr. Nuttli includes in his report a generalized isoseismal map for this particular shock (see Figure 2.5-26), but he does not extend the lines west of the epicenter because "no satisfactory intensity data are available for that area".

According to Nuttli, "It is difficult to assign intensities to the later principal shocks, because many of the published accounts describe the cumulative effects of all the earthquakes... There is insufficient information to construct isoseismal maps, such as that for the earthquake of Dec. 16. In all accounts the Feb, 7, 1812 earthquake was described as being the most severe....The town of New Madrid was completely destroyed. Whereas formerly it was 25 feet above river level, it was only 12 feet above after the earthquake. Near it the river overflowed its banks, and the land was covered with sand blows 12 to 50 feet in diameter (Pennsylvania Gazette, Mar. 18, 1812). From these and other similar accounts, it appears that the epicenter of the Feb. 7 earthquake was close to New Madrid."

Nuttli assumes the Feb. 7 earthquake to have been more severe (magnitude 7.1 as compared to 6.9 for the Dec. 16 shock). He also states that the epicenter was close to New Madrid, in which case it would have been about 220 miles from the Unit 2 site.

As previously mentioned, the limits of the New Madrid fault zone have not been definitely established in the literature. The southern end of the New Madrid fault zone was placed in extreme northeastern Arkansas by Heyl and Brock, 1961, almost 200 miles northeast of the site. King, (1965) extended the zone to about 25 miles south of the northeastern Arkansas/southeastern Missouri border, still over 150 miles east of the site. Based on the

locations of epicenters of earthquakes having intensities greater than V, McGinnis (1963) placed the southern limit of the zone just north of the Arkansas-Missouri border, which is south of New Madrid and over 200 miles from the site.

Recent work by Kisslinger and others (1971) and Followill (1972) indicates that earthquakes occurring in the New Madrid fault zone since 1970 may delineate the southern end of the New Madrid system more accurately. The epicenters of these earthquakes are distributed along a northeast-southwest trend west of New Madrid that is parallel to, but not coincident with previously mapped or inferred faults. The southern end of this trend, as defined by Kisslinger, is marked by a 4.5 magnitude event occurring in November of 1970, 10 miles south of the southwest Missouri-northeast Arkansas border, and almost 200 miles northeast of the site. This event coincides with the southern limit of the fault zone determined by Heyl and Brock, 1961, based on faulting evidence.

One other earthquake, farther south than the 1970 event, may possibly be associated with movement within the New Madrid fault zone. This 1955 event in northeastern Arkansas occurred along the trend established by Kisslinger and others, 1971. This maximum Intensity IV shock is the southernmost of any event occurring along the trend of the New Madrid fault zone as established by Kisslinger. It is over 160 miles from the site. Followill, in 1972, includes both the 1955 Arkansas event and the 1843 Memphis event (which is 180 miles from the site) within the limits of the New Madrid fault zone. All the above studies indicate that the New Madrid fault zone is over 150 miles from the ANO-2 site. It is conservative but reasonable to assume that the Maximum Earthquake for the Unit 2 site is another New Madrid earthquake occurring on the New Madrid fault zone at its closest approach (more than 150 miles) to the site. A study was made to estimate intensities that might be expected to occur at 150 miles from the epicenter.

Nuttli's isoseismal map indicates that 150 miles east of the Dec. 16, 1811 epicenter, intensities were VII-VIII. At Herculaneum, Mo., 150 miles northwest from the epicenter, Nuttli shows an intensity of only VI-VII. At St. Louis, almost 200 miles from the epicenter he indicates an intensity of VII-VIII, but some foundation conditions there are notably poor.

It is likely that intensities experienced to the east of the New Madrid earthquakes are not entirely representative of what might be expected to the west, toward the Unit 2 site. Most of the area to the east is in the Gulf Coastal Province, which contains a thick section of relatively unconsolidated material. To the west the area is part of the Ouachita Province which in general is underlain by more indurated material at a shallower depth than in the Gulf Coast Province. Consequently, it is likely that intensities 150 miles west of the "Maximum Earthquake" would be lower than Dr. Nuttli indicated as occurring 150 miles to the east of the 1811-1812 New Madrid earthquakes. Dr. Byerly supports this. As mentioned earlier, he has stated that he would estimate that the greatest intensity that could be expected at the site could be a high VI or low VII. Also, Dr. Algermissen, on his seismic Risk Map indicates an intensity of only V-VI was associated with the New Madrid earthquakes at 150 miles west of the epicentral area.

Isoseismal and attenuation data from several sources were considered. These included isoseismals by Nuttli, (February 1973) of the December 16, 1811 New Madrid earthquake (maximum Intensity X-XI); isoseismals for the November 8, 1968 south-central Illinois earthquake, maximum Intensity VII, prepared by Gordon, et al. (June, 1970); attenuation curves for eastern Canada prepared by Milne and Davenport (April 1969); and Weston Geophysical Engineer's attenuation curves for the Mississippi Valley area.

The above data indicate that an earthquake with epicentral Intensity X-XI at 150 miles, could be expected to cause an intensity at the site of low VII to a maximum of VII-VIII. The only exception to this are three VII-VIII intensities shown by Nuttli between 150 and 200 miles from the December 16, 1811 New Madrid earthquake. These anomalous intensities occurred at St. Louis, Missouri; Henderson, Kentucky and Nashville, Tennessee, all near major rivers and partially underlain by alluvium. St. Louis has some notably poor foundation conditions, as discussed elsewhere. These higher intensities may have been due to poor foundation conditions. Gordon's isoseismals clearly show lower attenuation at major rivers, presumably due to the alluvium and poorer foundations.

Foundations conditions at the Unit 2 site are certainly better than average conditions in the areas considered in the above described studies. An intensity of VII-VIII at the site, resulting from another New Madrid event 150 miles from the site, is a conservative value for the DBE based on the attenuation data described above.

It is conservative to assume that the "Maximum Earthquake" might result in Intensity VII-VIII at the site. Intensity VII-VIII on Neumann's curve corresponds to a maximum ground acceleration of slightly less than 0.20 g. The maximum earthquake for the site is therefore assumed, for design purposes, to result in a maximum ground acceleration of 0.20 g at the site. It is again stressed, that all Category 1 structures are founded on dense, unweathered bedrock. This acceleration is considered to be ample for design of the structures against postulated future seismic activity.

The site is in a region of gently folded sedimentary rocks of Paleozoic age. These rock units have been only slightly to moderately faulted, and the faults are probably related to the folding, which is pre-Cretaceous in age. In over 160 years of historical record, only three epicenters (all maximum Intensity V) have been located within 100 miles of the site, and none were closer than 50 miles. Recent investigations (Docekal, 1970) indicate that the October 22, 1882 epicenter (maximum Intensity VI-VII) previously shown about 50 miles from the site probably occurred near Bonham, Texas, or about 200 miles from the site.

No active faults are known to exist within 50 miles of the site, and there is no evidence of any seismically active zone near the site. Therefore, the possibility of an earthquake occurring sufficiently close to the site, and of sufficient intensity to cause ground accelerations greater than the DBE is apparently extremely remote.

2.5.2.9 <u>Design Basis Earthquake</u>

The DBE for vibratory ground motion, corresponds to a maximum ground acceleration of 0.20 g at the site. Figure 2.5-27 presents design spectra for the maximum vibratory acceleration of 0.20 g.

2.5.2.10 <u>Operating Basis Earthquake</u>

The OBE for the site is one-half of the DBE, or 0.10 g. Figure 2.5-28 shows the design spectra for the OBE.

2.5.3 SURFACE FAULTING

2.5.3.1 Geological Conditions of the Site

Regional and site geology are presented in Section 2.5.1 and shown on Figures 2.5-1 through 2.5-5. A map of the tectonic structures within 200 miles of the site is shown on Figure 2.5-6.

A literature study was made as part of the geologic evaluation of the Arkansas Nuclear One site to locate faults and other tectonic features that might be significant to the site. The following are descriptions of the faults evaluated as part of this study, with the conclusions drawn regarding their existence and importance to the site.

2.5.3.2 Evidence of Fault Offset

A number of inactive faults are mapped in the vicinity of the Arkansas River, particularly to the northwest and west of the site. These are primarily east-west trending, normal faults related to the broad anticlinal folds of the Arkansas Valley. Of these, the Prairie View and London faults (Figure 2.5-4) are the closest to the site. They are discussed below.

2.5.3.2.1 Prairie View Fault

The surface exposure of the Prairie View Fault closest to the site is approximately 12 miles west of the site, near Prairie View. It extends westward to a point about three miles northwest of Subiaco. Merewether and Haley (1961) projected the trace of this fault to a point about one mile southwest of Piney, six miles northwest from the site. This section of the fault trace is concealed by alluvial deposits along the Arkansas River. The Prairie Creek Fault is shown on the Arkansas state geologic map (1929) as a thrust fault. However, more recent work (Merewether and Haley, 1961) describes the fault as "a high angle north-dipping normal fault with the downthrown block on the north side." The maximum displacement along the fault is 350 feet, two miles west of the town of Prairies View (Haley, 1968). Near the western end of the fault the displacement is about 170 feet. The fault plane dips about 65 degrees north.

About three miles from the western end of the fault there is a small branch fault which is downthrown on the south side and is assumed to be dipping south. The Prairie View Fault follows an anticlinal axis (Prairie View anticline), and is similar to the faulted anticlines in the Fort Smith district discussed by Hendricks and Parks (1950). They state that the relationship between the compressional forces which caused the folding, and the displacement along the fault (downthrown side to the north) indicates contemporaneous folding and faulting. However, they also state that these faults may have formed as tensional faults at the time of the release of the compressional forces to the south. In either case, the last movement of these faults was prior to the Cretaceous, or over 135 million years ago.

2.5.3.2.2 London Fault

The London Fault is a primarily east-west trending zone which extends from Big Piney Creek on the west to about seven miles northeast of the town of London and about seven miles from the site. A number of smaller branch faults are associated with this fault zone. They occur to the northeast of the site (Figure 2.5-2) and extend to within about two and one-half miles of the site. The London Fault is a high angle south-dipping normal fault and is best exposed about eight miles northwest of the site at Big Piney Creek where the western part of the fault ends. At this locality the fault plane dips 58 degrees south and has an apparent displacement of about

20 feet. It is also exposed to the east along Flat Rock Creek and in a drainage ditch along a country road about eight miles from the site. An unnamed east-west trending fault lies about one mile south of the London Fault. The trend of this unnamed fault changes toward the east to generally southeast. It appears to intersect the London Fault in the vicinity of the north fork of Mill Creek (Haley, 1961). This fault is similar to the Prairie View Fault and is pre-Cretaceous in age.

In summary, the only faults within five miles of the site are the Prairie View Fault, and the London Fault and its branch faults. The closest fault is only a small branch fault and approaches within about two and one-half miles of the site. The last movement of these faults occurred prior to the Cretaceous.

2.5.3.3 Identification of Active Faults

As discussed in Section 2.5.3.2 above, the only faults within five miles of the site are the Prairie View and London Faults, neither of these has been active since Cretaceous time, or about 135 million years ago.

2.5.3.4 Earthquakes Associated with Active Faults

There are no earthquakes associated with faults within five miles of the site, and no active faults within five miles of the site.

2.5.3.5 Correlation of Epicenters with Active Faults

There are no active faults within five miles of the site.

2.5.3.6 Description of Active Faults

There are no active faults within five miles of the site.

2.5.3.7 Zone Requiring Detailed Fault Investigation

Recent work by Haley (1967), and Merewether and Haley (1961) for the Arkansas Geological Commission and the U.S. Geological Survey identify the faults in the vicinity of the site as pre-Cretaceous in age. There are no active faults within five miles of the site and no zones requiring detailed faulting investigation.

2.5.3.8 Results of Faulting Investigation

See Section 2.5.3.7. There are no active faults or fault zones requiring detailed investigation within five miles of the site.

2.5.3.9 Design Basis for Surface Faulting

There are no active faults within five miles of the site. Therefore, surface faulting is not a factor in the design of the Arkansas Nuclear One plant.

2.5.4 STABILITY OF SUBSURFACE MATERIALS

2.5.4.1 Geologic Features

Pennsylvanian rocks in the site area are in excess of 8,000 feet thick and consist primarily of shale and sandstone with some thin limestone horizons. There is no karstic or cavernous terrain in the area around the site, and geologic conditions necessary for their development do not exist at the site. No poorly consolidated or mineralogically unstable rocks occur at the plant site. No oil or other mineral extraction, or subsurface mining occurs or has occurred within three miles of the site. Natural gas production occurs in the area, but production is from well indurated rocks and subsidence is not a problem. It is therefore concluded that future subsurface subsidence is not a problem at the plant site.

A crustal movement map showing probable vertical movements of the Earth's surface was issued by the U.S. Commerce Department in August, 1972. The map does not show any movement within 150 miles of the site. However, they state that the blank areas simply mean there is not enough data to determine if they are being uplifted or subsiding. On the same map, the area of indicated movement closest to the site shows only slight regional uplift (1-5mm per year).

There are no shears, faults, or zones of crushed material in the rock which underlies the plant structures. The bedrock contains some joints and fractures, as does all rock to some degree. Some joints were encountered in the borings and noted during site foundation inspection, but these are not significant to site foundation conditions. Some crenulation of the bedding occurred when the rocks at the site were folded at the end of Paleozoic time. These crenulations occur in localized zones, and do not affect the site foundation. Rock at the site has been exposed at or near the surface since Cretaceous, over 135 million years ago, and shows no evidence of deformation since that time. Therefore, no unrelieved residual stresses should be expected to exist in the foundation rock and no evidence of unrelieved residual stress was observed during the exploration or excavation.

There are no rocks or soils at the site that are unstable because of mineralogy, lack of consolidation or water content, nor would any have potentially undesirable response to seismic events. Soils at the the site are hard clays and silty clays. There are no areas subject to liquefaction.

2.5.4.2 Properties of Underlying Materials

All Category 1 structures except the ECP inlet and outlet structures, electrical manholes, and the Condensate Storage Tank (T41B) pipe trenches are founded on competent unweathered bedrock. The properties of the bedrock materials are summarized in Table 2.5-2. Samples of rock core from the exploratory drilling were tested in the Bechtel Geologic Laboratory in San Francisco. Standard test procedures were followed, and the results of these tests are shown in Table 2.5-2. The lowest and highest unconfined compressive strength of the 45 samples tested are 2,420 psi (167 TSF) and 4,690 psi (338 TSF). The average is 3,460 psi or 249 TSF.

Minor slickensides along joint surfaces are not uncommon in shales, especially in a region where the rocks are very old and folding has occurred. No offsets were observed in drill holes, at foundation grade or anywhere in the site area. There are no soft, crushed or clayey materials associated with the slickensides. These slickensides are not considered to be significant to the stability of the foundations of any of the structures.

Where data on water levels observed during drilling are available, they are shown on the logs. The logs are shown on Figures 2.5-8 through 2.5-12.

Testing showed the specific gravity of the rock to be in the range of 2.51 to 2.67 with about 2.57 the average. Porosity varies from 2.0 percent to 7.81 percent with 5.9 percent about the average. Absorption ranges from 1.13 percent to 3.1 percent with an average of around 2.4 percent. The site seismic survey indicated P-wave velocities in the fresh rock to be from 10,000 to 14,500 fps. Results of this survey are shown on Figure 2.5-16. S-wave velocities were not measured in situ since the structures are founded on rock, but a value of 5,350 fps was calculated using a P-wave velocity of 10,000 fps and a Poisson's ratio of 0.30. The dynamic modulus of elasticity ranges from 2.8 (+6) psi to over 5 (+6) psi.

The engineering properties of the site soils are summarized in Table 2.5-3 and the soil properties used for design are summarized in Table 2.5-4. The data used to develop these tables are given in the Grubbs Consulting Engineering, Inc. reports of October 29, 1970 and July 21, 1972.

2.5.4.3 Plot Plan

The plot plan showing site exploration is attached as Figure 2.5-7. A geologic profile through the site showing foundation levels of Category 1 structures is shown as Figure 2.5-15. Site foundation materials are discussed in Section 2.5.1.2.5.

The locations of additional borings A23, and A126 through A132 which were inadvertently not shown earlier are now marked on Figures 2.5-7 and 2.5-14.

There are three borings (AH24, AH25 and A236) on the SW corner of the pond which are not within the pond but are within 200 feet to 300 feet of the edge of the pond. No further borings are considered necessary since the soil profile is uniform throughout the area. Soil samples have not been retained.

2.5.4.4 Excavations and Backfill

Plan and sections showing the extent of excavation and backfill at the plant site are shown in Figures 2.5-18 through 2.5-20. The compaction criteria for different categories of engineered backfill are given below.

A. Embankment Fill/Select Backfill. Impervious material for embankments and backfill consisted of red silty or sandy clay (CH) from selected borrow areas. These materials were placed in 8-inch loose layers, moisture conditioned and compacted to 95 percent of maximum dry density as determined by ASTM Designation D 1557.

B. Granular Backfill Material. Material classified as Granular Backfill Material was used for the following conditions.

    1. Beneath structural slabs on grade (95 percent compaction).

    2. Against exterior walls (90 percent compaction).

    3. Beneath footings and other foundations of Non-Category 1 structures which do not extend to firm rock (95 percent compaction).

Granular backfill material was placed in lifts not exceeding eight inches uncompacted thickness, moisture conditioned and compacted to the percent compaction specified above as determined by ASTM Designation D 1557, Method D. The limits of the granular backfill material are shown on Figure 2.5-20.

Granular backfill material did not contain more than 10 percent by weight of particles passing the No. 200 U.S. Standard Sieve. Tests were made on proposed material prior to backfilling to determine gradation, soundness and general suitability of material as granular backfill.

A. Placing Random Backfill Material. Random backfill material was used only in non-critical areas outside the limits of structural backfill as indicated in Figure 2.5-20. Where used, random backfill was placed in lifts not exceeding eight inches uncompacted thickness, moisture conditioned and compacted to 90 percent of maximum dry density as determined by ASTM Designation D 1557, Method D.

   Random backfill consisted of well graded material from plant excavation or trench excavation. The material contained no rocks having a dimension greater than six inches and it contained no organic or frozen material.

B. Clay Blanket Material. Clay blanket material was impervious material, obtained from the required plant excavation and stockpiled for this purpose.

C. Pipe Bedding. The bedding material was mechanically tamped, in lifts not exceeding eight inches uncompacted thickness for the depths indicated on the drawings, to 90 percent of maximum dry density determined by ASTM Test Designation D 1557.

   After placing and compacting, the bedding material was carefully shaped to fit the bottom quadrant of the pipe so as to provide full even support to the pipe.

   Bedding material was clean granular material, free of organic matter and of such gradation that at least 95 percent passed a one-half inch sieve, and no more than 15 percent by weight passed a No. 200 sieve when tested in accordance with ASTM Designation D 422.

2.5.4.5 Groundwater Conditions

Water levels in the site area range from elevation of 341 feet to 343 feet. These levels are about 10 feet below ground surface at the site and are about three feet higher than normal pool elevation in Dardanelle Reservoir. During construction of Unit 2, only small quantities of seepage were encountered. The water was removed as necessary with sump pumps. The natural groundwater regime will not be affected by plant operations.

The ECP, located about 1,200 feet northwest of the plant, is about 500 feet east of an embayment in Dardanelle Reservoir. Design of the pond is based on the consideration that seepage will raise the ground water level adjacent to the pond to the height of water in the pond, Elevation 347 feet. However, the low permeability of the foundation material precludes any large seepage losses, and any seepage that does develop (calculated to be 1.4 gpm) will migrate to the reservoir. Groundwater levels at the plant site will not be significantly affected. ECP level is carefully monitored as detailed in the Technical Specifications (Section 4.12).

A history of groundwater fluctuations at the plant site is not available since it was not required at the time the Unit 2 site study was performed. The design bases for hydrostatic loading on subsurface portions of safety-related structures are discussed in Sections 2.4.13 and 3.4.3.

2.5.4.6 Response of Soil and Rock to Dynamic Loading

The foundation rocks contain joints and fractures, as do essentially all rocks exposed at the earth's surface. However, these features should not be expected to affect the stability of the foundation rock during vibratory motion associated with the Design Basis Earthquake (DBE). The foundation loads are small in comparison to the rock's ultimate bearing capacity. There will not be loss of strength or stability of the foundation rock during vibratory motion. The soil at the site is not subject to liquefaction, and, therefore, response of the soil to dynamic loading was not evaluated.

2.5.4.7 Liquefaction Potential

All Category 1 structures except the ECP inlet and outlet structures, electrical manholes, and the Condensate Storage Tank (T41B) pipe trenches are founded on competent unweathered bedrock. The properties of the bedrock materials are summarized in Table 2.5-2.

2.5.4.8 Earthquake Design Basis

Site structures are designed for a DBE of 0.20g, and an Operating Basis Earthquake (OBE) of 0.10 g. The seismicity of the region and the basis for selection of these values are described in Section 2.5.2. The design spectra are shown on Figures 2.5-27 and 2.5-28. Foundation materials at the site were evaluated and their characteristics were considered with respect to the design spectra.

2.5.4.9 Static Analyses

All Category 1 structures except the ECP inlet and outlet structures, electrical manholes, and the Condensate Storage Tank (T41B) pipe trenches are founded on competent unweathered bedrock. The properties of the bedrock materials are summarized in Table 2.5-2. Tests were made in the laboratory to determine its unconfined compressive strength, static modulus of elasticity and Poisson's ratio. The lowest and highest unconfined compressive strengths of the 45 foundation rock core samples tested are 2,420 psi (167 TSF) and 4,690 psi (338 TSF), respectively. The average is about 3,460 psi or 249 TSF. The static modulus of elasticity measured from core samples ranges from 0.36(+6) psi to 1.0 (+6) psi and averages 0.7 (+6) psi. Poisson's ratio ranged from 0.24 to 0.34, averaging 0.30. Settlement of structures founded on rock will be slight and will occur almost simultaneously with imposition of the loads.

Security-Related Information
Text Withheld Under 10 CFR 2.390

2.5.4.10 Criteria and Design Methods

The results of laboratory tests on samples of the foundation rock are shown on Table 2.5-2. The results of the geophysical survey, made to evaluate the dynamic properties of the foundation rock, are shown in Figure 2.5-16. The unweathered bedrock, which is the foundation

rock for the Category 1 structures at the site, has an average unconfined compressive strength of 249 TSF, or over 10 times as great as the loads to be imposed by the structures. The static modulus of elasticity averages 0.7 (+6) psi and the dynamic modulus ranges from 2.8 (+6) psi to over 5 (+6) psi. Design response spectra for the site are shown on Figures 2.5-27 and 2.5-28.

Grouted anchor bars were installed in the Unit 1 holdup tank vault foundation to prevent flotation at the time of probable maximum flood. Pull-out tests on No. 8 deformed reinforcing bars, extending four feet into unweathered rock, were conducted during Unit 1 construction to test the capacity of these anchors. The results of the pull-out tests are shown on Table 2.5-10. The pull-out tests exceeded the yield point of the bars with no evidence of failure.

The same method of slope stability analysis were used for both intake and discharge canal slopes (Figures 2.5-29 through 2.5-30). The stability of excavated slopes and embankment slopes were analyzed by the modified Swedish Slip Circle Method of Analysis, known as the "Method of Slices" (Corps of Engineer Manual EM 110-2-1902) for typical sections, in each case. For the intake and discharge canal slopes, the stability computation was done manually, whereas for the final stability analyses for the ECP slopes, Bechtel Computer Program CE533 (Bechtel, 1966) was used. Experience has shown (Skempton, 1964 and Bjerrum, 1967) that the shear strength of over-consolidated clays in excavations progressively reduces from its peak value to its residual value, hence residual shear strength parameters were used for stability analyses in all the cases. For both natural soil and recompacted soil, design shear strength parameters were selected based on consolidated drained direct shear test data as detailed in Section 2.5.5. In the ECP area, it was not possible to obtain undisturbed samples of the weathered shale and, therefore, shear strength parameters for this material were evaluated from plate load tests made in the field. The evaluation was based on the following equation by Mayerhof (1957):

$$q = c\,(Nc_q) \;=\; Y\,(\frac{B}{2})\,N_{Yq}$$

where:

q is the ultimate bearing capacity in psf.

c is cohesion in psf.

Nc_q and N_{Yq} are bearing capacity factors.

B is the least width of footing in feet.

Y is the density of soil in pcf.

All slopes were evaluated under conditions of normal water level, rapid drawdown, and normal water level combined with earthquake loading. The earthquake ground acceleration used was 0.2g. For further details on evaluation of the design strength parameters, method of analyses and computed factors of safety see Section 2.5.5.

The over-consolidated clay at this site is not susceptible to liquefaction.

2.5.4.11 Techniques to Improve Subsurface Conditions

All Category 1 structures except the ECP inlet and outlet structures, electrical manholes, and the Condensate Storage Tank (T41B) pipe trenches are founded on competent unweathered bedrock. The properties of the bedrock materials are summarized in Table 2.5-2.

In the ECP area, the weathered rock surface, wherever exposed, was covered with a blanket of impervious fill to reduce seepage losses.

2.5.5 SLOPE STABILITY

2.5.5.1 Slope Characteristics

Intake and Discharge Canal Slopes - The overburden soils at this site are mainly stiff highly plastic clays. At the intake canal about 13 to 25 feet of clay overlies the weathered bedrock. Along the discharge canal it is 22 to 25 feet deep. The underlying bedrock is hard and consists of dense shale with about two to five feet of weathered shale. Typical sections of the slopes are shown on Figure 2.5-29.

Emergency Cooling Pond Slopes - The location of the pond, which is a Category 1 facility, is shown on Figure 2.5-17. Typical sections of the slopes are shown on Figure 2.5-21. The pond exploration holes show that the depth to sound bedrock varies from about 10 to 22 feet below the present ground surface. The results of permeability tests made on remolded samples of weathered shale indicated a permeability coefficient of 4.2(-6) cm/sec which is rather low. However, the influence of fissures or joints in the original material is not reflected in the remolded samples. Consequently, to ensure against seepage loss, an impervious blanket is provided at the bottom and on the side slopes of the pond. During construction no pervious layers were visible above the weathered rock surface layer. The pond slopes were later grassed to stabilize them against erosion.

The pond involves primarily shallow excavation in overburden. A limited height of embankment was required in certain sections to provide for necessary freeboard as discussed in Section 9.2.5.2.1. The impervious material used for the fill was obtained from required excavation and selected borrow material. The fill properties are discussed in Section 2.5.4.4 and shown in Tables 2.5-6 and 2.5-7 as well as in Figure 2.5-31 of Section 2.5.5.2.1. The material consisted of red silty or sandy clay free of gravel, cobbles, boulders or pockets of silt, sand or other non-plastic material. The side slopes adjacent to the spillway are protected with riprap as discussed in detail in Section 9.2.5.2.1.

2.5.5.2 Design Criteria and Analyses of Slopes

Since the soils at the site consist of overconsolidated clay, the residual shear strength and not the peak strength of the soil was considered in selecting the design shear strength parameters. The reason being that relief of pressure resulting from excavation, results in swelling and a progressive reduction in the shear strength of the soil. Experience has shown (References 8 and 9) that, in time, the soil strength reduces from the peak to its residual value. Based on the results of consolidated drained direct shear tests on undisturbed samples, the following shear strength parameters were adopted for design:

S = 200 + P(tan 23 degrees)

where

S = the residual shear strength of the soil in psf

P = the normal stress on the failure plane, in psf

The results of the tests and the design strength envelope are shown on Figure 2.5-22. Other engineering properties used in the analyses are tabulated in Table 2.5-3.

The stability analyses for the intake and discharge canal slopes and for the original ECP slopes were made in accordance with the modified Swedish Slip Circle method of analysis, known as "The Method of Slices." The earth pressures on the sides of the slices were neglected. The earthquake load used in the analysis was the Design Basis Earthquake (DBE). The effect of this load was introduced into the analysis as a static horizontal load equivalent to the DBE acceleration of 0.2g times the mass of soil and water. The load was applied at the center of gravity of the soil mass under investigation. All slopes were evaluated under conditions of normal water level, rapid drawdown, and normal water level combined with earthquake loading.

For the slopes added with construction of the reinforced concrete spillway for the ECP, the stability analyses were made in accordance with the Simplified Bishop Method, the Simplified Janbu Method, and the Spencer Method. These methods are also part of the family of “The Method of Slices,” and provide equivalent or conservative results compared to the Modified Swedish Method (see Army Corps of Engineers, “Slope Stability,” EM 1110-2-1902, 2003). For the seismic analysis of these added embankment slopes, the equivalent seismic DBE acceleration of 0.355g was used, which was obtained from an updated soil-structure interaction analysis. The same load conditions as used for the original ECP slopes were used for the analysis of these added embankments. Laboratory test results were used for the shear strength properties for the clay for the new embankments, with all other soil shear strength properties the same as for the original embankments.

The varying depth to bedrock below the bottom of the ECP was considered in the stability analysis of these slopes.

The results of the stability analyses made for the intake and discharge canal slopes are tabulated in Table 2.5-11 and the location of the critical slip surfaces are shown in Figure 2.5-29.

For the ECP slopes, two general slope conditions were analyzed. These were for slopes which are entirely in overburden soil and for slopes which are partly in soil and partly in weathered shale.

The results of long-term stability analysis of the ECP slopes in clay under different loading conditions are summarized in Table 2.5-5a for those slopes that are entirely in overburden. Graphic presentation of the test data and typical sections of the pond are shown in Figures 2.5-30, 2.5-31, 2.5-37, 2.5-47, and 2.5-49 through 2.5-54 and discussed in Section 2.5.5.2.1.

Based on this study, the ECP slopes were safely excavated to two and one-half horizontal to one vertical.

The results of long-term stability analysis of these embankment slopes, which have an impervious blanket to prevent seepage through joints in the weathered shale, are shown in Table 2.5-5b. Three cases were analyzed.

These were full reservoir at Elevation 347 feet with DBE seismic loading; minimum reservoir at Elevation 342.5 feet DBE seismic loading and groundwater table at Elevation 347 feet; and rapid drawdown to Elevation 341 feet from Elevation 347 feet. It should be noted that drawdown to Elevation 341 feet is considered for slope stability only. The soil properties used in the analysis are given in Table 2.5-3. The sections analyzed are discussed in Section 2.5.5.2.1. The results of the analysis are given in Table 2.5-5b.

The strength tests were not done in accordance with Appendix IXA of the U. S. Army Engineer Manual 1110-2-1906, dated November 1970. The use of residual shear strength tests of this type appear to be unduly conservative for cuts in clay having a height of 11 feet and where no previous history of sliding is recorded. The pond is excavated in natural soils with the normal water surface at Elevation 347 feet, which is below the below the surrounding ground level. Therefore, failure of a clay slope would not result in release of water from the pond.

Conventional stability analyses have been made using peak strength values for the condition of pond water surface at Elevation 347 feet combined with an earthquake acceleration of 0.2g (DBE). This is the most critical condition. Using a pseudostatic analysis and peak strength values, factors of safety were obtained and are presented in Table 2.5-5c.

2.5.5.2.1 <u>Soil Sampling and Testing to Determine Strength Properties of Compacted Clays and in situ Weathered Shale</u>

The following is a report of a soil testing program designed to provide information concerning the strength properties of compacted clay and in situ weathered shale for stability analyses of slopes in an ECP at Arkansas Nuclear One near Russellville, Arkansas. It was understood that the clays investigated in borrow pit studies may be used for blanketing portions of the sides and bottom of the reservoir. The in situ weathered shale stratum was investigated to enable a more complete stability analysis of the reservoir sideslope design. The study was conducted by Grubbs Consulting Engineers, Inc. and submitted to Bechtel Corp. on July 21, 1972.

In order to establish the strength properties requested, a program consisting of the following phases was adopted:

A. A field investigation wherein disturbed samples of potential borrow area soils were obtained from test pits;

B. A series of field plate load tests performed on weathered shale in the cooling reservoir area;

C. A laboratory testing program designed to establish properties and residual strengths of representative remolded clay samples; and,

D. The preparation of an engineering report with analysis of field and laboratory data and resulting residual strength parameters.

2.5.5.2.1.1 <u>Field Investigations</u>

2.5.5.2.1.1.1 <u>Borrow Areas</u>

Several spoil areas containing soil and rock removed from construction of other structural units at the site were under consideration for use as blanket material. Representative samples were obtained at random in several of these potential borrow areas. A total of nine test pits located as shown on Figure 2.5-31 were utilized to obtain disturbed samples of material for classification and strength studies. The test pits varied in depth from six to 10 feet and were generally terminated when an appreciable thickness of shale material was encountered or the percentage of shale fragments in the cohesive soils increased significantly.

Processes used to dry or wet the clay backfill were as follows:

A. Material found to contain too high water content was loosened by a rome disc and allowed to dry until material could be compacted to required density.

B. Material found to be too dry was loosened as required and sprinkled by a water wagon. After absorption the material was transported and/or compacted in place.

Descriptions of the various soils encountered in the test pits and some laboratory test results are presented on the test pit logs, Figures 2.5-32 through 2.5-36. With the exception of Test Pit 5, all test pits were located in existing spoil areas. In general, the spoil materials in the area of Test Pits 1 through 4 consisted of 4 to 8.5 feet of tan and gray with some red, silty clay and varying percentages of shale and weathered shale fragments. The thickness of clay decreased toward the north end of the spoil area. The material encountered in Test Pits 6 and 7 consisted of eight to 10 feet of red and gray with some tan clay with some weathered shale in the upper 1.5 feet. The silty clay soils in Test Pits 8 and 9 contained considerable shaley material overlying weathered shale spoil.

Visual inspection of borrow areas and evaluation of inplace compaction tests were used to ensure the exclusion of shale from backfill.

2.5.5.2.1.1.2 Plate Load Test Areas

At the time of this study, excavation of the cooling water reservoir was in progress and large areas of the weathered shale had been removed prior to selecting load test areas. Due to this fact, only a small unexposed area of the weathered shale in question remained to be removed, and it was necessary to locate the four tests in a relatively small portion of the total reservoir floor, as shown in Figure 2.5-37. Since the testing procedure provided for the use of construction equipment as reaction load for the jacking system in the plate load tests, the maximum reaction load was limited to 50,000 to 60,000 pounds. Consequently, to ensure that a failure could be achieved, test pits were excavated with a prepared slope on one end and load applied to a plate positioned at the top of the slope. Using this system, analysis of the failure could be performed using the Meyerhof Method of Analysis of Footings on Top of Inclined Slopes as discussed in "The Ultimate Bearing Capacity of Foundations on Slopes," Meyerhof, Proceedings Fourth International Conference on Soil Mechanics and Foundation Engineering, Vol. 1, pp. 384-86, London, 1957.

The test pits for the 4-plate load tests were prepared by excavating completely through the weathered shale zone and establishing a known slope on one end of the pit. The thickness of the weathered shale in the load test pit varied from 2.5 to 4.5 feet. A test pit width of at least three times the length of the load plate was utilized to reduce the effects of adjacent continuing pressures on test results. The slopes established varied from 2 to 1 for Tests 1 and 3, 1.75 to 1 for Test 2, and 2.5 to 1 in Test 4. In general, the weathered shale encountered in the plate load areas was fractured and jointed with numerous light gray and tan clay seams, partings and pockets. Occasionally more resistant shale inclusions of irregular dimension were noted, particularly in the excavation for Test Pit 4.

Plate load tests were performed on the weathered shale by applying a compressive load to a steel plate with either a 1 ft^2 or a 0.5 ft^2 contact area. In each of the tests, the load was applied through a hydraulic jack and gauge system in increments and deflections recorded from two or three dial indicators (Ames, reading to 0.001 inch) in contact with the load plate. A typical load

test arrangement is shown on Figure 2.5-38. A copy of load test data and load system calibration is included in Section 2.5.5.3.1. All load test were continued until a well-defined shear failure developed in the weathered shale stratum. The general configuration of the failure surfaces for the tests are shown on Figure 2.5-47. Results and analyses of the load tests are presented in subsequent sections of this report.

2.5.5.2.1.2 Laboratory Testing

The laboratory testing program conducted in this study was designed to establish the suitability of possible borrow area soils for use as the compacted clay blanket and to establish residual strength parameters for remolded specimens of two suitable blanket soils. A brief discussion of the procedures and results of shear strength and supplementary tests are presented below.

The classification of soils obtained from the adjacent borrow pits and in the cooling reservoir area were established by performing six Atterberg limit tests and six sieve analyses through the No. 200 sieve. On the basis of classification data, the two most suitable borrow areas were selected and the maximum dry density and optimum moisture content for these soils were determined using the Modified Compaction Procedures (ASTM D 1557). Moisture-density curves are shown on Figure 2.5-40. Soil classification data is summarized on Figure 2.5-41, and portions of the data are tabulated on the test pit logs. Based on the moisture-density criteria established in the compaction tests, one sample was prepared for each of the test pit soils at a minimum of 95 percent of maximum dry density to provide for direct shear test specimens. Three shear test specimens were carved from each of the larger compacted clay samples for residual direct shear testing.

The residual strength parameters requested required the performance of consolidated-drained direct shear tests on the six specimens. The direct shear procedure utilized provided for the placement of the 1-inch high, 2.5-inch O.D. specimen in the split brass shear ring with porous stones on the top and bottom to allow drainage. The split ring was then placed in the direct shear device, inundated, and a normal load applied. The rate of strain used was 0.001-inch per minute. The specimen had achieved essentially 100 percent primary consolidation under the applied normal load when zero movement of the vertical gauge occurred after a minimum period of 24 hours. Horizontal shearing force was applied as required to pass the peak strength and reach sufficient displacement to produce a residual strength condition (approximately 0.25 inch). The shear ring was pushed back to the original position, sheared again, and the process repeated until the strength of the clay obtained a constant residual value. The rate of strain was maintained at sufficiently low magnitude to ensure that no excess pore pressure developed during shear. This procedure was repeated for the three test specimens from each of the selected borrow area soils. Normal pressures of 0.4, 0.8, and 1.2 tons per square foot were used in the 3-specimen test series. Residual shear strength parameters established and other pertinent test data are presented graphically in Figure 2.5-42. No test data are available to check the degree of saturation attained at the end of the test.

2.5.5.2.1.3 Analysis and Conclusions

2.5.5.2.1.3.1 Compacted Clay

Results of the Modified Compaction Tests and residual direct shear tests performed on soils sampled from Test Pits 1 and 7 are summarized below:

Test Pit	Depth	Sample Y Dry	W. C., %	% of Max. Y Dry	Residual Strength Cohesion, tsf	Residual Strength ø, Degrees
1	0-4	113.2	17.8	96	0.08	25.5
7	0-4	107.4	19.6	96	0	29.0

Based on classification data and visual inspection of the test pits, it appears that the clay soils (CH, according to the Unified System) encountered in Test Pits 6 and 7 would be satisfactory for use in the compacted clay blanked required for the cooling water storage reservoir. The lateral extent of the CH soils encountered in the two pits is approximated by the shaded areas shown in Figure 2.5-31. It should be noted that discussions with project personnel indicate that the spoil materials were deposited in the areas investigated in a random pattern and considerable variation in soil properties should be anticipated.

At the time of the investigation, additional spoil was being placed in the area containing Test Pits 1 through 4, and an attempt was being made to separate the clay and weathered shale materials for possible future use. As a result, portions of the area recently deposited should exhibit more uniform soil characteristics. Even so, field density control criteria may require frequent revision during placement.

2.5.5.2.1.3.2 Load Tests in Weathered Shale

Load displacement curves were prepared from plate load test data collected in the four tests and are presented as Figures 2.5-43 through 2.5-45. As shown on the curves for Tests 1 and 2, failure developed in the shale following the instantaneous application of a load increment. The instantaneous load increases resulted from the method of load application, a condition which was alleviated in Tests 3 and 4. However, since the load was maintained in Tests 1 and 2 for a significant period after the load was applied, it is felt that the results are representative of the shear strength inherent to the weathered shale tested. Load Tests 3 and 4 were performed in general accordance with ASTM D 1194-57 criteria, with the exception of the items noted in Section 2.5.5.3.1.

Since the point of failure is clearly established on the load curves, these values were utilized in developing shear strength parameters from Meyerhof's Method of Analysis of Footings on Top of Inclined Slopes as discussed in the previously cited Proceedings of the Fourth International Conference on Soil Mechanics and Foundation Engineering.

Failure loads determined from the tests are as follows:

Load Test No.	Failure Load, ksf
1	21.5
2	14.0
3	24.0
4	20.0

Four plate load tests were made of which only one, Test 4, had a substantial drop in strength after the peak pressure was reached. This residual pressure was 16 KSF. However, the lowest pressure was recorded in Test 2 as 14 KSF and it was selected to develop the design shear strength parameters.

Using the failure loads noted in the formula $q = c(N_{cq}) + Y \left(\frac{B}{2}\right) N_{Yq}$ from the referenced source, analyses of Load Tests 1, 2, and 3 were performed for two conditions: c = 0 and ø = 0. These analyses indicate that the ø = 0 condition is most representative of the test results. Cohesion values determined are summarized in the following table. The cohesion value for Load Test 4 was determined using Meyerhof's Formula for the Ultimate Bearing Capacity of a Shallow Rectangular Footing in Cohesive Soil. It should be noted that the failures produced in all load tests resulted from a combination of crushing of the shale directly beneath the plate and a generally horizontal shearing along a clay parting or seam. Cohesion values established are considered to be representative of the average minimum strength of the weathered shale zone.

Load Test	Description of Soil and Failure Surface	Slope Angle, β	Computed c, psf, (From Meyerhof)
1	Gray and tan, weathered shale, horizontal, thin bedding	26.5	4,300
2	Gray and tan, weathered shale, soft, light gray clay seams along base of failure	30	2,690
3	Gray and tan, weathered shale with some light gray, clay partings	26.5	5,100
4	Failure occurred through light gray clay parting	22*	3,570

*Failure did not occur downslope. See Figure 2.5-47 for shape of failure.

2.5.5.2.2 Emergency Cooling Pond Stability Analysis

Stability analyses were carried out on a typical section of the emergency cooling pond slopes using Bechtel Program CE-533, a modification of the Method of Slices. (Stability of Earth and Rockfill Dams, Corps of Engineers, Civil Works Engineering Manual, EM 1110-2-1902.) To evaluate the stability of the slopes under seismic conditions, an equivalent horizontal static force equal to the maximum design ground acceleration times the weight of the soil and water in each slice was added and the same method was again used. These analyses were conducted by Bechtel Inc. and the results presented in August 1972.

The cross section and soil properties used in the analysis were chosen to represent the worst possible conditions. Figures 2.5-51, -52 and -53 show the sections analyzed and the soil properties used.

From the 4-plate load test results, the lowest recorded value, Test 2, was used from computing the shear strength parameters of weathered shale from design. The load deformation curve did not indicate a reduction of strength after the peak load had been reached. The only test in which a significant change in strength was indicated, was Test 4. But the residual strength was higher than in Test 2.

For the cooling pond stability analyses, the residual shear strength parameters were used for fill material. For weathered shale also, the shear strength parameters were computed from the lowest test results obtained from four field plate load tests.

The parameters used in the study are summarized below.

Material	Properties	Source
Clay Blanket	Saturated Unit Weight - 130 pcf Angle of Internal Friction - 25 degrees Cohesion - 100 psf	Results from study by Grubbs
Weathered Shale	Saturated Unit Weight - 145 pcf Angle of Internal Friction - 0 degrees Cohesion - 2,700 psf	Assumed Study by Grubbs
Filter	Saturated Unit Weight - 130 pcf Angle of Internal Friction - 35 degrees Cohesion - 0 psf	 Assumed

The minimum acceptable factors of safety under the conditions analyzed were as follows.

Case	Required Condition	Factor of Safety
I	Full Reservoir with Earthquake	1.1
II	Rapid Drawdown with no Earthquake	1.25
III	Minimum Reservoir Level with Earthquake	1.1

RESULTS

Stability analyses as described previously showed all three cases had an adequate factor of safety. The results are summarized below.

Case	Condition	Factor of Safety
I	Full Reservoir with Earthquake	1.4
II	Rapid Drawdown with no Earthquake	2.3
III	Minimum Reservoir Level with Earthquake	1.3

For the highly plastic clay and over-consolidated shale with low confining pressure, long-term stability is ensured by adopting conservative residual shear strength parameters. For these types of soil, no further reduction in strength will occur during transient loading, like the DBE.

In all cases, the critical circles passed through the upper portion of the clay blanket into the filter material and out at the toe.

Groundwater Table

For stability analysis, under full reservoir conditions, the groundwater table has been conservatively assumed to be the same as the full reservoir elevation of 347 feet. However, in reality, this shallow pond in shale, protected with an impervious blanket of two feet of clay, will not cause any significant change in the pre-existing groundwater table conditions. Please refer also to Section 2.4.

The phreatic lines are shown on Figures 2.5-51, -52, -53, and -54. Since the earlier assumptions of phreatic lines resulted in more conservative factors of safety, no reanalysis is required due to the change in the phreatic lines referred above.

Results of the direct shear tests are shown on Figures 2.5-55 through 2.5-62. The results are presented as a plot of accumulated strain in inches versus shearing stress in tons per square foot for each confining pressure and as a plot of normal stress versus shear stress for peak and residual stress.

The containment is founded on competent unweathered bedrock. The sand lens, which was shown at seven to 11 feet in Drill Hole 201, was sand which was stockpiled in that area during Unit 1 construction work and was removed during construction of Unit 2. The ECP is located on weathered, jointed shale, and no sand lenses were encountered, hence the problem of liquefaction during DBE will not arise.

Clay seams (six inches thick) were encountered in only one drill hole (DH-201) in the Unit 2 reactor areas, at depths of 77.4 and 92.5 feet. They were confined within hard, massive shale. They will have no influence on the performance of the structure, hence no tests were conducted.

2.5.5.3 Logs of Core Borings

The locations of exploratory holes within the ECP and its vicinity are shown on Figure 2.5-7 and the log of soil borings are discussed in Sections 2.5.5.2.1 and 2.5.5.3.1. Surface elevation, depth and bedrock elevations for borings within the emergency cooling pond and its vicinity are summarized in Table 2.5-1. Soil properties are shown in Table 2.5-3 and properties to be used for design are given in Table 2.5-4.

2.5.5.3.1 Soil Samples' Laboratory Test Results

The following is a tabulation outlining the samples and test made by Grubbs Consulting Engineers, Inc. for Bechtel Corp. on October 29, 1970.

Hole No.	Sample Depth (ft)	Classification Tests	Strength Tests
223	10.5-11.0	X	
224	11.0-11.5	X	X
225	10.5-11.0	X	
228	9.0-9.5	X	X
230	9.5-10.0	X	
232	15.5-16.0	X	X
234	15.5-16.0	X	X
234	20.5-21.0	X	
236	10.5-11.0	X	

2.5.5.3.2 Test Procedures

The liquid, plastic and shrinkage limits and moisture contents were determined using standard ASTM Laboratory Procedures. The unit weight was determined using water displacement methods in which the sample is weighted and submerged in water. The weight and volume of liquid displaced was used to determine the sample volume. The results of the classification tests are presented in tabular form on Table 2.5-12.

Appropriate ASTM designations for the tests are given below:

D423 - Liquid Limit of Soils

D424 - Plastic Limit and Plasticity Index of Soil

D427 - Shrinkage Factors of Soils

D2216 - Laboratory Determination of Moisture Content of Soil

The strength tests performed were the consolidated-drained direct shear test carried to a sufficient magnitude of strain to define the residual strengths. Each specimen was tested at 0.5, one and two tons per square feet confining pressure. In performing the test, a 1-inch high, 2.5-inch diameter specimen was placed in a split ring shear apparatus and allowed to saturate and consolidate under the specified confining pressure. The sample was then sheared repeatedly until a stabilized maximum shear resistance was reached. A separate specimen was used for each confining pressure. The sample which was tested from Boring 234 was large enough to obtain only two specimens for the direct shear test. Therefore, results are shown only for two confining pressures: 0.5 tsf and 1.0 tsf.

The direct shear apparatus used was a standard motorized direct shear apparatus manufactured by Soil Test, Inc., U.S.A. The direct shear apparatus has a shear box which is divided horizontally into two halves. A box contained the test specimen which was subjected to a constant normal load through a counter balance load hanger system. Loading for the shearing was accomplished at a predetermined strain rate by means of an electric transmission unit operating through a gear system. The horizontal and vertical displacements were measured by dial indicator gauges reading to 0.001 inch. The test specimens were 1-inch high and 2.5 inches in diameter.

The test specimen was placed in the shear box and the selected normal load was applied. The box was then filled with water and left overnight for a minimum period of 24 hours. The normal load was varied from 0.5 TSF to 2.0 TSF according to the pressure selected for the particular test. The vertical deflection dial was observed to ascertain when consolidation was completed.

The test method used to obtain the shearing stress results shown on Figure 2.5-62 was obtained by following the procedure given in "Soil Testing for Engineers" by T.W. Lambe, pages 138 to 146. Each specimen was sheared slowly using a strain rate 0.001 inch/min. During the tests, vertical and horizontal movements were recorded by dial gauges reading to 0.001 inch. Proving ring readings were taken to obtain the shearing load applied and from the maximum proving ring readings the peak shear strength was calculated.

To obtain residual shear strength, shearing was continued until a consistent shear strength value was obtained. The shear ring was pushed back to the original position, sheared again, and the process repeated until the strength of the clay attained a constant residual value. The same process, as detailed above, was repeated for peak and residual shear strengths at other confining pressures. The shearing strength vs. accumulated strain plot in Figure 2.5-55 provides the peak and residual shear strength and the corresponding strain. From the plot in Figure 2.5-56, the peak and the residual shear strength parameters c' and Ø' are obtained.

2.5.5.4 Compaction Criteria

Maximum dry density and the optimum water content of soil samples from the prospective borrow pits were determined in the laboratory in accordance with ASTM Designation D1557. Based on the moisture-density criteria established in the compaction tests, samples for consolidated-drained direct shear tests were compacted to 95 percent of the maximum dry density achieved in accordance with ASTM D1557. The design strength parameters for stability analyses were developed from the consolidated-drained direct shear strength tests referred to above. Based on the above laboratory test data, it was specified that embankment material should be placed in 8-inch loose lifts, moisture conditioned and compacted to 95 percent of the maximum dry density as determined in accordance with ASTM Test Designation D1557. The impervious material for embankment and the blanket consisted of red silty or sandy clay from selected borrow areas (Section 2.5.5.2.1).

2.5.5.5 Lateral Earth Pressure

The earth pressure diagrams were constructed following the basic principles outlined in "Soil Mechanics in Engineering Practice" by Terzaghi & Peak, 2nd Ed., Chapter 5, pages 184 to 216, with wall friction considered to be zero.

Security-Related Information
Text Withheld Under 10 CFR 2.390

According to Prof. H.B. Seed, the dynamic increment for structures founded on rock will be about three times the dynamic increment obtained from the Mononobe-Okabe procedure. It therefore will be:

$$\Delta P_{dyn} = 9/8\ Y\ H^2\ K_h$$

where

Y = the unit weight of the soil

H = the depth of soil above bed rock

K_h = the horizontal earthquake acceleration due to gravity

This force is applied as a triangular distribution with the maximum load applied at ground level and tapering to zero at bedrock (or bottom of structure).

The earth pressures developed during the response of structures to DBE are based on the Mononobe-Okabe case described above.

[a] The Forest Survey includes Arkansas Valley counties north of the river in the Southern Ozark Region and those south of the river in the Northern Ouchita Region. Based on A. Hedlund and J. M. Earles, FOREST STATISTICS FOR ARKANSAS COUNTIES, USDA Forest Service Resource Bulletin SO-22, Southern Forest Experiment Station New Orleans, La., 1970.

Table 2.1-14

STATE PARKS, NATIONAL FORESTS AND RECREATION AREAS WITHIN 50 MILES OF ARKANSAS PLANT

State Parks	Type[(a)]	Distance[(b)]	Direction			
Lost Valley	2	49.0	N			
Mount Nebo	1	4.6	SSW			
Petit Jean	1	22.0	SE			
Lake Ouachita	1	48.0	S			
Lake Dardanelle[(d)(e)]	1	3.2	S			
Ouita[(d)(e)]	1	2.8	E			
Russellville[(d)(e)]	1	1.3	SE			
National Forests					Attendance[(c)]	
				5-1-72 to 9-30-72	10-1-72 to 11-14-72	11-15-72 to 4-30-73
Ozark	1	18.0	S	141,100	26,453	8,801
Ouachita	1	7.3	WSW	NA	NA	NA

Table 2.1-14 (continued)

Other Recreation Areas	Type[a]	Distance[b]	Direction	Attendance, Total for 1972
Cabin Creek	1	9.3	WNW	19,100
Cane Creek	1	15.0	WNW	23,300
Dam Site[e]	2	3.8	SE	294,000
Delaware[e]	1	2.2	WSW	28,400
Dike View[e]	-	3.3	E	Leased to Arkansas Polytechnic College
Dublin	1	11.0	W	25,600
Flat Rock	1	4.8	WNW	30,700
Highway 64 Cove	-	6.3	WNW	Future Development
Horsehead	1	18.0	WNW	36,200
Illinois Bayou[e]	-	2.3	ENE	Leased to Arkansas Polytechnic College
O'Kane	1	27.0	W	51,400
Piney Bay	1	7.0	NW	40,400
Roseville	-	29.0	W	Future Development
Shoal Bay	1	11.0	W	68,100
Six Mile	1	21.0	W	11,200
Spadra	1	14.0	WNW	122,000
West Creek	1	30.0	WNW	28,800

(a) Type 1 - Recreation area with overnight facilities
2 - Recreation area with picnic facilities

(b) Distance in miles to area of park closest to site

(c) The list figures are for visitor days - A visitor day equals a stay of 12 hours

(d) The attendance figures for these state parks is a combined total of all three

(e) Recreation area located in low population zone

Table 2.1-15

VISITOR ACTIVITIES IN PERCENT* USAGE

LAKE DARDANELLE

Activity	Average Summer Weekend Day	June-August	Annual
Boating	1	2	5
Fishing	25	27	44
Water Skiing	12	10	6
Swimming	31	30	12
Camping	13	15	17
Picnicking	11	13	17
Sightseeing	41	38	36

* Column total more than 100% because many people participate in more than one activity.

Table 2.1-16

DARDANELLE RESERVOIR AND DOWNSTREAM ARKANSAS RIVER SURFACE WATER DIVERTERS

Name of Diverter	Location	Use	Annual Volume
John E. Shoemaker	Pope County Section 36**	Irrigation of Lawn and Garden	< 1 Acre-Ft.
Leonard Price	Pope County Section 29**	Irrigation of Small Home Garden, Approximately 1/8 Acre Vegetables	< 1 Acre-Ft.
Herbert Holzhaver	Arkansas County Approx. 185 Miles Downstream on Arkansas River	Irrigation of 133 Acres of Rice & 400 Acres of Soybeans	750 Acre-Ft.
Maumelle Golf Course	Pulaski County Approx. 80 Miles Downstream on Arkansas River	Irrigation of 78 Acres of Grass	1 Acre-Ft.
Walter C. Estes	Pulaski County Approx. 100 Miles Downstream on Arkansas River	Fish Farming 10 Acres	25 Acre-Ft.
Robert M. Carpenter	Pope County Section 29**	Irragation of 1 Acre	< 1 Acre-Ft.
Dr. Roy H. Kennon	Logan County Paris Address***	Irrigation	1 Acre-Ft.
Laurence P. Schultz	Logan County Section 33**	Irrigation of 1/4 Acre Garden	< 1 Acre-Ft.
Arkansas Kraft Corp.	Morrilton, Arkansas*	Industrial*	18,500 Acre-Ft.
James E. Danaher	Jefferson County Approx. 135 Miles Downstream on Arkansas River	Irrigation of 100 Acres of Cotton and 100 Acres of Soybeans	720 Acre-Ft.

*See Section 2.1.4.1
**See Figure 2.3-2
***See Figure 2.3-3

This information was obtained in May 1974, from the Soil and Water Division of the Arkansas Department of Commerce. Arkansas Power & Light was previously not aware of this source for this type of information.

* The origin from which these distances were measured is at the centerline of the Unit 2 Containment.

Table 2.3-51

STANDARD SAR METEOROLOGICAL ANALYSES OF ONSITE DATA, STEP-BY-STEP DESCRIPTION

Hourly (Minimum EZB)	• Calculate hourly averages values of X/Q using centerline invariant wind with wake effects, at the single, minimum exclusion zone (EZB). • Arrange values in cumulative frequency distribution. • Select 5% and 50% values.
Hourly (Actual EZB)	• The same as "Hourly" except that the calculation is made at the actual exclusion zone boundary as selected by the wind direction. • Data are arranged in a cumulative frequency distribution. • Select 5% and 50% values.
Eight Hourly	• The same as "Hourly" except the calculations are made at the minimum outer boundary of the low population zone in each sector as selected by the wind direction. • For each hour, in each sector, average the past 8 hour X/Q values, using X/Q = O when wind direction is not in the sector (running 8-hour average). • Determine the probability of each sector being affected. • Arrange all eight-hourly average values for all sectors in a cumulative frequency distribution. • Select the worst, the 5% and 50% values and the respective sectors.
Sixteen Hourly	• The same as "Eight Hourly" except: (A) sector spread replaces centerline wind assumption. (B) notation for wake effect, (C) 8-hour running averages replaced with 16-hour running average.
Three Day	• The same as "Sixteen Hourly" except that the past 16-hour averages are replaced with a 72-hour running average.
Twenty-six	• The same as "Sixteen Hourly" except that the last 16-hour averages are replaced by a 624-hour running average.
Average Annual Concentrations	• Calculate average hourly X/Q values using sector spread equations, including wake effect, at the exclusion zone boundary distance in each sector, and out to 50 miles. • Average the X/Q values for the entire year at each radial distance in each sector (X/Q = 0 if wind is in another sector). • Provide analyses for determining the finite cloud parameters for annual average release calculations.

SUMMARY OF LABORATORY ROCK TESTS

1967 Investigation-Data from DH-2, 38.5-40.5 feet, and DH-5, 28.9-38.0 feet

		RESULTS		
TEST	NO. OF TESTS	HIGH	LOW	AVERAGE
A. Specific Gravity	10	2.59	2.53	2.57
B. Porosity	10	5.8%	2.0%	5.5%
C. Absorption	10	3.1%	2.1%	2.4%
D. Unconfined Compression	9	3740 psi	3140 psi	3470 psi
E. Modulus of Elasticity	9	1.0×10^6 psi	0.7×10^6 psi	0.8×10^6 psi
F. Poisson's Ratio	4	.26	0.10	0.18

Ten triaxial compression tests resulted in an average 0 = 37° and Cohesion = 890 psi.

1968 Investigations -Data from D-120, 30.0-62.0 feet, D-121, 25.0-51.0 feet

		RESULTS		
TEST	NO. OF TESTS	HIGH	LOW	AVERAGE
A.Unconfined Compression	17	4680 psi	2940 psi	3800 psi
B.Modulus of Elasticity	9	1.08×10^6 psi	$.25 \times 10^6$ psi	$.64 \times 10^6$ psi

Report in Section 2.5.5.2.1.

Table 2.5-4

STATIC ENGINEERING PROPERTIES FOR DESIGN

(EMERGENCY COOLING POND)

Static Properties	Undisturbed Foundation Clay	Clay Blanket	Weathered Shale	Filter
Saturated Unit Weight (pcf)	124	130	145	130*
Angle of Internal Friction Φ, (Degrees)	23	25	0	35*
Cohesion, c (tsf)	0.10	0.05	1.35	0*

* Design properties are assumed.

Table 2.5-5a

LONG-TERM STABILITY EMERGENCY COOLING WATER POND

Excavation Slope	Loading Condition	Required Factor of Safety	Minimum Computed Factor of Safety
2-1/2 to 1	Normal	1.5	1.67
2-1/2 to 1	Seismic	1.1	1.1
2-1/2 to 1	Rapid Drawdown	1.25	1.77

Table 2.5-5b

FACTORS OF SAFETY OF EMERGENCY COOLING POND SLOPE

Case	Condition	Required Factor of Safety	Computed Factor of Safety
I	Full Reservoir at El. 347 with Earthquake (0.2g)	1.1	1.4
II	Rapid Drawdown to El. 341 with no Earthquake	1.25	2.3
III	Minimum Reservoir Level at El. 342.5 with Earthquake (0.2g)	1.1	1.3

For further discussion and details on factor of safety of pond slope stability, refer to Section 2.5.5.2 and Section 2.5.5.2.2.

Table 2.5-5c

FACTORS OF SAFETY OF EMERGENCY COOLING POND SLOPE USING PEAK STRENGTH VALUES

Case	Type of Strength Used in Analysis	c, tsf	Φ, degrees	Factor of Safety
1	Drained Strength (lowest test value)	0.165	32	2.0
2	Drained Strength (design value)	0.2	22	1.5
3	Undrained Strength (lowest test value)	0.6	0.	2.1

Note: An effective stress analysis was used for Cases 1 and 2 and a total stress analysis for Case

3. The criteria for acceptability of slope stability analyses are given in Table 2.5-5a. Since the earthquake analysis indicated a factor of safety of 1.5 or greater, the normal pool and rapid drawdown analyses, being less severe, will yield even higher values; therefore, analyses were not considered necessary and were not carried out.

Table 2.5-8

MODIFIED MERCALLI INTENSITY SCALE OF 1931

(Abridged)

I. Not felt except by a very few under especially favorable circumstances. (I Rossi-Forel scale).

II. Felt only by a few persons at rest, especially on upper floors of building. Delicately suspended objects may swing (I to II, Rossi-Forel scale).

III. Felt quite noticeably indoors, especially on upper floors of buildings, but many people do not recognize it as an earthquake. Standing motor cars may rock slightly. Vibration like passing truck. Duration estimated (III Rossi-Forel scale).

IV. During the day felt indoors by many, outdoors by few. At night some awakened. Dishes, windows, doors disturbed; walls made creaking sound. Sensation like heavy truck striking building. Standing motor cars rocked noticeably (IV to V Rossi-Forel scale).

V. Felt by nearly everyone; many awakened. Some dishes, windows, etc., broken; a few instances of cracked plaster; unstable objects overturned. Disturbance of trees, poles, and other tall objects sometimes noticed. Pendulum clocks may stop (V to VI Rossi-Forel scale).

VI. Felt by all; many frightened and ran outdoors. Some heavy furniture moved; a few instances fallen plaster or damaged chimneys. Damage slight (VI to VII Rossi-Forel Scale).

VII. Everybody runs outdoors. Damage negligible in buildings of good structures; considerable in poorly built or badly designed structures; some chimneys broken. Noticed by persons driving motor cars (VIII Rossi-Forel scale).

VIII. Damage slight in specially designed structures; considerable in ordinary substantial buildings with partial collapse; great in poorly built structures. Panel walls thrown out of frame structures. Fall of chimneys, factory stacks, columns, monuments, walls. Heavy furniture overturned. Sand and mud ejected in small amounts. Changes in well water. Disturbed persons driving motor cars (VIII+ to IX Rossi-Forel scale).

IX. Damage considerable in specially designed structures; well designed frame structures thrown out of plumb; great in substantial buildings, with partial collapse. Buildings shifted off foundations. Ground cracked conspicuously. Underground pipes broken (IX+ Rossi-Forel scale).

X. Some well-built wooden structures destroyed; most masonry and frame structures destroyed with foundations, ground badly cracked. Rails bent. Landslides considerable from river banks and steep slopes. Shifted sand and mud. Water splashed (slopped) over banks. (X Rossi-Forel scale).

XI. Few, if any, (masonry) structures remain standing. Bridges destroyed. Broad fissures in ground. Underground pipe lines completely out of service. Earth slumps and land slips in soft ground. Rails bent greatly.

XII. Damage total. Waves seen on ground surfaces. Lines of sight and level distorted. Objects thrown upward into the air.

DEPARTMENT OF THE ARMY
LITTLE ROCK DISTRICT, CORPS OF ENGINEERS
Post Office Box 867
Little Rock, Arkansas 72203

SWLRE-A

24 September 1976

Colonel Charles L. Steel
Vice President, Public Affairs
Arkansas Power and Light Company
P. O. Box 551
Little Rock, Arkansas 72203

Dear Colonel Steel:

Please refer to your letter of 20 May 1976 and subsequent correspondence with regard to modifying the conditions of the restrictive easement area granted to the Arkansas Power and Light Company for lands in the Lake Dardanelle project for use of the company's nuclear station in that area.

Inclosed is the easement deed, No. DACW03-2-76-322, which replaces our Easement No. DACW03-2-68-787.

It is hoped that this meets with the approval of all concerned.

Sincerely yours,

CHARLES E. BURCHAM
Chief, Real Estate Division

1 Incl
As stated

DEPARTMENT OF THE ARMY
RESTRICTIVE EASEMENT (EXCLUSION AREA)
DARDANELLE RESERVOIR

No. DACW03-2-76-322

WHEREAS, the Secretary of the Army has determined that it is in the best interests of the government to terminate Easement No. DACW03-2-68-787 for the purpose of revising it to more nearly meet the needs and requirements of the U.S. Nuclear Regulatory Commission, and to hereinafter convey said revised and modified grant to the present grantee, Arkansas Power and Light Company.

NOW, THEREFORE, the Secretary of the Army, under and by virtue of the authority vested in him by the Act of Congress approved October 23, 1962 (76 Stat. 1129), hereby grants to ARKANSAS POWER AND LIGHT COMPANY, a corporation duly organized and existing under and by virtue of the laws of the State of Arkansas, with its principal office at Little Rock, Arkansas, hereinafter designated as the grantee, for a period not exceeding fifty (50) years from March 26, 1968, a Restrictive Easement for the establishment, maintenance, operation, and use of an exclusion area in connection with a nuclear generating unit located in the vicinity of the Dardanelle Reservoir, Pope County, Arkansas. The easement herein granted shall include the rights to prohibit human habitation and to exclude all persons from the said area, before and after the occurrence of any conditions which would present a hazard to the health and safety of the public, which is in, over, across, and upon lands under the control of the Secretary of the Army at the locations shown in red on Exhibit "A" and described in Exhibit "B", both of which are attached hereto and made a part hereof.

THIS EASEMENT is granted subject to the following conditions:

1. Whereas, the grantee has paid to the United States, under prior Contract No. DACWO3-2-68-787, compensation in the amount of FOUR THOUSAND FIVE HUNDRED DOLLARS ($4,500.00) for the term hereof, said sum having been made payable to the Treasurer of the United States and heretofore receipted by the Finance Officer for the Little Rock District, Corps of Engineers, P.O. Box 867, Little Rock, Arkansas 72203, and also in further consideration the grantee has agreed to the cancellation of prior Easement No. DACWO3-2-68-787.

2. That the establishment, maintenance, operation, and use of the exclusion area shall be accomplished without cost or expense to the United States under the general supervision and subject to the approval of the officer having immediate jurisdiction over said lands. It is understood that this does not include the right of said officer to make a rule inconsistent with the grantee's exercise of complete control over the exclusion area.

3. Any property of the United States damaged or destroyed by the grantee incident to the use and occupation of the said premises shall be promptly repaired or replaced by the grantee to the satisfaction of the said officer, or in lieu of such repair or replacement, the grantee shall, if so required by said officer, pay to the United States money in an amount sufficient to compensate for the loss sustained by the United States by reason of damages to or destruction of government property.

4. The use and occupation of said lands of the United States for the purposes authorized by this instrument shall be subject to such rules and regulations as the said officer may prescribe from time to time in order to properly protect the interests of the United States. It is understood that said officer does not have the right to make a rule inconsistent with the grantee's exercise of complete control over the exclusion area.

5. The United States reserves to itself and its assigns the right to construct, use, and maintain across, over, and/or under the easement hereby granted, roads and streets, electric transmission, telephone, telegraph, water, gas, gasoline, oil, and sewer lines, and other facilities, in such manner as not to create any unreasonable interference with the use of the easement right herein granted. It is agreed, however, that any reservation of access herein does not include the right of control over said access since that could be inconsistent with the use of the easement hereby granted.

6. It is to be understood that this instrument is effective only insofar as the rights of the United States in the said property are concerned, and that the grantee shall obtain such permission as may be necessary on account of any other existing rights.

7. The easement rights herein granted may be terminated by the Secretary of the Army for failure to comply with any and all terms or conditions of this grant or for non-use for a two-year period or abandonment of rights granted herein.

8. Upon expiration or termination of this grant, the grantee shall, without expense to the United States and within such time as the Secretary of the Army may indicate, remove any and all property from said land and restore the premises hereby authorized to be used and occupied to conditions satisfactory to said offer. In the event the grantee should fail, neglect, or refuse to remove the said property and so restore the premises, the United States shall have the option either to take over the said property as property of the United States without compensation therefor or to restore the said property and perform the restoration work as aforesaid at the expense of the grantee, and in no event shall the grantee have any claim for damages against the United States or its officers or agents on account of the taking over of said property or on account of its removal.

9. Conditions of this instrument shall extend to and be binding upon and shall inure to the benefit of the representatives, successors, and assigns of the grantee.

10. It is understood that the provisions of Condition No. 2, supra, shall not abrogate or interfere with any agreements or commitments made or entered into between the grantee and any other agency of the United States with regard to financial aid to the grantee in connection with the establishment, maintenance, operation, and use of said exclusion area.

11. The United States shall not be responsible for damages to property or injuries to persons which may arise from or be incident to the use and occupation of the said premises, nor for damages to the property of the grantee, nor for damages to the property or injuries to the person of the grantee's officers, agents, servants, or employees, or others who may be on said premises at their invitation or the invitation of any one of them, arising from or incident to governmental activities, and the grantee shall hold the United States harmless from any and all such claims. The above disclaimer is not intended to be inconsistent with the government insurance coverage under the Price-Anderson Act (Public Law 85-256, 42 U.S.C. 2210).

12. The United States shall not be responsible for damages to property or injuries to persons which may arise from or be incident to the establishment, maintenance, operation, and use of said exclusion area.

13. That the right is hereby reserved to the United States, its officers, agents, and employees, to enter upon the premises at any time for inspection and for any purpose necessary or convenient in connection with government work, to remove therefrom timber or other material, except property of the grantee, required or necessary for such work, to sell and remove merchantable timber therefrom, to flood the premises whenever necessary, to manipulate the level of the reservoir or pool in any manner whatsoever, and to draw down the reservoir or pool to any extent or at any time, and the grantee shall have no claim for damages of any character on account thereof against the United States or any officer, agent, or employee thereof. The grantor agrees to notify the grantee before any of its personnel re-enter the land so that the exact location and number of personnel will be known in the event of a nuclear accident. Also, the grantee is given the right to evacuate the premises of grantor's personnel in the event a danger of impermissible radiation doses is discovered by the grantee.

IN WITNESS WHEREOF, I have hereunto set my hand this 17th day of September, 1976, by authority of the Secretary of the Army.

WOODROW BERGE
Director of Real Estate
Officer, Chief of Engineers
Department of the Army

ACKNOWLEDGMENT

DISTRICT OF COLUMBIA SS

On this 17th day of September, 1976, before me, Theresa A. Thomas, a Notary Public in and for the District of Columbia, duly commissioned and sworn, personally appeared Woodrow Berge, known to me to be Director of Real Estate, and the person who executed the foregoing instrument by the authority of the Secretary of the Army and acknowledged to me that he extended the same as the free and voluntary act and deed of the United States of America, for the uses and purposes therein set forth.

IN WITNESS WHEREOF, I have hereunto set my hand and official seal.

THERESA A. THOMAS
Notary Public
District of Columbia

My Commission Expires January 31, 1981.

PARCEL "A"

A tract of land situated in the County of Pope, State of Arkansas, being a part of the SW¼ and a part of the S½ of the NW¼ of Section 28, Township 8 North, Range 21 West of the Fifth Principal Meridian, and being more particularly described as follows:

> Beginning at the southwest corner of the SE¼ of the NW¼; thence northeasterly to the northeast corner of the SW½ of the S½ of the SW¼ of the said SE¼ of the NW¼; thence south to the southeast corner thereof, thence southwest to the center of the NE¼ of the NW¼ of the NE¼ of the SW¼; thence south to the center of the SE¼ of the said NW¼ of the NE¼ of the SW¼, thence southeast to the southeast corner thereof; thence east to the northeast corner of the W½ of the E½ of the SE¼ of the said NE¼ of the SW¼; thence southwesterly to the southwest corner thereof; thence south to the southwest corner of the N½ of the NE¼ of the NE¼ of said SE¼ of the SW¼; thence southeasterly to the southeast corner of the N½ of the SE¼ of the said NE¼ of the SE¼ of the SW¼; thence south to the southeast corner of the N½ of said SE¼ of the SW¼; thence west to the southeast corner of the W½ of the NE¼ of said SE¼ of the SW¼; thence northwesterly to the northwest corner thereof; thence northwest to the center of the SW¼ of the NE¼ of said SW¼; thence west to the center of the SW¼ of the NW¼ of said SW¼; thence northeasterly to the northwest corner of the W½ of the SW¼ of the SE¼ of the SW¼ of the NW¼; thence southeasterly to the southeast corner thereof; thence east to the point of beginning, and containing 46.00 acres, more or less.

PARCEL "B"

A tract of land situated in the county of Pope, State of Arkansas, being a part of the N½ and a part of the N¼ of the fractional NE¼ of the fractional SW¼, and a part of the fractional NW¼ of the fractional NW¼ of the fractional SE¼ of Fractional Section 33, Township 8 North, Range 21 West of the Fifth Principal Meridian, and being more particularly described as follows:

> Beginning at the northeast corner of the SE¼ of the NE¼ of Section 33; thence southwesterly to a point 660 feet west and 330 feet south of the northeast corner of the S½ of the fractional NE¼; thence south to the center of the fractional SE¼ of the said fractional NE¼; thence northwesterly to a point 495 feet south of the northwest corner of said fractional SE¼ of the fractional NE¼; thence southwesterly to a point 165 feet west and 495 feet north of the southeast corner of the fractional SW¼ of the said fractional NE¼; thence southwesterly to the southwest corner of the E½ of the said fractional SW¼ of the fractional NE¼; thence west to a point 165 feet east of the center of Fractional Section 33; thence southwest to the southwest corner of the E½ of the NE¼ of the NE¼ of the NE¼ of the SW¼; thence northwesterly to a point on the north line of the S½, said point being 379.5 feet east of the northwest corner of said NE¼ of the SW¼; thence northwesterly to the northwest corner of the S½ of the SE¼ of the SW¼ of the NW¼ of the NW¼ of Fractional Section 33; thence east to the northeast corner thereof; thence northeasterly to the center of the NW¼ of the SE¼ of the said NW¼ of the NW¼; thence southeasterly to the southwest corner of the SE¼ of the NE¼ of the SE¼ of said NW¼ of the NW¼; thence northeast to the northeast corner thereof; thence northeasterly to the center of the SW¼ of the NW¼ of the NE¼ of the said NW¼; thence southeasterly to the southwest corner of the SE¼ of the NE¼ of the SE¼ of said NW¼ of the NW¼; thence northeast to the northeast corner thereof; thence northeasterly to the center of the SW¼ of the NW¼ of the NE¼ of the said NW¼; thence southeasterly to the northeast corner of the W½ of the NW¼ of the SE¼ of said NE¼ of the NW ¼; thence southwesterly to the southwest corner thereof; thence south to a point which is 125 feet north of the southwest corner of the N½ of the SW¼ of the said SE¼ of the NE¼ of the NW¼; thence north 72° 28' east 175 feet to a point; thence south 89° 06' east 140 feet to a point; thence south 26° 04' east 151.8 feet to a point; thence south 5° 47' east 211.48 feet to a point on the south line of said NE¼ of the NW¼; thence south 10° 31' west 120 feet to a point; thence north 78° 30' east 130 feet to a point; thence north 57° 00' east 110 feet to a point; thence north 36° 12' 30" east 72.40 feet to a point; thence east 20 feet parallel to the south line of said NE¼ of the NW¼ to a point on the east line of said NE¼; thence north to the northwest corner of the S½ of the fractional NW¼ of said fractional NE¼; thence northeast to the center of the fractional NW¼ of said fractional NW¼ of the fractional NE¼; thence east to the northwest corner of the E½ of the fractional SW¼ of the fractional NE¼ of the said fractional NW¼ of the fractional NE¼; thence southeasterly to the southeast corner thereof; thence east to the northeast corner of the S½ of said fractional NW¼ of the fractional NE¼; thence northeasterly to the northwest corner of the S½ of the fractional SE¼ of the fractional NW¼ of the fractional NE¼ of the said fractional NE¼; thence southeasterly to the southeast corner thereof; thence southwesterly to the southwest corner of the E½ of the fractional NE¼ of the fractional SW¼ of the fractional NE¼ of the fractional NE¼; thence east to the northeast corner of the W½ of the fractional SW¼ of the fractional SE¼ of the said fractional NE¼ of the fractional NE¼; thence northeasterly to a point on the east line of Fractional Section 33, which is 495 feet north of the southeast corner of the N½ of the said fractional NE¼; thence south along said east line 495 feet to the point of beginning, and containing 160.00 acres, more or less.

PARCEL "C"

A tract of land situated in the county of Pope, State of Arkansas, being a part of the SE¼ of the SW¼ and a part of the SW¼ of the SE½ of Section 27, and a part of the fractional NE¼ of the fractional NW¼ of Fractional Section 34, Township 8 North, Range 21 West of the Fifth Principal Meridian, and being more particularly described as follows:

> Beginning at the northeast corner of the NW¼ of Section 34; thence southwesterly to the center of the fractional NW¼ of the fractional NE¼ of the fractional NE¼ of said fractional NW¼; thence northwest to the northwest corner of the E½ of the fractional NE¼ of the fractional NW¼; thence northeasterly to the northeast corner of the S½ of the S½ of the SE¼ of the SW½ of Section 27; thence northeasterly to the northeast corner of the W½ of the NW¼ of the SE¼ of the said SW¼ of the SE¼; thence south to the southeast corner of the W½ of the SW½ of said SE¼ of the SW¼ of the SE¼; thence west to the point of beginning, and containing 14.00 acres, more or less.
>
> The above parcels contain, in the aggregate, 220.0 acres, more or less.

EXPLANATION

AGE:		SYMBOL:	DESCRIPTION:
QUATERNARY	Alluvium	Qal / Qar	Qal, alluvial deposits along stream channels and, in same places, parts of the lowermost terrace. Qar, alluvial deposits along Arkansas River
	Terrace Deposits	Qt / Qtr	Includes alluvial deposits in two undivided terrace levels: Qt, stream terrace: Qtr, river terrace.
UNCONFORMITY			
PENNSYLVANIAN	Savanna formation	Ps	
	McAlester formation	Pm / Pms	Pm, shale, siltstone, and thin beds of sandstone or silty sandstone. Pms, sandstone, silty sandstone, or interbedded sandstone, siltstone and shale.
	Hartshorne formation	Ph / Phs	Ph, shale, siltstone, and thin beds of sandstone or silty sandstone. Phs, sandstone, silty sandstone, or interbedded sandstone, siltstone and shale.
	Atoka formation	Pa / Pas	Pa, shale, siltstone, and thin beds of sandstone or silty sandstone. Pas, sandstone, silty sandstone, or interbedded sandstone, siltstone and shale.

EXPLANATION OF SYMBOS

- Geologic contact
- Fault
- Syncline
- Anticline

AMENDMENT 19

BASED ON DRAWING NO	SHEET	REV.

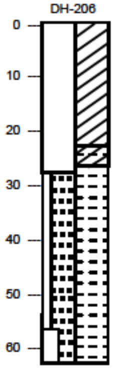
DH-206



0 – 23.0' <u>OVERBURDEN</u>: fill, clay and weathered shale to 10'. 10' and below tan, moderately plastic clay.

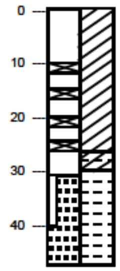
23.0' – 27.0' <u>HIGHLY WEATHERED SHALE</u>: brown to dark gray clay and weathered clay, stiff soil consistency increasing to very soft rock at 29.5'.

27.0' – 63.0' <u>SHALE</u>: black, horizontally bedded, some weathered seams and layers to 37', parts easily along bedding planes, clayey shale in zones, vertical joint. Average core length 3" with lengths to 18". Competent rock.

Core recovery 93%

<u>GROUND WATER EL.</u>: NOT RECORDED

DH-207



0 – 26.5' <u>OVERBURDEN</u>: fill, clay and weathered shale to 6'. Tan, red and gray clay below.

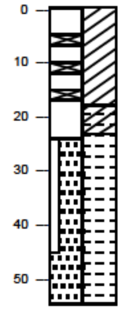
26.5' – 29.5' <u>HIGHLY WEATHERED SHALE</u>: tan to light gray stratified clay with gray and brown weathered shale fragments. Stiff soil at 26.5' grades in to very soft rock at shale contact.

29.5' – 45.5' <u>SHALE</u>: unweathered, dark gray to black, horizontally bedded. One joint at 38" with 20° dip. Average core length 5", with pieces to 2.5'. Competent rock.

Core recovery 97%

<u>GROUND WATER EL.</u>: NOT RECORDED

DH-208



0 – 18.0' <u>OVERBURDEN</u>: clay, slightly silty-sandy, tan, light gray and red.

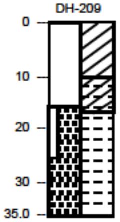
18.0' – 24.0' <u>HIGHLY WEATHERED SHALE</u>: tan and light gray clay with weathered shale fragments grading down to dark gray weathered shale. Stiff soil varies to very soft rock.

24.0' – 55.0' <u>SHALE</u>: dark gray, unweathered, dense, horizontally bedded, unjointed, core parts along bedding planes in clean breaks, longest core 3' with an average length of 1.5'. Competent rock.

Core recovery 95%

<u>GROUND WATER EL.</u>: NOT RECORDED

DH-209



0 – 10.0' <u>OVERBURDEN</u>: tan and red sandy clay.

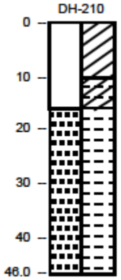
10.0' – 16.5' <u>HIGHLY WEATHERED SHALE</u>: stratified tan stiff clay with weathered shale fragments to dark gray very soft weathered shale.

16.5' – 35.0' <u>SHALE</u>: dark, gray, horizontally bedded, unweathered. No jointing. Average core length 5" with pieces to 15". Competent rock.

Core recovery 95%

<u>GROUND WATER EL.</u>: NOT RECORDED

DH-210



0 – 9.0' <u>OVERBURDEN</u>: tan plastic clay.

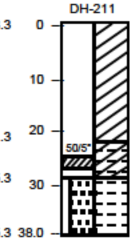
9.0' – 16.0' <u>HIGHLY WEATHERED SHALE</u>: tan clay with shale fragments to gray weathered shale. Soil grades from stiff clay to a very soft rock.

16.0' – 46.0' <u>SHALE</u>: dense, unweathered, dark gray to black unjointed shale with interbedded 1/8 to 1/16" light gray well cemented sandstone lenses. 85% shale, 15% s.s. Average core length 4" with pieces to 18". Competent rock.

Core recovery 100%

<u>GROUND WATER EL.</u>: NOT RECORDED

DH-211



0 – 22.0' <u>OVERBURDEN</u>: red and weathered shale fill to 9'. Red and tan clay 9 to 22'.

22.0' – 28.0' <u>HIGHLY WEATHERED SHALE</u>: tan stratified clay with weathered shale particles. 26' to 28' dark gray weathered shale. Hard soil increasing to very soft rock down thru zone.

28.0' – 38.0' <u>SHALE</u>: black, dense, unweathered horizontally bedded, few 60° joints. Longest core piece 12"; average core length 4". Competent rock.

Core recovery 85%

<u>GROUND WATER EL.</u>: NOT RECORDED

CONSTRUCTION SEQUENCE:

1. REMOVE EXISTING SOD AND USE IN STEP 5 WHEN POSSIBLE.
2. PLACE 2.0' ± LAYER OF ARMOR RIP RAP BY DUMPING, IF PRACTICLE, ON THE BOTTOM OF THE POND.
3. PLACE 0.5' OF BEDDING
. PLACE BALANCE OF ARMOR RIP RAP ON FACE OF DIKE AND BR NG UP TO CREST ELEVATION OF 353.0'.
5. REPLACE SOD IF POSSIBLE OR SEED EXISTING SLOPE.

GENERAL NOTES

1. EXCAVATION SHALL CONFORM TO THE REQUIREMENTS OF SPECIFICATION 6600 C-6 .
2. DEPTH OF STRIPPING MAY VARY FROM ONE TO FOUR FEET BEFORE SUITABLE MATERIAL IS ENCOUNTERED THE CONTRACTORS DECISION OF SUITABLE SUBBASE SHALL BE FINAL.
3. EXCAVATION SHALL CONFORM TO THE LIMITS AND GRADES AS SHOWN WITH A TOLERANCE OF PLUS OR M NUS 0.10 FEET.
. EXCAVATED MATERIAL MAY BE USED FOR EMBANKMENT WHEN APPROVED BY THE CONTRACTOR, IN ACCORDANCE WITH SEC. 3.9 OF SPEC. 6600 C-6
5. WHERE THE TOP OF ROCK OR WEATHERED SHALE S AT OR ABOVE THE POND BOTTOM SUCH UNSUITABLE MATERIAL SHALL BE REMOVED AS SHOWN AND REPLACED WITH IMPERVIOUS BACKF LL. THE CONTRACTORS DECISION ON THE EXTENT TO WHICH UNSUITABLE MATERIAL IS TO BE REMOVED SHALL BE FINAL.
6. CONSTRUCTIN OF UNIT 2 CLASS 1 STRUCTURES SHALL NOT COMMENCE UNTIL ISSUANCE BY A.B.C. OF A CONSTRUCT ON PERMIT.
7. FILTER MATERIAL SHALL GRADED AS FOLLOWS:

SIEVE SIZE U.S. STD. SQ. MESH	% PASSED
3/8	100
NO.	95 - 100
NO. 16	5 - 80
NO. 50	10 - 30
NO. 100	2 - 10
NO. 200	0

BACKFILL FILTER MATERIAL SHALL BE PLACED IN L FTS OF 8 N. & COMPACTED TO 90% OF MAX. DRY DENSITY DETERMINED BY THE MODIFIED COMPACTION PROCEDURE A.S.T.H. D 1957 METHOD D.

8. UNDERDRAIN SHALL BE 16 ga. GALV. CORRAGATED PERFORATED METAL PIPE CONFORMING TO THE REQUIREMENTS OF THE STANDARD SPECIFICATION FOR CORRUGATED METAL P PE CULVERTS, H-136 OF THE AMERICAN ASS'N OF STATE HIGHWAY OFFICIALS.
9. THE SUBCONTRACTOR SHALL TAKE EXTREME CARE TO ASSURE THAT THE FILTER MATERIAL IS NOT CONTAIM NATED BY SILT OR CLAY. ALL CONTAMINATED FILTER MATERIAL SHALL BE REMOVED FROM THE SLOPE AND REPLACED WITH FILTER MATERIAL CONFORMING TO THE REQUIREMENTS OF NOTE #7.
10. ARMOR RIP RAP GRADATION N POUNDS
   MAX. 1000
   25% GREATER THAN 300
   5% TO 75% FROM – TO 10-300

EXPLANATION

Roman Numeral indicates the epicenter of an earthquake, the epicentral intensity of which was given on the Modified Mercalli Scale.

Intensities IV – V and greater are shown.

Dates of earthquakes indicated

ZONE 0 – No damage

ZONE 1 – Minor damage; distant earthquakes may cause damage to structures with fundamental periods greater than 1 0 seconds; corresponds to intensities V and VI of the M.M.* Scale.

ZONE 2 – Moderate damage; corresponds to intensity VII and higher of the M.M.* Scale.

ZONE 3 – Major damage; corresponds to intensity VIII and higher of the M.M.* Scale.

This map is based on the known distribution of damaging earthquakes and the M M.* intensities associated with these earthquakes; evidence of strain release; and consideration of major geologic structures and provinces believed to be associated with earthquake activity. The probable frequency of occurrence of damaging earthquakes in each zone was not considered in assigning ratings to the various zones.

*Modified Mercalli Intensity Scale of 1931.

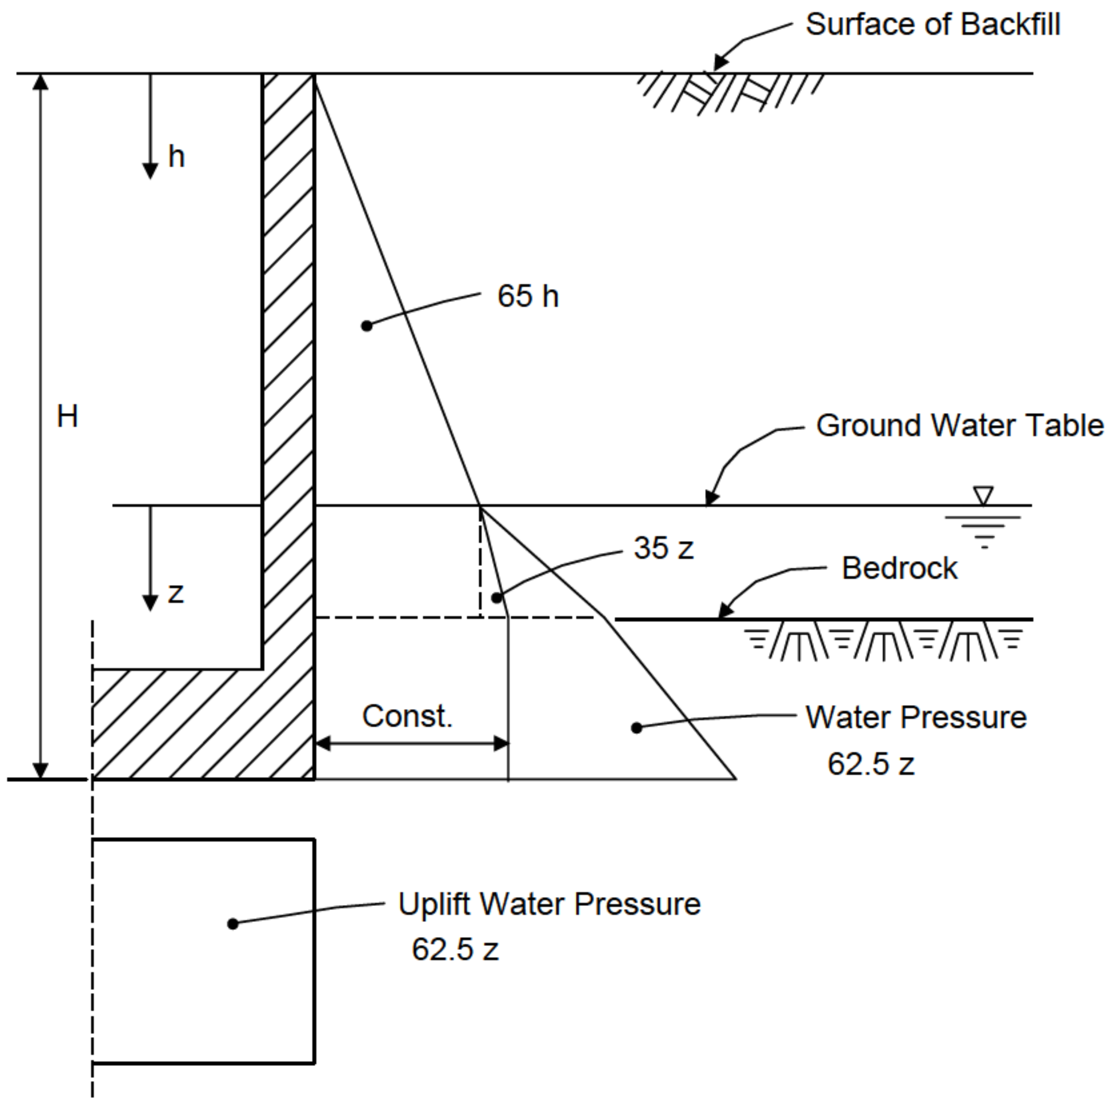
LOG OF BORING NO. 236	BASED ON DRAWING NO	SHEET / REV.

At rest earthpressures without influence of surcharge loads for cohesionless backfill material with $\Phi \geq 30°$, $\gamma \leq 130$ lb/cu. ft.



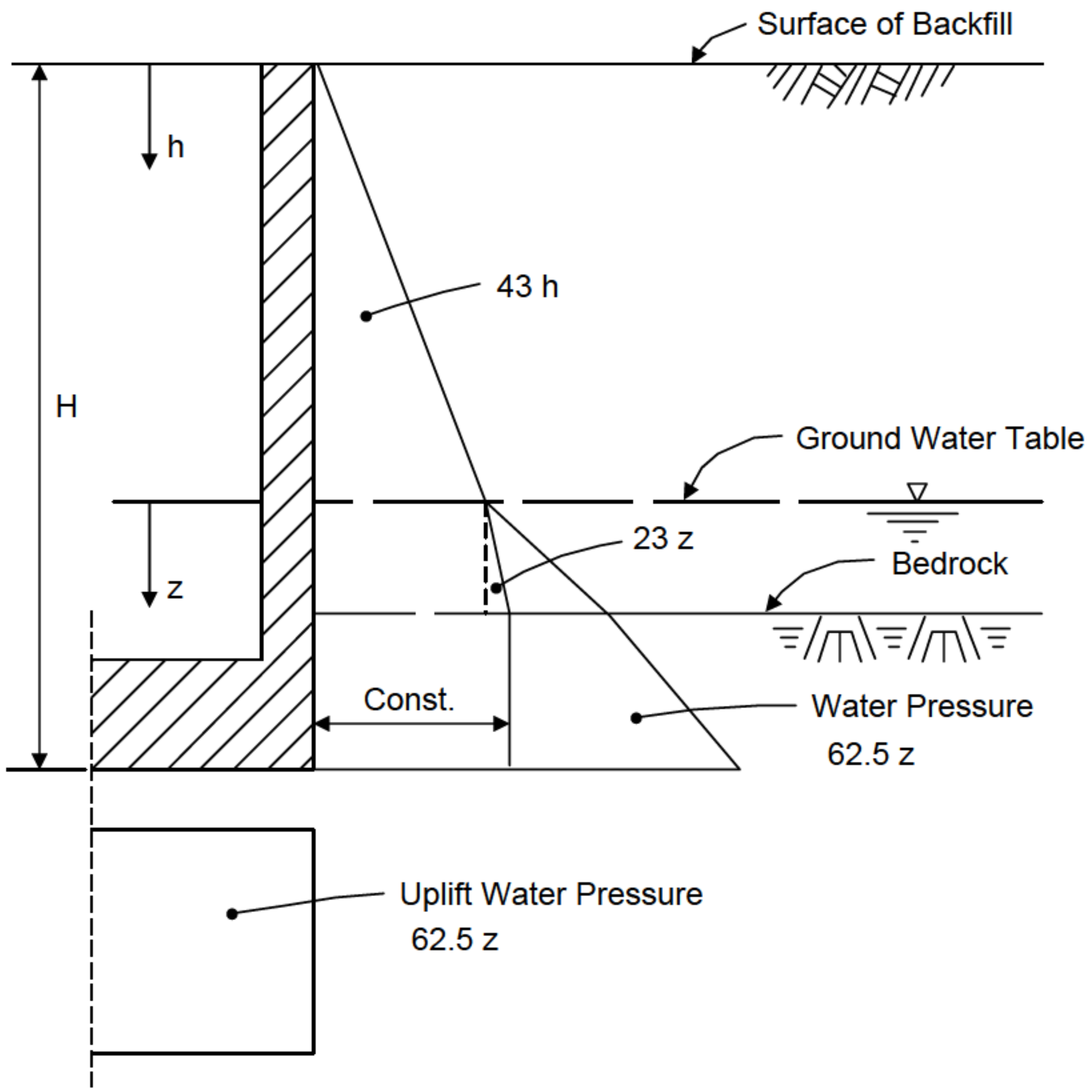
At rest pressures develop, when the wall deflect less than 0.001 H.
(All units in lbs and ft)

SAR FIGURE NO. 2.5-99

AMENDMENT 19

ARKANSAS NUCLEAR ONE UNIT 2 RUSSELLVILLE, ARKANSAS	Entergy	SCALE: NONE DRAWN: DESIGN: ENTERGY CAD NO:
AT REST EARTHPRESSURE DIAGRAM	BASED ON DRAWING NO	SHEET / REV.

Active earthpressures without influence of surcharge loads for cohesionless backfill material with $\Phi \geq 30°$, $\gamma \leq 130$ lb/cu. ft.

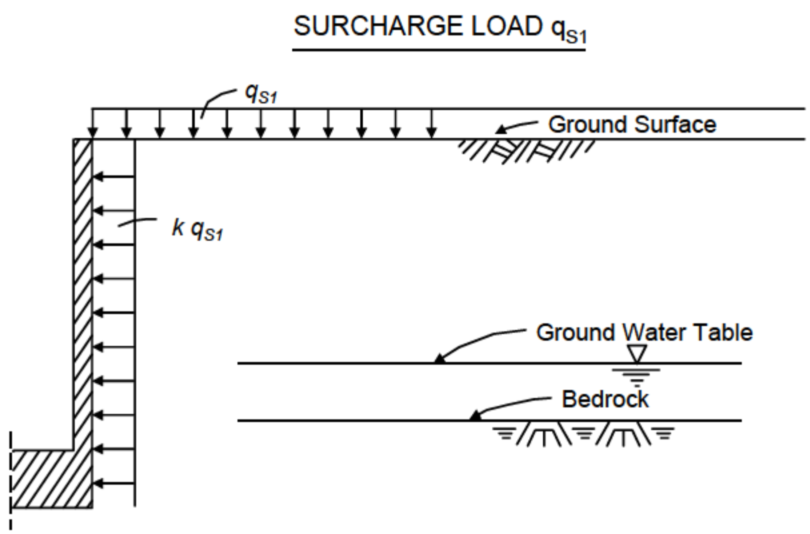


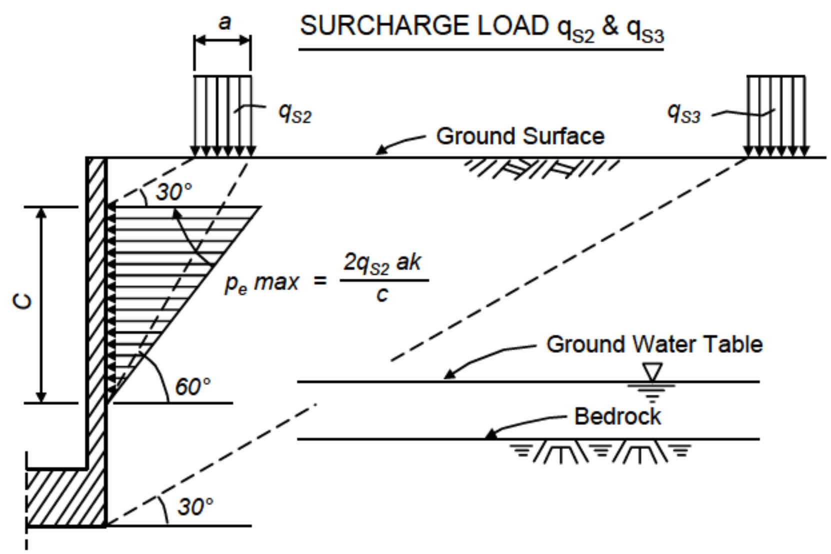
Active pressures develop, when the wall can deflect ≥ 0.001 H.
(All units in lbs and ft)

SAR FIGURE NO. 2.5-100

AMENDMENT 19

ARKANSAS NUCLEAR ONE UNIT 2 RUSSELLVILLE, ARKANSAS	Entergy	SCALE: NONE DRAWN: DESIGN: ENTERGY CAD NO:
ACTIVE EARTHPRESSURE DIAGRAM	BASED ON DRAWING NO	SHEET / REV.





q_{S3} at the surface behind the 30° line has no influence in the lateral earth pressure on the wall.

For Active Pressure Conditions	$k = k_A = 0.33$
For At Rest Pressure Conditions	$k = k_O = 0.5$ (for normally compacted fill)
	$k = k_O = 0.7$ (for highly compacted fill)

This pressure distribution is based on the assumption of cohesionless backfill material with $\Phi \geq 30°$.

LATERAL EARTHPRESSURES DUE TO SURCHARGE LOADS

3 DESIGN OF STRUCTURES, COMPONENTS, EQUIPMENT, AND SYSTEMS

3.1 CONFORMANCE WITH AEC GENERAL DESIGN CRITERIA

Arkansas Nuclear One - Unit 2 (ANO-2 or Unit 2) was originally designed to comply with the 70 "Proposed General Design Criteria for Nuclear Power Plant Construction Permits," published in July 1967. However, Sections 3.1.1 through 3.1.6 provide a comparison with the AEC General Design Criteria (GDC) published as Appendix A to 10 CFR 50 in 1971. Each criterion is followed by a summary discussion of the design and procedures which are intended to meet the design objectives reflected in the criterion.

Each of the Engineered Safety Features (ESF) is designed to tolerate a single failure during the period of recovery following an incident without loss of its protective function. This period of recovery consists of two segments, the injection phase and the recirculation phase. During the injection phase the single failure is limited to the failure of a single active component to complete its function as required. During the recirculation phase, assuming there were no failures during the injection phase, the ESF are designed to tolerate either a single active failure or a single passive failure without loss of their protective functions.

3.1.1 OVERALL REQUIREMENTS

CRITERION 1 - QUALITY STANDARDS AND RECORDS

Structures, systems, and components important to safety shall be designed, fabricated, erected, and tested to quality standards commensurate with the importance of the safety functions to be performed. Where generally recognized codes and standards are used, they shall be identified and evaluated to determine their applicability, adequacy, and sufficiency and shall be supplemented or modified as necessary to assure a quality product in keeping with the required safety function. A quality assurance program shall be established and implemented in order to provide adequate assurance that these structures, systems and components will satisfactorily perform their safety functions. Appropriate records of the design, fabrication, erection, and testing of structures, systems, and components important to safety shall be maintained by or under the control of the nuclear power unit licensee throughout the life of the unit.

<u>Response</u>

All structures, systems and components of the facility are classified according to their importance in the prevention and mitigation of accidents.

Seismic Category 1 structures, systems and components, listed in Section 3.2.1, may be essential to the protection of the health and safety of the public in the event of hypothetical accidents. Consequently, they are designed, fabricated, inspected and erected, and the materials selected to the applicable provisions of recognized codes, good nuclear practice and to quality standards that reflect their importance. Discussions of applicable codes and standards, code classes and other quality related criteria are given in the sections cited in Section 3.2.1. The quality group classifications as defined in Regulatory Guide 1.26 are discussed in Section 3.2.2. System descriptions contain more specific information on particular components and application of the quality criteria. Quality Assurance programs for Seismic Category 1 structures, systems and components conform with the requirements of 10 CFR 50, Appendix B. Quality related activities ensure compliance with Regulatory Guides 1.10, 1.15, 1.18, and 1.19 on containment construction. Quality Assurance programs meet Regulatory Guides 1.26, 1.28, 1.29, 1.30 and 1.33.

The following codes and standards are also utilized within the QA program as applicable to those activities to which they are referenced within various sections of this document and the QA Program Manual.

ASME B&PVC Section III, Division 1, 1992 Edition, No Addenda – Nuclear Power Plant Components [In lieu of the original Construction Code, all or portions of later editions/addenda of ASME Section III may be specified for repair or replacement (including system changes) of components or systems, within the rules of ASME B&PVC Section XI and 10 CFR 50.55a. If later editions/addenda are selected, design, fabrication, and examination requirements shall be reconciled with the Owner's specification.] When performing repair/ replacement activities in accordance with ASME Section XI, 2001 Edition / 2003 Addenda, to comply with IWA-4540(a)(2), nondestructive examination method and acceptance criteria of the 1992 Edition (or later) of ASME Section III shall be met for welds when a system leakage test is performed in lieu of a hydrostatic pressure test.

ASME B&PVC Section XI – Rules for Inservice Inspection of Nuclear Power Plant Components. The testing of ASME Class 1, 2, 3, MC and CC components shall be performed in accordance with periodically updated versions of Section XI of the ASME Boiler and Pressure Vessel Code and Addenda as required by 10 CFR 50.55a. Qualification and certification of ultrasonic examination personnel performing inservice inspections shall be performed in accordance with the 1995 edition with addenda through 1996, as required by the NRC.

ASNT SNT-TC-1A, 1984 Edition – Recommended Practice for Nondestructive Testing Personnel Qualification and Certification [This edition shall be used in lieu of earlier editions that might be referenced in other codes or standards to which ANO is committed.]

AWS D1.1, 1992 or later approved Edition – Structural Steel Welding Code. As an alternative to AWS requirements, Welding Procedure Specifications (WPS's), and/or Welder Performance Qualification (WPQ), meeting the ASME Section IX Code requirements may be utilized for structural steel applications provided all other applicable provisions of AWS D1.1 are met unrelated to WPS's and WPQ's.

The sufficiency of the chosen Seismic Category 1 quality standards is shown by the analysis results, which assume maximum defects allowable by the standards and by prior successful applications of these same standards in nuclear power plant design, fabrication, construction, test and operation.

The owner maintains, either in its possession or under its control, the required records of design, fabrication, construction and testing of Category 1 plant components throughout the life of the plants. Construction and test records are developed as outlined throughout the FSAR. Operating records to be maintained throughout the life of the unit are discussed in the Quality Assurance Program Manual (QAPM).

CRITERION 2 - DESIGN BASES FOR PROTECTION AGAINST NATURAL PHENOMENA

Structures, systems, and components important to safety shall be designed to withstand the effects of natural phenomena such as earthquakes, tornadoes, hurricanes, floods, tsunami, and seiches without loss of capability to perform their safety functions. The design bases for these structures, systems, and components shall reflect: (1) appropriate consideration of the natural phenomena that have been historically reported for the site and surrounding area, with sufficient margin for the limited accuracy, quantity, and period of time in which the historical data have

been accumulated, (2) appropriate combinations of the effects of normal and accident conditions with the effects of the natural phenomena and (3) the importance of the safety functions to be performed.

Response

All systems and components designated as Seismic Category 1 are designed so that there is no loss of function as a consequence of ground accelerations associated with the Design Basis Earthquake (DBE). The working stresses for Seismic Category 1 items are kept within allowable values for the Operating Basis Earthquake (OBE). Section 2.5, Geology and Seismology, establishes the seismic design bases.

Design bases for other natural phenomena are established in Sections 2.3, Meteorology; 2.4, Hydrologic Engineering; 3.3, Wind and Tornado Loadings; 3.4, Water Level (Flood) Design; and parts of 3.5, Missile Protection. The application and combination of these bases with accident related plant process conditions are discussed in Chapter 15.

Each system description evaluates functional performance under the appropriate natural phenomena conditions. The classification of a structure, system or component as Seismic Category 1 indicates that a safety function exists and must be met under the identified accident and natural phenomena conditions. Design assumptions of natural phenomena and plant process conditions are used which meet Regulatory Guides 1.4, 1.25, and 1.27.

Instrumentation to measure and document natural phenomena meets Regulatory Guides 1.12 and 1.23. The Emergency Plan, which is part of the designed protective action against adverse natural phenomena, complies with the requirements of 10CFR50, Appendix E.

CRITERION 3 - FIRE PROTECTION

Structures, systems, and components important to safety shall be designed and located to minimize, consistent with other safety requirements, the probability and effect of fires and explosions. Noncombustible and heat resistant materials shall be used wherever practical throughout the unit, particularly in locations such as the containment and control room. Fire detection and fighting systems of appropriate capacity and capability shall be provided and designed to minimize the adverse effects of fires on structures, systems, and components important to safety. Fire fighting systems shall be designed to assure that their rupture or inadvertent operation does not significantly impair the safety capability of these structures, systems, and components.

Response

Structures, systems, and components important to safety are designed to comply with the AEC "General Design Criteria for Nuclear Power Plants" and are located to minimize, consistent with other safety requirements, the probability and effect of fires and explosions. Noncombustible and heat resistant materials are used wherever practical throughout the unit, particularly in locations such as the containment and control room. Fire detection and fighting systems of appropriate capacity and capability are provided and designed to minimize the adverse effects of fires on structures, systems, and components important to safety. Fire fighting systems are designed to assure that their rupture or inadvertent operation does not significantly impair the safety capability of these structures, systems, and components.

In addition, the ANO-2 fire protection program has been revised and updated in accordance with NFPA 805, "Performance-Based Standard for Fire Protection for Light Water Reactor Electric Generating Plants," 2001 Edition, as allowed by 10 CFR 50.48. This improved program includes procedures, personnel training, and risk-informed, performance-based analysis of the plant in terms of fire protection. Section 9.5.1 provides a detailed description of the ANO-2 fire protection program.

CRITERION 4 - ENVIRONMENTAL AND MISSILE DESIGN BASES

Structures, systems, and components important to safety shall be designed to accommodate the effects of and be compatible with the environmental conditions associated with normal operation, maintenance, testing, and postulated accidents, including Loss of Coolant Accidents (LOCAs). These structures, systems, and components shall be appropriately protected against dynamic effects, including the effects of missiles, pipe whipping, and discharging fluids, that may result from equipment failures and from events and conditions outside the nuclear power unit.

However, dynamic effects associated with postulated pipe ruptures in nuclear power units may be excluded from the design basis when analyses reviewed and approved by the Commission demonstrate that the probability of fluid system piping rupture is extremely low under conditions consistent with the design basis for the piping. [52FR41288]

Response

The environmental design of safety-related items is discussed in Section 3.8 for the design of structures, Sections 6.2.2 and 6.2.3 for containment heat removal and air purification and Section 9.4 for ventilation systems. Safety-related systems and components use the input from these sections for design as discussed in Section 3.11.

Conservative design methods, segregated routing of piping, missile shield walls and engineered hangers and pipe restraints are all used to accommodate dynamic effects of postulated accidents. These same features as well as the strength of the auxiliary building, containment and intake structure protect the safety-related equipment from missiles which might be generated either within or outside the plant. Sections 3.5 and 3.6 detail the design assumptions, methods and results for missiles and postulated piping ruptures.

In 1987, the Commission modified GDC 4 to allow crediting of a leak-before-break (LBB) technology for an exclusion from the design basis of dynamic effects. Since this time, ANO-2 has credited the LBB technology for various plant modifications. See Section 3.6 of the SAR for additional information.

CRITERION 5 - SHARING OF STRUCTURES, SYSTEMS, AND COMPONENTS

Structures, systems, and components important to safety shall not be shared among nuclear power units unless it can be shown that such sharing will not significantly impair their ability to perform their safety functions, including, in the event of an accident in one unit, an orderly shutdown and cooldown of the remaining units.

Response

The interrelationship between Unit 1 and Unit 2 is discussed in Section 1.2.2.10. The safety of either unit would not be impaired by the failure of the facilities and systems which are shared. Separate systems and equipment are provided for each unit with few exceptions. The shared systems are specifically listed in Section 1.2.2.10 and the individual system descriptions discuss their adequacy to perform safety-related functions for both units.

3.1.2 PROTECTION BY MULTIPLE FISSION PRODUCT BARRIERS

CRITERION 10 - REACTOR DESIGN

The reactor core and associated coolant, control and protection systems shall be designed with appropriate margins to assure that specified acceptable fuel design limits are not exceeded during any condition of normal operation, including the effects of anticipated operational occurrences.

Response

In ANS N18.2, plant conditions have been categorized in accordance with their anticipated frequency of occurrence and risk to the public, and design requirements are given for each of the four categories. The categories covered by this criterion are Condition I - Normal Operation and Condition II - Faults of Moderate Frequency.

The design requirement for Condition I is that margin shall be provided between any plant parameter and the value of that parameter which would require either automatic or manual protective action; it is met by providing an adequate control system (see Section 7.7). The design requirement for Condition II is that such faults shall be accommodated with, at most, a shutdown of the reactor, with the plant capable of returning to operation after corrective action; it is met by providing an adequate protective system (see Section 7.2 and Chapter 15).

Specified acceptable fuel design limits are stated in Section 4.4. Minimum margins to specified acceptable fuel design limits are prescribed in the Technical Specifications (Limiting Conditions for Operations) which support Chapters 4 and 15. The plant is designed such that operation within Limiting Conditions for Operation, with safety system settings not less conservative than Limiting Safety System Settings prescribed in the Technical Specifications, assures that specified acceptable fuel design limits will not be violated as a result of anticipated operational occurrences. During non-accident conditions, operation of the plant within Limiting Conditions for Operation ensures that specified acceptable fuel design limits are not approached within the minimum margins. Operator action, aided by the control systems and monitored by plant instrumentation, maintains the plant within Limiting Conditions for Operation during non-accident conditions.

CRITERION 11 - REACTOR INHERENT PROTECTION

The reactor core and associated coolant systems shall be designed so that in the power operating range the net effect of the prompt inherent nuclear feedback characteristics tends to compensate for a rapid increase in reactivity.

Response

In the power operating range, the combined response of the fuel temperature coefficient, the moderator temperature coefficient, the moderator void coefficient, and the moderator pressure coefficient to an increase in reactor power in the power operating range will be a decrease in reactivity; i.e., the inherent nuclear feedback characteristics will not be positive.

The reactivity coefficients for this reactor are listed in Table 4.3-1 and are discussed in detail in Section 4.3.

CRITERION 12 - SUPPRESSION OF REACTOR POWER OSCILLATIONS

The reactor core and associated coolant, control, and protection systems shall be designed to assure that power oscillations which can result in conditions exceeding specified acceptable fuel design limits are not possible or can be reliably and readily detected and suppressed.

Response

Power level oscillations outside of a nominal control band do not occur during normal plant operation. The effect of the negative power coefficient of reactivity (see Criterion 11), together with the coolant temperature program maintained by control of regulating rods and soluble boron, provides fundamental mode stability. Power level is continuously monitored by neutron flux detectors (Chapter 7).

Power distribution oscillations are detected by neutron flux detectors. Axial mode oscillations are suppressed by means of neutron absorber rods. All other modes of oscillation are expected to be convergent. Monitoring and protective requirements imposed by Criteria 10 and 20 are discussed in those responses and in Chapter 4.

CRITERION 13 - INSTRUMENTATION AND CONTROL

Instrumentation shall be provided to monitor variables and systems over their anticipated ranges for normal operation, for anticipated operational occurrences, and for accident conditions as appropriate to assure adequate safety, including those variables and systems that can affect the fission process, the integrity of the reactor core, the reactor coolant pressure boundary, and the containment and its associated systems. Appropriate controls shall be provided to maintain these variables and systems within prescribed operating ranges.

Response

Instrumentation is provided to monitor and maintain significant process variables which can affect the fission process, the integrity of the reactor core, the reactor coolant pressure boundary, and the containment and its associated systems. Controls are provided for the purpose of maintaining these variables within the limits prescribed for safe operation.

The principal process variables to be monitored and controlled are neutron level (reactor power); axial neutron flux shape; CEA position; reactor coolant temperature and pressure; reactor coolant pump speed; pressurizer liquid level; and steam generator level and pressure. In addition, instrumentation is provided for continuous automatic monitoring of activity level in the reactor coolant.

The Plant Protection System (PPS) consists of the Reactor Protective System (RPS) and the Engineered Safety Features Actuation System (ESFAS). The RPS is designed to monitor the reactor operating conditions and to perform an on-line calculation of the limiting core parameters. Systems are provided to affect reliable and rapid reactor trip if a safety limit may be reached (see Section 7.2). The ESFAS is designed to monitor plant operating conditions and to initiate engineered safety features operation in the event of an accident (see Section 7.3).

The Core Operating Limit Supervisory System (COLSS) provides the operator with an independent indication of the proximity to a Limiting Condition for Operation (LCO) and an alarm when an LCO is reached.

Incore instrumentation is provided to supplement information on core power distribution and to provide a means for calibration of out-of-core flux detectors.

The instrumentation and control systems are described in detail in Chapter 7, and the boronmeter and the process radiation monitor are discussed in Section 9.3.4.

CRITERION 14 - REACTOR COOLANT PRESSURE BOUNDARY

The reactor coolant pressure boundary shall be designed, fabricated, erected and tested so as to have an extremely low probability of abnormal leakage, of rapidly propagating failure and of gross rupture.

Response

Reactor Coolant System (RCS) components are designed in accordance with the ASME Code, Section III. To establish operating pressure and temperature limitations during startup and shutdown of the RCS, the fracture toughness rules defined in Appendix G of the ASME Code, Section III were followed. Quality control, inspection, and testing as required by this standard and allowable reactor pressure-temperature operations ensure the integrity of the RCS.

The Reactor Coolant Pressure Boundary (RCPB) is designed to accommodate the system pressures and temperatures attained under all expected modes of unit operation including all anticipated transients, and maintain the stresses within applicable stress limits.

Design pressures, temperatures and transients are listed in Chapter 5 and details of the transient analysis are provided in Chapter 15.

Means are provided to detect significant leakage from the RCPB with monitoring readouts and alarms in the control room as discussed in Chapters 5 and 12.

The pressure boundary has provisions for inservice inspection in accordance with ASME Code, Section XI, to ensure continuance of the structural and leak tight integrity of the boundary. For the reactor vessel, a material surveillance program conforming with ASTM-E-185 is provided as discussed in Chapter 5.

CRITERION 15 - REACTOR COOLANT SYSTEM DESIGN

The RCS and associated auxiliary, control, and protection systems shall be designed with sufficient margin to assure that the design conditions of the RCPB are not exceeded during any condition of normal operation including anticipated operational occurrences.

Response

The design criteria and bases for the RCPB are described in the response to Criterion 14.

The operating conditions established for normal steady state and transient plant operations are discussed in Chapter 5. The normal operating limits are selected so that an adequate margin exists between them and the design limits. The plant control systems are designed to ensure that plant variables are maintained well within the established operating limits. The plant transient response characteristics and pressure and temperature distributions during normal operations are considered in the design as well as the accuracy and response of the instruments and controls. These design techniques ensure that a satisfactory margin is maintained between normal operating conditions, including design transients, and design limits for the RCPB.

The RPS functions to minimize the deviation from normal operating limits in the event of anticipated operational occurrences (ANS N18.2 Condition II occurrences). Analyses for this plant show that the design limits for the RCPB are not exceeded in the event of any ANS N18.2 Condition II occurrence.

CRITERION 16 - CONTAINMENT DESIGN

Reactor containment and associated systems shall be provided to establish an essentially leak tight barrier against the uncontrolled release of radioactivity to the environment and to assure that the containment design conditions important to safety are not exceeded for as long as postulated accident conditions require.

Response

Reactor containment and associated systems are provided and establish an essentially leak tight barrier against the uncontrolled release of radioactivity to the environment. The quality requirements of Regulatory Guides 1.10, 1.15, 1.18, and 1.19 are met. The upper limit for containment leakage is 0.1 percent volume per day at 59 psig internal pressure. The containment is tested prior to initial plant operation, uprated operation, and periodically throughout plant life.

The containment, including access openings and penetrations, has a structural design pressure of 59 psig and a design temperature of at least 300 °F. The electrical penetrations are qualified to design basis accident conditions. The greatest transient peak condition, associated with a postulated rupture of the piping in the RCS and the calculated effects of a metal-water reaction, does not exceed these values.

The containment and engineered safety features have been evaluated for various combinations of credible energy releases. The analysis accounts for system energy and decay heat. The cooling capacity of the containment heat removal systems is adequate to prevent overpressurization of the structure.

Sections 3.8.1, 6.2, and 6.5 describe and evaluate the containment and its associated system.

CRITERION 17 - ELECTRICAL POWER SYSTEMS

An onsite electric power system and an off-site electric power system shall be provided to permit functioning of structures, systems, and components important to safety. The safety function for each system (assuming the other system is not functioning) shall be to provide sufficient capacity and capability to assure that (1) specified acceptable fuel design limits and design conditions of the RCPB are not exceeded as a result of anticipated operational occurrences and (2) the core is cooled and containment integrity and other vital functions are maintained in the event of postulated accidents.

The onsite electric power supplies, including the batteries, and the onsite electric distribution system, shall have sufficient independence, redundancy, and testability to perform their safety functions assuming a single failure.

Electric power from the transmission network to the onsite electric distribution system shall be supplied by two physically independent circuits (not necessarily on separate rights-of-way) designed and located so as to minimize to the extent practical the likelihood of their simultaneous failure under operating and postulated accident and environmental conditions. A switchyard common to both circuits is acceptable. Each of these circuits shall be designed to be available in sufficient time following a loss of all onsite alternating current power supplies and the other off-site electric power circuit, to assure that specified acceptable fuel design limits and design conditions of the RCPB are not exceeded. One of these circuits shall be designed to be available within a few seconds following a LOCA to assure that core cooling, containment integrity, and other vital safety functions are maintained.

Provisions shall be included to minimize the probability of losing electric power from any of the remaining supplies as a result of, or coincident with, the loss of power generated by the nuclear power unit, the loss of power from the transmission network, or the loss of power from the onsite electric power supplies.

Response

The electric power systems conform to this criterion through the provision of an off-site 500 kV/161 kV transmission system and onsite diesel engine generators and batteries. Each of these systems provides sufficient capacity and capability to assure operation of the necessary safety functions during anticipated operational occurrences and postulated accidents, assuming the other system is not functioning.

The onsite power supplies, including the diesel generators, batteries and distribution system, have sufficient independence, redundancy and testability to perform their safety functions in the event of a single failure.

Electric power is supplied to the station switchyard by five separate transmission lines. Three lines, one from the Mabelvale substation, one from Pleasant Hill and the other from the Ft. Smith substation, feed the 500 kV bus. The remaining two lines, one line from the Russellville East substation and the other from the Pleasant Hill substation, feed the 161 kV ring bus. Startup Transformer 3 is supplied by the autotransformer bank through underground cables, and Startup Transformer 2 is supplied by the 161 kV ring bus.

The onsite electrical distribution system arrangement minimizes the vulnerability of vital circuits to physical damage. Two independent circuits can supply power from the different off-site transmission lines through the corresponding transformer to safety oriented components during operating and postulated accident and environmental conditions. Each of these circuits (Startup Transformer 3 and 2) are designed to be available in sufficient time following a loss of all onsite alternating current power supplies and the other offsite electric power circuit, to assure that specified acceptable fuel design limits and design conditions of the reactor coolant pressure boundary are not exceeded. One of these circuits is designed to be available within a few seconds following a loss-of coolant accident to assure that core cooling, containment integrity, and other vital safety function are maintained.

Both ANO Unit 1 and Unit 2 are prevented from automatic transfer to Startup Transformer 2 during normal power operations for all buses except buses A1/A3 (Unit 1) and 2A1/2A3 (Unit 2). Procedures administratively control Unit 1 and Unit 2 access to Startup Transformer 2. Procedures may allow other fast transfer capabilities to Startup Transformer 2 for specifically analyzed conditions and restrictions defined in approved Engineering Calculations and Evaluations.

Two emergency diesel generators are provided for use in the event off-site power is lost. Normally, the two 4160-volt ESF buses are fed either from the Unit Auxiliary Transformer (UAT), or from either of the two startup transformers. Upon loss of normal (auxiliary transformer) and preferred (off-site) power sources, the two 4160-volt ESF buses are each energized from their respective diesel generator. The ESF power system is designed to provide continuous power for control instrumentation, reactor protection and engineered safety features systems, safety features actuation control systems and other loads. Two independent and physically separate 125-volt batteries and DC control centers will provide necessary instrumentation through inverters. Each battery is sized to carry the continuous emergency and vital AC loads for a minimum period of eight hours in addition to supplying power for the operation of momentary loads during the 8-hour period.

Provisions are included to minimize the probability of losing electrical power from the remaining sources as a result of, or coincident with, a loss of the nuclear power unit, the transmission network, or the onsite power sources. With a loss of the electrical power generated by the nuclear power unit, auxiliary plant loads will be transferred automatically by bus transfer devices to an off-site power source. With the loss of off-site power to the ESF buses, each ESF bus is cleared of all auxiliaries and ties prior to the application of the associated diesel generator. This prevents loss of the diesel generator as a result of an off-site power fault. Because of the design of the fault protection system, there is a very low probability that loss of onsite diesel generator power sources could cause loss of either the off-site or nuclear unit electrical power sources.

Separation of circuits, switching capability, protective relaying, adequacy of redundancy are all used in system design to assure a higher probability of available electric power for safety-related systems. Chapter 8 discusses in detail each of the electric power systems for Unit 2.

CRITERION 18 - INSPECTION AND TESTING OF ELECTRICAL POWER SYSTEMS

Electrical power systems important to safety shall be designed to permit periodic inspection and testing of important areas and features, such as wiring, insulation, connectors, and switchboards, to assess the continuity of the systems and the condition of their components. The systems shall be designed with a capability to test periodically (1) the operability and

functional performance of the components of the systems, such as onsite power sources, relays, switches, and buses, and (2) the operability of the systems as a whole and, under conditions as close to design as practical, the full operation sequence that brings the systems into operation, including operation of applicable portions of the protection system, and the transfer of power buses, the off-site power system, and the onsite power system.

Response

All important passive components of the emergency power system such as wiring, insulation, connection, and switchboards are designed to permit appropriate periodic inspection and testing to assess their continuity and condition.

Protective equipment and instrumentation have provisions for inservice testing and calibration. The diesel generators are equipped with means for starting periodically to test for readiness, means for synchronizing the unit onto the bus without interrupting the service, and means for loading.

Surveillance systems, along with periodic tests of power and control circuits for ESF equipment not normally exercised during operation of the station, ensure required performance.

CRITERION 19 - CONTROL ROOM

A control room shall be provided from which actions can be taken to operate the nuclear power unit safely under normal conditions and to maintain it in a safe condition under accident conditions, including LOCAs. Adequate radiation protection shall be provided to permit access and occupancy of the control room under accident conditions without personnel receiving radiation exposure in excess of 5 rem whole body, or its equivalent to any part of the body, for the duration of the accident.

Equipment at appropriate locations outside the control room shall be provided: (1) with a design capability for prompt hot shutdown of the reactor, including necessary instrumentation and controls to maintain the unit in a safe condition during hot shutdown, and (2) with a potential capability for subsequent cold shutdown of the reactor through the use of suitable procedures.

Response

The control room contains the necessary indications and controls for normal operation and post-accident shutdown. The various system descriptions throughout the SAR generally discuss the associated equipment located in the control room.

The post-accident environment and habitability in the control room is described and evaluated in Sections 6.4, 9.4, 12.1, and 12.2.

Instrumentation and controls are provided outside the control room at various locations so that the plant may be safely brought to hot shutdown and potentially to cold shutdown. These provisions are discussed in Section 7.4.1.

3.1.3 PROTECTION AND REACTIVITY CONTROL SYSTEMS

CRITERION 20 - PROTECTION SYSTEM FUNCTIONS

The protection system shall be designed (1) to initiate automatically the operation of appropriate systems including the reactivity control systems, to assure that specified acceptable fuel design limits are not exceeded as a result of anticipated operational occurrences and (2) to sense accident conditions and to initiate the operation of systems and components important to safety.

Response

A PPS is provided to monitor reactor and plant operating conditions and automatically initiate a reactor trip when the monitored variable or combination of variables exceeds its normal operating range. The trip function setpoints are selected to ensure that anticipated operational occurrences do not cause acceptable fuel design limits (linear heat rate and minimum Departure from Nucleate Boiling Ratio [DNBR]) to be violated. Specific reactor trips are described in Section 7.2.

Reactor trip is accomplished by de-energizing the Control Element Drive Mechanism (CEDM) holding latch coils through the interruption of the CEDM power supply. The Control Element Assemblies (CEAs) are, thus released to drop into the core, reducing reactor power. The CEDMs are described in Section 4.2.

The PPS also functions to monitor potential accident conditions and automatically initiate engineered safety features operation when the monitored variables reach their setpoints. The parameters which automatically actuate engineered safety features are described in Section 7.3. Controls are provided for manual actuation of engineered safety features.

CRITERION 21 - PROTECTION SYSTEM RELIABILITY AND TESTABILITY

The protection system shall be designed for high functional reliability and inservice testability commensurate with the safety functions to be performed. Redundancy and independence designed into the protection system shall be sufficient to assure that (1) no single failure results in loss of the protection function and (2) removal from service of any component or channel does not result in loss of the required minimum redundancy unless the acceptable reliability of operation of the protection system can be otherwise demonstrated. The protection system shall be designed to permit period testing of its functioning when the reactor is in operation, including a capability to test channels independently to determine failures and losses of redundancy that may have occurred.

Response

The PPS is designed to provide high functional reliability and inservice testability. The protection system is designed to comply with the requirements of IEEE 279-1971. No single failure will result in the loss of the protection function. The protection channels are independent, e.g. with respect to piping, wire routing, mounting and supply of power. This independence permits testing and the removal from service of any component or channel without loss of the protection function.

Each channel of the PPS, including the sensors up to the final actuation device, is capable of being checked during reactor operation. Measurement sensors of each channel used in protection systems are checked by comparison of outputs of similar channels which are presented on indicators and recorders on the control board. Trip units and logic are tested by inserting a signal into the measurement channel ahead of the readout and, upon application of a trip level input, observing that a signal is passed through the trip units and the logic to the logic output relays. The logic output relays are tested individually for initiation of trip action. The parallel trip circuit breakers which supply power to the CEDM holding coils may be tested during reactor operation without affecting a reactor trip.

CRITERION 22 - PROTECTION SYSTEM INDEPENDENCE

The protection system shall be designed to assure that the effects of natural phenomena, and of normal operation, maintenance, testing and postulated accident conditions on redundant channels do not result in loss of the protection function, or shall be demonstrated to be acceptable on some other defined basis. Design techniques, such as functional diversity or diversity in component design and principles of operation, shall be used to the extent practical to prevent loss of the protection function.

Response

The PPS conforms to the provisions of IEEE 279-1971. Four independent measurement channels complete with sensors, sensor power supplies, signal conditioning units and bistable trip units are provided for each protective parameter monitored by the protection systems. The measurement channels are provided with a high degree of independence by separate connection of the channel sensors to the process systems. Power to the channels is provided by independent vital power supply buses. See Chapter 7.

Functional diversity has been incorporated in the system design to the extent that is practical to prevent loss of the protection function.

The PPS is functionally tested to ensure satisfactory operation prior to installation in the plant. Environmental and seismic qualifications are also performed utilizing type tests and specific equipment tests. Seismic qualification of CE supplied instrumentation is described in detail in CENPD-61, "Seismic Qualification of Category 1 Electric Equipment for Nuclear Steam Supply Systems," November 1972, and complies with IEEE 344-1971. Seismic qualification of non-CE supplied instrumentation complies with IEEE 344-1971, 1975, or 1987.

CRITERION 23 - PROTECTION SYSTEM FAILURE MODES

The protection system shall be designed to fail into a safe state or into a state demonstrated to be acceptable on some other defined basis if conditions such as disconnection of the system, loss of energy (e.g., electric power, instrument air) or postulated adverse environments (e.g., extreme heat or cold, fire, pressure, steam, water, and radiation) are experienced.

Response

PPS trip channels have been designed to fail into a safe state or into a state established as acceptable in the event of loss of power supply or disconnection of the system. A loss of power to the CEDM holding coils results in gravity insertion in the core. Redundancy, channel independence, and separation are incorporated in the PPS design to minimize the possibility of the loss of a protection function under adverse environmental conditions. See Chapter 7 and the response to Criterion 22.

CRITERION 24 - SEPARATION OF PROTECTION AND CONTROL SYSTEMS

The protection system shall be separated from control systems to the extent that failure of any single control system component or channel, or failure or removal from service of any single protection system component or channel which is common to the control and protection systems leaves intact a system satisfying all reliability, redundancy, and independence requirements of the protection system. Interconnection of the protection and control systems shall be limited so as to assure that safety is not significantly impaired.

Response

The protection systems are separated from the control instrumentation systems so that failure or removal from service of any control instrumentation system component or channel does not inhibit the function of the protection system (see Section 7.2).

CRITERION 25 - PROTECTION SYSTEM REQUIREMENTS FOR REACTIVITY CONTROL MALFUNCTIONS

The protection system shall be designed to assure that specified acceptable fuel design limits are not exceeded for any single malfunction of the reactivity control systems, such as accidental withdrawal (not ejection or dropout) of control rods.

Response

Shutdown of the reactor is accomplished by the opening of the reactor trip breakers which interrupt power to the CEDM holding coils. Actuation of the trip breakers is independent of any existing control signals.

The protection system is designed such that specified acceptable fuel design limits are not exceeded for any single malfunction of the reactivity control systems, including the withdrawal of a single CEA. Analyses of possible control malfunctions are discussed in Chapter 15.

CRITERION 26 - REACTIVITY CONTROL SYSTEM REDUNDANCY AND CAPABILITY

Two independent reactivity control systems of different design principles shall be provided. One of the systems shall use control rods, preferably including a positive means for inserting the rods, and shall be capable of reliably controlling reactivity changes to assure that under conditions of normal operation, including anticipated operation occurrences, and with appropriate margin for malfunctions such as stuck rods, specified acceptable fuel design limits are not exceeded. The second reactivity control system shall be capable of reliably controlling the rate of reactivity changes resulting from planned, normal power changes (including xenon burnout) to assure acceptable fuel design limits are not exceeded. One of the systems shall be capable of holding the reactor core subcritical under cold conditions.

Response

Two independent reactivity control systems of different design principles are provided. The first system, using CEAs, includes a positive means (gravity) for inserting CEAs and is capable of reliably controlling reactivity changes to assure that under conditions of normal operation, including anticipated operational occurrences; specified acceptable fuel design limits are not

exceeded. The CEAs can be mechanically driven into the core. The appropriate margin for stuck rods is provided by assuming in the analyses of anticipated operational occurrences that the highest worth CEA does not fall into the core.

The second system, the Chemical and Volume Control System (CVCS), using neutron absorbing soluble boron, is capable of reliably compensating for the rate of reactivity changes resulting from planned normal power changes (including xenon burnout) such that acceptable fuel design limits are not exceeded. This system is capable of holding the reactor subcritical under cold conditions.

Either system is capable of making the core subcritical from a hot operating condition and holding it subcritical in the hot standby condition.

Either system is able to insert negative reactivity at a rate sufficient to prevent exceeding acceptable fuel design limits as the result of a power change, i.e., the positive reactivity added by burnup of xenon.

CRITERION 27 - COMBINED REACTIVITY CONTROL SYSTEMS CAPABILITY

The reactivity control systems shall be designed to have a combined capability, in conjunction with poison addition by the Emergency Core Cooling System (ECCS), of reliably controlling reactivity changes to assure that under postulated accident conditions and with appropriate margin for stuck rods the capability to cool the core is maintained.

Response

The reactivity control systems which provide the means for making and holding the core subcritical under postulated accident conditions are discussed in Sections 9.3 and 4.3. Combined use of CEAs and chemical shim control by the CVCS provides the shutdown margin required for plant cooldown and long-term xenon decay, assuming the highest worth CEA is stuck out of the core.

During an accident, the safety injection system functions to inject concentrated boric acid into the RCS for long-term and short-term cooling and for reactivity control. Details of the system are given in Section 6.3.

CRITERION 28 - REACTIVITY LIMITS

The reactivity control systems shall be designed with appropriate limits on the potential amount and rate of reactivity increase to assure that the effects of postulated reactivity accidents can neither (1) result in damage to the RCPB greater than limited local yielding nor (2) sufficiently disturb the core, its support structures or other reactor pressure vessel internals to impair significantly the capability to cool the core. These postulated reactivity accidents shall include consideration of rod ejection (unless prevented by positive means), rod dropout, steam line rupture, changes in reactor coolant temperature and pressure, and cold water addition.

Response

The bases for CEA design include ensuring that the reactivity worth of any one CEA is not greater than a pre-selected maximum value. The CEAs are divided into two sets, a shutdown set and a regulating set, further subdivided into groups as necessary. Administrative

procedures and interlocks ensure that only one group is withdrawn at a time (except for allowed overlap regions in the regulating groups), and that the regulating groups are withdrawn only after the shutdown groups are fully withdrawn. The regulating groups are programmed to move in sequence and within limits which prevent the rate of reactivity addition and the worth of individual CEAs from exceeding limiting values. See Sections 4.3 and 7.7.

The maximum rate of reactivity addition which may be produced by the CVCS is too low to induce any significant pressure forces which might rupture the RCPB or disturb the reactor vessel internals.

The RCPB (Chapter 5) and the reactor internals (Chapter 4) are designed to appropriate codes (refer for instance, to the response to Criterion 14) and will accommodate the static and dynamic loads associated with an inadvertent, sudden release of energy, such as that resulting from a CEA ejection or a steam line break, without rupture and with limited deformation which will not impair the capability of cooling the core.

CRITERION 29 – PROTECTION AGAINST ANTICIPATED OPERATIONAL OCURRENCES

The protection and reactivity control systems shall be designed to assure an extremely high probability of accomplishing their safety functions in the event of anticipated operational occurrences.

Response

Plant conditions designated as Condition I and Condition II in ANS N18.2 have been carefully considered in the design of the RPS and the Reactivity Control Systems. Consideration of redundancy, independence and testability in the design, coupled with careful component selection, overall system testing, and adherence to detailed quality assurance, assure an extremely high probability that safety functions are accomplished in the event of anticipated operational occurrences.

3.1.4 FLUID SYSTEMS

CRITERION 30 – QUALITY OF REACTOR COOLANT PRESSURE BOUNDARY

Components which are part of the reactor coolant pressure boundary shall be designed, fabricated, erected, and tested to the highest quality standards practical. Means shall be provided for detecting and, to the extent practical, identifying the location of the source of reactor coolant leakage.

Response

The RCPB components have been designed, fabricated, erected and tested in accordance with the ASME Code Section III, and in conformance with the requirements of 10 CFR 50.55a. The RCPB was specified as "AEC Classification Group A" at the time the construction permit was granted. This classification corresponds to Quality Group A as defined in Regulatory Guide 1.26, issued March, 1972. System classification is discussed in Section 3.2.

Multiple and diverse means are provided for detecting and to the extent practical identifying the location of reactor coolant leakage. These methods include monitoring of the containment atmosphere, sump level and coolant inventory. Section 5.2.7 details these detection and identification methods.

CRITERION 31 - FRACTURE PREVENTION OF REACTOR COOLANT PRESSURE BOUNDARY

The RCPB shall be designed with sufficient margin to assure that when stressed under operating, maintenance, testing, and postulated accident conditions (1) the boundary behaves in a nonbrittle manner and (2) the probability of rapidly propagating fracture is minimized.

The design shall reflect consideration of service temperatures and other conditions of the boundary material under operating, maintenance, testing and postulated accident conditions and the uncertainties in determining (1) material properties, (2) the effects of irradiation on material properties, (3) residual, steady state and transient stresses, and (4) size of flaws.

Response

All the RCPB boundary components are designed and constructed in accordance with ASME Code Section III and comply with the test and inspection requirements of these codes. These test and inspection requirements assure that flaw sizes are limited so that the probability of failure by rapid propagation is extremely remote. Particular emphasis is placed on the quality control applied to the reactor vessel, on which tests and inspections exceeding ASME code requirements are performed. The tests and inspections performed on the reactor vessel are summarized in Section 5.4.

Excessive embrittlement of the reactor vessel material due to neutron radiation is prevented by providing an annulus of coolant water between the reactor core and the vessel. In addition, to minimize the effects of irradiation on material toughness properties on core beltline material, restrictions on upper limits for residual elements that directly influence the Nil Ductility Transition Temperature (NDTT) shift were required by the design specification for the deposited welds. Specifically, upper limits were placed on copper, phosphorous, sulfur and vanadium. The actual change in material toughness properties due to irradiation is verified periodically during plant lifetime by a material surveillance program conforming to the requirements of ASTM-E-185. Based on the reference Nil Ductility Temperature (NDT), operating restrictions will be applied as necessary to limit stresses. Fluence and fracture toughness aspects, in regards to the reactor vessel, are discussed in Section 4.3.3.3 and Section 5.2.4.

During normal startup for power operation, the reactor will not be made critical until the RCS temperature is 120 °F greater than the predicted NDTT based on plant records of fast neutron dose to the vessel. The stress criteria in Chapter 5 include the maximum loads associated with the most severe transients during emergency conditions at operating temperature. The operational restrictions that will be invoked will maintain the minimum temperature above NDTT +120 °F for reactor operation. This will assure that a reactivity induced loading which would contribute to elastic or plastic deformation cannot occur below a reactor operating temperature corresponding to NDTT +120 °F in this plant.

Adverse effects that could be caused by exposure of equipment or instrumentation to containment spray water is avoided by designing the equipment or instrumentation to withstand direct spray or by locating it or protecting it to avoid direct spray.

Actuation of the safety injection system will introduce highly borated water into the RCS at pressure significantly below operating pressures and will not cause adverse pressure or reactivity effects.

The thermal stresses induced by the injection of cold water into the vessel have been examined. The test results and analysis have shown that there is no gross yielding across the vessel wall using the minimum specified yield strength in the ASME Code, Section III. The results of this study are given in the following Combustion Engineering (CE) reports:

A. A-68-9-1, "Thermal Shock Analysis on Reactor Vessels Due to Emergency Core Cooling System Operation," March 15, 1968, submitted with Amendment 9 to the Maine Yankee PSAR, Docket No. 50-309.

B. A-68-10-2, "Experimental Determination of Limiting Heat Transfer Coefficients During the Quenching of Thick Steel Plates in Water," Simon, J. J., Davis, M. W. and Tuppeny, W. H., Jr., December 13, 1968, submitted to the AEC in January 1969 and made a part of the public record.

C. A-70-19-2, "Finite Element Analysis of Structural Integrity of a Reactor Pressure Vessel During Emergency Core Cooling," Ayres, D. J. and Siddal, W. F., January 1970, submitted to the AEC and made a part of the public record.

In addition, CE has completed a detailed analysis of crack arrest under thermal shock conditions. This study was submitted to the AEC as a Topical Report, CENPD-116, "Analysis of the Structural Integrity of CE Reactor Vessel subject to Emergency Core Cooling Conditions," September 1973.

CRITERION 32 - INSPECTION OF REACTOR COOLANT PRESSURE BOUNDARY

Components which are part of the RCPB shall be designed to permit (1) periodic inspection and testing of important areas and features to assess their structural and leak tight integrity, and (2) an appropriate material surveillance program for the reactor pressure vessel.

<u>Response</u>

Provisions have been made in the design for inspection, testing, and surveillance of the RCPB as required by ASME Code Section XI.

The reactor vessel surveillance program conforms with ASTM-E-185 and is compatible with proposed Appendix H to 10CFR50 as published in the Federal Register on July 3, 1971.

The details of the reactor surveillance program are given in Section 5.2.4.4. Sample pieces taken from the same shell plate material used in fabrication of the reactor vessel are installed between the core and the vessel inside wall. These samples will be removed and tested at intervals during vessel life to provide an indication of the extent of the neutron embrittlement of the vessel wall. Charpy tests will be performed on the samples to develop a Charpy transition curve. By comparisons of this curve with the Charpy curve and drop weight tests for specimens taken at the beginning of the vessel life, the change of NDTT will be determined and operating instructions adjusted as required.

CRITERION 33 - REACTOR COOLANT MAKEUP

A system to supply reactor coolant makeup for protection against small breaks in the RCPB shall be provided. The system safety function shall be to assure that specified acceptable fuel design limits are not exceeded as a result of reactor coolant loss due to leakage from the RCPB and rupture of small piping or other small components which are part of the boundary. The system shall be designed to assure that for onsite electric power system operation (assuming off-site power is not available) and for off-site electric power system operation (assuming onsite power is not available) the system safety function can be accomplished using the piping, pumps and valves used to maintain coolant inventory during normal reactor operation.

Response

Reactor coolant makeup during normal operation is provided by the CVCS which includes three positive displacement charging pumps rated at 44 gpm each. The design incorporates a high degree of functional reliability by provision of redundant components (three pumps), and an alternate path for charging. The charging pumps can be powered from either onsite or off-site power sources, including the emergency diesel generators. The system is described in Section 9.3. It is not the function of the CVCS to provide protection against small breaks; this safety function is provided by the safety injection system. The CVCS does have the capability of replacing the flow loss to the containment for leaks in the reactor coolant piping up to 0.30-inch equivalent diameter with only one charging pump available. However, loss of this CVCS capability in no way compromises the safety of the reactor plant.

CRITERION 34 - RESIDUAL HEAT REMOVAL

A system to remove residual heat shall be provided. The system safety function shall be to transfer fission product decay heat and other residual heat from the reactor core at a rate such that specified acceptable fuel design limits and the design conditions of the RCPB are not exceeded.

Suitable redundancy in components and features, and suitable interconnections, leak detection, and isolation capabilities shall be provided to assure that for onsite electrical power system operation (assuming off-site power is not available) and for off-site electrical power system operation (assuming onsite power is not available) the system safety function can be accomplished, assuming a single failure.

Response

Residual heat removal capability is provided by the shutdown cooling system for reactor coolant temperature less than 275 °F. For temperatures greater than 275 °F, this function is provided by the steam generators. The design incorporates sufficient redundancy, interconnections, leak detection, and isolation, assuming failure of a single active component. Within appropriate design limits, either system will remove fission product decay heat at a rate such that specified acceptable fuel design limits and the design conditions of the RCPB will not be exceeded.

The Shutdown Cooling (SDC) System and the steam generator auxiliaries are designed to operate either from off-site power or from onsite power sources.

Further discussion is included in Chapter 9 for SDC and in Chapter 10 for the steam and power conversion system.

CRITERION 35 - EMERGENCY CORE COOLING

A system to provide abundant emergency core cooling shall be provided. The system safety function shall be to transfer heat from the reactor core following any loss of reactor coolant at a rate such that (1) fuel and clad damage that could interfere with continued effective core cooling is prevented and (2) clad metal-water reaction is limited to negligible amounts.

Suitable redundancy in components and features, and suitable interconnections, leak detection, isolation, and containment capabilities shall be provided to assure that for onsite electrical power system operation (assuming off-site power is not available) and for off-site electrical power system operation (assuming onsite power is not available) the system safety function can be accomplished, assuming a single failure.

Response

Emergency core cooling is provided by the Safety Injection System (SIS) described in Section 6.3. The system is designed to provide abundant cooling water to remove heat at a rate sufficient to maintain the fuel in a coolable geometry and to assure that zirconium-water reaction is limited to a negligible amount (less than one percent). Detailed analysis has been performed to verify that the system performance is adequate to satisfy the new NRC Acceptance Criteria for ECCS for Light Water Reactors (10 CFR 50, Appendix K, January 4, 1974). Details of this analysis are provided in Section 6.3 and Chapter 15.

The system design includes adequate provisions to assure that the required safety functions are provided with single active failure of any component and with either onsite electrical power system operation or off-site electrical power system.

CRITERION 36 - INSPECTION OF EMERGENCY CORE COOLING SYSTEM

The ECCS shall be designed to permit appropriate periodic inspection of important components, such as spray rings in the reactor pressure vessel, water injection nozzles and piping to assure the integrity and capability of the system.

Response

Design provisions facilitate access to the critical parts of the reactor vessel internals, injection nozzles, pipes and valves for visual or nondestructive inspection.

The components outside the containment which include the pumps and shutdown cooling heat exchangers are accessible for leak tightness inspection during operation of the reactor. All valves, piping and the safety injection components located inside the containment may be inspected during refueling. Details of the inspection program for the reactor vessel internals are included in Section 5.2.8 and inspection of the SIS is discussed in Section 6.3.4.

CRITERION 37 - TESTING OF EMERGENCY CORE COOLING SYSTEM

The ECCS shall be designed to permit appropriate periodic pressure and functional testing to assure: (1) the structural and leak tight integrity of its components, (2) the operability and performance of the active components of the system, and (3) the operability of the system as a whole and, under conditions as close to design as practical, the performance of the full

operational sequence that brings the system into operation, including operation of applicable portions of the protection system, the transfer between normal and emergency power sources, and the operation of the associated cooling water system.

Response

The ECCS (SIS) is provided with testing capability to demonstrate system and component operability. Testing can be conducted during normal plant operation with the test facilities arranged not to interfere with the performance of the systems or with the initiation of control circuits, as described in Section 6.3.4.

The SIS is designed to permit periodic testing of the delivery capability up to a location as close to the core as practical. Periodic pressure testing of the SIS to assure system integrity is possible using the cross connection to the charging pumps in the CVCS.

With the plant at operating pressure, operation of high pressure and low pressure safety injection pumps may be verified by recirculation back to the refueling water tank. This will permit verification of flow path continuity in the High Pressure Safety Injection (HPSI) lines and suction lines from the refueling water tank.

In addition, the low pressure safety injection pumps are used as shutdown cooling pumps during normal plant cooldown. The pumps discharge into the safety injection header via the shutdown cooling heat exchangers and the Low Pressure Safety Injection (LPSI) lines.

Borated water from the safety injection tanks may be bled through the drain header to verify flow path continuity from each tank to its associated safety injection header.

The operational sequence that brings the SIS into action, including transfer to alternate power sources, can be tested in parts as described in Sections 6.3, 7.3 and 8.3.

CRITERION 38 - CONTAINMENT HEAT REMOVAL

A system to remove heat from the reactor containment shall be provided. The system safety function shall be to reduce rapidly, consistent with the functioning of other associated systems, the containment pressure and temperature following any LOCA and maintain them at acceptably low levels.

Suitable redundancy in components and features, and suitable interconnections, leak detection, isolation, and containment capabilities shall be provided to assure that for onsite electric power system operation (assuming off-site power is not available) and for off-site electric power system operation (assuming onsite power is not available) the system safety function can be accomplished, assuming a single failure.

Response

The Containment Heat Removal System (CHRS), which consists of the Containment Spray System (CSS) and the Containment Cooling System (CCS), will reduce the post-accident containment pressure and temperature to a low level following an accident and maintain this low level thereafter. This is demonstrated by the post-accident containment pressure analysis.

The two diverse systems are both designed with redundant components so that a single failure of a component of either system will not prevent the function from being fulfilled. Portions of the system may be isolated for leakage control. The containment heat removal systems may be operated from either onsite or off-site power supplies. The containment design capabilities, heat removal systems and isolation system are described in Section 6.2.

CRITERION 39 – INSPECTION OF CONTAINMENT HEAT REMOVAL SYSTEM

The containment heat removal shall be designed to permit appropriate periodic inspection of important components, such as the torus, sumps, spray nozzles, and piping to assure the integrity and capability of the system.

Response

The containment heat removal systems consist of the CSS and the CCS.

Performance testing of all active components of the CSS is accomplished as described in Criterion 40. During these tests, the equipment is visually inspected for leaks. Valves and pumps are operated and inspected after any maintenance to ensure proper operation.

The equipment, piping, valves, and instrumentation of the CCS are arranged so they can be visually inspected. The cooling units and associated piping are outside the concrete secondary shield around the RCS loops. Personnel can enter the containment periodically to inspect and maintain this equipment. Service water piping and valves outside the containment, except buried pipe, are inspectible at all times. Operational tests and inspections are performed prior to initial startup.

CRITERION 40 - TESTING OF CONTAINMENT HEAT REMOVAL SYSTEM

The containment heat removal system shall be designed to permit appropriate periodic pressure and functional testing to assure: (1) the structural and leaktight integrity of its components, (2) the operability and performance of the active components of the system, and (3) the operability of the system as a whole, and, under conditions as close to the design as practical, the performance of the full operational sequence that brings the system into operation, including operation of applicable portions of the protection system, the transfer between normal and emergency power source, and the operation of the associated cooling water system.

Response

The components of the containment heat removal systems are tested on a regular schedule as discussed in Section 6.2.2. The capability is provided to test under conditions as close to design as practical the full operational sequence that would bring the containment pressure reducing system into action just prior to the spray system isolation valves. Test of the transfer to alternate power sources is accomplished by use of a test switch in the control room. Indicating lights will show the source of power being used. The cooling units' service water supply is tested in accordance with Section 9.2.1.4.

Arrangements for testing the CSS components are described in Section 6.2. A test connection is provided for the air test of the spray nozzles and a line is provided for an operational test of the spray pumps by recirculating back to the refueling water tank.

CRITERION 41 - CONTAINMENT ATMOSPHERE CLEANUP

Systems to control fission products, hydrogen, oxygen, and other substances which may be released into the reactor containment shall be provided as necessary to reduce, consistent with the functioning of other associated systems, the concentration and quality of fission products released to the environment following postulated accidents, and to control the concentration of hydrogen or oxygen and other substances in the containment atmosphere following postulated accidents to assure that containment integrity is maintained.

Each system shall have suitable redundancy in components and features, and suitable interconnections, leak detection, isolation, and containment capabilities to assure that for onsite electrical power system operation (assuming off-site power is not available) and for off-site electrical power system operation (assuming onsite power is not available) its safety function can be accomplished, assuming a single failure.

Response

The CSS serves to scrub most fission products from the containment atmosphere. The system is provided with the necessary redundancy and is designed to operate under post-accident conditions from either off-site or onsite power sources. Sections 6.2.2 and 6.2.3 evaluate the capability of this system to remove fission products. Containment cooling units also provide mixing of the containment atmosphere.

The generation of hydrogen in the containment following a LOCA has been evaluated in accordance with Regulatory Guide 1.7 and is presented in Section 6.2.5.3. Two hydrogen recombiners are provided (see Section 6.2.5). The recombiners are redundant and can be powered from either off-site or onsite electrical power.

Four 5,000 cfm containment recirculation fans were originally designed to ensure an even distribution of hydrogen and prevent local pockets of high hydrogen concentration from forming (see Section 6.2.5); however, these fans are not credited in any design basis accident or transient analysis and are not credited in the probabilistic risk assessment for accomplishing the hydrogen mixing function.

CRITERION 42 - INSPECTION OF CONTAINMENT ATMOSPHERE CLEANUP

The containment atmosphere cleanup systems shall be designed to permit appropriate periodic inspection of important components, such as filter frames, ducts, and piping to assure the integrity and capability of the systems.

Response

All critical parts of the containment atmosphere cleanup systems can be physically inspected. The components external to the containment can be inspected during reactor operation and the components inside the containment can be inspected during shutdown. Specific inspection programs are discussed in Section 6.2.3.4.

CRITERION 43 - TESTING OF CONTAINMENT ATMOSPHERE CLEANUP SYSTEMS

The containment atmosphere cleanup systems shall be designed to permit appropriate periodic pressure and functional testing to assure (1) the structural and leaktight integrity of its components, (2) the operability and performance of the active components of the systems such as fans, filters, dampers, pumps, and valves and (3) the operability of the systems as a whole and, under conditions as close to design as practical, the performance of the full operational sequence that brings the systems into operation, including operation of applicable portions of the protection system, the transfer between normal and emergency power sources, and the operation of associated systems.

Response

Testing of the CSS and cooling units is as required by Criterion 40. Spray, cooling, purge, and hydrogen recombiner systems can be tested for integrity, operability, and performance under conditions which approximate design conditions as much as is practical. Detailed information concerning containment atmosphere cleanup systems is provided in Sections 6.2.2, 6.2.3, and 6.2.5.

CRITERION 44 - COOLING WATER

A system to transfer heat from structures, systems, and components important to safety, to an ultimate heat sink shall be provided. The system safety function shall be to transfer the combined heat load of these structures, systems and components under normal operating and accident conditions.

Suitable redundancy in components and features, and suitable interconnections, leak detection, and isolation capabilities shall be provided to assure that for onsite electrical power system operation (assuming off-site power is not available) and for off-site electrical power system operation (assuming onsite power is not available) the system safety function can be accomplished, assuming a single failure.

Response

Structures, systems and components important to safety are cooled by the Service Water system (SWS). The SWS is redundant with two 100 percent capacity trains and three 100 percent capacity pumps which can be operated either from off-site power or from onsite emergency power. The SWS consists of Seismic Category 1 and non-Seismic Category 1 portions. Non-Seismic Category 1 portions of the system are automatically isolated from the system upon receipt of a safety injection actuation signal. The ultimate heat sink for the SWS is either the Dardanelle Reservoir or the emergency cooling pond.

Process radiation monitors will indicate any leakage of reactor coolant into the SWS. The SWS is described and evaluated in Section 9.2.1.

CRITERION 45 - INSPECTION OF COOLING WATER SYSTEM

The cooling water system shall be designed to permit appropriate periodic inspection of important components, such as heat exchangers and piping, to assure the integrity and capability of the system.

Response

The SWS is designed to permit the required periodic inspections of heat exchangers and piping. Three service water pumps are provided which serve the two system loops. The third pump can operate on either loop, allowing inspection and maintenance of a pump while maintaining redundant system capability.

CRITERION 46 - TESTING OF COOLING WATER SYSTEM

The cooling water system shall be designed to permit appropriate periodic pressure and functional testing to assure (1) the structural and leak tight integrity of its components, (2) the operability and the performance of the active components of the system, and (3) the operability of the system as a whole and, under conditions as close to design as practical, the performance of the full operational sequence that brings the system into operation for reactor shutdown and for LOCAs including operation of applicable portions of the protection system and the transfer between normal and emergency power sources.

Response

The SWS is designed to permit the required testing. See Section 9.2.1.4.

3.1.5 REACTOR CONTAINMENT

CRITERION 50 - CONTAINMENT DESIGN BASIS

The reactor containment structure, including access openings, penetrations and the containment heat removal system shall be designed so that the containment structure and its internal compartments can accommodate, without exceeding the design leakage rate and, with sufficient margin, the calculated pressure and temperature conditions resulting from any LOCA. This margin shall reflect consideration of: 1) the effects of potential energy sources which have not been included in the determination of the peak conditions, such as energy in steam generators and energy from metal-water and other chemical reactions that may result from degraded emergency core cooling functioning, 2) the limited experience and experimental data available for defining accident phenomena and containment responses, and 3) the conservatism of the calculational model and input parameters.

Response

The containment, including access openings and penetrations, has a structural design pressure of 59 psig and a design temperature of at least 300 °F. The electrical penetrations are qualified to design basis accident conditions. The greatest transient peak condition, associated with a postulated rupture of the piping in the RCS and the calculated effects of metal-water reaction, does not exceed these values. Additionally, the containment was subjected to an initial Structural Integrity Test (SIT) at 62 psig. Following the containment uprate, the containment was subjected to a second SIT to 68 psig which is 1.15 times the new design pressure, prior to start up following steam generator replacement outage 2R14.

Design pressure and associated conditions specified for the containment consider both blowdown, post-blowdown and long-term mass and energy releases resulting from postulated LOCA's. These design conditions include peak pressure margins and long-term design capability margins which envelop the accident performance predictions using established

analytical methods and conservative assumptions. The design margins specified reflect an inherent containment capability which is demonstrated to exceed, at all times, the expected conditions during postulated LOCAs. Design margins are related to additional releases of reactor system energy not actually expected. These design margins are considered sufficient to envelop any remaining thermodynamic, geometric or accident phenomena effects currently considered in the containment design.

The cooling capacity of the CCS, CSS, and SIS is adequate to prevent overpressurization of the structure. Electric motors and valves which must function within the containment during accident conditions are designed to operate in a steam-air atmosphere at design basis accident conditions. Sections 6.2.2 and 15.1.13 describe the analyses and margin available.

CRITERION 51 - FRACTURE PREVENTION OF CONTAINMENT PRESSURE BOUNDARY

The reactor containment boundary shall be designed with sufficient margin to assure that under operating, maintenance, testing, and postulated accident conditions (1) its ferritic materials behave in a nonbrittle manner and (2) the probability of rapidly propagating fracture is minimized. The design shall reflect consideration of service temperatures and other conditions of the containment boundary material during operation, maintenance, testing, and postulated accident conditions, and the uncertainties in determining (1) material properties, (2) residual, steady state, and transient stresses, and (3) size of flaws.

Response

The details of provisions for sufficient margins of safety have been described in Section 3.8 and meet the requirements of this criterion.

Basically, two different levels in design basis have been evaluated to predict the performance and the capacity of the containment structure and its components: 1) the lower level is that needed to withstand design basis loads during the normal operating condition, and 2) the higher level is that needed to withstand the most severe design basis loads generated from natural phenomena or from postulated accident conditions.

A further level of conservatism results from the use of capacity reduction factors which derate components, elements or materials below the strength levels found by tests. The margins provided and the manner in which the materials are used provide assurance that the ferritic materials behave in a non-brittle manner and thus minimize the probability of a rapidly propagating brittle fracture. The ferritic penetration materials are selected and fabricated in accordance with the rules of the ASME Code as referenced in section 3.8. Other members and materials are selected and used on the basis of previous history of both testing and actual use for similar environments and load conditions of the containment structure.

The design reflects consideration of temperature extremes as well as service temperature and categories of plant conditions which include but are not limited to those required by this criterion. The method of providing design margins specifically and explicitly considers uncertainties as to material capabilities and predicted stresses.

CRITERION 52 - CAPABILITY FOR CONTAINMENT LEAKAGE RATE TESTING

The reactor containment and other equipment which may be subjected to containment test conditions shall be designed so that periodic integrated leakage rate testing can be conducted at containment design pressure.

Response

The containment structure and equipment which will be subjected to containment test conditions are designed so that periodic Integrated Leakage Rate Tests (ILRTs) can be conducted at the containment design pressure, as required. Appropriate connection points, temperature, pressure, and humidity instrumentation, spare penetrations, air cooling and moving equipment, etc., are incorporated in the design to facilitate integrated leakage rate testing of the containment. Provisions to facilitate local leakage rate testing are discussed in response to Criterion 53. Additional discussions of the provisions for integrated leakage rate testing of the containment are in Section 6.2 and the Technical Specifications.

CRITERION 53 - PROVISIONS FOR CONTAINMENT TESTING AND INSPECTION

The reactor containment shall be designed to permit (1) appropriate periodic inspection of all important areas, such as penetrations, (2) an appropriate surveillance program, and (3) periodic testing at containment design pressure of the leak tightness of penetrations which have resilient seals and expansion bellows.

Response

The containment design permits Local Leak Rate Test (LLRT) inspection of penetrations and a surveillance program. The ability to test the penetrations is met by conformance to the criteria listed in Appendix J to 10 CFR 50. Electrical penetrations, the refueling transfer tube blind flange, personnel locks and equipment hatches have provisions for pressurizing between the double leak seals to design pressure. There are no piping system penetrations to the containment which require a bellow seal between the pipe and the containment.

The LLRT is described in Section 6.2 and the Technical Specifications.

CRITERION 54 - PIPING SYSTEMS PENETRATING CONTAINMENT

Piping systems penetrating primary reactor containment shall be provided with leak detection, isolation and containment capabilities having redundancy, reliability, and performance capabilities which reflect the importance to safety of isolating these piping systems. Such piping systems shall be designed with a capability to test periodically the operability of the isolation valves and associated apparatus, and to determine if valve leakage is within acceptable limits.

Response

The general design basis governing isolation valve requirements is: leakage through all fluid penetrations not serving accident consequence limiting systems is to be minimized by a double barrier so that no single, credible failure or malfunction of an active component can result in loss of isolation or intolerable leakage. The installed double barriers take the form of closed piping systems, both inside and outside the containment, and various types of isolation valves. See Section 6.2.4 for a detailed discussion of the Containment Isolation System (CIS).

The Technical Specifications discuss the requirements to test periodically the operability of containment isolation valves and associated apparatus and the requirements for determining if valve leakage is within acceptable limits. Piping systems penetrating containment are designed with the capability to perform the functions required in the Technical Specifications.

CRITERION 55 - REACTOR COOLANT PRESSURE BOUNDARY PENETRATING CONTAINMENT

Each line that is part of the RCPB and that penetrates primary reactor containment shall be provided with containment isolation valves as follows, unless it can be demonstrated that the containment isolation provisions for a specific class of lines, such as instrument lines, are acceptable on some other defined basis: (1) one locked closed isolation valve inside and one locked closed isolation valve outside containment; or (2) one automatic isolation valve inside and one locked closed isolation valve outside containment; or (3) one locked closed isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment; or (4) one automatic isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment.

Isolation valves outside containment shall be located as close to containment as practical and upon loss of actuating power, automatic isolation valves shall be designed to take the position that provides greater safety.

Other appropriate requirements to minimize the probability or consequences of an accidental rupture of these lines or of lines connected to them shall be provided as necessary to assure adequate safety. Determination of the appropriateness of these requirements, such as higher quality in design, fabrication, and testing, additional provisions for inservice inspection, protection against more severe natural phenomena, and additional isolation valves and containment, shall include consideration of the population density, use characteristics, and physical characteristics of the site environs.

Response

Penetration and valving design meets this criterion. Table 6.2-26 lists containment isolation valve information for each penetration. Valves covered by this criterion are defined in Section 6.2.4.

CRITERION 56 - PRIMARY CONTAINMENT ISOLATION

Each line that connects directly to the containment atmosphere and penetrates primary reactor containment shall be provided with containment isolation valves as follows, unless it can be demonstrated that the containment isolation provisions for a specific class of lines, such as instrument lines, are acceptable on some other defined bases: (1) one locked closed isolation valve inside and one locked closed isolation valve outside containment; or (2) one automatic isolation valve inside and one locked closed isolation valve outside containment; or (3) one locked closed isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment; or (4) one automatic isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment.

Isolation valves outside containment shall be located as close to the containment as practical and upon loss of actuating power, automatic isolation valves shall be designed to take the position that provides greater safety.

Response

Valves which are covered by the above criterion are defined in Section 6.2.4. The following components have double resilient leakage seals and meet the requirements of the above criterion on an “other defined basis:” the refueling transfer tube blind flange, personnel locks, and equipment hatches. Penetration and valving information is given in Table 6.2-26. The penetration and valving design meet this criterion.

CRITERION 57 - CLOSED SYSTEM ISOLATION VALVES

Each line that penetrates primary reactor containment and is neither part of the RCPB nor connected directly to the containment atmosphere shall have at least one containment isolation valve which shall be either automatic, or locked closed, or capable of remote manual operation. This valve shall be outside containment and located as close to the containment as practical. A simple check valve may not be used as the automatic isolation valve.

Response

Penetration and valving design meet this criterion. Valves covered by the above criterion are defined in Section 6.2.4. Penetration and valving information is given in Table 6.2-26.

3.1.6 FUEL AND RADIOACTIVITY CONTROL

CRITERION 60 – CONTROL OF RELEASES OF RADIOACTIVITY MATERIALS TO THE ENVIRONMENT

The nuclear power unit design shall include means to control suitably the release of radioactive materials in gaseous and liquid effluents and to handle radioactive solid wastes produced during normal reactor operation, including anticipated operational occurrences. Sufficient holdup capacity shall be provided for retention of gaseous and liquid effluents containing radioactive materials, particularly where unfavorable site environmental conditions can be expected to impose unusual operational limitations upon the release of such effluents to the environment.

Response

The radioactive Waste Management Systems (WMSs), as described in Sections 11.2, 11.3, and 11.5, are designed to provide controlled handling and disposal of liquid, gaseous, and solid wastes. The systems are designed to ensure that the general public and plant personnel are protected against exposure to radioactive material as intended by 10 CFR 20 and 10 CFR 50, Appendix I.

All liquid and gaseous radioactive releases from the WMS are designed to be accomplished on a batch basis. All radioactive materials are sampled prior to release to ensure compliance with 10 CFR 20 and 10 CFR 50, Appendix I and to determine release rates. Radioactive materials which do not meet release requirements will not be discharged to the environment. The systems are designed with sufficient holdup capacity and flexibility for reprocessing of wastes to ensure that release limitations are met.

The radioactive WMSs are designed to preclude the inadvertent release of radioactive material.

All storage tanks in the liquid waste and gaseous waste systems are administratively controlled to prevent the addition of waste to a tank which is being discharged to the environment. Each discharge path is provided with a radiation monitor which alerts plant personnel and initiates automatic closure of the appropriate isolation valve(s) to halt the release in the event of noncompliance with 10 CFR 20 (see Section 11.4 for details).

The plant design for handling of solid wastes is discussed in Section 11.5.

CRITERION 61 - FUEL STORAGE AND HANDLING AND RADIOACTIVITY CONTROL

The fuel storage and handling, radioactive waste, and other systems which may contain radioactivity shall be designed to assure adequate safety under normal and postulated accident conditions. These systems shall be designed (1) with a capability to permit inspection and testing of components important to safety, (2) with suitable shielding for radiation protection, (3) with appropriate containment, confinement, and filtering systems, (4) with a residual heat removal capability having reliability and testability that reflects the importance to safety of decay heat and other residual heat removal, and (5) to prevent significant reduction in fuel storage coolant inventory under accident conditions.

Response

The fuel storage facility meets Regulatory Guide 1.13 as discussed in Section 9.1. Inspection, testability, purification, and heat removal capability of the fuel storage and handling system is designed to meet Criterion 61 as described in Section 9.1. Adequate shielding is provided as discussed in Section 12.1. Most of the components and systems in this category are in frequent use and no special testing is required. Those systems and components important to safety which are not normally operating will be tested periodically, e.g., the fuel handling equipment (prior to each refueling).

The spent fuel storage racks are located to provide sufficient shielding water over stored fuel assemblies to limit radiation in working areas to no more than 2.5 mrem/hr during the storage period (100 hours after shutdown). The exposure time during refueling will be limited so that the integrated dose to operating personnel does not exceed the limits of 10 CFR 20.

The WMSs are designed to permit controlled handling and disposal of liquid, gaseous, and solid radioactive wastes which will be generated during operation. The principal design criterion is to ensure that plant personnel and the general public are protected against exposure to radiation from wastes as discussed in Chapters 11 and 12.

The spent fuel pool and waste management equipment are located in restricted areas of the auxiliary building. These areas provide confinement capability in the event of an accidental release of radioactive materials. All components important to safety in these functions are designed and located to permit periodic inspection as required and are tested in accordance with accepted codes and standards.

Analysis has indicated that the accidental release of the maximum activity content of a gas decay tank will not result in doses in excess of the guidelines of 10 CFR 100 (see Chapter 15).

Cooling for the spent fuel pool is designed to prevent damage to the fuel in storage facilities that could result in radioactivity release to the plant operating areas or the public environs.

The spent fuel pool is designed to withstand the postulated missiles and seismic events without loss of the pool water or damage to stored fuel.

CRITERION 62 – PREVENTION OF CRITICALITY IN FUEL STORAGE AND HANDLING

Criticality in the fuel storage and handling system shall be prevented by physical systems or processes, preferably by use of geometrically safe configuration.

Response

The new fuel storage rack, spent fuel storage rack, and associated handling equipment are designed with physical spacing, restraints, and interlocks to maintain a subcritical array during flooding with non-borated water under all design loading conditions including a Design Basis Earthquake (DBE) as discussed in Section 9.1.

CRITERION 63 - MONITORING FUEL AND WASTE STORAGE

Appropriate systems shall be provided in fuel storage and radioactive waste systems and associated handling areas (1) to detect conditions that may result in loss of residual heat removal capability and excessive radiation levels and (2) to initiate appropriate safety actions.

Response

New fuel is stored in a dry pit in which no credible conditions exist which could cause excessive radiation levels.

Failure of the spent fuel pool cooling system or high radiation would cause annunciation of alarms. Through appropriate operator action, backup spent fuel residual heat removal can be provided by flooding with water from the refueling water tank (see Section 9.1.3). Normal radiation control precautions and corrective action will take place following a high radiation alarm.

Heat generated in the waste storage facilities does not require a heat removal system. The gas analyzer and radiation monitors associated with waste system equipment and storage areas are equipped with appropriate indication and alarms to allow automatic and/or operator corrective action in the event of high radiation levels.

CRITERION 64 - MONITORING RADIOACTIVITY RELEASES

Means shall be provided for monitoring the reactor containment atmosphere, spaces containing components for recirculation of LOCA fluids, effluent discharge paths, and the plant environs for radioactivity that may be released from normal operations, including anticipated operational occurrences, and from postulated accidents.

Response

Means are provided as described in Sections 11.4 and 12.1.4 to monitor the containment environment. This includes an air particulate detector, a gaseous monitor, and high level area monitors. Spaces containing components for recirculation of LOCA fluids are monitored via the penetration rooms ventilation described in Section 6.5.

All effluent discharge paths are monitored. This includes the containment purge system described in Section 11.4, the liquid and gaseous waste process systems described in Sections 11.2 and 11.3, and the plant ventilation system described in Section 12.2.

Monitoring of radioactivity releases is designed such that Criterion 60 and Appendix 1 to 10 CFR 50 are met. Means are provided for monitoring the plant environs as described in Section 11.6.

3.2 CLASSIFICATION OF STRUCTURES, COMPONENTS AND SYSTEMS

This section provides a guide to the method of classification of structures, components and systems of Unit 2. The method used recognizes the need to establish relationships to criteria, philosophy, codes, and regulations which must be met in order to give assurance that a quality product will result. In this regard, it is recognized that during the design and construction of Unit 2, significant industrial and regulatory action has been taken to establish common and agreed upon methods of classification, i.e. Regulatory Guides 1.26 and 1.29. These methods define two groups of classifications: (1) the seismic classification of structures, systems and components; and (2) the system quality group classification for pressure containing components of fluid systems.

The basic approach used in the classification method (Table 3.2-1) is to first categorize structures, systems and components in two categories, Category 1 and Category 2, depending upon whether an item is safety-related or not. Then in the case of fluid systems, components are grouped into four Quality Groups: A, B, C, and D. Generally, A, B, and C are in Category 1 and D is in Category 2. There are, however, numerous examples of Unit 2 Category 2 equipment which are designed to Quality Group B and C standards. Components of the fuel pool system, the quench tank and the tube side of the letdown heat exchanger are some examples. All components grouped in A are Category 1. See Tables 3.2-2 and 3.2-3 for a detailed listing. The slight variance from the correlations made in Table 3.2-1 is a result of compliance with the intent of Regulatory Guides 1.26 and 1.29.

The codes and standards used to define the Unit 2 Quality Groups changed due to new rulemaking and code changes. The codes used for each Quality Group component category are divided as to date of purchase, before or after July, 1971. For components purchased after July, 1971 the codes used are those specified by 10CFR50 and Regulatory Guide 1.26. A guide used for components purchased before July, 1971 was "Summary of Codes and Standards for Components of Water Cooled Nuclear Power Units" which was submitted to Unit 2 by the AEC and is incorporated in Amendment 4 to the Unit 2 PSAR.

Table 3.2-6 maintains the Q-list of safety-related structures, systems, and components required to be within the scope of the Quality Assurance Program Manual (QAPM).

3.2.1 SEISMIC CLASSIFICATION

3.2.1.1 Definitions

Seismic Category 1 structures, components, and systems are defined in accordance with Regulatory Guide 1.29 as those necessary to assure:

A. the integrity of the Reactor Coolant Pressure Boundary (RCPB);

B. the capability to shut down the reactor and maintain it in a safe shutdown condition; and

C. the capability to prevent or mitigate the consequences of accidents that could result in potential off-site doses comparable to the guideline doses of 10 CFR 100.

Category 1 structures, components, and systems are designed to withstand the appropriate seismic loads of the DBE as discussed in Section 3.7, Seismic design, and other applicable loads without loss of function. Category 1 structures are sufficiently isolated or protected from other structures to ensure that their integrity is maintained at all times.

Those structures, systems and components which are not Seismic Category 1 are designated Seismic Category 2. The failure of Seismic Category 2 structures, systems or components may interrupt power generation, but will not reduce the function of Category 1 structures, systems or equipment to an unacceptable safety level. For a more complete discussion, see Section 3.7.2.

3.2.1.2 Seismic Classifications

Table 3.2-2 provides a listing of structures, components, and systems and identifies those which are Seismic Category 1.

Where only portions of systems are identified as Seismic Category 1 in this table, the boundaries of the Seismic Category 1 portions of the system are shown on the piping and instrument diagrams in appropriate sections of this report (see Table 1.7-2). The above seismic classifications meet the intent of Regulatory Guide 1.29. The two dissimilarities with the regulatory position on Category 1 systems are cooling to the spent fuel pool and the reactor coolant pumps. The spent fuel pool cooling system is Category 2, however there is a Seismic Category 1 makeup path and source provided to the pool. Cooling water supplied to the reactor coolant pumps is not Category 1 since operability of the pumps is not relied upon to perform a safety function. Therefore the seismic classifications are in compliance with Regulatory Guide 1.29 except as noted above.

3.2.2 SYSTEM QUALITY GROUP CLASSIFICATION

This section provides the system quality group classification for each fluid system pressure containing component. Components are classified according to safety-related importance as dictated by service and functional requirements and by the consequences of failure. The design, fabrication, inspection, and testing requirements fixed for each classification provide the required degree of conservatism in assuring pressure integrity.

3.2.2.1 Code Requirements

The design bases for those systems that do not meet the strict definitions of Regulatory Guide 1.26 were established prior to issuance of revised codes and standards and Regulatory Guide 1.26. However, the design specifications for systems and components that were designed and built to codes and standards, outside Regulatory Guide 1.26 definitions, specified additional quality assurance and nondestructive testing requirements and have met the intent of these documents considering the date of component design and purchase.

Codes and standards used for components signify and specify design and quality assurance requirements. The codes and standards applicable to each quality group are given in Table 3.2-4.

Table 3.2-5 separately lists equipment from Tables 3.2-2 and 3.2-3 which were not designed and built to the exact codes and standards specified in Regulatory Guide 1.26. Table 3.2-5 also briefly summarizes salient NDT and Quality Assurance requirements imposed by individual equipment design specifications.

3.2.2.2 Quality Group Classifications

Equipment quality group classifications are indicated in Table 3.2-3. System quality group classifications and interfaces between classification in systems with components of different classifications are indicated on the system piping and instrumentation diagrams (see Table 1.7-2). Quality groups are classified according to the intent of Regulatory Guide 1.26 (Quality Groups B, C, and D) and 10 CFR 50.55a (Quality Group A).

3.3 WIND AND TORNADO LOADINGS

Seismic Category 1 structures were designed for the most severe local wind phenomena and tornado effects which can be expected to occur at the site (see Section 2.3). These structures are identified in Table 3.3-1. The refueling water tank is a Seismic Category 1 component not required for safe shutdown after a tornado and was designed for wind loadings as described in Section 3.3.1.1. below. Considerations of tornado loadings on the structural steel framing over the spent fuel pool area are discussed in Section 3.8.4.1.1.

3.3.1 WIND LOADINGS

Wind loadings for all Seismic Category 1 structures have been selected on the basis of ASCE Paper No. 3269, "Wind Forces on Structures." However, these wind loadings acting on the Seismic Category 1 structures produced forces which were less critical than those produced by the tornado loadings. Therefore, tornado loadings governed the design.

3.3.1.1 Design Wind Velocity

The design wind velocity for the refueling water tank was 80 mph at 44 feet, 9 inches above ground for a 100-year recurrence interval. For all other Category 1 structures, tornado loadings governed the design (see Section 3.3.2).

3.3.1.2 Basis for Wind Velocity Selection

The "fastest mile of wind" at the plant site is 67 mph, according to Figure 1(b) of Reference 45. For additional conservatism, the margin of safety was increased by using a ground level wind of 80 mph.

3.3.1.3 Vertical Velocity Distribution and Gust Factor

The design wind velocity of 80 mph included a gust factor of 1.1 for the total 44 feet, 9 inches height of the refueling water tank.

3.3.1.4 Determination of Applied Forces

The method used to translate the wind velocity into applied forces for the refueling water tank was based on wind pressure coefficients shown in Table 4(f) of Reference 45. For Category 1 structures which were designed for tornado loading, the applied forces due to wind were calculated to determine if they were less severe than the applied forces due to tornado loadings. The applied tornado force magnitude and distribution were determined as discussed in Section 3.3.2.2 below. Appropriate stress levels and load factors discussed in Section 3.8 were considered in determination of the governing loads.

3.3.2 TORNADO LOADINGS

3.3.2.1 Applicable Design Parameters

Tornado protected Seismic Category 1 structures were analyzed for tornado loadings not coincident with any unrelated accident condition or earthquake.

For Seismic Category 1 structures, designed to withstand tornadoes and tornado generated missiles, the following three parameters were applied in combinations to produce the most critical conditions.

A. Dynamic Wind Pressure

The dynamic wind pressure is caused by a tornado funnel having a peripheral tangential velocity of 300 mph and a forward progression of 60 mph. The tornado resistant design of the ANO Units was completed prior to the issuance of Regulatory Guide 1.76. As a result, the radius of maximum rotational speed is not significant to the ANO design, and Category I structures were designed considering a uniform pressure resulting from the 300 mph wind velocity (Reference 0CAN059609), except for casks which are governed by Holtec HI-Storm and VSC-24 CFSARs. The applicable portions of wind design methods described in ASCE Paper No. 3269 (Reference 45) were used, particularly for shape factors. The provisions for gust factors and variation of wind velocity with height were not applied.

B. Pressure Differential

The structure interior bursting pressure is taken as rising 1 psi/sec for three seconds, followed by a 2-second calm, then decreasing at 1 psi/sec for three seconds. This cycle accounted for reduced pressure in the eye of a passing tornado. All fully enclosed Seismic Category 1 structures were designed to withstand the full 3 psi pressure differential. A failure mode analysis of safety-related structures for the maximum pressure differential change with time is not normally performed. No such analysis was performed for Unit 2. The degree of conservatism in the design of safety-related structures is assured by the inherent margin of safety provided in the allowable stress values given in the applicable codes and standards listed in Sections 3.8.1.2.1 and 3.8.4.2.1.

C. Missile Impingement

Three types of tornado missiles were considered. Each type was considered to act independently, with only one type occurring at any one time. The three types of missiles are as follows:

1. A wood plank, 4"x12" in cross section, weighing 108 pounds, traveling end on at a speed of 300 mph and striking the structure at any elevation.

2. A steel pipe, schedule 40, 3"x10' long, weighing 75.8 pounds, traveling end on at 100 mph and striking the structure at any elevation.

3. An automobile of 4,000-pound weight, striking the structure at 50 mph on a contact area of 20 square feet, any portion of the impact area being not more than 25 feet above grade.

3.3.2.2 Determination of Forces on Structures

Tornado loads were applied to the Seismic Category 1 structures in the same manner as the wind loads described in Section 3.3.1.4 with the exception that gust factor and variation of wind velocity with height did not apply. The load combinations and involving tornadoes are given in Section 3.8.

The load factor selected for tornado loadings was 1.0, based on the short duration of the loading condition, and the degree of conservatism in the selection of design tornado velocity.

3.3.2.3 Ability of Seismic Category 1 Structures to Perform Despite Failure of Structures Not Designed for Tornado Loads

Failure of Category 2 structures is not expected to affect the ability of Seismic Category 1 structures to perform their functions for the following reasons:

A. Tornado missiles that may be formed by the failure of Category 2 structures will not exceed the force of those postulated and described in Section 3.3.2.1, against which Seismic Category 1 structures were designed.

B. An investigation of the structural frame of the Category 2 turbine building in the vicinity of the auxiliary building showed it will not collapse when subjected to tornado loadings, assuming that one-third of the exterior metal siding would be exposed to the full tornado load. The structural steel framing enclosing the auxiliary building spent fuel pool area has also been checked for the same conditions, with the same results. This condition is commonly observed in tornado damage. The fasteners are known to be much weaker in shear and in pull out than the continuous sheet acting as a catenary. Therefore, in the event of a tornado, the fasteners on the two ends of the sheet can be expected to fail and the sheathing assumed to remain balanced and restrained by the central portion of the panel against the girts.

3.4 WATER LEVEL (FLOOD) DESIGN

Seismic Category 1 structures were designed to protect safety-related equipment from external flooding.

3.4.1 FLOOD ELEVATIONS

Flood elevations are discussed in Sections 2.4.2, 2.4.3 and 2.4.4, and expected groundwater elevation in Section 2.4.13. All Seismic Category 1 structures have been designed to resist buoyancy and hydrostatic pressure using the design flood elevation of 361 feet.

3.4.2 PHENOMENA CONSIDERED IN DESIGN LOAD CALCULATIONS

Security-Related Information
Text Withheld Under 10 CFR 2.390

3.4.3 FLOOD FORCE APPLICATION

Security-Related Information
Text Withheld Under 10 CFR 2.390

3.4.3.1 Consideration of Hydrostatic Pressures

Seismic Category 1 structures and component parts were designed for the hydrostatic forces due to the PMF.

A triangular hydrostatic pressure diagram was used in the wall design and a uniform hydrostatic load application was used in the base and cover slab designs.

The effects on the containment structure were considered in accordance with the load factors and loading combinations stated in Section 3.8.1.3.

3.4.3.2 Stability of Structures Against Buoyancy

Uplift forces during the PMF were accounted for in the design of structures. The calculated minimum factor of safety against buoyancy for structures during the PMF condition was 1.25.

3.4.3.3 Effect of Wave Action

Based on the conditions described in Section 3.4.2, and by the use of the Minikin Method for computing wave forces as detailed in the Corps of Engineers' Technical Report No. 4, "Shore Protection Planning and Design," the maximum wave force at the face of the wall was computed to be less than five kips per foot at the wall support. Seismic Category 1 structures have exterior concrete walls a minimum of two feet thick at this elevation with sufficient strength to resist this wave force.

3.4.4 FLOOD PROTECTION

Seismic Category 1 structures were designed for the PMF (see Section 2.4.3 for a description of the bases for the flood protection criteria). All Category 1 systems and equipment susceptible to the effects of flooding are either located above Elevation 369 feet to protect against splash, or are protected up to flood Elevation 361 feet by the following measures:

A. Wall thicknesses in Seismic Category 1 structures below flood level were provided a minimum of two feet with certain exceptions, which have been evaluated to ensure their design is adequate to withstand the hydrostatic forces associated with external flooding.

B. Potential flood paths through construction joints are addressed through the use of waterstops or other seal materials to maintain the required flood protection for Class 1 structures.

C. The number of openings in walls and slabs below flood level was kept to a minimum.

D. Watertight doors, watertight equipment hatches, and flood seals were installed as required.

Additional specific provisions for flood protection include administrative procedures to assure that all watertight doors will be locked closed in the event of a flood warning. If local seepage occurs through the walls, it will be controlled by sumps and sump pumps.

As discussed in Section 2.4.14, an extremely unusual occurrence of flood levels approaching Elevation 354 feet would take from two days to several weeks to develop. This would allow ample lead time to perform necessary emergency actions for all accesses which need to be protected. These actions will be implemented in accordance with abnormal operating procedures for natural emergencies.

Security-Related Information
Text Withheld Under 10 CFR 2.390

The watertight doors were assembled complete with coaming and hydrostatically tested prior to shipment. All watertight doors were shop tested to a pressure equivalent to 27 feet of water which corresponds to the highest head of water above the lowest exposed watertight door during the design flood. The doors were then dogged down, crated and shipped as a complete unit. The door coaming was seal welded to the frame and the weld was tested by the liquid penetrant method. Section 2.4.14 discusses shutdown bases.

Note: The above paragraph is considered obsolete. New watertight doors are purchased in accordance with current design documents which require that watertight doors be designed and fabricated to withstand the applicable pressure due to the design flood with a safety factor of 1½ (Table 3.2-6, Item 6.6, lists the purchase specifications for watertight doors which document these requirements).

The high quality concrete used in the containment structure, with compressive membrane stresses, was considered practically waterproof. In addition, the duration of water pressure on the 3-foot, 9-inch thick wall was not expected to be more than a few days. As a secondary precaution, a drainage system was installed behind the liner plate up to flood level and pressure would be released by drainage to the tendon gallery which in turn would drain to the auxiliary building sump.

During the PMF, the distance between the plant and nearest high ground is never more than 2,000 feet. Only a limited number of inspection and maintenance personnel will be required during a flood; heavy equipment will not be required. Access to the plant would be by vehicle, boat, and/or helicopter, depending upon flood level conditions. Passageways from the administration building and/or central support building above flood level provide access to all Seismic Category 1 equipment in the auxiliary building and in the containment.

3.4.4.1 Seepage Into Seismic Category 1 Buildings

Seepage into Seismic Category 1 buildings can be expected to occur via the following:

A. Through Seismic Category 1 structure walls;

B. Cracks in the concrete; and

C. Water stops at construction joints.

The seepage through a two feet thick wall is calculated using Darcy's equation $Q = KA\ (\Delta h/1)$. The permeability factor (K) used is 10E-12 feet/second. This value was obtained from Troxell based on a conservative evaluation of the concrete properties. Using the above factor, a conservative seepage rate of 2.2E-10 cu-feet/second per square foot of wall is calculated. At this low seepage rate, the water would evaporate before it would accumulate.

A significant crack in the concrete or a faulty water stop to a construction joint is not likely to occur. However, assuming either one to the present, the method of analysis is to consider it as a reservoir draining through a pipe. On this basis, Bernoulli's equation may be used in calculating the flow. Using a 1/32-inch wide smooth opening, a flow rate of 0.49E-4 cubic foot/second per foot of crack length is obtained. This value is extremely conservative since it does not account for the roughness of the concrete, the possible impending effect of the lime leached out of the concrete nor the reduction in crack width as it tapers down to an uncracked section. Since the estimated rate of flow is very low, it can easily be accommodated by the building sump system.

3.4.4.2 Sumps and Sump Pumps Inside Seismic Category 1 Buildings

The sumps and sump pumps located inside Seismic Category 1 buildings include the following:

A. Containment sump;

B. Auxiliary building sump and sump pumps;

C. Regenerative waste holdup tank room sump and sump pumps;

D. Auxiliary building chiller and pipeway area sumps and sump pumps.

E. Emergency diesel fuel storage vault sump and sump pump.

3.4.4.2.1 Containment Building Sump

The containment sump is designed to collect all equipment and flow drainage and system leakages within the containment. The liquid collected in the sump is drained by gravity into the auxiliary building sump described in Section 3.4.4.2.2. Redundant isolation valves which close on CIS are provided in the drain line to maintain the containment integrity during the unlikely event of a Design Basis Accident (DBA). The containment sump level is monitored in the control room by an indicator and high level alarm.

Reactor cavity drainage must limit retention of sump inventory in post-accident conditions, but also must prevent flooding of the reactor vessel cavity. A 10 inch diameter drain path with a check valve exists to prevent thermal shocking of the reactor vessel. The drain is integral with the personnel hatch for accessing the reactor vessel cavity. This arrangement will drain excess water in the reactor cavity to the containment building sump and also inhibit water from entering the cavity from the containment building floor area. Such conditions could be the result of an open leak such as a service water or chilled water system pipe break.

3.4.4.2.2 Auxiliary Building Sump and Sump Pumps

The auxiliary building sump is designed to handle the equipment drainage, leakage and possible seepage through the walls into the auxiliary building and the drainage from the containment sump. The auxiliary building sump has a capacity of approximately 1,130 gallons and is equipped with two sump pumps, each with a design capacity of 75 gpm. Sump and sump pump capacity is based on five minutes flow of waste through one 4-inch diameter drain pipe at the rate of 70 gpm. If waste liquid flow volume is greater, the standby pump will start. A sump level indicator and alarm are located in the control room.

3.4.4.2.3 Regenerative Waste Holdup Tank Room Sump and Sump Pump

The regenerative waste holdup tank room sump and sump pump are designed to contain the leakage and accidental release or overflow of the waste liquid inside the tank room.

The waste liquid collected in the sump is pumped back into one of the three holdup tanks in the room at the rate of 25 gpm. The sump pump is designed for submerged operation so that the waste liquid can be removed even if failure of one of the tanks occurred. The pump is controlled by a local level switch.

As shown in Table 3.4-2, the sump and sump pump are Quality Group D and Seismic Category 2. This portion of the Unit 2 Auxiliary Building is not protected from external flooding events. There is no safety-related equipment located in this portion of the auxiliary building and therefore sump level monitoring and level indication in the control room are not required.

3.4.4.2.4 Auxiliary Building Chiller and Pipeway Area Sumps and Sump Pumps

The auxiliary building chiller and pipeway area sumps are designed to collect liquid from local drainage, equipment leakage and periodic washdown. The liquid is uncontaminated. The pumps are designed for 25 gpm and are controlled by level switches mounted on the pumps.

As shown in Table 3.4-2, the sumps and sump pumps are Quality Group D and Seismic Category 2. This portion of the Unit 2 Auxiliary Building is not protected from external flooding events. There is no safety-related equipment located in this portion of the auxiliary building and therefore sump level monitoring and level indication in the Control Room are not required.

3.4.4.2.5 Emergency Diesel Fuel Storage Vault Sump and Sump Pump

Each emergency diesel fuel storage tank vault has a sump which in turn is connected to a main sump equipped with a sump pump. The pump is designed for 15 gpm.

As shown in Table 3.4-2, the sump and sump pump are Seismic Category 2. A level switch in the sump annunciates a high level alarm in the Control Room.

3.4.4.2.6 Safety Evaluation

As indicated in Section 3.4.4.1, the seepage into the Seismic Category 1 buildings is of such minute quantity that the failure of the sump pumps would have no adverse effect on the flood protection of the buildings.

The only sump pumps that are discharging liquid outside of Seismic Category 1 buildings are the auxiliary building chiller and pipeway area sump pumps and the emergency diesel fuel storage vault sump and sump pump. The discharge lines are furnished with backflow valves to prevent backflow of liquid from the outside into the building. The other sump pumps discharge the waste liquid into holdup tanks within the Seismic Category 1 buildings.

3.4.4.3 Local Probable Maximum Precipitation

All Seismic Category 1 structures and safety-related systems and components susceptible to the effects of flooding are protected against flooding due to a sudden local (10 square miles or less) probable maximum storm, which could happen without advance warning. There are a total of five doors and three hatches in the Seismic Category 1 structures located at places and elevations where ponded water could conceivably enter. All of the doors are equipped with intrusion alarms monitored in the control room and are normally closed. Administrative procedures require that these doors must be closed and remain closed during local flood conditions. The containment equipment hatch and the emergency escape hatch are located at Elevation 357 feet. Since it would take several hours for ponded water to reach this elevation, and since the same administrative procedures applicable to the doors also apply to the hatches, ample time is available to secure these hatches. The tendon gallery escape hatch is at Elevation 355 feet and is normally closed. It is spring loaded to assist personnel egress, but is designed to remain closed under the weight of the hatch.

3.5 MISSILE PROTECTION

Missile protection criteria for the facilities conform to 10 CFR 50 General Design Criterion 4, "Environmental and Missile Design Bases." Protection against the missiles identified in Section 3.5.2, Missile Selection, is provided to fulfill the following design criteria.

A. Reactor Coolant Pressure Boundary Missiles

A missile generated from a loop in the Reactor Coolant System (RCS) pressure boundary will not cause:

1. loss of integrity to another loop of the reactor coolant pressure boundary;

2. loss of integrity of the containment liner; or

3. loss of integrity of the main stream or feedwater system.

It will not cause loss of function to systems required to mitigate the consequences of the postulated Loss of Coolant Accident (LOCA) assuming the failure of single active component. These systems are:

1. Containment Spray System (CSS) (Section 6.2.2, 6.2.3);

2. Containment Cooling System (CCS) (Section 6.2.2);

3. Penetration Rooms Ventilation System (Section 6.5);

4. Containment Isolation System (CIS) (Section 6.2.4);

5. Combustible gas control systems (Section 6.2.5);

6. Safety Injection System (SIS) (Section 6.3);

7. Control room habitability systems (Section 6.4);

8. Reactor Protective System (RPS) (Section 7.2) and safety-related display instrumentation for reactor protection trip parameters (Section 7.5);

9. Engineered Safety Features Actuation System (ESFAS) (Section 7.3) and safety-related display instrumentation for Engineered Safety Features (ESF) actuation parameters (Section 7.5) required for operation of other listed systems;

10. The onsite power system including generators, batteries, and distribution systems (Section 8.3) and the diesel fuel oil (Section 9.5.4), cooling water (Section 9.5.5), starting (Section 9.5.6) and lubrication (Section 9.5.7) systems;

11. Portions of the Service Water System (SWS) required for operation of other listed systems (Section 9.2.1); and,

12. Air conditioning cooling and ventilation systems required for operation of other listed systems (Section 9.4).

B. Main Steam and Feedwater Missiles

A missile generated from the main steam or main feedwater pump discharge pressure boundary will not cause:

1. Loss of integrity to the Reactor Coolant Pressure Boundary (RCPB);

2. Loss of integrity to unisolable main steam or feedwater piping in the other loop; or

3. Loss of integrity to the containment liner or CIS (Section 6.2.4), if the missile is generated inside containment.

   It will not cause loss of function to systems required to mitigate the consequences of a steam or feedwater line break accident assuming the failure of a single active component. These systems are:

1. CSS (Section 6.2.2) and CCS (Section 6.2.2), if the missile is generated inside containment;

2. SIS (Section 6.3);

3. The RPS (Section 7.2) and safety-related display information for reactor protection trip parameters (Section 7.5);

4. ESFAS (Section 7.3) and safety-related display instrumentation for engineered safety features actuation parameters (Section 7.5) required for operation of other listed systems;

5. The onsite power system including generators, batteries, and distribution systems (Section 8.3) and diesel fuel (Section 9.5.4), cooling water (Section 9.5.5), starting (Section 9.5.6) and lubrication (Section 9.5.7) systems;

6. Portions of the SWS required for operation of other listed systems (Section 9.2.1); and

7. Air conditioning cooling and ventilation systems required for operation of other listed systems (Section 9.4).

   It shall not cause loss of function to the systems required to maintain the plant in a hot shutdown condition assuming the failure of a single active component. These systems are:

1. Pressurizer heaters (Section 5.5) and controls (Section 7.7) as required for hot shutdowns;

2. CCS (Section 6.2.2);

3. Actuation systems (Section 7.4) and safety-related display instrumentation for hot shutdown control parameters (Section 7.5) for other listed systems.

4. The onsite power system including generators, batteries and distribution systems (Section 8.3), and the diesel fuel oil (Section 9.5.4), cooling water (Section 9.5.5), starting (Section 9.5.6) and lubrication (Section 9.5.7) systems;

5. Portions of the SWS (Section 9.2.1) required for operation of other listed systems;

6. Air conditioning, cooling and ventilation systems required for operation of other listed systems (Section 9.4);

7. Main steam supply to the turbine driven auxiliary feedwater pump and the power operated dump valves (Section 10.3); and,

8. The Emergency Feedwater (EFW) System (Section 10.4.9) and the service water supply to the pump suctions.

   A missile generated from the main steam or main feedwater pump discharge pressure boundary will not cause loss of function to the systems required to cool down the plant to at or near ambient conditions. These systems are:

1-8. Same as 1 through 8 above for hot shutdown;

9. The Shutdown Cooling (SDC) System (Section 9.3.6); and,

10. The Chemical and Volume Control System (CVCS) components required to increase boron concentration for cold shutdown (Section 9.3.4).

C. Internal Missiles Other Than Reactor Coolant, Main Steam or Feedwater

A missile generated from any plant system, other than the RCS, the main steam system, or main feedwater pump discharge lines shall not penetrate the containment or control room boundary or cause loss of integrity to the spent fuel pool. (Criteria for missiles generated from the reactor coolant and main steam systems and main feedwater pump discharge lines are discussed above). It shall not cause loss of function to any system required to mitigate the consequences of a postulated LOCA or a steam or feedwater line break accident, or to any system required for hot or cold shutdown of the reactor as listed in Criterion B above. Since such missiles do not result in a LOCA or a steam generator steam/water release requiring protective action, a loss of redundancy for such systems is permitted, but a loss of function is not permitted.

D. Tornado Missiles

Missiles generated by a tornado shall not cause loss of containment integrity or penetrate the control room boundary or cause loss of integrity to the spent fuel pool. They shall not cause loss of function to any system required for hot shutdown of the reactor from the control room as listed in Criterion B above even assuming the failure of a single active component. They shall not cause loss of function of any system required for cold shutdown, as listed in Criterion B above.

3.5.1 MISSILE BARRIERS AND LOADINGS

A tabulation of protected components and the structures, shields and barriers that were designed to withstand missile effects is presented in Table 3.5-1.

3.5.1.1 Missile Barriers Within Containment

The secondary shield and the refueling cavity walls act as missile barriers separating each reactor coolant loop from other protected components and missile sources. Structural floor members provide additional missile protection. These barriers, as well as any additional barriers as may be required, prevent a postulated missile from penetrating the RCPB in another loop, the containment structure or liner, containment penetrations, a steam generator shell, steam generator steam side instrumentation connections, the steam, feedwater or blowdown piping or the steam generator drain pipes within the containment structure. They also protect the RCPB in each loop from those identified missiles generated elsewhere in the containment.

Except for short piping runs in the SIS which must supply cooling water to the RCS after a LOCA, the ESF are located outside the secondary shield. The SIS lines which penetrate the secondary shield do so in the vicinity of the primary loop segment to which they are attached.

A missile shield structure is provided over the Control Rod Drive Mechanisms (CRDMs) to block any identified missiles generated in that location. To protect against identified missiles originating in the region of the pressurizer, barriers or suitable restraints are provided as required.

Barriers or retainers are provided as required to prevent missiles generated by the failure of main steam or feedwater components inside containment from causing loss of integrity to the containment liner, isolation system or the steam system associated with the other steam generator, or causing loss of function to other required systems or components inside containment in accordance with the missile protection design criteria above.

3.5.1.2 Missile Barriers Within Category 1 Structures Other Than Containment

Missile barriers or restraints have been provided within Category 1 Structures outside containment in conformance with the missile protection design criteria given previously in Section 3.5.

For the pressurized and rotating component failure missiles identified in Section 3.5.3, which originate outside containment, the following steps are taken to assure that the missile protection design criteria have been met:

A. Missiles have been categorized as to the system in which they originate.

B. The components which must be protected from a missile have been identified in accordance with the missile protection design criteria given above.

C. The following methods have been used as required to prevent a missile from causing loss of function to a protected component:

    1. The missile characteristics have been determined using the procedures given in Section 3.5.3.

2. A determination has been made as to whether the missile characteristics are severe enough to cause loss of function to protected components. Credit has been taken for existing structures or components which are interposed between the missile origin and the protected component.

3. The trajectory has been altered by changing the orientation or position of the missile and/or the position of the protected component if this is feasible.

4. If loss of function of the protected component can occur due to missile damage, either suitable restraints have been provided to prevent the missile from leaving its point of origin, or barriers have been installed to intercept the missile trajectory.

3.5.1.3 Barriers for Missiles Generated Outside of Category 1 Structures

A tabulation of protected components and the structures, shields, and barriers that were designed to provide protection from identified missiles generated outside these structures, shields, and barriers is given in Table 3.5-1. The missile barriers indicated were designed for the tornado and accident missile loadings described in Sections 3.5.2 and 3.5.3 utilizing the procedures given in Section 3.5.4.

3.5.1.4 Barriers for Site Proximity Missiles

Section 2.2 provides the locations, routes and descriptions of nearby industrial, transportation and military facilities. There is no credible basis for anticipating site proximity missiles, and no site proximity missile barriers were considered in the design.

3.5.2 MISSILE SELECTION

3.5.2.1 General

The sources of missiles which, if generated, could affect the safety of the plant were considered as discussed in the following sections. These are rotating component failure missiles, pressurized component failure missiles, and tornado generated missiles.

3.5.2.2 Rotating Component Failure Missiles

3.5.2.2.1 Turbine Missile Generation

Assessment of current turbine failure missile potential has indicated that there is no failure probability of sufficient magnitude to justify installation of turbine failure missile shields.

Analyses of known failures of turbine generator rotating elements have revealed two circumstances when failures have occurred: (1) brittle failure at or near rated operating speed and (2) failure by ductile yielding at overspeed conditions as the result of overspeed trip/speed control malfunctions.

3.5.2.2.1.1 Missiles Generated At or Near Rated Speed

The cause of failures at or near rated speed has been found to be combinations of severe strain concentrations, developed from hydrogen flaking or nonmetallic inclusions, and relatively brittle metals. Progress and development of new alloys and processes, identification and reduction of Nil Ductility Transition Temperatures (NDTTs), saliently improved techniques of quality control

and quality assurance, and application of efficient equipment, instrumentation, and operating procedures have been utilized in the design and manufacture of the turbine components. With all these latest technological developments applied to turbine design, it is highly unlikely that there could be any burst failures of turbine generator rotors operating at or near rated speed.

3.5.2.2.1.2 Missiles Generated by Turbine Overspeed

Significant steps in turbine design have been taken in order to prevent overspeed.

Moreover, exhaustive inspection and testing procedures have been developed to assure proper overspeed protection. To prevent long-term buildups of salts or oxides on valve mechanisms with the eventual result of impairing valve shutting rates, the valves are periodically cycled. As the result of these efforts, the probability of destructive overspeed causing failure of a modern unit has been substantially reduced.

3.5.2.2.2 Hypothetical Rotating Element Failure

General Electric, manufacturer of the turbine generator, determined the most severe turbine missile by assuming instantaneous loss of load from full load operation. In addition, it was postulated that the normal speed governing system and independent overspeed governing systems fail to shut the emergency stop valves. The turbine can then accelerate to approximately 170 percent of rated speed before severe generator damage due to thrown windings and probable retaining ring failure will decelerate the turbine. The last stage, low pressure turbine vanes are postulated to fail when turbine speed reaches 177 percent of rated speed, but wheel burst is unlikely at that point. However, should wheel burst occur, 120 degree segment fragments would be ejected. Such a turbine rotor fragment with a mass of 8,264 pounds and kinetic energy of 2.15E7 foot-pounds upon exit from the turbine casing is determined to be the most dangerous of those which could be formed. High pressure turbine rotors are not expected to fail at destructive overspeed, but, even if failure did occur, the fragments should be retained by the high pressure shells. Generator field and retaining ring parts are expected to be retained by the generator housing, which, by its construction, is an ideal energy absorber.

During the 2R6 Refueling Outage a monoblock type rotor was installed in the "B" section of the low pressure turbine and in LP "A" during 2R7. These rotors differ from the low pressure rotors described in the previous paragraph in that the previous rotors were a "built up" design with shrunk on wheels whereas the monoblock design is a one piece forging. General Electric's position is that the missile generation criteria for the shrunk on wheels does not apply to the monoblock design. A failure for the monoblock assumes the stresses due to centrifugal forces exceed material strength, and calculations performed by G.E. show the required overspeed to develop such centrifugal forces can not be reached even at a loss of full load. The amount of steam entering the turbine from the time of full load loss to stop valve closure is insufficient to drive the turbine to the overspeed required to fail the monoblock. Should the stop valves fail to close, other turbine parts such as the last stage buckets, generator wedges, and bearings (if high vibrations occur) would fail, stopping the turbine, at speeds below that required to burst the forged monoblock rotor.

3.5.2.2.2.1 Probability of Missile Genesis (P1)

The probabilities of missiles generated due to failure of the turbine at or near rated turbine speed (low speed burst) or during destructive overspeed (high speed burst) were provided by the respective vendors, G.E. for Unit 2 and Westinghouse for Unit 1, for a standard 6-flow low pressure turbine.

G.E.: (for 30-year lifetime)

- Low speed failure: 2.6×10^{-7}
- High speed failure: 1.5×10^{-7}
- LP "B" monoblock rotor: 1.0×10^{-8}

Westinghouse: (annual probabilities)

- Low speed failure: 1.0×10^{-7}
- High speed failure: 1.0×10^{-8}

The numbers for the low and high speed failures were taken from the G.E. memo report, "Hypothetical Turbine Missiles - Probability of Occurrence," by J. E. Downs (Reference 53) and, the N.E.S. Turbine Missiles Report for Byron-Braidwood for the Westinghouse turbine. The probability of generating missiles for the LP "B" monoblock rotor was taken from the August 19, 1987, G.E. letter from G. B. Landes to G. Hayes.

For use in the analysis of turbine missile damage for the Arkansas Nuclear One Units, the P1 values were converted to annual probabilities and multiplied by 2/3 in order to give P1 values for four flow turbines. For the case of a high speed failure in the G.E. turbine, separate analyses were done for missiles generated by the inner wheels and those generated by the end wheels due to differences in the possible missile trajectories. The value of P1 for failure of the inner wheels was taken as 6/7 the value for the entire turbine. For failure of an end wheel the P1 value was 1/7 times the value for the entire turbine. For a low speed failure of the G.E. turbine only the end wheels were postulated to produce missiles external to the turbine case.

For the Westinghouse unit, a separate analysis was done for the failure of each wheel, so that the value of P1 taken for each wheel was 1/6 times the value for the entire turbine (six wheels per Westinghouse turbine flow path). The appropriate P1 values used were accordingly:

<u>G.E.</u>

High Speed Burst, the 24 Inner Wheels	2.86×10^{-9}
High Speed Burst, the 4 End Wheels	4.76×10^{-10}
Low Speed Burst, the 4 End Wheels	5.78×10^{-9}

<u>Westinghouse</u>

Low Speed Burst, per wheel (for any one flow path)	1.1×10^{-8}
High Speed Burst, per wheel (for any one flow path)	1.1×10^{-9}

A meaningful, alternate method of determining missile generation probabilities based on direct statistical observation is not available. The use of past data for a probabilistic estimate is justifiable only where the past data are demonstrated to be reasonably representative of the expected future population. The historical data of failures are based on turbines with integral rotors, and are not representative of the low pressure, shrunk on wheels of modern nuclear power plant turbines manufactured under the current metallurgical and quality control practices.

Further, the total turbine years of operation accumulated by the industry are not long enough to lend a meaningful analysis by such a simplistic approach (Reference 53, page 40). Significant among turbine design advances have been the replacement of the turbine's mechanical-hydraulic speed control system with an electrohydraulic system of increased reliability. The electrohydraulic control system employs three electrical and one mechanical speed input. Logic signals are redundantly processed in both electronic and hydraulic channels. Valve opening actuation is provided by a 1,600 psig hydraulic system which is totally independent of the bearing lubrication system. Valve shutting actuation is provided by springs and aided by steam forces upon the reduction or relief of fluid pressure. The system is designed so that loss of hydraulic fluid pressure for any reason leads to valve shutting and consequent shutdown (fail-safe).

The main steam valves are provided in series arrangements: a group of stop valves actuated by either of two overspeed trip signals followed by a group of controlling valves modulated by the speed governing system, and tripped by either overspeed trip signal.

The intermediate valves are arranged in series pairs, consisting of an intermediate stop valve and an intercept valve in one casing. The closure of either one of the two valves will close the corresponding steam line.

A single failure of any component will not lead to destructive overspeed. A multiple failure, involving combinations of undetected electronic faults and/or mechanically stuck valves and/or hydraulic fluid contamination at the instant of load loss would be required. The probability of such joint occurrences is extremely remote due to the inherently high reliability of components and design.

Note: This analysis applies to the original LP Turbine design. During 2R6 and 2R7, AP&L replaced the "B" and "A", LP turbine rotors, respectively, with a monoblock type rotor. A description of the monoblock type rotor design and its missile generation capability is provided in section 3.5.2.2.2.

3.5.2.2.2.2 Probability of Missile Strike (P2)

From the standpoint of reactor safety it is necessary to consider the probability that, given a turbine failure missile has occurred, the missile will impact the containment, control room, or other structure which houses components or systems required for safe shutdown. The product of the probability of missile genesis (P1) and the probability of missile strike (P2) yields the probability that a turbine missile will impact the structure.

A Fortran program was written to analyze the probability of a turbine missile striking a cylindrical or rectangular target (building containing safety-related equipment). The analysis was based on the following assumptions:

A. The missile has a uniform probability of ejection at any angle of the 360-degree arc around the turbine axis.

B. The missile has a uniform probability of ejection at any angle with respect to the vertical radial plane passing through the disc within a range of five degrees for the inner turbine wheels and 25 degrees for the General Electric turbine outer wheels and five to 25 degrees for the Westinghouse wheels. The manufacturer's postulated missile data provides the basis for the angular limitations given above. Westinghouse postulates that their outer wheel would be ejected only towards the adjacent coupling on the rotor shaft.

C. The probability of ejection at a given initial velocity is uniform over the range of possible missile ejection velocities.

D. The trajectory of the missile from source to target is assumed parabolic.

E. Secondary particles resulting from collisions with obstructions or missiles resulting from the reflection of a missile from an obstruction were not considered.

Figure 3.5-1 shows the orientation of the turbine centerline with respect to the postulated targets.

The missile strike probabilities were divided into high trajectory (lob shot) and low trajectory (elevation angle that could cause a direct strike on a target) components. With the G.E. turbine of Unit 2 as the missile source, the missile damage probabilities (P4) for each target are the sum of the separate products of P1, P2 and P3 (defined in Section 3.5.2.2.2.3). Three possible modes of turbine missile genesis were considered, each with a different probability (P1): the bursting of an interior turbine wheel during turbine overspeed (high speed burst); the bursting of an end turbine wheel during turbine overspeed; and, the bursting of an end turbine wheel near rated turbine speed (low speed burst). These modes of turbine missile genesis are based on the turbine manufacturer's hypothetical missile data.

For the Westinghouse turbine of Unit 1, the value of P4 is the sum of the product of P1 and P2 for a low speed burst and a high speed burst. However, the P1 and P2 represented in Table 3.5-3 for the Unit 1 turbine are defined differently since each wheel was analyzed separately. P1 represents the probability of missile genesis per wheel and P2 is the sum of the probabilities of missile strike for each wheel. The damage probability (P3) was conservatively assumed to be equal to 1.0 for the Westinghouse turbine missiles; hence, any strike is assumed to cause damage.

Note: This analysis applies to the original LP Turbine design. During 2R6 and 2R7, AP&L replaced the "B" and "A" LP turbine rotors, respectively, with a monoblock type rotor. A description of the monoblock type rotor design and its missile generation capability is provided in section 3.5.2.2.2.

It may be noted that the probabilities of a missile generated by the Unit 1 turbine striking any target other than the containment and auxiliary building of Unit 2 were so small as to be negligible.

3.5.2.2.2.3 Probability of Penetration of Missile Targets (P3)

In addition to the probability of a missile strike, there is also the probability, given a strike, that the missile will not damage the component which is housed by the structure. We conservatively define the probability of damage (P3) to be the probability of a missile causing spalling within the enclosing structure.

Table 3.5-2 shows an example of the breakdown of P2 and P3 for the spectrum of missile fragments postulated by G.E. The computer program used in the analyses calculates both the strike and damage probabilities for an individual missile in each fragment group postulated. The P2 and P3 column shown in the example represents the probability of each postulated missile fragment causing damage to the target. A binomial distribution is then used, taking into account the number of fragments generated in each postulated fragment group, to determine the

probability that any one missile fragment will not damage the target. This probability is then subtracted from unity, which results in the P2 x P3 damaged probability listed in Table 3.5-3. Hence, P2 x P3 is the probability that at least one missile fragment causes damage to the specified target.

The Ballistic Research Laboratory (BRL) formula has been used to calculate the thickness of concrete perforated by a missile. The concrete thickness required to prevent spalling is then determined by doubling the perforation thickness. Of the two formulas commonly used for the calculation of missile damage to concrete structures, the modified Petry and BRL formulas, the BRL formula has been shown to be slightly more conservative for the range of typical turbine missile masses and velocities. The BRL formula determines the concrete thickness corresponding to the initiation of perforation by a cylindrical missile impacting normal to the concrete surface. Because the turbine missile fragments postulated are not cylindrical, the variable (D) in the BRL formula, is calculated as the diameter of a cylinder with cross-sectional area equal to the projected frontal area of the missile. Since the geometry of the enclosing structures and missile trajectories sometimes result in oblique impact angles, the normal missile velocity was determined for input into the BRL formula. In addition, the following assumptions were made in calculating the damage probability:

A. Intermediate concrete barriers were added to the wall thickness assumed for the structure. Therefore, equipment on lower floors have the added protection of the concrete floors above.

B. The missile fragments rotate when ejected, therefore, a spectrum of impact areas are equally probable for the 120° and 60° wheel section fragments.

The concrete thickness of the target roof or wall is inserted, along with the appropriate missile data, into the BRL formula to calculate the normal impact velocity sufficient to induce spalling. Then for each initial ejection vector, the ejection velocity sufficient to cause spalling is calculated and a probability of damage determined.

The product of the strike probability increment and the corresponding damage probability determine an increment in the strike and damage probability. The increments are then summed to determine a total strike and damage probability for the particular missile-target combination. An average damage probability for the target is then extracted by dividing the strike and damage probability by the strike probability. This average damage probability is represented by P3 in the example breakout of P2 and P3 shown in Table 3.5-2.

Table 3.5-3 shows the missile ejection probabilities and the resultant total missile damage probabilities for each listed target. For missiles generated from the Unit 2 (GE) turbine, the strike and damage probabilities have been calculated and combined as previously described. For missiles generated from the Unit 1 (Westinghouse) turbine, the damage probability is assumed to be 1.0.

3.5.2.2.2.4 Turbine Missile Damage Probability (P4)

The probability of significant damage to critical components in the plant due to turbine failure (P4) is the product of the probabilities of: (1) turbine failure and ejection of an energetic missile (P1); (2) a missile from the turbine striking a structure enclosing a critical component (P2); and, (3) spalling occurs inside the structure (P3). That is, the overall probability, P4, is the product of P1 x P2 x P3. Using the values developed above, the annual probability of a turbine failure missile damaging a critical component is determined to be 6.3×10^{-10}. This value is sufficiently low that no specific protective measures are required.

Note: This analysis applies to the original LP turbine design. During 2R6 and 2R7, AP&L replaced the "B" and "A" LP turbine rotors, respectively, with a monoblock type rotor. A description of the monoblock type rotor design and its missile generation capability is provided in Section 3.5.2.2.2.

3.5.2.2.3 Conclusions

Periodic cycling of the steam stop valves will be performed with visual observation of valve motion in accordance with the Technical Requirements Manual. Control valves are periodically exercised to insure that they are free to operate in the event of a turbine trip. Disassembly and inspection of the steam stop valves, the control valves, and the combined stop and intercept valves will be conducted during refueling shutdowns in accordance with the Technical Requirements Manual. Disassembly and inspection of the turbine generator will be conducted on a scheduled basis in accordance with vendor recommendations.

Due to the redundancy and testing features of the turbine overspeed protection, the quality control of manufacturing processes and materials, and the calculated probabilities of the low pressure turbine last stage wheel failure, damage from turbine failure missiles is considered so improbable that specific protective measures are not required.

3.5.2.3 Pressurized Component Failure Missiles

3.5.2.3.1 Nuclear Steam Supply System

Credible missiles resulting from failure of pressurized components in the Nuclear Steam Supply System (NSSS) are listed and described in Table 3.5-4.

3.5.2.3.2 Systems Other Than NSSS

Credible missiles resulting from failures of pressurized components in the balance of plant area given in Table 3.5-5. The bases for selection are discussed below.

Pressurized components in systems whose service temperature exceeds 200 °F or whose design pressure exceeds 275 psig were evaluated as to their potential for becoming a missile.

Temperature or other detectors installed on piping or in wells were evaluated as potential missiles if failure of a single circumferential weld would cause their ejection.

Unrestrained sections of piping such as vents, drains, and test connections were evaluated as potential missiles if the failure of a single circumferential weld could cause their ejection.

Dead end flanges were evaluated as potential missiles.

Valves procured for service at Unit 2 employ one of four valve bonnet attachment methods. The type of valve bonnets used are pressure seal, bolted, breechlock, and welded.

Most ASME Section III valves of ANSI 900 psig rating and above, constructed in accordance with Bechtel specifications are pressure seal bonnet type valves. For pressure seal bonnet valves, valve bonnets are prevented from becoming missiles by the retaining ring, which would have to fail in shear, and by the yoke, which would capture the bonnet or reduce bonnet energy.

Because of the conservative design of the retaining ring of these valves, bonnet ejection is highly improbable and bonnets were not considered credible missiles.

Most valves of ANSI rating 600 psig and below are valves with bolted bonnets. Valve bonnets are prevented from becoming missiles by limiting stresses in the bonnet-to-body bolting material by rules set forth in ASME Code, Section III, and by designing flanges in accordance with applicable code requirements. Even if bolt failure were to occur, the likelihood of all bolts experiencing a simultaneous complete severance failure is very remote. The widespread use of valves with bolted bonnets and the low historical incidence of complete severance valve bonnet failures, Reference 44, confirms that bolted valve bonnets need not be considered as credible missiles.

The remaining valves, those equipped with breechlock or welded bonnets, have two separate bonnet retaining features to preclude their ejection as a potential missile. Both methods of bonnet-to-body attachment use a sealing circumferential weld. In addition, valve bonnets which are welded, also feature a screwed bonnet. Valves with breechlock bonnets, employed for high pressure service, use a key or breech connection. When the bonnet is inserted into the valve body, it is rotated. With the bonnet in this locked position the bonnet is seal welded to the body; hence, valve bonnets are not considered credible missiles.

Valve stems were not considered as potential missiles if at least one feature in addition to the stem threads is included in their design to prevent ejection. Valves with backseats are prevented from becoming missiles by this feature. In addition, air or motor operated valve stems are effectively restrained by the valve operators.

Potential missile sources that are shown to be not credible do not require missile protection features. Among those that have been shown to be not credible are studs, nuts, and bolts. For ANO Unit 2 steam generators, the studs and nuts for the manways, handholes, and inspection ports were designed, manufactured, and analyzed to the requirements of the ASME Code Section III. Preload values or elongation values are specified on the component drawings. These preload or elongation values are used in procedures for installation of the manways, handholes, and inspection ports for closure of the primary and secondary pressure boundaries. The design analyses demonstrate that the bolt stresses are well within the elastic range. Therefore, the generation of missiles by the studs, nuts, or bolts of the SG is not considered to be credible.

Nuts, bolts, nut and bolt combinations, and nuts and stud combinations have only a small amount of stored energy. However, for components other than steam generators, they were considered potential missiles, and an example of their missile characteristics is listed in Table 3.5-5.

3.5.2.4 <u>Tornado Generated Missiles</u>

The tornado generated missiles selected from the design of structures are described in Section 3.3.2.1.

The bases for tornado missile selection were:

A. Eyewitness accounts from persons making observations during tornadoes.

B. Results of analyses of photograph taken during tornadoes.

C. Results of analyses of tornado caused damage or of lack of tornado caused damage.

D. Results of analyses of the physical aspects of tornado phenomena.

E. Recommendations of persons familiar with the effects of tornadoes.

3.5.3 SELECTED MISSILES

3.5.3.1 Nuclear System Supply System Missiles

The characteristics of missiles resulting from the failure of pressurized components in the NSSS are given in Table 3.5-4.

3.5.3.2 Missiles From Systems Other Than NSSS

For each selected missile appropriate parameters identifying its characteristics are given in Table 3.5-5. The basis for identifying selected missile parameters is discussed below.

Once an object has been assumed to be a missile, and the mass and shape are known, the initial velocity is determined as follows:

A. For missiles acted upon by a jet of escaping fluid (gas, liquid/gas, liquid) for a certain distance the calculational techniques given in ORNL-NSIC-5, Reference 44, Section 6.6.1.3, are used to determine missile kinetic energy.

   Calculational techniques utilized in obtaining jet velocity at the break are:

   1. For a gas/liquid jet with system L/D (pipe length/pipe hydraulic diameter) ratio equal to or greater than 12, Moody, Reference 69, is used.

   2. For a gas/liquid jet with system L/D ratio less than 12, ORNL-NSIC-22, Reference 25, Section 4.1.2, is used.

   3. For a single phase (gas or liquid), ORNL-NSIC-22, Section 4.1.2, is used.

B. For missiles acted upon by a single phase liquid stream for a certain distance, kinetic energy for these missiles is determined by converting work energy into kinetic energy. The calculational technique utilized in obtaining missile velocity is found in ORNL-NSIC-22, Section 4.1.1.

C. For missiles which are generated by release of stored strain energy, the strain energy is equated to kinetic energy in determining missile velocity. The ultimate stress of the material is used resulting in a large amount of energy than would be present at fracture. Losses due to heating, friction, and the relaxation of the material are ignored.

3.5.3.3 Tornado Missiles

Appropriate parameters identifying the characteristics of tornado generated missiles are given in Table 3.5-6.

3.5.4 BARRIER DESIGN PROCEDURES

The procedures and calculations employed in design of missile resistant barriers are described in the following sections.

3.5.4.1 Reinforced Concrete Targets

Missile resistant concrete barriers and structures were designed to withstand and absorb missile impact loads without being fully penetrated in order to prevent damage to protected components.

The design procedures and calculations used to predict local damage in the impact area included estimating the depth of penetration, minimum thickness required to prevent perforation, and minimum thickness required to preclude spalling. Table 3.5-7 shows results of calculations performed for the selected missiles discussed in Section 3.5.3. The penetration and perforation formulae assumed that the missile strikes the target normal to the surface, and the axis of the missile was assumed parallel to the line of flight. These assumptions resulted in a conservative estimate of local damage to the target.

3.5.4.1.1 Penetration

The depth to which a rigid missile will penetrate a reinforced concrete target of infinite thickness was estimated by the modified Petry formula:

$$X = 12\,K_p\,A_p\,\mathrm{Log}_{10}\left(1+\frac{V_s^2}{215{,}000}\right)$$

where

X = Depth of missile penetration into concrete element of infinite thickness (inches)

Note: Usually this equation expresses the depth of penetration in feet; however, in this text it has been modified to express it in inches.

K_p = Penetration coefficient for reinforced concrete (see Figure 3.5-2)

A_p = Missile weight/projected frontal area of missile (psf)

V_s = Striking velocity of missile (ft/sec). (Limit $V_s \le 1000$ ft/sec)

When the element has a finite thickness the depth of penetration is:

$$X_1 = \left(1 + \exp\left(-4\left\{\frac{t}{X} - 2\right\}\right)\right) X$$

where

X_1 = Depth of penetration of missile into a concrete element of finite thickness (inches)

T = Thickness of concrete element (inches) (Limit t > 2X).

3.5.4.1.2 Perforation

The thickness of a concrete element that will just be perforated by a missile was estimated by the Ballistic Research Laboratory (BRL) formula:

$$T = \frac{427}{\sqrt{F'_c}}\,\frac{W}{D^{1.8}}\left(\frac{V_s}{1000}\right)^{1.33}$$

where

- T = Thickness of concrete element to be just perforated (inches)
- W = Weight of missiles (lb)
- D = Diameter of missiles (inches)
- Note: For irregularly shaped missiles, an equivalent diameter was used. The equivalent diameter was taken as the diameter of a circle with an area equal to the circumscribed contact, or projected frontal area, of the noncylindrical missile.
- V_s = Striking velocity of missile (ft/sec)
- F'_c = Compressive strength of concrete (psi)

The thickness, T_p, of a concrete element required to prevent perforation must be greater than T. The design considered an increase of T by 25 percent, but not more than 10 inches, to obtain the T_p, required to prevent perforation:

$$T_p = 1.25T \leq T + 10 \text{ (in inches)}$$

3.5.4.1.3 <u>Spalling</u>

Spalling of concrete from the side opposite the contact surface of the element may occur even if the missile will not perforate the element. For an estimate of the thickness that will just start spalling, the following equation was used:

$$T_s = 2T$$

where

- T_s = Concrete element thickness that will just start spalling (inches)
- T = Concrete thickness to be just perforated (inches). (See Section 3.5.4.1.2)

The thickness, T_s, of a concrete element required to prevent spalling must be greater than T_s. The design considered an increase of T_s by 25 percent, but not more than 10 inches, to prevent spalling.

3.5.4.2 <u>Steel Targets</u>

Missile resistant barriers were designed to withstand and absorb missile impact loads without being fully penetrated in order to prevent damage to protected components.

The design procedures and calculations used to predict local damage in the impact areas are given in BC-TOP-9A, Revision 2.

3.5.5 MISSILE BARRIER FEATURES

The layout and principal design features of structures serving primarily as missile resistant barriers are shown on Figures 3.5-7 and 3.5-8.

3.6 PROTECTION AGAINST DYNAMIC EFFECTS ASSOCIATED WITH THE POSTULATED RUPTURE OF PIPING

In accordance with 10 CFR 50 General Design Criterion No. 4, "Environmental and Missile Design Bases," special measures have been taken in the design and construction of Unit 2 to protect structures, systems and components required to place the reactor in a safe cold shutdown condition from the dynamic effects associated with the postulated rupture of piping. This section defines the criteria used in the evaluation of postulated breaks, the analyses performed and the protective measures taken to mitigate the consequences of these breaks. Regulatory Guide 1.46 (dated May, 1973), "Protection Against Pipe Whip Inside Containment" was the basic document used in establishing the design criteria for piping systems inside containment. The difference which exists between this regulatory guide and the criteria defined herein concerns design break geometry. In postulating the types of breaks which occur at the break locations established in accordance with Section 3.6.2.1., the criteria presented in the ANS draft standard, ANSI N176, "Design Basis for Protection of Nuclear Plants Against Effects of Postulated Pipe Rupture" (Draft 3 dated June, 1974), was used. These criteria are presented in Section 3.6.2.2.

High energy line break evaluations, performed for changes or additions to systems inside containment, may utilize the criteria of USNRC Standard Review Plan 3.6.2, Revision 1, July 1981, in lieu of the above mentioned criteria.

For the purposes of environmental qualification, many of the high energy line break evaluations were re-performed to obtain more detailed analytical results in the area of compartment pressurization and temperature responses. These analyses are described in greater detail in ANO Environmental Qualification - Environmental Service Conditions, Engineering Standard NES-13.

In establishing the design criteria for piping systems outside containment, the AEC document "General Information Required For Consideration of the Effects of a Piping System Break Outside Containment," and the errata sheet thereto, was used. In establishing intermediate break locations, which this document states shall be "selected on a reasonable basis as necessary to provide protection," the criteria defined in the ANS draft standard ANSI N176 were used.

High energy line break evaluations, performed for changes or additions to systems inside containment, may utilize the criteria of USNRC Standard Review Plan 3.6.2, Revision 1, July 1981, in lieu of the above mentioned criteria.

NRC Generic Letter 87-11 (Ref. 83) relaxed the arbitrary intermediate pipe rupture requirements based on the highest stresses. Accordingly, postulation of the arbitrary intermediate break locations is no longer required. As such, arbitrary intermediate break locations previously postulated may be eliminated. The generic letter also explicitly allows relief from both the dynamic effects (i.e. pipe whip, jet impingement, compartment pressurization, etc.) and all environmental effects (i.e. temperature, pressure, humidity, flooding, etc.) resulting from these postulated arbitrary intermediate breaks. NRC generic letter relief provisions are adopted for the postulation of high-energy line breaks for ANO Unit 2. The consequences of a pipe break were considered to manifest themselves by the following methods:

A. pipe whip;

B. jet impingement;

C. compartment pressurization;

D. compartment flooding; and

E. high temperature/high humidity environment.

In evaluating these consequences, the following assumptions were made:

A. Concurrent loss of off-site power was assumed for any postulated pipe break which resulted in protective system actuation effecting a plant trip.

B. The energy level in a whipping pipe was considered as insufficient to rupture an impacted pipe of equal or greater nominal pipe size and equal or heavier wall thickness. An unrestrained whipping pipe is considered capable of rupturing impacted pipes of small nominal pipe sizes and developing through-wall leakage in equal or larger nominal pipe sizes with thinner wall thickness.

C. In addition to the postulated break, a single active component failure was assumed within the systems required to mitigate the consequences of the break and to place the reactor in a safe cold shutdown condition.

D. In addition to the postulated break and single active failure, one channel of each RPS and ESFAS function is bypassed.

3.6.1 SYSTEMS IN WHICH DESIGN BASIS PIPING BREAKS OCCUR

Piping systems in which, during normal operating or hot standby conditions, the fluid temperature exceeds 200 °F or the pressure exceeds 275 psig were evaluated for the effects of pipe breaks. The following systems, or portions of systems, were included in this evaluation:

A. Inside containment

1. Reactor coolant piping, including pressurizer surge line and spray line piping

2. Chemical and Volume Control System (CVCS) letdown and makeup piping

3. Safety Injection System (SIS) piping (only the portions of this system normally subjected to safety injection tank pressure)

4. Main steam piping

5. Steam generator blowdown piping

6. Main feedwater piping

7. Emergency feedwater piping

8. Shutdown Cooling Piping from reactor coolant nozzle to the first isolation valve

B. Outside containment

1. Main steam piping (including extraction steam piping and steam supply piping to the main feedwater pump turbine drivers and the emergency feedwater pump turbine driver)

2. Main feedwater piping

3. Steam generator blowdown piping

4. CVCS letdown piping (from containment penetration to letdown heat exchanger) and makeup piping (from charging pump discharge to containment penetration)

5. Emergency feedwater piping (from pump discharge to containment penetration)

6. Safety Injection System piping (from pump discharge to containment penetration)

Breaks in the Shutdown Cooling (SDC) line from the reactor coolant pipe nozzle to the first isolation valve have the same consequences as a LOCA, as such breaks have been postulated in this section of the SDC line. Pipe breaks were not postulated in the SDC piping downstream of the isolation valve 2CV-5086-2. The shutdown cooling mode is a manually initiated operation and is initiated only under strict administrative controls when the reactor coolant temperature and pressure are below 275 °F and 300 psia. The system exceeds 200 °F and 275 psig less than two percent of the system operating time. This is based on the following conservative assumptions:

- Refueling occurs once every 18 months and the SDC System is in operation for an average of 21 days (500 hours) each refueling period over the plant life.

- In addition, 20 shutdowns to cold shutdown condition were assumed to occur over the life of the plant, each lasting four days or 96 hours.

- During each shutdown, the system is assumed to operate over 200 °F and 275 psig for six hours. This assumes an average cooldown rate of 25 °F per hour while maximum cooldown rate is 75 °F per hour. The SDC System is not used to heat up the Reactor Coolant System (RCS) after shutdown.

The AEC report entitled ″Nuclear Power Plant Operating Experience During 1973″ (OOE-ES-004 dated December 1974) shows that the average refueling time is approximately 1,500 hours. This would increase the time during which the system operates below 200 °F and 275 psig without increasing the time above this temperature and pressure. Whenever possible, maintenance and repairs are scheduled during refueling periods to minimize the number of non-refueling shutdowns.

3.6.2 DESIGN BASIS PIPING BREAK CRITERIA

3.6.2.1 <u>Pipe Break Locations</u>

A. The original design basis for the ANO-2 reactor coolant system (RCS) included postulated breaks for the purposes of evaluating for protection from the dynamic and environmental effects of the main coolant line (MCL) breaks. This basis was consistent with the practices and regulatory requirements in place at the time of the

original design and licensing of Unit 2. Due to changes in the regulations, General Design Criterion 4 (Reference 82) was revised to allow the application of Leak Before Break (LBB) criteria for the selection of MCL breaks. As discussed in section 6.2.1, this criteria has been implemented in Unit 2 in conjunction with modifications such as the permanent reactor seal plate and replacement of the steam generators. The application of LBB per GDC 4 has eliminated the postulated breaks on the MCL for purposes of the dynamics effects design basis of the RCS. However, in accordance with NUREG-1061 Volume 3, the non-mechanistic MCL piping rupture design basis is maintained for containment design, ECCS performance analysis, and electrical and mechanical environmental qualification.

The original design basis assumed the following locations and types of breaks in the MCL piping (see Figure 3.6-31 for RCS piping arrangement):

1. Reactor vessel outlet pipe: Circumferential breaks were postulated at the terminal ends. Based on the Combustion Engineering report “Design Basis Pipe Breaks for the Arkansas Nuclear One, Unit 2 Reactor Coolant System” (ref. 2CAN067607), longitudinal (slot) breaks do not have to be postulated on the reactor vessel outlet (hot leg) piping. However, it should be noted that as documented in the Unit 2 SAR section 6.2.1, for the purposes of analyzing subcompartment differential pressures, a longitudinal break was postulated for the hot leg based on the Combustion Engineering Report CENPD-168, “Design Basis Pipe Breaks for the Combustion Engineering Two Loop Reactor Coolant System.” Although the ANO-2 specific CE report later eliminated the requirement for postulation of longitudinal breaks on the hot leg, the subcompartment differential pressure analysis was conservative since it had considered more than was required, and the analysis did not have to be revised. Therefore, the apparent discrepancy between this section and section 6.2.1 is acceptable and does not violate the pipe break criteria stated herein.

2. Pump suction pipe: Circumferential breaks were postulated at the terminal ends, and longitudinal breaks were postulated at the first elbow closest to the terminal ends. The basis for this criteria is documented in the Combustion Engineering Report “Design Basis Pipe Breaks for the Arkansas Nuclear One, Unit 2 Reactor Coolant System” (ref. 2CAN067607).

3. Pump discharge pipe: Circumferential breaks were postulated at the terminal ends, and no longitudinal breaks were postulated. The basis for this criteria is documented in the Combustion Engineering Report “Design Basis Pipe Breaks for the Arkansas Nuclear One, Unit 2 Reactor Coolant System” (ref. 2CAN067607).

   Following the application of LBB, the remaining pipe breaks in the dynamic effects design basis of the RCS are all primary and secondary side branch line pipe breaks (BLPBs) interfacing with the RCS. Of these, the controlling breaks with respect to RCS response are breaks in the largest tributary pipes.

   - main steam line (MSL)
   - feedwater line (FW)
   - surge line (SL)
   - safety injection line (SI)
   - shutdown cooling line (SDC)

A review of pipe stresses for the as-built configurations of these piping systems eliminated the intermediate breaks in all but the surge line, and a review of loadings on the RCS for remaining terminal end breaks eliminated the BLPBs at the far terminal ends with respect to their effect on RCS response. Therefore, the final set of BLPBs postulated and analyzed for RCS response for the replacement steam generator configuration with power uprate consisted of fifteen (15) BLPBs listed in Table 3.6-1A (see Section 3.9.1.7 for BLPB analysis of RCS).

B. In Seismic Category 2 piping which has not been analyzed and designed to withstand the loads associated with the Design Basis Earthquake (DBE), breaks are postulated to occur at any fitting.

C. In Seismic Category 1 piping (other than the RCS main coolant line) and in the Seismic Category 2 piping which has been analyzed and designed to withstand the loads associated with the DBE, postulated break locations were determined as follows:

1. ASME Code Section III Class 1 piping

a. The terminal ends;

b. Any intermediate locations between terminal ends where the primary plus secondary stress intensities (circumferential or longitudinal) derived on an elastically calculated basis under the loadings associated with specified seismic events and operational plant conditions exceeded 2.0 S_m for ferritic steel and 2.4 S_m for austenitic steel, where S_m is the design stress intensity as specified in Section III ASME Code;

c. Any intermediate locations between terminal ends where the cumulative usage factor (U) derived from the piping fatigue analysis under the loadings associated with specified seismic events and operational plant conditions exceeded 0.1, where U is the cumulative usage factor as specified in ASME Code, Section III; and,

d. As a minimum, when the limits defined in (b) and (c) above are not exceeded, at least two intermediate locations for each piping run or branch run. The intermediate points selected were the ones having the highest combined stress intensities. However, based on the criteria outlined in Section 3.6, postulation of these arbitrary intermediate break locations is no longer required. These break locations may be eliminated if previously postulated.

2. ASME Section III Code Class 2 and 3, and non-nuclear piping

a. The terminal ends;

b. Any intermediate locations between terminal ends where either the circumferential or longitudinal stresses derived on an elastically calculated basis under the loadings associated with specified seismic events and operational plant conditions exceeded 0.8 (1.2 S_h + S_A), where S_h and S_A are stresses calculated by the rules of Articles NC-3600 and ND-3600 in ASME Code, Section III. In lieu of 0.8 (1.2 S_h + S_A), a more conservative stress limit of 0.8 (S_h + S_A) may be used.

c. As a minimum, at least two intermediate locations between each piping run or branch run. The intermediate points selected were those having the highest combined stress intensities. However, based on the criteria outlined in Section 3.6, postulation of these arbitrary intermediate break locations is no longer required. These break locations may be eliminated if previously postulated.

With the exception of the main steam lines, portions of piping which penetrate containment are not exempt from the above criteria. Breaks are not postulated on the main steam lines between the containment penetrations and the isolation valves outside containment. Restraints are provided to ensure valve operability and containment leak tight integrity in the event of a break downstream of the main steam isolation valves. In addition, this section of the main steam piping is designed to meet the following criteria:

A. The maximum stress ranges as calculated by Equations 9 and 10 in Paragraph NC-3652, ASME Code, Section III, considering normal and upset plant conditions and an Operating Basis Earthquake (OBE) event, will not exceed 0.8 (1.2 S_h + S_A).

B. The maximum stress, as calculated by Equation 9 in Paragraph NC-3652, under the loadings resulting from a postulated piping failure of fluid system piping beyond this portion of piping will not exceed 1.8 S_h.

In addition to the break locations specified above, cracks were postulated in these piping systems outside containment at the most adverse locations with regard to essential structures and systems. The crack size was taken to be one-half the pipe internal diameter in length and one-half the wall thickness in width.

3.6.2.2 <u>Design Break Geometry</u>

As discussed in Section 3.6.2.1.A, application of LBB criteria has eliminated the postulated breaks on the MCL for purposes of the dynamic effects design basis of the RCS. However, the non-mechanistic MCL piping rupture original design basis is maintained for containment design, ECCS performance analysis, and electrical and mechanical environmental qualification. In evaluating the effects of postulated breaks in the piping systems identified in Section 3.6.1, the following types of breaks were originally assumed:

A. Circumferential Break - a break perpendicular to the longitudinal axis of the pipe. The break area was assumed to be equivalent to the internal cross-sectional area of the pipe at the break location, except for those cases where restraints have been provided to limit the break area, and/or analyses performed to show that complete separation of the piping at the break point will not occur.

For a circumferential break in the 42-inch I.D. RCS hot leg piping at either the reactor vessel nozzle weld or the steam generator nozzle weld, analyses have shown that the steam generator support system and the reactor vessel support system will limit the separation of the piping such that the resulting maximum break openings will be limited to 100 square inches and 850 square inches, respectively. For the circumferential break in the 30-inch I.D. RCS cold leg piping at the reactor vessel nozzle weld, the reactor vessel support system and cold leg restraint system will limit the separation of the piping such that the resulting maximum break openings will be limited to 200 square inches. These analyses are presented in Combustion Engineering Report

CENPD-168, "Design Basis Pipe Breaks for C-E Two Loop Plants," and CE Report, “Design Basis Pipe Breaks for the Arkansas Nuclear One, Unit 2 Reactor Coolant System,” (2CAN067607).

B. Longitudinal Break - a break in the pipe wall parallel to the longitudinal axis of the pipe having a length of two pipe inside diameters. With the exception of the RCS piping, the flow area of the break was assumed to be equivalent to the internal cross-sectional area of the ruptured pipe.

For the 42-inch I.D. RCS hot leg piping, analyses were performed which show that the flow area of a break, propagated from a crack in this piping which is twice the pipe inside diameter in length, will not exceed an area equivalent to 0.6 times the pipe cross-sectional area. For the 30-inch I.D. pump suction and discharge piping, these analyses have shown that the maximum break area will not exceed an area equivalent to 0.8 times the pipe cross-sectional area. These analyses are presented in the Combustion Engineering Report CENPD-168, "Design Basis Pipe Breaks for C-E Two Loop Plants"

The following criteria were used to determine the specific type of break assumed in the analysis:

1. No breaks were postulated in piping having a nominal diameter less than or equal to one inch.

2. Circumferential breaks were postulated in piping having a nominal diameter between one and four inches.

3. In piping having a nominal diameter equal to or greater than four inches both circumferential and longitudinal breaks were assumed at each of the postulated break locations unless: (1) the primary plus secondary stress in the axial direction was found to be at least twice that in the circumferential direction for the most severe normal and upset load combination transients in which case only a circumferential break was postulated; or conversely, (2) the primary plus secondary stress in the circumferential direction was found to be at least twice that in the axial direction for the most severe normal and upset transients; in which case only a longitudinal break was postulated. Longitudinal breaks were not postulated at terminal ends, provided the piping at the terminal ends contained no longitudinal welds, or at the arbitrary intermediate locations if considered to satisfy the criterion for a minimum number of break locations (per SAR Section 3.6.2.1).

3.6.3 DESIGN LOADING COMBINATIONS

3.6.3.1 <u>Reactor Coolant System</u>

The design loading combinations applied in the design of RCS major components and supports, as appropriate, include the loads produced by the following conditions:

A. normal operating conditions;

B. vibratory motion of the DBE; and,

C. dynamic effects resulting from postulated pipe rupture conditions.

Specifically, the following design loading combinations are applied in the design of equipment restraints:

A. Loading Combination 1 - normal operating loads plus OBE loads;

B. Loading Combination 2 - normal operating loads plus DBE loads;

C. Loading Combination 3 - normal operating loads plus DBE loads plus pipe rupture loads.

The design stress limits applied in evaluating Loading Combination 1 are in accordance with the rules of the ASME Code, Section III, Paragraph NB-3223 for Upset Conditions. The design stress limits applied in evaluating Loading Combinations 2 and 3 are dependent upon the type of system or subsystem analysis used to establish design loadings.

Elastic methods are employed in the system or subsystem analysis used to determine the design loadings produced by Loading Combination 2. With the possible exclusion of those local elements of the restraint system which sustain the direct thrust produced by the postulated rupture, elastic methods are also employed in the system or subsystem analysis used to determine the design loadings produced by Loading Combination 3.

When an elastic system or subsystem analysis is used to determine the design loadings produced by Loading Combinations 2 and 3, the associated design stress limits applied in the design of supports and restraints are in accordance with the rules of the ASME Code, Section III, Appendix F, Subparagraph F-1323.3, for component supports.

Inelastic response of supports and restraints is permitted only during postulated pipe rupture conditions and, when permitted, is limited to those local elements of the system which sustain the direct thrust produced by the postulated rupture, and to the piping segment within which the postulated rupture is assumed. When inelastic response is permitted, the system or subsystem analysis used to determine design loadings is modified to consider the inelastic action, including the compatibility of inelastic strains in the supports and the supported equipment. When inelastic response is permitted, the strains produced by Loading Combination 3, above, are limited to 50 percent of the uniform strain (strain at ultimate stress) of the material.

3.6.3.2 <u>Other Systems</u>

Pipe and pipe restraint motion and design of the pipe restraints and supports for postulated pipe breaks (other than the RCS) were analyzed in accordance with the methods described in Section 3 of Bechtel Topical Report BN-TOP-2, Revision 2. Where plastic deformation of the restraint structure was permitted, the deformation was limited to 10 times the yield deformation, i.e., $\mu \leq 10$.

3.6.4 DYNAMIC ANALYSES

The piping systems requiring dynamic analyses to ensure that the safe shutdown capability of the plant is not compromised following a postulated pipe break are listed in Table 3.6-1. Isometric drawings of these piping systems showing location of the postulated break points are referenced in Sections 3.6.4.1 and 3.6.4.2. Additionally, tables showing historical values for the calculated stress levels, usage factors, and jet thrust forces at these points are contained in Tables 3.6-2 through 3.6-24. For actual current calculated stresses or usage factors, refer to the latest qualifying pipe stress analysis calculation(s).

In determining the dynamic force acting on a pipe following a postulated break, a time independent forcing function was utilized. The forcing function accounts for both the pressure existing in the pipe at the break point and the reaction force exerted on the pipe by the escaping fluid. Pipe friction and restrictions in the flow line were taken into account in the determination of the value of this forcing function. A time independent blowdown model was utilized in the determination of the mass and energy release rates resulting from the postulated break. Isenthalpic flow conditions and constant source pressure were assumed.

In determining the effects of the jet impingement force resulting from a postulated break or crack in a pipe, the total jet force was assumed constant throughout the travel of the escaping fluid and the jet area was assumed to expand uniformly at a half angle of 10°.

A complete description of the mathematical models employed in the dynamic analyses of the piping systems (other than the RCS) is contained in Section 2 of Bechtel Topical Report BN-TOP-2, Revision 2, "Design for Pipe Break Effects." Section 3.9.1.6 addresses the dynamic analysis of the RCS piping performed by CE.

The effects of unrestrained motion of ruptured piping on the containment liner and on structures providing barrier protection for safety-related components were evaluated using the mathematical models described in Bechtel Topical Report BC-TOP-9, Revision 1, "Design of Structures for Missile Impact."

3.6.4.1 High Energy Pipe Break Outside Containment

3.6.4.1.1 Main Steam Lines

3.6.4.1.1.1 General Description

The main steam headers are 38 inches O.D., carbon steel piping. The piping from the steam generators to the main steam isolation valves is Seismic Category 1, designed and fabricated in accordance with the ASME Code, Section III, Class 2 criteria. The remainder of this piping is designed and fabricated in accordance with ANSI B31.1. The wall thickness of the main steam headers is 1.167 inches, however, the portion of the main steam header to which the main steam safety valves are attached has an increased wall thickness of 1.875 inches. The main steam lines pass through the auxiliary building via a pipe tunnel at Elevation 346 feet. Although only the piping upstream of the main steam isolation valves is Seismic Category 1, the entire lengths of both main steam headers have been completely analyzed and designed to withstand the forces associated with the DBE and the OBE.

3.6.4.1.1.2 Safety Evaluation

The historical calculated stress level values at the postulated break points are contained in Tables 3.6-2 and 3.6-3. Section 10.3 describes the main steam lines in detail and discusses the equipment necessary to mitigate the consequences of a break in these lines. A flow restriction is installed in each main steam line inside containment to limit the blowdown rate following a postulated pipe rupture outside containment. In addition, integral flow limiting devices are installed in each steam generator outlet nozzle. This flow restricting nozzle has not been credited in the dynamic analysis but has been credited in the environmental effects analysis.

Breaks are not postulated on these lines between the containment penetrations and the restraints just beyond the main steam isolation valves. This portion of piping has been designed in accordance with criteria listed in Section 3.6.2.1. Restraints have been provided on

both main steam headers which are capable of resisting bending and torsional moments produced by postulated pipe ruptures downstream of the restraints below the isolation valves. Restraints are located above both main steam headers which prevent vertical uplift of the piping in the event of a break on the main steam risers. The restraints provided just below the main steam isolation valves, in conjunction with the restraints above the main steam headers, will ensure the leak tight integrity of containment in the event of any pipe rupture downstream of the valves.

In addition to the break points postulated below the main steam isolation valves, seven additional breaks are postulated on 2EBD-1 and eight additional breaks are postulated on 2EBD-2. All of these additional postulated breaks on 2EBD-1 are located within the turbine building. This structure is not Seismic Category 1 and safety-related equipment is not located in this building. Breaks in this building will not adversely affect the ability to mitigate the consequences of the breaks or reach cold shutdown. The affects of a break postulated at point 30, just outside the auxiliary building will be limited by restraints at the auxiliary building wall (the east end of the main steam tunnel) and at the west end of the main steam tunnel. The bumper at the west end of the tunnel will prevent uncontrolled whip of the main steam risers as well as reduce the impact loading on the wall. The restraints at the east end of the main steam tunnel will act as a guide, and in conjunction with the bumpers prevent pipe whip in the tunnel.

On 2EBD-2, one break is postulated in the main steam tunnel on the elbow at the west end of the tunnel. The remainder of the postulated breaks are located in the turbine building. The main steam tunnel has been modified to withstand the effects of a full area main steam rupture. Grating has been placed over the main steam tunnel which will provide enough vent area to limit the pressure to 14.14 psig with the grating secured. The design pressure of the tunnel walls is 15 psig. The room above the main steam tunnel (to which a postulated main steam break would vent steam) contains component cooling water pumps, heat exchangers, and piping. This equipment is not safety-related and is not Seismic Category 1. This postulated break was reanalyzed for the environmental effects for a power level of 3026 MWt with credit for the flow limiting device located in each steam generator outlet nozzle. The results remain bounded by the above description. Breaks at either point 65 or 73 on 2EBD-2 will not damage any safety-related structure or equipment due to restraint and wall placement.

The main steam headers in the main steam tunnel pass by the emergency feedwater pump rooms. A 2-foot thick Seismic Category 1 wall separates the main steam tunnel from this room. The emergency feedwater pump discharge piping runs parallel to the main steam piping and at its closest point, it is within 10 feet of main steam header #1. The above mentioned wall provides protection for the piping. The location of the postulated break points on the main steam piping, the positioning of restraints, and the design of the main steam tunnel walls will prevent any loss of integrity of the emergency feedwater system due to a break in the main steam headers.

3.6.4.1.2 <u>Main Feedwater Lines</u>

3.6.4.1.2.1 <u>General Description</u>

The main feedwater piping is 24-inch Schedule 80, carbon steel piping (alternate material may be used provided the material is evaluated and approved for use by Engineering, and satisfies the applicable Codes and Standards). Between the steam generators and the main feedwater isolation valves in the north piping penetration room, the main feedwater piping is designed and fabricated in accordance with the ASME Code, Section III, Class 2 criteria. The remainder of the feedwater piping is designed and fabricated in accordance with ANSI B31.1. The portions

of the main feedwater piping from the steam generators to the last stage feedwater heaters (2E1A, 2E1B) have been analyzed and designed to withstand the loads imposed by the DBE and OBE. The piping is routed through non-Seismic 1, non-safety-related areas.

3.6.4.1.2.2 Safety Evaluation

Historical calculated stress level values at the postulated break points are contained in Table 3.6-4. Both main feedwater lines enter containment through the north piping penetration room which is directly below the safety-related electrical penetration room. Main feedwater header #1 (2DBD-2) passes near the electrical equipment room which contains safety-related motor control centers. Check valves are located on each main feedwater line inside the containment. These valves will prevent blowdown of the steam generators following a break at any location in the main feedwater lines outside containment. Even in the event of check valve failure (valve is stuck open) blowdown will be severely restricted by the steam generator feed ring design.

Break points are postulated on each of these lines at the containment penetrations where the line is anchored by the flued head (terminal end). Access to the piping penetration room is available from the chemical storage area, through a locked closed, watertight door, or from the piping room directly below by means of a spiral staircase. The piping room is accessible via a door (3' x 7' x 2") which opens into a large corridor on the 335-foot elevation level. This door is normally closed since the pipe room is directly connected to the piping penetration room and, upon receipt of a containment isolation signal, the penetration room ventilation system functions to maintain a slight vacuum in the penetration rooms.

Design of this door is such that it blows open with a pressure buildup in this compartment of 0.25 psid, which limits peak pressure in the piping and piping penetration rooms. The peak pressure calculated due to a critical crack, using a frictionless subcooled flow model, was determined to be less than 2.2 psig. The room directly above the piping penetration room is the electrical penetration room which contains Channel 4 safety features instrumentation cabling. As the piping penetration room is normally sealed off, the releases of high energy feedwater from a full area break in the feedwater piping in this area would result in overpressurization of the room. The consequences of this failure would be lifting of the ceiling (floor of the electrical penetration room) and damage to safety-related electrical equipment. Therefore, to limit the blowdown from a full area circumferential in the feedwater lines at the containment penetrations, pipe whip restraints are installed in this room to prevent these lines from "backing out" of the flued heads. In conjunction with these restraints, a flow limiting annulus is installed around each of those lines at the penetrations. These annuli are steel plates capable of withstanding full feedwater system pressure and are welded to the penetrations. The clearance between the plates and the feedwater piping is designed such that the blowdown into the piping penetration room, following a line break at the penetration, is limited to that which results from a "critical crack" in this piping. The ceiling of the piping penetration room has been strengthened to withstand a pressure of 2.2 psi in the piping penetration room resulting from a critical crack in the main feedwater piping. The remainder of the postulated break points on the main feedwater lines lies outside the piping penetration room. It was determined that the energy release from a main feedwater "Critical Crack" results in higher peak pressures than for other postulated pipe breaks located in the north piping penetration room.

The electrical equipment room is located in the Seismic Category 1 portion of the auxiliary building at floor Elevation 368 feet. Access to the electrical equipment room is available through a locked closed door from the non-Seismic Category 1 portion of the auxiliary building. The feedwater piping is routed within six feet of this door. A missile proof door installed for the

electrical equipment room is capable of withstanding the jet impingement forces resulting from a full area break in this piping. Seismic Category 1 walls provide separation and protection of the electrical equipment from the effects of a full feedwater line break in other areas.

Breaks have been postulated at every fitting, valve or welded attachment on the main feedwater piping between the pumps discharge and the last stage feedwater heaters. Although the piping is routed through non-safety-related areas, loadings on required structures due to the effects of pipe break have been analyzed to ensure the integrity of the structures.

One main feedwater line, 2DBD-4-24", is routed over the Seismic Category 1 floor slab at Elevation 354 feet which also acts as a ceiling for the emergency feedwater pump rooms. This slab is two feet thick and can withstand the jet thrust load without failure or spalling of the slab. A concrete pad is provided to limit the gap between the pipe and the concrete and reduce the dynamic load factor.

The emergency feedwater pumps and discharge piping, the steam supply to the turbine driven emergency feedwater pump, electrical equipment required to initiate Main Steam Isolation Signal (MSIS) and Emergency Feedwater Actuation Signal (EFAS), and systems required for the safe shutdown will not be impaired as a result of the consequences of a postulated main feedwater pipe break.

3.6.4.1.3 Steam Generator Blowdown

3.6.4.1.3.1 General Description

The steam generator blowdown lines outside containment are 4-inch Schedule 80, carbon steel piping. The portion of piping from the containment penetrations to the containment isolation valves is Seismic Category 1, designed in accordance with the ASME Code, Section III, Class 2 criteria. The remainder of the piping is designed and fabricated in accordance with ANSI B31.1.0. The blowdown control valves, located at the steam generator blowdown tank, reduce steam generator pressure to condenser pressure. A flow measuring orifice is located outside the containment on both lines which will restrict blowdown in the event of a break downstream of the orifice. The blowdown lines from steam generator 2E24A, 2DBD-9, is routed through the south piping penetration room, through the auxiliary building to the steam generator blowdown tank 2T67 located at floor Elevation 354 feet. The blowdown line from steam generator 2E24B, 2DBD-10, is routed through the north piping penetration room, down a hallway at Elevation 335 feet, through the charging pump rooms and to the steam generator blowdown tank.

3.6.4.1.3.2 Safety Evaluation

A detailed stress analysis was not performed on these lines to determine break points. Breaks have been postulated at the terminal ends and at each intermediate pipe fitting, welded attachment, and valve. Section 10.4.8 describes system design and operation.

A postulated break in one of the steam generator blowdown lines does not require safety system actuation to mitigate the consequences of the event.

Four postulated break locations on 2DBD-9 are located in the south piping penetration room. The blowdown and energy release associated with blowdown line breaks was determined using a 2-phase, frictionless flow model. The design of this piping penetration room door is such that it blows open when differential pressure reaches 0.25 psid. Analyses showed that a maximum pressure of less than 2.0 psig, resulting from a guillotine break of the steam generator

blowdown line, was reached in the room. This break was determined to be the worst case break for pressurization of the south piping penetration room. The walls, floors, and ceiling of the penetration room are designed to withstand a pressure of 2 psig, so pressurization will not cause failure of the structure. Safety-related cable trays and cabling which could be affected by breaks at these locations include power to a number of containment isolation valves and power to train 'A' ESF pumps 235A, 2P60A, and 2P89A. Failure of these components due to a break in the blowdown line from steam generator 2E24A will not impair the ability to shutdown. Isolation of containment is not required as a result of the event, however, valves inside containment will assure containment integrity.

Breaks are also postulated on 2DBD-9 in the piping room below the south penetration room. One safety-related cable tray is located in this room. Shutdown cooling system valves which are powered from this tray include one suction valve from the RCS and one of four Low Pressure Safety Injection (LPSI) valves. These valves can be manually opened when required to safely shutdown the plant. A cable providing power to the train 'A' suction valves from both the refueling water and the NaOH tanks are located near break points postulated on both 2DBD-9 and 2DBD-10 in the room below the steam generator blowdown tank.

Failure of these valves does not impair the ability to reach cold shutdown. One restraint has been provided to prevent impact of the shutdown cooling line, 2GCB-5-14" by 2DBD-9. This restraint provided sufficient protection to ensure the integrity of this line. There is no other safety-related cabling or equipment located in this room.

Two postulated break points on 2DBD-10 are located in charging pump room A and one postulated break point is located in charging pump room B. Due to separation by barriers, a steam generator blowdown line break in any one room cannot cause loss of function to more than one pump and its associated controls. Therefore, two pumps, powered from separate power supplies, are available in the event of these postulated pipe breaks to borate the RCS, if required for shutdown.

Safety-related cables are also located in a hallway outside the charging pump room 5 through which 2DBD-10 is routed. However, the cabling at this location, if damaged by the effects of high energy pipe break, will not impair the ability to reach cold shutdown. With the exception of one safety-related cable tray, safety-related electrical cables, instrumentation and equipment are not located in the piping hallway at Elevation 335. This cable tray contains cables for the motor driven emergency feedwater pump and associated equipment. Loss of this equipment is acceptable since the turbine driven emergency feedwater pump is available for plant cooldown. If off-site power is available, the normal condensate system can also bring the plant to a hot shutdown condition. The energy associated with a steam generator blowdown line break is insufficient to impair safety-related piping in the area.

A number of postulated break points on 2DBD-10 are located in the piping room below the north piping penetration room. This room and the penetration room above are connected via a spiral staircase. Pressurization of these rooms due to a steam generator blowdown line break has been determined to result in less severe consequences than a main feedwater critical crack which is also postulated to occur in these rooms. Safety-related cabling which could possibly be affected by these breaks include control cables for the emergency feedwater containment isolation valves, an emergency feedwater flush line valve, and a service water valve on the return header to the reservoir. One isolation valve in each of the emergency feedwater supply lines is designed to fail closed upon loss of electrical power. Since these lines feed the affected steam generator, isolation is required and assured by this design. Safe shutdown may be attained via emergency feedwater to the unaffected steam generator. Breaks on 2DBD-10 are

also postulated to occur in the north piping penetration room above the floor at Elevation 356. Containment isolation valves for emergency feedwater supply to 2E24B, the blowdown line from 2E24B, and the service water supply and return to two of four containment cooling coils and their associated power cables are located in this room. The loss of these valves, however, is inconsequential to the safe shutdown capability of the plant.

Steam generator blowdown line pipe breaks outside containment may be isolated when detected by closure of the inner containment isolation valve in the same line. Indication of the break is provided by high auxiliary building sump level, low steam generator level and high feedwater flow, and no flow to the steam generator blowdown tank from the affected steam generator. With the exception of the one restraint provided on 2DBD-9, which ensures the integrity of the shutdown cooling line, restraints are not required on the steam generator blowdown lines outside containment for plant safety. Analysis has shown that the consequences of any one postulated pipe break will not result in loss of function to systems required for safe shutdown.

3.6.4.1.4 Emergency Feedwater

3.6.4.1.4.1 General Description

The discharge piping for the safety related emergency feedwater pumps (2P7A and 2P7B) discharge piping is 4-inch Schedule 80 carbon steel piping designed in accordance with ASME Code, Section III Class 3 criteria up to the containment isolation valves. The remainder of the emergency feedwater discharge piping is designed in accordance with the ASME Code, Section III, Class 2 criteria. The entire piping, from the pump discharges to the connections on the main feedwater lines inside containment, is designed to withstand the DBE and OBE. The discharge piping from both pumps is routed outside the individual pump rooms and to a piping hallway at floor Elevation 335 feet. At this location both discharge lines split into two lines, with one of each being routed to the north piping penetration and one of each to the south piping penetration room. Lines 2DBC-1 and 2DBC-4 are routed to the south piping penetration room where the lines combine into 2DBB-3 before penetrating containment. Lines 2DBC-2 and 2DBC-3 are routed to the north piping penetration room where these lines combine into 2DBB-4 before penetrating containment. System operation is described in Section 10.4.9.

The discharge piping for the non-safety related Auxiliary Feedwater pump (2P75) is 4-inch Schedule 80 carbon steel, designed in accordance with ASME Code, Section III, Class 3 criteria from the first of the two series check valves to its tie-in with the EFW discharge piping. This portion of the piping is designed to withstand the DBE and OBE.

3.6.4.1.4.2 Safety Evaluation

A detailed stress analysis was not performed on these lines to determine break points. Alternatively, pipe breaks have been postulated at the terminal ends and at each intermediate pipe fitting, welded attachment, and valve. A postulated break of an emergency feedwater pipe would not result in protective system actuation. Therefore the consequences of any one break cannot result in loss of function to required safety systems, but loss of redundancy is permitted.

The emergency feedwater piping is routed through the same rooms as the steam generator blowdown lines. Therefore similar safety-related equipment and piping could be effected by a postulated break of these lines in the two piping penetration rooms and the two piping rooms below. In the south piping penetration, however, pipe whip of 2DBC-4 could cause damage to the integrity of 2GCB-7-6", a shutdown cooling return line. A restraint will be provided to prevent this. Further protection is not required in either piping room or piping penetration room.

Both the emergency feedwater pump discharge piping and suction piping is located in the hallway just outside the emergency feedwater pump rooms. The service water supply to the pump suction is of larger nominal pipe size but thinner wall thickness than the pump discharge piping. Therefore, a through-wall crack was postulated to occur in the one pump suction piping due to a rupture of the other pump discharge piping. The flow rate through this crack is not sufficient however to cause loss of pressure or flow to the pump suction. The required flow rate of the pumps is well below the makeup capability of the service water system.

The routing of the service water supply lines to both the emergency feedwater pumps and their associated room coolers provides sufficient separation to ensure the operation of one pump and cooler in the event of any postulated pipe break in the other pump's discharge line. Therefore, pipe break restraints are not required nor provided in this area. The protection provided on these lines ensures that any postulated emergency feedwater pipe break will not result in loss of function to required safety systems.

3.6.4.1.5 Main Steam Supply to Emergency Feedwater Pump Turbine Driver

3.6.4.1.5.1 General Description

The main steam supply lines to the turbine driven emergency feedwater pump, 2P7A, are 4-inch Schedule 40, carbon steel piping. The main steam supply to the pump driver may be drawn from either or both main steam headers. Connections are provided on both main steam headers upstream of the main steam isolation valves, on the Seismic Category 1 portion of piping. Motor operated gate valves are provided to isolate either or both main steam headers from the emergency feedwater pump driver. The two steam supply connections are run together and one line is routed to the emergency feedwater pump room. Check valves are provided before this junction to prevent loss of steam supply in the event of a break in one main steam header. The entire main steam supply line is Seismic Category 1, designed in accordance with the ASME Code, Section III, Class 3 criteria. The supply line is routed through a vertical shaft near the new fuel storage area and piping drops from Elevation 418 feet, 4 inches to 350 feet, 3 inches. The piping then runs through the fuel pool pump rooms to the emergency feedwater pump room. The safety-related piping located in the area includes service water, service water supply to emergency feedwater pump suction, and emergency feedwater pump discharge piping as well as electrical cabling.

3.6.4.1.5.2 Safety Evaluation

Historical calculated stress level values at the postulated break points determined by stress profile are contained in Table 3.6-5. A summary description of the main steam and emergency feedwater systems are provided in Sections 10.3 and 10.4.9, respectively. A break in this 4-inch steam line will not require safety systems actuation since the blowdown in the line is within the makeup of the main feedwater pumps to the steam generators.

Breaks postulated between the main steam header nozzles and the junction of the two lines are located above Elevation 420 feet. The only safety-related electrical equipment or cabling in this area are the control channels to the steam supply isolation valves 2CV-1000-1 and 2CV-1050-2. A break in one line, however, could not result in failure of the other line's isolation valve control channel due to separation by distance and location of the main steam headers. The breaks postulated at points 53 and 55 are located over the new fuel storage area, at least 11 feet above the 404 feet floor elevation. There is no safety-related equipment in the area to be affected by breaks in that portion of piping. The piping then makes a 68-foot vertical drop through an enclosed shaft to Elevation 350 feet.

Breaks postulated at points 76, 80, 82, 100 and 105 are located in a piping hallway and the fuel pool pump room at floor Elevation 335 feet. The safety-related piping in this area is all of equal or larger nominal diameter and equal or larger wall thickness so the integrity of other piping will not be impaired. A cable tray containing channellized safety-related cables also passes in the area. The cables include power supply for the emergency feedwater motor driven pump suction valves and room cooler. A barrier has been provided to protect this cable tray from the dynamic effects of pipe whip and jet impingement. The safety-related cabling is rated for environmental conditions associated with a LOCA. The barrier provided and the low blowdown rate will ensure that the design ratings of the cable are not exceeded.

During normal plant operating conditions, this line is pressurized to valve 2CV-0340-2 which is normally closed. Accordingly, the terminal end of the line is postulated to be at the piping connection to the closed valves. These valves have been located outside the emergency feedwater pump room. The valves are located such that the consequences of a postulated break at the valve would not cause loss of function to systems required for plant shutdown.

3.6.4.1.6 Main Steam Supply to the Atmospheric Dump Valves

3.6.4.1.6.1 General Description

The main steam supply lines to the atmospheric dump valves are 10-inch Schedule 60, carbon steel piping. Both lines are Seismic Category 1 and are designed in accordance with the ASME Code, Section III, Class 2 criteria up to and including the dump valves. The piping connection for the atmospheric dumps is provided upstream of the main steam isolation valves. This ensures the capability of plant cooldown via steam dump in the event of a Main Steam Isolation Signal (MSIS). See Section 10.3 for further discussions of system operation.

3.6.4.1.6.2 Safety Evaluation

Historical calculated stress level values at the postulated break points are contained in Table 3.6-6. The two atmospheric dump paths, one connected to each of the redundant main steam headers, are located such that a pipe break in either 2EBB-8 or 2EBB-9 will not impact or damage the other pipe. In the event of the failure of one atmospheric dump valve to open, in addition to the break of the other line, the main steam safety valves enable the plant to cooldown.

Power to the main steam isolation valves will not be impaired by a postulated pipe break of either atmospheric dump line. Separation by distance and the location of structures and equipment will ensure that systems required to mitigate the consequences of the pipe break or shutdown the plant are not damaged. Section 10.3 describes equipment required to mitigate the consequences of a break in these lines.

3.6.4.1.7 Charging

3.6.4.1.7.1 General Description

The charging line outside containment is 2- or 3-inch Schedule 160, carbon steel piping designed in accordance with the ASME Code Section III, Class 2 criteria. The charging pump discharge piping is the only portion of the charging line which qualifies as high energy piping. The three charging pumps are located in separate rooms at Elevation 335 feet. The pump discharges are run through the neighboring piping rooms, the south piping penetration room

and into containment. In the piping penetration room, the charging line reduces from 3-inch to 2-inch nominal piping. At this point the line number changes from 2CCB-8 to 2CCB-25. The charging pump discharge and suction paths are Seismic Category 1. System operation is discussed in Section 9.3.4.

3.6.4.1.7.2 Safety Evaluation

Historical calculated stress level values at the postulated break points are contained in Table 3.6-7. In accordance with the criteria outlined in Section 3.6.2.2, only guillotine breaks are postulated in the line.

The postulated break points are located in one of three rooms: the charging pump room, the south piping penetration room, and the piping room below. The three charging pumps are each located in a separate room. A second charging path is provided through the High Pressure Safety Injection (HPSI) line. Each pump is capable of being isolated so that a break in any one of the three charging pump rooms will not result in the loss of more than one charging pump or charging path. Power supplies for each of the pumps and associated instrumentation are also separated by the rooms.

Breaks postulated on 2CCB-25 are located in the south piping penetration room. Safety-related electrical trays, piping, and valves located in the vicinity of the line were assumed to fail. However, the ability of the plant to shutdown was not impaired assuming a single active failure in addition to the consequences of the pipe break. Since a break of the charging line will not cause protective system actuation, loss of required safety system redundancy is acceptable.

One break has been postulated on 2CCB-8 in the piping room below the south piping penetration room. The consequences of this postulated charging line break could cause a through-wall crack in the shutdown cooling line 2GCB-5. To ensure the availability and performance of the shutdown cooling system, one restraint has been placed on 2CCB-8 which will prevent impact of 2GCB-5 by 2CCB-8. The consequences of this postulated break will not impair the ability to shutdown, or cause loss of both redundant trains of a safety system. Therefore, adequate protection has been provided for the charging lines by existing layout, restraints, and structures.

3.6.4.1.8 Letdown

3.6.4.1.8.1 General Description

The letdown line outside containment is 2-inch Schedule 160 and Schedule 40 stainless steel piping designed in accordance with the ASME Code, Section III, Class 2 criteria up to the letdown heat exchanger. The line is designed for the effects of a DBE up to the first pipe anchor downstream of the letdown control valves. The letdown control valves are located in the south piping penetration room. The letdown heat exchanger is located in a room on the floor below. System operation is described in Section 9.3.4.

3.6.4.1.8.2 Safety Evaluation

Historical calculated stress level values at the postulated break points are contained in Table 3.6- 8. Downstream of the letdown control valves breaks are postulated at every fitting. In the event of a letdown line break outside containment, the high break flow will cause a high temperature alarm at the regenerative heat exchanger discharge and generate a signal to close the letdown valve inside containment. A low pressure alarm at the letdown heat exchanger

discharge will also alert the operator. A letdown line break results in blowdown of the RCS and subsequent Safety Injection Actuation Signal (SIAS) generation. Redundant SIAS signals are provided to the two letdown valves inside containment which close the valves and terminate the high pressure blowdown and terminate the event. Therefore operator action is not required to mitigate the consequences of the event.

Breaks postulated in the south piping penetration room will not impair plant shutdown capability or cause loss of redundancy to required safety systems.

The mass and energy release rate to the room was determined using a frictionless subcooled flow model and RCS pressure was assumed to remain constant. As a result of this analysis it was determined that steam generator blowdown in the penetration room results in higher room pressure and therefore is more limiting.

Breaks postulated in the piping room below the penetration room and in the letdown heat exchanger room will not result in consequences unacceptable to plant safety. Although the letdown line passes over the shutdown cooling line, whip of a 2-inch Schedule 40S pipe will not damage the 14-inch Schedule 20 shutdown cooling piping. Therefore, restraints are not required on this line to ensure plant safety.

3.6.4.1.9 <u>Steam Supply to Concentrators</u>

The boric acid concentrator and the waste concentrator are currently not in use and are maintained in long term shutdown condition. The following description and safety evaluation are provided in the event the concentrators are placed in service.

3.6.4.1.9.1 <u>General Description</u>

Steam is supplied to the boric acid concentrator (2M39) and waste concentrator (2M41) from the Unit 1 or Unit 2 main steam lines or from the Unit 1 startup boiler. The concentrators do not perform safety-related functions and therefore the steam supply lines are designed to non-Seismic quality group D requirements. The main steam supply piping to the pressure control valves is 3-inch Schedule 40 carbon steel piping. The pressure reducing station and distribution header is located in the south end of the piping hallway at Elevation 335 feet. Here the steam supplies from all three sources are reduced in pressure to 100 psig and run into a common header. From this header, two 6-inch Schedule 40 carbon steel lines are routed to the concentrators. Within the concentrator rooms the steam is reduced in pressure and desuperheated prior to entering the concentrator package. The piping from the second pressure control valves to the concentrators is 10-inch.

3.6.4.1.9.2 <u>Safety Evaluation</u>

Pipe breaks have been postulated at the terminal ends and at each intermediate pipe fitting, welded attachment, and valve on all high energy piping supplying steam to the boric acid or waste concentrators. A break occurring at any of the postulated locations would not result in protective system actuation. Therefore the consequences of any one postulated break cannot result in loss of function to required safety systems, but loss of safety system redundancy is permitted.

The main steam supply lines from Unit 1 and Unit 2 are routed from the east and north ends of the piping hallway to the pressure reducing station. The main service water headers, emergency feedwater discharge piping and steam supply to the emergency feedwater pump

driver are located in the vicinity of postulated breaks. However the size and wall thickness of the steam supply piping is insufficient to damage the safety-related piping listed. Also the consequences of any postulated break will not cause loss of function to any safety-related system due to the separation provided in redundant systems.

For pipe breaks postulated downstream of the first pressure reducing valves the energy of the whipping pipe will be greatly reduced due to the lower steam pressure. With the exception of breaks postulated near the waste concentrator on 2HBD-180-6 inches/10 inches, adequate separation is provided for postulated breaks on the lower pressure steam supply lines. The consequences of postulated breaks located in the concentrator room could result in the development of throughwall leakage cracks in either the refueling water tank or sodium hydroxide tank discharge lines. Since the Refueling Water Tank Discharge line serves both safety trains, loss of integrity is not acceptable. Three restraints have been added to preclude this discharge piping failure as a result of the consequences of postulated pipe breaks in the steam supply piping.

3.6.4.1.10 Safety Injection System

3.6.4.1.10.1 General Description

The discharge piping from the High Pressure Safety Injection pumps to the isolation valves at the containment penetration is 4" Schedule 80 stainless steel pipe which splits into four 3" Schedule 160 pipes per train and is reduced to 2" Schedule 160 pipe at the isolation valves. This piping is designed to the ASME Code, Section III, Class 2 criteria. The Safety Injection System provides both passive and active means of injection to the RCS in the event of a design basis event. The portion of the piping from the pump discharge to the isolation valve is pressurized to 635 psig during normal operation by the HPSI Pressurization System in order to prevent leakage from the Safety Injection Tanks into the HPSI header, which could result in gas voids. Since this system only provides enough flow to keep the system pressurized, the temperature of the piping and the fluid contained in it will be ambient. This portion of the system will be at higher pressures during a design basis event; however, this will occur less than 2% of the time and, therefore, only the pressurization due to the HPSI Pressurization System and/or leakage is considered for high energy line breaks.

3.6.4.1.10.2 Safety Evaluation

Pipe breaks were considered to be possible at any location. Analysis has shown that a line break will not result in more severe effects than if the piping were moderate energy, since the source of pressurization is extremely low flow. The piping will depressurize very quickly and the jet forces resulting from a break will be negligible. Spray effects and flooding are enveloped by the effects of other line breaks which have already been considered.

3.6.4.2 High Energy Pipe Break Inside Containment

3.6.4.2.1 Reactor Coolant System

3.6.4.2.1.1 General Description

The RCS major piping is stainless steel clad, carbon steel piping; designed and fabricated in accordance with the ASME Code, Section III, Class 1 criteria. The major piping consists of four 30-inch I.D. cold legs (reactor coolant pump suction and discharge) and two 42-inch I.D. hot legs. A plan view showing the location and configuration of the reactor coolant piping with respect to structures, equipment, and restraints is shown in Figure 3.6-31. System operation is described in Section 5.1.

3.6.4.2.1.2 Safety Evaluation

Postulated RCS piping break locations, break orientations, and break areas are described in Section 3.6.2.

As discussed in paragraph 3.6.2.1.A, postulated breaks in the RCS main loop piping were eliminated from the ANO-2 RCS dynamic effects design basis by application of leak-before-break (LBB) methodology. However, in accordance with NUREG-1061 Volume 3, the non-mechanistic RCS main loop pipe rupture design basis is maintained for containment design, ECCS performance analysis, and electrical and mechanical environmental qualification.

The original design effort for the ANO-2 RCS included the placement of restraints and barriers to meet the requirements for the protection of systems and components from the dynamic effects of LOCA. The wire rope restraints on the reactor coolant pumps shown in Figure 3.6-31 were originally installed to limit the horizontal movement of the pumps following postulated guillotine pipe breaks in the pump suction and discharge piping. To limit the vertical motions of the pumps following a postulated guillotine break at the pump suction, built-up beams (not shown in Figure 3.6-31) were located directly above each of the pump motors. The restraints located in the pipe tunnels for each of the pump discharge pipes, shown in Figure 3.6-31, were originally installed to limit the motion of this piping following a postulated guillotine rupture at any of the four reactor vessel cold leg pipe nozzles. In the case of a postulated guillotine break within the vessel subcompartment in either of the two hot leg pipe spools, the steam generator support system and the reactor vessel support system would have limited the separation of the piping at the break and maintain the resulting subcompartment pressure transient within the design limits of the vessel support system. The original design basis for the reactor and steam generator subcompartment differential pressurization did take credit for the LOCA restraints on the MCL when calculating the break size, as discussed in Section 6.2.1.2.3.1.

Steam generator cavity walls and primary shield walls provide barriers which limit jet impingement and other effects of pipe break. The results of containment and subcompartment pressure analyses are provided in Section 6.2.1.

The reactor vessel is mounted on three column supports as shown in Figures 3.8-13A and 5.5-12. These supports, in conjunction with the horizontal supports, also shown in Figure 3.8-13A, serve to limit motion of the reactor vessel under the combined jet thrust and the vessel subcompartment pressure loading conditions resulting from postulated pipe breaks within the vessel subcompartment. The restraints located in the pipe tunnels for each of the pump discharge pipes, shown in Figure 3.6-31, serve to limit the motion of this piping following a postulated guillotine rupture at any of the four reactor vessel cold leg pipe nozzles. In the case of a postulated guillotine break within the vessel subcompartment in either of the two hot leg pipe spools, the steam generator support system and the reactor vessel support system will limit the separation of the piping at the break and maintain the resulting subcompartment pressure transient within the design limits of the vessel support system. As described in Section 6.2.1.2.2, the reactor vessel cavity is no longer required to consider the dynamic effects of a postulated pipe rupture based upon leak-before-break (LBB) considerations. However, the previous analysis remains bounding and is the basis for support design.

3.6.4.2.2 Main Steam

3.6.4.2.2.1 General Description

The main steam piping inside containment is 38-inch O.D. carbon steel with a wall thickness of 1.167 inches. Both headers are Seismic Category 1 up to the main steam isolation valves outside containment. This portion of the main steam headers is designed in accordance with the ASME Code, Section III, Class 2 criteria. The location and configuration of the main steam headers with respect to structures, equipment, restraints and other piping is shown in Figure 3.6-32. The main steam headers connect to a 36-inch diameter (nominal) nozzle at the top of the steam generators. A 38 inches x 36 inches reducer is located at the steam generator nozzle, and the pipe then passes over the steam generator cavity wall at Elevation 436 feet, and along the containment wall to the penetrations. Venturi flow elements are located in each header which limit blowdown in the event of a break downstream of the element. Integral flow limiting devices are also installed in the steam generator nozzles which further reduce the dynamic effects. This reduction has not been credited in the dynamic analysis.

3.6.4.2.2.2 Safety Evaluation

Historical calculated stress level and jet thrust force values at the postulated break points are contained in Tables 3.6-9 and 3.6-10. The systems and equipment necessary to mitigate the consequences of a main steam break are described in Sections 10.3 and 15.1.14.

The main steam piping inside the containment was reanalyzed due to replacement of the steam generators and power uprate. Based on the criteria outlined in Section 3.6.2.1, the reanalysis eliminated the arbitrary intermediate breaks previously postulated. However, the pipe whip restraints originally installed on these lines to mitigate the effects of these breaks are left in place. Break points were postulated only at the terminal ends of the piping. The steam generator nozzles and the flued heads at the containment penetration are considered terminal ends. A total of eight restraints are provided on 2EBB-1 and seven are provided on 2EBB-2. The 15 restraints provided will prevent impact on the containment liner by the main steam piping. The environmental conditions in containment which result from main steam breaks are discussed in Section 6.2.1. A main steam break inside containment cannot, due to separation and location of structures and restraints, affect the initiation of Main Stream Isolation Signal (MSIS) or Containment Spray Actuation System (CSAS), or prevent isolation of feedwater to the affected steam generator. Also, a break will not affect the integrity of the other steam generator or its association main steam line or cause loss of the emergency feedwater, shutdown cooling, or safety injection systems.

3.6.4.2.3 Main Feedwater

3.6.4.2.3.1 General Description

The main feedwater piping inside containment is Schedule 80, 24-inch O.D. carbon steel piping. Each line is Seismic Category 1 up to the motor operated isolation valve outside containment and the piping is designed in accordance with the ASME Code, Section III, Class 2 criteria. With the exception of the 18-inch steam generator nozzles, the entire main feedwater line lies outside the secondary shield walls. Immediately outside the steam generator cavity walls, the piping drops down with a 90 degree 18 inch by 24 inch reducing elbow. Check valves are provided in both main feedwater lines which prevent blowdown of the steam generators in the event of a main feedwater break on the pump side of the valves.

3.6.4.2.3.2 Safety Evaluation

Historical calculated stress level and jet thrust force values at the postulated break points are contained in Tables 3.6-11 and 3.6-12. The systems and equipment necessary to mitigate the consequences of a main feedwater break are the same as those required for a main steam break. Six pipe break restraints are provided on each main feedwater header. These 12 restraints together with structures and physical separation guarantee the ability to mitigate the consequences of the event and bring the plant to cold shutdown.

The main feedwater piping inside the containment was reanalyzed due to replacement of the steam generators and power uprate. Based on the criteria outlined in Section 3.6.2.1, the reanalysis eliminated the arbitrary intermediate breaks previously postulated. However, the pipe whip restraints originally installed on these lines to mitigate the effects of these breaks are left in place. Break points were postulated only at the terminal ends of the piping. The steam generator nozzles and the flued heads at the containment penetration are considered terminal ends. For the breaks postulated at the steam generator nozzles, one restraint is provided on each line which will prevent pipe whip. The steam generator and steam generator cavity wall also act as physical barriers which limits the effects of a break at the nozzles. The effects of breaks which are postulated at the piping penetrations are limited by separation and the steam generator cavity walls. A break on 2DBB-2 at the penetration could also cause loss of emergency feedwater supply to the same steam generator and/or loss of service water supply to two of four containment cooling coils. Loss of both emergency and main feedwater to one steam generator does not affect the ability to mitigate the consequences of the break or to reach cold shutdown. The MSIS will isolate both steam generators and Emergency Feedwater Actuation Signal (EFAS) then will supply emergency feedwater to the intact steam generator only. The energy released to containment atmosphere will be limited by check valves in the feedwater lines which prevent blowdown of the affected steam generator and isolation of main feedwater flow affected by MSIS. There are no safety-related electrical equipment or cables, that are required to mitigate the event or shutdown the plant, which could be adversely affected either by direct jet impingement, pipe whip, or environmental conditions associated with breaks postulated at the piping penetrations.

The environmental conditions caused by a main feedwater break inside containment are less severe than that due to a main steam line rupture. Safety features equipment required to mitigate the consequences of a secondary system pipe rupture have been designed for a main steam break environment. See Section 6.2.1 for the environmental conditions associated with the worst case main steam break.

3.6.4.2.4 Steam Generator Blowdown

3.6.4.2.4.1 General Description

The steam generator blowdown lines are 4-inch nominal diameter Schedule 80, carbon steel piping designed and fabricated in accordance with the ASME Code, Section III, Class 2 criteria. The blowdown lines are Seismic Category 1 up to the air operated isolation valves outside containment. The steam generator blowdown lines are routed from the steam generator nozzles to penetrations in the steam generator cavity wall near Elevation 351 feet, and then continue to the blowdown tanks which are located outside containment. Motor operated isolation valves are located inside containment near the penetrations.

3.6.4.2.4.2 Safety Evaluation

Historical calculated stress level and jet thrust force values at the postulated break points are contained in Tables 3.6-13 and 3.6-14. Section 10.4.8 describes system design and operation.

The steam generator blowdown piping inside the containment was analyzed due to replacement of the steam generators and power uprate. Based on the criteria outlined in Section 3.6.2.1, the analysis eliminated the arbitrary intermediate breaks previously postulated. Breaks were postulated only at the terminal ends of the piping. The steam generator nozzles, the flued heads at the containment penetrations, and the anchor support at elevation 355′-7″ on line 2DBB-7 are considered terminal ends.

A full break of a steam generator blowdown line would have the same effect as a main feedwater break of approximately six percent full break area. This small break is not large enough to constitute protective action. The blowdown from this break is within the additional capacity of the main feedwater pumps, and in conjunction with the feedwater control system, EFAS will not be initiated. The affected steam generator can be determined by instrumentation in the control room. Indication of low steam generator level, high feedwater flow, high containment temperature and pressure, and high sump level would be obtained.

Steam generator instrument tubing associated with RPS and ESFAS is in the affected area of postulated pipe breaks of the steam generator blowdown lines. Because of separation by distance or barriers such as the steam generator cavity walls and the steam generator, the effect of pipe whip and jet impingement on the instrument tubing is insignificant.

Restraints are not provided on the steam generator 2E24A and 2E24B blowdown lines because of the small energy involved in these lines and the inability of jet impingement or pipe whip to disable required equipment and piping.

One break, outside the steam generator 2E24B cavity wall, which is postulated on 2DBB-8 is located at the containment penetration at Elevation 358 feet. The energy associated with 2DBB-8 is insufficient to damage other safety-related piping in the area such as the containment cooling coil service water supply, 2HBC-104-12", and the emergency feedwater, 2DBB-4-4". A conduit carrying an instrument cable from a speed indicator element on RC Pump 2P32C is in the vicinity of the fluid jet from the circumferential break in the blowdown nozzle of steam generator 2E24B. Due to the distance of the conduit from the jet source, the effect of jet impingement on the conduit is insignificant.

There are two breaks postulated outside the steam generator 2E24A cavity wall on 2DBB-7. One is located at the containment penetration and the other at the in-line anchor located at Elevation 355′-7″. The safety-related piping located in this piping penetration area include containment cooling coil service water supply, 2HBC-103-12", containment spray headers, 2HCB-3-10", and 2HCB-4-10", safety injection headers, and emergency feedwater, 2DBB-3-4". The energy associated with a break of 2DBB-7 is insufficient to damage this safety-related piping. The floor over the piping penetration area is 1-foot, 6-inch thick concrete, therefore providing protection for safety-related electrical equipment above. A red channel ground cable is located near the postulated breaks, however loss of this cable will not cause loss of functions to the equipment which it serves.

3.6.4.2.5 Emergency Feedwater

3.6.4.2.5.1 General Description

The emergency feedwater piping inside containment is 4-inch Schedule 80 carbon steel piping. Both emergency feedwater lines are Seismic Category 1 inside containment and are designed in accordance with the ASME Code, Section III, Class 2 criteria. The emergency feedwater lines are connected to the main feedwater lines downstream of the main feedwater check valves. Check valves on the emergency feedwater lines are located close to these connections. This prevents losing both feedwater sources to one steam generator in the event of a pipe rupture in either pipe on the pump side of the check valves. In addition to the check valves inside containment, motor operated gate valves provide isolation outside containment.

3.6.4.2.5.2 Safety Evaluation

Historical calculated stress level and jet thrust force values at the postulated break points are contained in Tables 3.6-15 and 3.6-16. Section 10.4.9 describes system design and operation.

A break in one of the emergency feedwater lines upstream of the check valves does not require safety system actuation to mitigate the consequences of the event.

The emergency feedwater piping inside the containment was reanalyzed due to replacement of the steam generators and power uprate. Based on the criteria outlined in Section 3.6.2.1, the reanalysis eliminated the arbitrary intermediate breaks previously postulated. Breaks are postulated only at the terminal ends of the emergency feedwater piping. The containment penetrations and the connections to the main feedwater piping are considered terminal ends. Under normal power generation operating conditions the emergency feedwater piping up to the check valve inside containment is not pressurized. This portion of pipe is pressurized during startup, hot standby, hot shutdown, and plant cooldown. The breaks postulated on the pump side of the check valve will be of small consequence. Blowdown from the steam generator is prevented by the check valve. The pump discharge pressure will quickly decrease when the pipe breaks. The energy involved in the emergency feedwater breaks is not sufficient to impair the function of other safety-related piping in the same penetration areas.

Breaks postulated at the connections to the main feedwater lines will be treated as small main feedwater breaks. This piping is on the main feedwater side of the check valves and will be hot and pressurized during normal operation. Postulated breaks at these locations will not prevent isolation of the effected steam generator, or impair emergency feedwater supply to the intact steam generator assuming a single active failure. The energy of an emergency feedwater break is not sufficient to damage other safety-related piping. Electrical equipment and instrumentation located in the areas of postulated breaks on 2DBB-4 is not safety-related.

Below the 2DBB-3 connection to the south steam generator (SG-A) are located Channel 1 cable trays containing steam generator pressure and level signals as well as Channel 3 pressure and level transmitters, none of which are affected by a break of the emergency feedwater line at its connection to the main feedwater line.

3.6.4.2.6 Pressurizer Surge

3.6.4.2.6.1 General Description

The pressurizer surge line is Schedule 160, 12-inch stainless steel pipe designed in accordance with the ASME Code, Section III, Class I criteria. The piping is part of the RCS and is Seismic Category 1. The surge line is located totally within the south steam generator cavity and is routed from the reactor coolant hot leg to the nozzle at the bottom of the pressurizer. Pressurizer operation is discussed in Section 5.5.10.

3.6.4.2.6.2 Safety Evaluation

Historical calculated stress level, usage factor, and jet thrust force values at the postulated break point are contained in Table 3.6-17. The reanalysis performed due to replacement of the steam generators and power uprate did not change these break locations.

One of the four safety injection lines, 2CCA-22-12", is located in the vicinity of the pipe breaks postulated at the 45° elbow. While the safety injection line is the same nominal pipe size as the pressurizer surge line, it is of thinner wall thickness. Therefore, in the event of a postulated pipe break at the 45° elbow, a through-wall crack on the safety injection line has been assumed. This would not cause loss of function of the safety injection line but will result in lower injection flow rate to the RCS. This through-wall crack, of course, will result in loss of less injection flow to the reactor vessel than if a complete break of one of the reactor coolant pump discharge pipes is postulated. Also, the surge line break area is smaller than the original non-mechanistic design basis break area. Therefore, the capability of the plant to mitigate the consequences of the break will not be impaired. Furthermore, as noted in paragraph 3.6.2.1.A, the postulated break locations on the surge line were considered in the RCS structural analysis. Surge line response to RCS hot leg motions from Breaks 1 to 5 listed in Table 3.6-1A was determined by analysis. Response of the surge line to pressurizer motions is based on smaller pipe breaks at the top of the pressurizer. These breaks are not affected by LBB, replacement steam generators, or power uprate, and their effects on the surge line are enveloped by the effects of the five major branch line pipe breaks listed in Table 3.6-1A.

As shown on the isometric, pipe break restraints have been provided at five locations which minimize the effects of pipe break. Restraints are suitably located to limit pipe whip as a result of plastic hinge formation at the other postulated break points. A pressurizer surge line break results in a small break LOCA. The consequences of these breaks will be less severe than that of the original non-mechanistic design basis event described in Section 6.2.1. A pipe break at any of the postulated locations will not prevent required safety system actuation or impair the ability to mitigate the consequences of the surge line break.

3.6.4.2.7 Shutdown Cooling

3.6.4.2.7.1 General Description

The shutdown cooling line is Schedule 140, 14-inch stainless steel pipe designed in accordance with the ASME Code, Section III, Class I or 2 criteria. The piping up to valve 2CV-5084-1 is normally exposed to reactor coolant temperature and pressure and therefore is high energy piping. The remainder of the shutdown cooling piping inside containment is moderate energy. Valves 2CV-5084-1 and 2CV-5086-2 are closed when the RCS pressure is above 300 psia. Shutdown cooling may be initiated by opening these valves following cooldown of RCS via steam dump. System operation is described in Section 9.3.6.

3.6.4.2.7.2 Safety Evaluation

Pipe breaks have been postulated to occur at the terminal ends and at each intermediate pipe fitting, welded attachment, and valve. Uncontrolled pipe whip of the shutdown cooling line will not damage the containment liner, result in a LOCA break size larger than the design basis event, or impair the ability to mitigate the consequences of the event and reach cold shutdown. The location of structures and safety-related components will also ensure that jet impingement will not impair safety features actuation. Breaks in the shutdown cooling line up to the first isolation valve will have the same consequences as a LOCA. Breaks have not been postulated in the shutdown cooling system downstream of 2CV5086-2 because the piping is above 275 psig or 200 °F less than two percent of system operating time. See Section 3.6.1.

3.6.4.2.8 Safety Injection

3.6.4.2.8.1 General Description

The Safety Injection System (SIS) provides both passive and active means of injection to the RCS in the event of a design basis event. The piping from the safety injection tanks to the RCS nozzles and to the check valves just inside containment is normally pressurized to 610 psig, safety injection tank pressure. Portions of the SIS outside containment will be above 275 psig or 200 °F high energy piping criteria less than two percent of system operating time and, therefore, are considered moderate energy. The portion of SIS from the pump stop check valves to the HPSI Injection MOVs will be pressurized above 275 psig by the HPSI Pressurization System as discussed in Section 3.6.4.1.10.1 and Section 3.6.4.1.10.2. The effects of cracks postulated in this piping are discussed in Section 3.6.4.3. The piping between the safety injection tanks and the RCS nozzles is 12-inch Schedule 140 stainless steel piping. A 3-inch high pressure and 6-inch low pressure injection line combine just inside containment to an 8-inch Schedule 120 pipe. These lines are Seismic Category 1 and have been designed in accordance with the ASME Code, Section III, Class 1 or 2 criteria. The four injection paths tee into their four respective 12-inch injection lines between the safety injection tanks and the RCS nozzles. A description of the SIS design and function is included in Section 6.3.

3.6.4.2.8.2 Safety Evaluation

Historical calculated stress level, usage factor, and jet thrust values at the postulated break points are provided in Tables 3.6-18, 3.6-19, 3.6-20 and 3.6-21.

The consequences of the postulated safety injection line breaks will not require protective system initiation. Each of the four injection paths enter containment through the south piping penetration room. Separation is maintained by both distance and elevation. The high and low pressure lines join together inside containment and are run along the outer steam generator cavity wall. The four safety injection tanks are separately located in the four different quadrants of the containment, also outside the steam generator cavity wall. The 12-inch tank discharge lines are routed through penetrations in the cavity walls, teed with the 8-inch injection paths, and run to their respective reactor coolant pump discharge nozzles. Restraints have been placed on the safety injection lines primarily to ensure the integrity of the containment liner. Uncontrolled whip of the safety injection piping within the steam generator cavity walls will not cause failure of any safety-related instrumentation, piping, or equipment required to mitigate the consequences of the event. Breaks up to the first check valves from the reactor coolant piping nozzle have been considered as small break LOCAs. The containment temperature and pressure response due to the LOCA is discussed in Section 6.2.1.

Safety injection piping was reanalyzed due to replacement of the steam generators and power uprate using ASME code, 1980 edition. This resulted in substantial reduction of the originally postulated intermediate break locations. A few new locations were, however, needed to be postulated due to the reanalysis. These new locations are all in the vicinity of the originally postulated locations. The placement of restraints, the location of structures, and physical separation ensures the integrity of the shutdown cooling line and the ability to shutdown in the event of a postulated safety injection pipe break.

3.6.4.2.9 Charging

3.6.4.2.9.1 General Description

The charging line inside containment is Schedule 160, 2-inch pipe designed in accordance with the ASME Code, Section III, Class 1 or 2 criteria. The two charging lines and the auxiliary spray line are Class 1 from the RCS to the second isolation valve in each line. The remainder of the charging line is Class 2. The charging line penetrates containment at Elevation 362 feet and passes through the south steam generator cavity to the regenerative heat exchanger nozzle. The charging flow is then heated by the letdown flow in the heat exchanger before entering the RCS. The charging flow may be directed to pump 2P32C discharge cold leg, pump 2P32B discharge cold leg, or the pressurizer spray line. The charging line inside containment is Seismic Category 1. System operation is described in Section 9.3.4.

3.6.4.2.9.2 Safety Evaluation

For 2CCB-25 and 2CCB-9 intermediate break points were postulated on the basis of highest stress in accordance with the criteria listed in Section 3.6.2.1. Historical stress profiles for these lines are provided in Tables 3.6-22 and 3.6-23, respectively. Break points were postulated at the terminal ends and at each intermediate pipe fitting, welded attachment, and valve for 2CCA-16, 2CCA-26 and 2CCA-27. Breaks postulated on 2CCA-16, 2CCA-26 and 2CCA-27 between the RCS and check valves will have the same consequences as a small LOCA. Systems required to mitigate the consequences of the break will not be impaired by jet impingement or uncontrolled whip of this piping. The shutdown cooling line and valve operators will be protected from the whip of 2CCA-26. Three restraints in addition to existing piping and structures will ensure the availability of the shutdown cooling line if required. The routing of 2CCB-9 and 2CCB-25, the proximity of structures and equipment, and the location of postulated break points will ensure that systems required for safety and shutdown will not be impaired. Breaks located upstream of the check valves, 2CCB-9 and 2CCB-25 will not result in protective system actuation. Blowdown of the RCS is prevented by check valves in the charging lines. If the failure of the check valve is postulated, allowing blowdown of the RCS, safety systems will be available to mitigate the consequences of the break.

3.6.4.2.10 Letdown

3.6.4.2.10.1 General Description

The letdown line inside containment is Schedule 160, 2-inch pipe designed in accordance with the ASME Code, Section III, Class 1 or 2 criteria. The line is Seismic Category 1 from the RCS nozzle to the letdown valves outside containment. The letdown lines runs to the regenerative heat exchanger, where the flow is cooled by charging flow, and then to the containment penetration at Elevation 370 feet. System operation is described in Section 9.3.4.

3.6.4.2.10.2 Safety Evaluation

A detailed stress analysis was performed on 2CCB-2 and intermediate break points were postulated on the basis of highest stress. Table 3.6-24 lists the historical calculated stress level values at the intermediate break points. Breaks were postulated to occur at the terminal ends and at each intermediate pipe fitting, welded attachment, and valve on 2CCA-12. Line 2CCB-1 is composed of 2-inch, 2½-inch and 8-inch diameter sections. For jet impingement evaluations for line 2CCB-1, breaks are postulated to occur at the terminal ends and at each intermediate pipe fitting, welded attachment, and valve for the 2½-inch and 2-inch diameter sections. No breaks are postulated in the 8-inch diameter section of line 2CCB-1 when considering pipe whip evaluations. This is based on the fact that stress analysis of this line has shown that the bending stresses in the 8-inch section are approximately 1/20th of the magnitude of the bending stresses in the 2½ inch-diameter section, due to the large section modulus of the 8-inch pipe. Thus a break would occur at the terminal end of the 2½-inch diameter pipe or in the 2-inch diameter pipe before pipe stresses reach the yield point in the 8-inch diameter pipe. Layout of the letdown lines with respect to required safety systems, structures, and equipment ensures that systems required for safety will not be impaired by the consequences of a letdown line pipe break. A restraint has been placed on 2CCB-2 to protect the containment liner plate. Additional protection is not required to mitigate the consequences of the plant or reach cold shutdown.

3.6.4.2.11 Pressurizer Spray

3.6.4.2.11.1 General Description

The pressurizer spray line is designed in accordance with the ASME Code, Section III, Class I criteria. A portion of the reactor coolant pump 2P32A and 2P32B discharge is diverted to the pressurizer spray piping. Two 3-inch Schedule 160 lines from the pump discharges are run together into a 4-inch Schedule 140 line which discharges to the pressurizer steam space. The entire pressurizer spray line is Seismic Category 1. Pressurizer operation is discussed in Section 5.5.10.

3.6.4.2.11.2 Safety Evaluation

Pipe breaks have been postulated to occur at the terminal ends and at each intermediate pipe fitting, welded attachment, and valve. The pressurizer spray line is located within the south steam generator cavity and the cavity walls provide protection for the containment liner and required systems outside the cavity. Inside the cavity major equipment; steam generator 2E24A, reactor coolant pumps 2P24A and 2P32B, and the pressurizer 2T1, provide separation and protection from the effects of jet impingement and pipe whip. In addition, six restraints have been located to minimize the effects of pipe whip and protect the pressurizer level and pressure instrumentation lines. Only guillotine breaks were postulated to occur on the 3-inch portion of the line.

Analysis has shown that the consequences of a postulated spray line break will not result in a more severe LOCA than the Design Basis Accident (DBA), will not impact the containment liner, and will not impair systems required to mitigate the event or shutdown the plant.

3.6.4.2.12 Pressurizer Low Temperature Overpressure Protection

3.6.4.2.12.1 General Description

The pressurizer low temperature overpressure protection (LTOP) line is designed in accordance with the ASME Code, Section III, Class 1 and 2 criteria. At the pressurizer nozzle, the LTOP line is a 6-inch Schedule 120 line which tees into two 4-inch Schedule 120 lines. Each side of the tee has two motor-operated isolation valves and a relief valve. The line between the second isolation valve and the relief valve is 4-inch Schedule 40S. The line downstream of the relief valve is 6-inch Schedule 40S and is considered part of the pressurizer safety relief valve discharge line to which it connects. An emergency vent line is also provided which connects to the LTOP line on one side between the two isolation valves and to the discharge line downstream of the relief valve on the same side.

A motor-operated isolation valve is included on the emergency vent line. The LTOP line is Seismic Category I. The discharge piping is Seismic Category II. The LTOP operation is described in Section 5.2.2.4, 7.6.1.3 and 7.6.2.3.

3.6.4.2.12.2 Safety Evaluation

Due to the limited operation of the LTOP system, only the piping between the pressurizer nozzle and the first isolation valve on each side of the tee is classified as high energy. On this portion of this line, pipe breaks have been postulated to occur at the terminal end, at each fitting, and at the valve ends.

For all breaks, it was shown that either: 1) no adjacent safety-related equipment would be affected by the break; or 2) an alternate path to safe shutdown was identified assuming that potentially affected safety-related equipment would become inoperable. Similar to the pressurizer spray line discussed above, a postulated LTOP line break will not result in a more severe LOCA than the DBA.

Structural steel frames around the upper pressurizer pressure nozzles provide adequate protection against the effects of an LTOP line break.

3.6.4.3 Protection From Flooding of Equipment Important to Safety

3.6.4.3.1 Scope

The following contains the results of an evaluation of systems design and layout of the auxiliary building regarding the effects of flooding resulting from postulated breaks in non Seismic Category 1 piping systems. "Guidelines for Protection from Flooding of Equipment Important to Safety" (presented to Arkansas Power and Light Co. at Unit 2 DRL Meeting held at Bethesda, Maryland on May 17, 1973) provided the basis for the criteria employed in this evaluation. The following outlines the criteria employed in this evaluation, identifies the areas of investigation, and describes the features incorporated into the plant design in order to comply with these criteria.

3.6.4.3.2 Criteria/Protective Guidelines

The criteria employed in this evaluation are as follows:

A. Separation for redundancy - single failures of non-Class I system components or pipes shall not result in loss of a system important to safety. Redundant safety equipment shall be separated and protected to assure operability in the event a non-Class I system or component fails.

B. Access doors and alarms - watertight barriers for protection from flooding of equipment important to safety shall have all access doors or hatches fitted with reliable switches and circuits that provide an alarm in the control room when the access is open.

C. Sealed water passages - passages or piping and other penetrations through walls of a room containing equipment important to safety shall be sealed against water leakage from any postulated failure of non-Class I water systems. The seals shall be designed for the SSE, including seismically induced wave action of water inside the affected compartment during the SSE.

D. Class I watertight structures - walls, doors, panels, or other compartment closures designed to protect equipment important to safety from damage due to flooding from a non-Class I system rupture shall be designed for the SSE, including seismically induced wave action of water inside the affected compartment during the SSE.

E. Water level alarms and trips - rooms containing non-Class I system components and pipes whose rupture could result in flood damage to equipment important to safety shall have level alarms and pump trips (where necessary) that alarm in the control room and limit flooding to within the design flood volume. Redundancy of switches is required. Critical pump (i.e, high volume flow, such as condenser circulating water pumps) trip circuits should meet IEEE 279 criteria.

F. Class I equipment should be located or protected such that rupture of a non-Class I system connected to a tower containing water or body of water (river, lake, etc.) will not result in failure of the equipment from flooding.

G. The safety analysis shall consider simultaneous loss of offsite power with the rupture of a non-Class I system component or pipe.

3.6.4.3.3 Evaluation

The areas listed below contain safety-related equipment. The equipment and piping layout in these areas have been evaluated using the above guidelines. Consequences of potential flooding and/or spray from failure of non-Seismic Category 1 components or pipes within these areas and/or in adjacent areas were considered in the evaluation.

3.6.4.3.3.1 Engineered Safety Equipment Pump Rooms

Three separate rooms containing Engineered Safety Features (ESF) equipment are located in the auxiliary building at Elevation 317 feet. The west room contains Train A pumps for the HPSI, LPSI and containment spray systems and the Train A shutdown cooling heat exchanger. The center room contains HPSI pump C. The east room contains Train B pumps for the HPSI, LPSI and containment spray systems and the Train B shutdown cooling heat exchanger. Each of the three rooms is watertight.

The Train A ESF Pump room contains the following non-Seismic Category 1 piping:

A. Drain piping from the safety injection tanks to the refueling water tank. This pipe is not considered a source of flooding since it is normally isolated from the safety injection tanks and the refueling water tank by locked closed Seismic Category 1 manual isolation valves.

B. Drain piping from the containment sump to the auxiliary building sump. This piping is provided to gravity drain the containment sump to the auxiliary building. Since it is normally isolated from the containment sump by redundant containment isolation valves, this piping is not considered a potential source of flooding.

C. Piping from the Reactor Drain Tank (RDT) to the reactor drain pumps. The total capacity of the RDT is 1,600 gallons. This tank is primarily used during plant shutdown periods to collect liquid drained from piping and equipment inside the containment. The tank will contain only a small amount of liquid during normal power operation. This piping is automatically isolated from the RDT by redundant isolation valves upon receipt of the Containment Isolation Signal (CIS). Irrespective of the fact that the automatic valves would isolate this piping in the event of a postulated LOCA (when the equipment located within this room is required to function), the postulated rupture of this piping and the draining of the RDT into this room would represent no hazard to the equipment within this room.

With regard to the Train B ESF pump room, the only non-Seismic Category 1 piping located in this room is a portion of the letdown piping between the letdown heat exchanger and the volume control tank in the CVCS. Although this piping does not require Seismic Category 1 classification per Section C.1 of Regulatory Guide 1.29, Revision 1, that portion of the piping which passes through this room is seismically analyzed and restrained in accordance with Section 2.C of the regulatory guide.

No non-Seismic Category 1 piping is located in the room containing HPSI Pump C.

Conductance type level detectors have been installed in each of the ESF pump rooms to monitor any significant accumulation of liquid in these rooms. Alarms indicating an increasing water level in these rooms are displayed in the control room. In ESF pump rooms “A” and “B”, these level detectors have been installed in the floor drains near each of the HPSI pumps. In HPSI pump room “C”, this level detector has been installed on the floor near the floor drain.

3.6.4.3.3.2 <u>Emergency Feedwater Pump Rooms</u>

The Emergency Feedwater (EFW) pumps, one motor driven (2P7B) and one turbine driven (2P7A) are located in the auxiliary building at Elevation 329 feet. Access to the pump room is via an open stairway from the fuel pool pump area at Elevation 335 feet.

Since the area surrounding the pump rooms contains non-Seismic Category 1 piping whose failure could otherwise jeopardize the operation of these pumps, features are incorporated into the design of these rooms in compliance with the guidelines described below.

A watertight door is installed in the passageway to the east EFW pump room and a wall with a watertight door is installed in the west room to provide independent water tight compartments. Each watertight door is fitted with an intrusion alarm displayed in the control room.

Watertight seals on all penetrations into and out of the room are utilized to prevent cross-flooding or flooding from external sources. Backflow preventer valves are installed in the drain lines from each of these rooms to avoid flooding from the drain system. Float type level switches with alarms in the control room have been installed in each EFW pump room near the floor to detect gross leakage accumulation.

3.6.4.3.3.3 Emergency Diesel Generator Rooms

The emergency diesel generators are located in the auxiliary building, at Elevation 369 feet. Surrounding rooms are at Elevation 372 feet and Elevation 374 feet, 6 inches. Access to the diesel generator rooms is via the access corridor near the south stairwell at Elevation 372 feet to the south diesel generator room and a ramp corridor from the electrical equipment area at Elevation 372 feet to the north room. A fireproof door and a watertight door are provided for access between the rooms. Both rooms are equipped with separate fire protection sprinkler systems, separate drainage systems sized to accommodate the sprinkler system, and diesel exhaust piping.

The non-Seismic Category 1 fire water header supplies the seismically supported deluge water spray systems in each of the diesel generator rooms. This header is located in the ramp access corridor to the north room. The deluge valve supplying each of these rooms is located just outside the room. In case of a rupture of the fire water header, a watertight door is available if needed to protect the north room.

A fire standpipe and hose reel are located in the hallway near the entrance to the south diesel generator room. Although there are sufficient drainage paths which would preclude a significant buildup of water, a 5-inch curb is installed in this doorway to hold back any water that may accumulate in the hallway from a rupture of this standpipe. Also, the watertight door between the rooms may be used if necessary to prevent a cross flooding between the two rooms. Float type level switches have also been provided to detect any gross leakage. Intrusion alarms for the watertight doors and the flood alarms are displayed in the control room.

To avoid inadvertent spray down of the diesel generator equipment, the pre-action automatic deluge spray has been coupled with wet pipe sprinkler system fusible heads as described in Section 9.5.1.2.3. These fusible heads provide a second pressure boundary should the deluge valves fail or inadvertently open with no existing fire in these rooms.

3.6.4.3.3.4 Electrical Equipment

As described in Section 8.3.1.1.4, ESF Motor Control Centers (MCCs) are located throughout the Seismic Category 1 structure. The MCCs are enclosed in NEMA Type I light splash resistant cabinets and are designed such that up to six inches of standing water may accumulate on the floor before shorting of electrical connections may be expected. Two of the ESF MCCs are located in the upper and lower electrical penetration rooms and are discussed in Section 3.6.4.3.3.5. One ESF MCC is located in the passageway near the spent resin storage tank. Several low energy non-Seismic Category 1 piping systems pass above this MCC. To protect the MCC from possible spray from these pipes, a spray shield has been constructed over the MCC.

ESF 120-volt AC and 125-volt DC distribution panels are located in the hallway connecting the battery rooms to the north diesel generator room at Elevation 372 feet. A fire protection standpipe and hose reel is located at the east end of the hallway near the entrance to the turbine building. An additional hose reel and standpipe are installed at the west end of the hallway near the volume control tank to meet NFPA requirements described in Section 9.5.1.2.2.

3.6.4.3.3.5 Electrical Penetration Rooms

These four rooms are located in the auxiliary building at Elevation 374 feet, 6 inches and 386 feet. The two north electrical penetration rooms contain only electrical cabling to the containment building. The south electrical penetration rooms both contain electrical cabling and an ESF motor control center. Each room is fitted with a seismically supported deluge water spray system.

In addition, the automatic deluge water spray system for each of the electrical penetration rooms has been coupled with fusible heads as described in Section 3.6.4.3.3.3.

3.6.4.3.3.6 Non-Seismic Category 1 Systems

Below are listed the non-Seismic Category 1 systems, components and piping that were considered in this analysis. Some of the systems listed in the NRC guidelines do not appear in this report either because the systems do not pass through areas where safety-related equipment is located or the systems are Seismic Category 1 in those areas.

A. Auxiliary Cooling Water

B. Plant Makeup Water

C. Chemical and Volume Control (non-Seismic Category 1 portion)

D. Condensate

E. Fuel Pool

F. Drains

G. Heating and Ventilation

H. Component Cooling Water

I. Waste Management

J. Boron Management

K. Fire Protection

3.6.4.3.4 Summary/Conclusions

A review of all areas containing safety-related mechanical and electrical equipment was conducted. This focuses only on those areas where potential problems existed and where changes in the plant design and layout were found to be necessary. Consequently, some of the safety-related equipment areas, such as the control room and the battery rooms, are not evaluated.

It has been concluded that the plant layout and design meets the criteria set forth in Section 3.6.4.3.2.

3.6.4.4 Liquid Storage Tanks

3.6.4.4.1 Purpose

The following evaluation was made to determine the effects of flooding resulting from a postulated failure of a liquid storage tank. Tables 3.6-25 through 3.6-27 list all Unit 2 liquid storage tanks and indicate by figures their locations.

3.6.4.4.2 Criterion

The criterion used in this evaluation is that a failure of a tank does not result in the flooding of safety-related equipment that would impair the safe shutdown of the plant.

3.6.4.4.3 Evaluation

Table 3.6-25 lists all Unit 2 liquid storage tanks located outside the confines of the Unit 2 buildings. These tanks are located at ground level and are not considered a flood hazard to safety equipment contained within the Unit 2 buildings.

Table 3.6-26 lists all Unit 2 liquid storage tanks located within the Unit 2 containment. These tanks are not considered a flood hazard to safety equipment since the equipment within the containment has been designed to operate under the post-LOCA spray environment and since any accumulation of liquid from a tank failure will not exceed the design water level in the containment.

Table 3.6-27 lists all liquid storage tanks located within the Unit 2 auxiliary building. Each tank listed in Table 3.6-27 is discussed below.

The boric acid makeup tanks (2T6A, B) are located in the south end of the auxiliary building at Elevation 386 feet. Other than the tanks themselves, there is no safety-related equipment in the immediate area. Sufficient physical barriers and drainage via floor drains and the adjacent stairwell exist to preclude the fluid from these tanks from impacting safety-related equipment.

The boron management holdup tanks (2T12A, B, C, and D) are located in the south end of the auxiliary building at Elevation 327 feet. Each tank is contained within a separate vault with access hatches at the 355 feet, 4 inches elevation. Fluid from a failure of any of these tanks would be contained within the vault since the drainage system from each vault is isolated.

The waste tanks (2T20A and B) are located in the south end of the auxiliary building at Elevation 317 feet. All safety-related equipment located at this elevation is protected from internal flooding as described in Section 3.6.4.3.

The waste condensate tanks (2T21A and B) are located in the south end of the auxiliary building at Elevation 335 feet. Although fluid from a failure of one of these tanks would enter the charging pump room, sufficient drainage is available to limit water accumulation so as not to damage the charging pumps which are mounted on elevated pads. Drainage via the floor drains in the tank room, charging pump rooms, and the access corridor are provided. The bulk of the water would drain out of the tank room to the access corridor and down the stairwell across from the center charging pump room, the hatch at the east end of the access corridor, and the stairway at the west end of the access corridor.

The plant heating boiler fuel oil day tank (2T22) is located in the north end of the auxiliary building at Elevation 354 feet. The tank is enclosed in a vault that would contain any fluid from a tank failure.

The clean and dirty lube oil storage tank (2T26) is located in the north end of the auxiliary building at Elevation 335 feet. Fluid from a failure of this tank will drain to the turbine building away from any safety-related equipment.

The emergency diesel generator fuel oil day tanks (2T30A and B) are located inside the emergency diesel generator rooms at Elevation 369 feet. Each tank is enclosed by a fire wall which will limit the amount of fluid flowing to the surrounding diesel generator room. The floor drains in the diesel generator rooms are of adequate capacity to prevent any accumulation of fluid.

The hydrazine tank (2T43) is located in the east side of the auxiliary building. No safety-related equipment is located in the vicinity of this tank and sufficient barriers and floor drains are available which ensure that a failure of this tank would not pose a flood hazard to this equipment.

The domestic water pressure tank (2T44) is located in the north end of the auxiliary building at Elevation 374 feet, 6 inches. It also is located well apart from any safety-related equipment and sufficient barriers and floor drains are available which ensure that a failure of this tank would not pose a flood hazard.

The boric acid condensate tanks (2T69A and B) are located in the southeast corner of the auxiliary building at Elevation 327 feet. The tanks are contained within a room with a normally closed drain system that is designed to contain the contents of one tank in the event of a tank failure. These tanks do not pose a flood hazard to safety-related equipment.

The concentrator bottoms storage tank (2T78) is located in the south end of the auxiliary building at Elevation 354 feet. This tank has been abandoned. It is drained and maintained isolated from any potential source of effluent. However, fluid from a failure of this tank would have sufficient drainage paths via floor drains, the opening at the west end of the corridor and the hatch at the southeast corner of the building to limit any water accumulation to less than six inches. The safety-related MCCs located on the same elevation approximately 40 feet east of this tank are designed such that six inches of water may accumulate before shorting of electrical connections is possible.

The waste solidifier storage tank (2T80) and the waste catalyst storage tank (2T81) are located in the north end of the Unit 1 auxiliary building at Elevation 354 feet. This area does not contain any safety-related equipment. Neither Unit 1 nor Unit 2 currently solidify waste for off-site transport and both 2T80 and 2T81 have been abandoned.

The regenerative waste tanks (2T92A, B and C) are located in the north end of the auxiliary building at Elevation 332 feet. The tanks are located in a room designed to contain the liquid in the event of a tank failure. This area of the building does not contain any safety-related equipment.

3.6.4.5 Moderate Energy Pipebreak Outside Containment

This section presents the results of the analysis performed on moderate energy Seismic Category 1 piping systems to ensure that adequate protection is provided in the plant layout and system design to meet the criteria set forth in Branch Technical Position APCSB 3-1, Section B.3. This analysis covers only Seismic Category 1 piping and was performed in conjunction with the analysis contained in Section 3.6.4.3, "Protection From Flooding of Equipment Important to Safety," for non-Seismic Category 1 piping systems. As outlined in Branch Technical Position APCSB 3-1, Section B.3, the following demonstrates that arrangement and design features provide the necessary protection of the systems and components required to shut down the reactor and mitigate the consequences of a postulated moderate energy piping failure. The offsite dose consequences are within the guidelines of 10 CFR Part 50.67 and the environmental conditions resulting from the following postulated pipe failures do not preclude habitability of the control room or access to surrounding areas important to the safe control of reactor operations needed to cope with the consequences of the failure.

3.6.4.5.1 Dual Purpose Moderate Energy Essential Systems

This section discusses the results of the analysis of postulated piping failures assumed to occur in one of two or more redundant trains of a dual purpose moderate energy essential system. Dual purpose moderate energy essential systems are those systems which are required to operate during normal plant conditions as well as during reactor shutdown and post-accident. These systems are designed to Seismic Category 1 standards, are powered from both off-site and onsite sources and are constructed, operated and inspected to quality assurance testing and in-service inspection standards appropriate for nuclear safety systems. Postulated failures within any of these dual purpose moderate energy systems will not cause protective system actuation.

3.6.4.5.1.1 Service Water System

3.6.4.5.1.1.1 General Description

The Service Water System (SWS) (see Figure 9.2-1) consists of two independent Seismic Category 1 flow paths which furnish water to ESF equipment and three Seismic Category 2 flow paths which furnish water to non-safety-related portions of the plant. The Seismic Category 1 portion of the SWS serves two identical (full capacity) loops of ESF equipment each consisting of one shutdown cooling heat exchanger, one emergency diesel generator, one emergency feedwater pump, one train of room and pump cooler for ESF equipment and two containment cooling coils. System function and component descriptions are in Section 9.2.1.

3.6.4.5.1.1.2 Safety Evaluation

A review of the SWS piping in the north and south electrical switchgear rooms indicated that a potential problem existed in these areas. These switchgear rooms contain safety-related switchgear and are located in the auxiliary building at Elevation 372 feet. The north switchgear room contains the red channel equipment; the south room contains the green channel equipment. Each of these rooms is cooled by a unit cooler which receives cooling water from the associated SWS train. Originally, both trains of SWS piping passed through both of these rooms. Since this arrangement did not meet the criteria set forth in Branch Technical Position APCSB 3-1, the piping was rerouted such that only the SWS piping from the associated SWS train passes through each switchgear room.

Accordingly, the redundant trains of the SWS and the redundant safety-related equipment served by the SWS are designed such that a piping failure in either SWS train will not result in the loss of the unaffected SWS train or the loss of any of the safety-related equipment serviced by the unaffected train.

3.6.4.5.1.2 Shutdown Cooling System

3.6.4.5.1.2.1 General Description

The Shutdown Cooling (SDC) System piping and components are fabricated in accordance with ASME Code, Section III, Class 2 and are Seismic Category 1. The major components of redundant trains outside the containment are the shutdown cooling heat exchangers and the LPSI pumps. The system functional description is in Section 9.3.6.

3.6.4.5.1.2.2 Safety Evaluation

Each train of SDC is contained within the watertight compartment of the ESF equipment rooms at Elevation 317 feet such that a single postulated piping failure will not affect the other train. As indicated in Section 3.6.4.3.3.1, conductance type level detectors have been installed in the drains near each of the HPSI pumps to monitor any significant leakage in the associated room.

3.6.4.5.1.3 Emergency Feedwater System

3.6.4.5.1.3.1 General Description

The moderate energy piping and components of the EFW System are designed to meet Seismic Category 1 requirements and ASME Code, Section III requirements. The system functional description is in Section 10.4.9.

3.6.4.5.1.3.2 Safety Evaluation

Each train of the EFW System is contained in a water tight compartment as described in Section 3.6.4.3.3.2 such that the effects of spray or flooding will not affect the other train. The common suction line from the condensate storage tank and the condenser hotwell is isolable by closing motor operated valves 2CV-0795-2 for the turbine driven EFW pump (2P7A) and 2CV-0789-1 for the motor driven EFW pump (2P7B) and by closing supply valves 2CV-0707 or 2EFW-0706. Service water can then be supplied to the EFW pumps by opening motor operated valves 2CV-0711-2 for 2P7A or 2CV-0716-1 for 2P7B. However, the service water supply would only be used in emergency cases in the event that the normal condensate storage tank supply or the alternate condenser hotwell supply is unavailable. Automatic operation of these valves on receipt of EFAS signal is described in Section 10.4.9.2.2. Condensate is also available from the Unit 1 Safety grade Condensate Storage Tank, T41B, by manually opening valves 2CS-0816 and 2CS-0817.

3.6.4.5.2 Moderate Energy Safety Systems

This section discusses the results of the analysis of postulated piping failures in Seismic Category 1 safety systems in the auxiliary building which are in a standby status during normal plant operations.

3.6.4.5.2.1 Containment Spray System

3.6.4.5.2.1.1 General Description

The Containment Spray System (CSS) is designed to Seismic Category 1 requirements. System piping and components are designed to meet ASME Code, Section III Class 2 requirements. The system functional description is in Section 6.2.2.2.1.

3.6.4.5.2.1.2 Safety Evaluation

Each loop of the CSS is located in a watertight compartment located at Elevation 317 feet. The containment spray pump and shutdown cooling heat exchanger of each train are in the same compartment with LPSI pump and HPSI pump that are powered from the same safety system power supply. A single postulated piping failure would only affect one train and would not cause safety system actuation. Any significant leakage can be detected by conductance type level detectors installed in the drain piping of each water tight compartment. Should one train of CSS become inoperable, plant operation would be administratively controlled and limited by the Technical Specifications.

3.6.4.5.2.2 Emergency Core Cooling System

3.6.4.5.2.2.1 General Description

The Emergency Core Cooling System (ECCS) or Safety Injection System (SIS) is designed to Seismic Category 1 requirements. Components and piping are designed to ASME Code, Section III, Class 2 and ASME Pump & Valve Code Class II requirements. The system functional description is in Section 6.3.

3.6.4.5.2.2.2 Safety Evaluation

The HPSI pump and the associated LPSI pump of each train are contained in ESF equipment rooms with the containment spray and shutdown cooling heat exchanger of the same train. The ESF equipment rooms are water tight compartments and are arranged such that a postulated piping failure will not affect more than one room. As indicated in Section 3.6.4.3.3.1, level detectors are installed to detect any significant leakage in any of the ESF equipment rooms. A single postulated piping failure will not cause automatic safety system actuation, and in the event of a piping break in either train, plant operation would be administratively controlled in accordance with the Technical Specifications.

3.6.5 PROTECTIVE MEASURES

3.6.5.1 Separation

Separation between redundant safety-related components and separation between these components and high energy piping systems has been provided in the design and layout of this plant. This separation provides the primary means of assuring safe plant shutdown capability following a postulated high energy pipe break.

3.6.5.2 Pipe Whip Restraints

Pipe whip restraints were utilized on those piping systems in which adequate protection of components and structures could not be provided either by separation or the presence of suitable structures or barriers. Figure 3.6-1 contains sketches of two typical pipe whip restraints utilized in this plant. Restraint locations are shown on the piping isometrics discussed in Section 3.6.4.

3.6.5.3 Barrier Protection

Floors, walls, and columns within the plant provide barrier protection for safety-related equipment. The containment liner provides barrier protection against the uncontrolled release of radioactivity to the environment in the event of a pipe break within the RCS. Where the unrestrained motion of a high pipe, following a postulated break could result in impact of the pipe with the containment liner or walls and floors providing barrier protection for safety-related equipment, the effects of this impact were evaluated as discussed in Section 3.6.4. If the impact of the whipping pipe could result in loss of integrity of the containment liner or damage to a floor or wall to the extent that the equipment protected by the structure could be rendered inoperative, pipe restraints were provided to prevent this impact.

These structural barriers were designed to withstand the pressure and temperature transients resulting from high energy piping system breaks. The results of the containment pressurization analyses are contained in Section 6.2.1. The results of the pressurization analyses performed on structures outside of the containment building are contained in Section 3.6.4.

3.6.5.4 Electrical Equipment Environmental Qualification

Special design requirements were placed on safety-related electrical equipment, instrumentation and cabling, required to function following a postulated break, to ensure the operability of this equipment under the environmental conditions existing as a result of the break. Section 3.11 lists equipment within the containment required to function following a postulated LOCA or main steam line rupture. The testing and analyses performed to ensure the operability of this equipment under the resulting environmental conditions has been documented in accordance with 10 CFR 50.49. In addition to the environmental conditions specified in Table 3.11-1 for safety-related equipment located in the auxiliary building, the equipment located in those areas described in Section 3.6.5.3 above are qualified to operate under the environmental conditions which would exist in these areas following the postulated pipe break.

3.6.5.5 Control Room Habitability

The control room is located within the auxiliary building on floor Elevation 386 feet, immediately adjacent to the Unit 1 control room. No high energy pipes are located in or around this area. During normal operation the control room environment is maintained suitable for personnel and equipment with the use of fresh air makeup and chilled water cooling units. Redundant split system air conditioning units, cooled by the Seismic Category 1 portion of the SWS, in conjunction with recirculation fans, powered from the engineered safety features buses, provide a backup means of maintaining a suitable control room environment. See Section 9.4.1 for a detailed description.

3.6.6 LEAK-BEFORE-BREAK EVALUATION

This section describes the Leak-Before-Break (LBB) analysis for the Main Coolant Loop (MCL) piping, hot and cold legs. LBB analysis is used to eliminate from the structural design bases the dynamic effects of double-ended guillotine breaks and equivalent longitudinal breaks for the MCL piping system.

3.6.6.1 Applicability of Leak-Before-Break

MCL piping systems for which LBB is demonstrated are first shown to meet the applicability requirements for NUREG-1061, Volume 3. Specifically, the points considered for applicability for LBB are:

1. Regulatory requirements – level of susceptibility of failure from erosion, erosion/corrosion, corrosion/cavitation, waterhammer, creep fatigue, corrosion resistance, indirect causes, cleavage type failure, and fatigue cracking.

2. Technical requirements – pipe properties, normal operation, and seismic load levels.

Topical Report CEN-367-A, Reference 79 describes the applicability of LBB for the ANO-2 main loop piping.

3.6.6.2 Leak Detection

In order to apply the LBB concept to eliminate consideration of breaks in the MCL piping, leakage detection systems must be capable of detecting RCS leakage before it approaches the leakage rate associated with a critical-sized crack. There are two major aspects to leak rate detection that are based on crack detection in addition to the crack opening size: leak detection capability and flow rate correlation for leakage through a crack.

3.6.6.2.1 Leak Detection System

ANO-2 has an installed leakage detection system, described in Section 5.2.7.1.1, that meets the requirements of Regulatory Guide 1.45. Reference 80 describes the leak detection systems in detail.

3.6.6.2.2 Flow Rate Correlation

The flow rate correlation for leakage through a given crack size cannot be predicted precisely. Variables such as surface roughness of the side walls of the crack, the nonparallel relationship of the side walls due to the elongated crack shape, and possibly zigzag tearing of the material during crack formation, all introduce uncertainties in defining an exact flow rate correlation. Topical Report CEN-367-A, Reference 79, describes the flow rate correlation in detail.

3.6.6.3 Material Properties

The main loop piping material is SA516Gr70. All hot and cold leg pipe-to-pipe welds and pipe-to-reactor vessel and steam generator safe ends are carbon steel welds. The pump case is 304 stainless steel, causing the pipe to pump safe end weld to be a bimetallic weld.

The detailed analyses of cracks in pipe welds require consideration of the properties of the pipe and weld materials. Section 7.1 of Reference 79 describes the material properties applicable to the LBB evaluation.

The Replacement Steam Generator nozzles to piping weld material properties are discussed in Section 3.6.6.3.1.

3.6.6.3.1 Weld Material Properties

The material properties for the RSG to MCL welds have been reviewed and determined to meet criteria presented in Reference 79.

3.6.6.4 Leakage Crack Length Determination

Hypothetical through-wall cracks must open significantly to allow detection by normal leakage monitoring under normal full power loading. The method for determining the appropriate leakage crack length is described in Reference 79.

3.6.6.5 Stability Evaluations

The stability evaluations, including determination of crack size and detail J-integral calculation, are described in Reference 79.

3.6.6.6 Results

The evaluations performed confirm that the bases for the LBB acceptance criteria according to NUREG 1061, Volume 3, are satisfied by the as-built design and materials of the MCL piping system.

References 79, 80, and 82 identify the acceptability of applications of LBB to the Main Loop piping for ANO-2.

3.7 SEISMIC DESIGN

This section indicates the techniques and discusses the parameters used to develop seismic loadings and criteria for Seismic Category 1 structures, systems, and components. In BC-TOP-4, Revision 1, Reference 35, and BP-TOP-1, Reference 4, the Design Basis Earthquake (DBE) and the Operating Basis Earthquake (OBE) correspond to the Safe Shutdown Earthquake (SSE) and one half magnitude of Safe Shutdown Earthquake (½SSE), respectively.

3.7.1 SEISMIC INPUT

The DBE and the OBE were used as the basic seismic input. The DBE was assumed to represent the maximum vibratory ground motion at the site, during which all Category 1 structures, systems and components important to safety were designed to remain functional. The OBE was assumed to represent a vibratory ground motion at the site for which the plant would be permitted to continue to generate power without a thorough check of all safety-related items.

3.7.1.1 Design Response Spectra

The site design response spectra are illustrated in Figures 3.7-1 and 3.7-2 for the DBE and the OBE, respectively.

The shapes of the site design response spectra are in general agreement with the Regulatory Guide 1.60. However, the shapes of the spectra were derived in accord with the method discussed in Section 2.5.1 (b) of BC-TOP-4, Revision 1. These design spectra were based on the existing strong motion earthquake ground records of various durations, and were recorded at sites having different geologic conditions, epicentral distances, and their associated spectral amplification factors.

A discussion of the effects of historical seismic events on the site is given in Section 2.5. Because the modified design spectra were based on the properties of several strong motion records of the earthquakes recorded at sites of various geologic conditions and epicentral distances, the effects of duration, distance, and depth were automatically taken into account.

For the coupled reactor buildings/RCS seismic analysis, the design seismic ground motions are discussed in Section 3.7.2.15.

3.7.1.2 Design Response Spectra Derivation

A synthetic earthquake acceleration time history was generated (Figure 3.7-3), because the response spectra of recorded earthquake motions did not necessarily envelop the site design response spectra. The 24-second duration used was comparable to the strong motion duration of earthquake records. The duration was therefore considered to be adequate for the types of analyses used for the structures and equipment. Figure 3.7-4 shows that the response spectra for two percent, three percent and five percent of critical damping of the synthetic time history envelop the corresponding site design response spectra. The frequency ranges and frequency increments at which the response spectra values of the synthetic time history were calculated are shown in Table 3.7-1. Section 2.5.1(c) of BC-TOP-4, Revision 1, describes the generation of typical synthetic earthquake time histories.

3.7.1.3 Critical Damping Values

3.7.1.3.1 Category 1 Structures Systems and Components Other Than NSSS

The range of damping values in percent of critical damping, and the applicable allowable design stress levels used for Category 1 structures, systems, and components are given in Table 3.7-2.

The damping values used, as listed in Table 3.7-2, are in general agreement and more conservative than the Regulatory Guide 1.61. The only exceptions are for A) welded steel structures during DBE condition where a five percent damping was used and B) vital piping where ASME Code Case N-411 damping values may be used in lieu of those listed in the table with the following conditions:

1. Code Case N-411 damping values will be utilized in response spectrum analyses only, and not in time history analyses.
2. The damping values of Code Case N-411 will not be a mixture of Code Case N-411 and Regulatory Guide 1.61.
3. If pipe supports are removed or relocated as a result of using the Code Case damping values, the displacements of the piping will be reviewed to insure that inline components and adjacent structures are not affected.

All major Seismic Category 1 structures are founded on competent unweathered bedrock and no soil damping was considered in the seismic analysis.

For the coupled reactor building/RCS seismic analysis, the critical damping values are discussed in Section 3.7.2.15.

3.7.1.3.2 Nuclear Steam Supply System

The damping values used in the seismic analysis of the Nuclear Steam Supply System (NSSS) are discussed in Section 3.7.3.4.2.

3.7.1.4 Bases for Site Dependent Analysis

Since the major structures are founded on competent unweathered bedrock, site dependent analysis was not used to develop the design response spectra. Section 2.5.2 of the SAR and Sections 2.4 and 2.5 of BC-TOP-4, Revision 1, describe the bases for specifying the vibratory ground motion for design use.

3.7.1.5 Soil Supported Category 1 Structures

All major Category 1 structures are founded on competent unweathered bedrock. The soil supported Category 1 structures are identified as follows:

Category 1 Structure	Depth of Soil Foundation Over Bedrock
A. Emergency Cooling Pond	
Pipe Inlet	5 feet
Pipe Outlet	10 feet
B. Electrical Manholes	5 - 20 feet
C. Condensate Storage Tank (T41B) Pipe Trenches	~20 feet

Those Seismic Category 1 structures for which a dynamic analysis described in Section 3.7.2.1 was not performed, were checked for their adequacy to withstand loads under the DBE and OBE conditions. These structures are identified as:

A. Emergency Diesel Fuel Storage Vault

B. Emergency Cooling Pond Inlet and Pipe Outlet Structures

C. Electrical Manholes

D. Condensate Storage Tank (T41B) Pipe Trenches

E. Condensate Storage Tank (T41B) Foundation

They are described in Sections 3.8.4.1.3, 3.8.4.1.4, 3.8.4.1.5, 3.8.4.1.6 and 3.8.4.1.7 respectively.

The method used to compute the lateral seismic loads was in accordance with the method described in the Seed and Whitman paper, "Design of Earth Retaining Structures for Dynamic Loads," Reference 20.

This method is based on developing a total lateral pressure which is composed of a dynamic lateral earth pressure applied as an equivalent static load at two-thirds the height above the base slab and a static earth pressure applied at one-third the height above the base slab. Representative margins of safety of typical walls are indicated as follows:

STRUCTURE	MAXIMUM REQUIRED CAPACITY*	CAPACITY
Emergency Diesel Fuel Storage Vault	46.4 Ft.-Kips (OBE)	113 Ft.-Kips
	46.1 Ft.-Kips (DBE)	113 Ft.-Kips
Emergency Cooling Pond Pipe Inlet and Outlet Structure	17.2 Ft.-Kips (OBE)	20 Ft.-Kips
	12.8 Ft.-Kips (DBE)	20 Ft.-Kips
Electrical Manholes	7.3 Ft.-Kips (OBE)	9.2 Ft.-Kips
	5.8 Ft.-Kips (DBE)	9.2 Ft.-Kips
Condensate Storage Tank (T41B) Trenches	7.0 Ft.+Kips (OBE)	11.1 Ft.-Kips
	7.2 Ft.+Kips (DBE)	11.1 Ft.-Kips

*Design Equations: OBE: See Section 3.8.4.3.2.1
DBE: See Section 3.8.4.3.2.2

The analysis procedure for buried piping is described in Section 3.7.3.12. The calculated seismically induced stresses were combined with normal operating stresses and the resultant stresses were considerably less than the design allowable stresses. Since the calculated stresses were within the elastic limit values, no permanent deformations of the pipes are expected to occur.

A similar analysis was performed for the reinforced concrete duct banks which encase the Seismic Category 1 underground conduits and the Condensate Storage Tank (T41B) pipe trenches. The allowable stress values used in the duct bank analysis were in accordance with values described in Section 3.8.4.4. The results of the analysis showed that the calculated stresses are within the elastic limit values and, therefore, no permanent deformations of the duct banks are expected to occur.

The Condensate Storage Tank (T41B) Foundation Analysis is described in Section 3.7.1.7.

3.7.1.6 Soil Structure Interaction

Since the major Seismic Category 1 structures are founded on competent unweathered bedrock, a soil spring approach to characterize soil structure interaction was not used in the dynamic analysis. A simplified lumped mass method using a fixed base model was used.

The selection of a fixed base mathematical model was based on the high quality of foundation rock and was justified by comparing the foundation rocking and sliding motion frequencies with the primary fixed base structural frequencies. The minimum ratios of these frequencies are 3.3 and 2.9, respectively. The foundation vertical motion frequencies are within the rigid range for all structures except the containment. For the containment, the comparison of foundation vertical motion frequency with the primary fixed base structural vertical frequency yields a ratio of 1.7. These minimum values show a sufficient deviation in frequencies to justify the fixed base model assumption.

The average basic foundation rock properties were determined to be as follows:

Modulus of Elasticity (static)	=	6.7E5 psi
Modulus of Elasticity (dynamic)	=	2.8E6 to 5.0E6 psi
Compression Wave Velocity	=	10,000 to 14,500 fps

3.7.1.7 Pier Support Category 1 Structures

3.7.1.7.1 Condensate Storage Tank (T41B) Foundation Analysis

The dynamic analysis of the Condensate Storage Tank (T41B) was performed as follows. A synthetic time history for ground motion was generated from the site response spectra. The peak acceleration computed was .1855 g. To match the required design spectra of .2 g, all points were arbitrarily multiplied by 1.10. The resulting artificial time history spectra envelopes the site design spectra at all points.

This artificial time history was input to the structure model for the computer program FLUSH (see Section 3.7.1.7.2) and the design spectra with soil-structure interaction effects at the top of the foundation was developed. Hand calculations were used to check the FLUSH results and showed good agreement for the calculated fundamental frequencies.

The FLUSH model was a two-dimensional representation of the tank and foundation assuming fixed conditions at the base of the piers.

3.7.1.7.2 FLUSH Computer Program

The Computer Program FLUSH was developed by the University of California, Berkeley. It is a computer program for complex response analysis of soil-structure systems by the finite element method. The analysis is performed iteratively to allow for the strain dependent nature of the non-linear soil-characteristics. In each iteration, the analysis is linear but the soil properties are adjusted from iteration to iteration until the computer strains are compatible with the soil properties used in the analysis. FLUSH allows the adjustment of damping ratios to specified values in each element.

The soil-structure system is represented as a two-dimensional finite element model which provides good evaluations of the response at the base of the structure.

3.7.2 SEISMIC SYSTEM ANALYSIS

Major Seismic Category 1 structures were analyzed for seismic events. These structures include the containment, internal structures, auxiliary building and the intake structure. Seismic Category 2 structures were checked for the design basis loads so that collapse of the structure would not affect the ability of Category 1 structures to perform their intended design functions.

3.7.2.1 Seismic Analysis Methods

3.7.2.1.1 Category 1 Structures

An outline of the procedure used in analyzing structures and equipment for seismic effects is as follows. First an appropriate description of the earthquake was obtained (see Section 3.7.1). Second, the structure was idealized by a mathematical model. Third, the natural frequencies and mode shapes of the model were determined. Fourth, appropriate damping values were selected. Fifth, the spectrum response and time history technique were used in analyzing the structure. (In this phase of the analysis, inertial forces, shear forces, moments, accelerations and displacements were calculated at various elevations in the structure.) Sixth, seismic effects on equipment were determined. The spectrum response method was used to analyze the structure, system or component. Results obtained by the time history technique were compared to the results obtained by the spectrum response method. Time histories, which were produced at floors or nodes, were principally used to determine floor or nodal response spectra.

A separate analysis was made on the model for the two mutually perpendicular horizontal directions and the vertical direction. Since the containment is axisymmetric, only one model was used for both horizontal directions. Design response spectra generated from the acceleration time histories at each floor were used to design or check the adequacy of Category 1 equipment. For the NSSS equipment, acceleration time histories were computed at support points and later used in system design. Stress criteria were determined in accordance with the applicable concrete and steel codes. The material (ø) factors for concrete are those specified in ACI 318-63. Load factors are given in Sections 3.8.1, 3.8.3 and 3.8.4. The predicted displacement response was used to check against the allowable clearances between structures or equipment.

In the mathematical model, the locations for lumped masses were chosen at floor levels and other points of interest, such as supports of major systems or equipment. The structural properties between mass points were reduced to uniform segments of cross-sectional area, effective shear area and moments of inertia. The mathematical model of the containment and the internal structures is shown in Figures 3.7-5 and 3.7-6.

3.7.2.1.2 Nuclear Steam Supply System

The methods used in the seismic analysis of the NSSS are described in Sections 3.7.3.4.2.1.2 and 3.7.3.4.2.1.3.

3.7.2.1.3 Equipment Other Than NSSS

The dynamic analysis of systems and equipment was performed using one of the following methods. Each case was evaluated individually to determine the approach to be used.

A. For structurally simple equipment, the dynamic model could consist of a single mass and a single spring. Using the values of the mass and the spring constant, the natural frequency of the equipment was determined. An acceleration response spectrum yields the equipment acceleration when used in conjunction with the natural frequency and the equipment's damping. The inertia force was obtained by multiplying the mass of the equipment by the acceleration value.

   In lieu of a detailed dynamic analysis, for those items of equipment which could be adequately represented by a single degree of freedom system, the peak acceleration of the response spectrum curve was applied. This acceleration value was then used to calculate the inertia force as outlined above.

B. For structurally complex equipment the following method of analysis was used:

   1. The equipment was modeled by using lumped masses and spring constants.

   2. The natural frequencies and mode shapes for the equipment were determined.

   3. The applicable damping value of the equipment was determined.

   4. Using the natural frequencies, damping and the appropriate acceleration response spectrum, the spectral accelerations, per mode, were determined.

   5. The effective forces and weights, per mode, were calculated from the acceleration values obtained in "4" above.

   6. The resulting response values, per mode, of inertia forces, shear forces and moments were determined from these effective forces and weights. The response values, per mode, were combined by using the square root of the sum of the squares.

C. For rigid equipment having fundamental natural frequencies greater than 30 cps, the response accelerations were equal to the accelerations of the supporting structure at the support point elevation.

D. For flexible equipment having fundamental natural frequencies smaller than 30 cps, the response accelerations were obtained by same method as discussed in Section 3.7.2.1.3.A.

E. For equipment, where the structural support system between the ground and Category 1 equipment had a first mode natural frequency below 30 cps, spectrum response curves were generated for vertical and horizontal directions at the equipment support. In generating the vertical curves, the time history utilized at the ground was scaled to two-thirds of the maximum horizontal acceleration value.

F. An alternative method for the seismic design and verification of new, modified and replacement equipment (e.g., seismic equipment qualification) is to use earthquake and seismic testing experience.

The techniques used in the dynamic analysis of piping are described in BP-TOP-1, Sections 2.0 through 2.4.

3.7.2.2 Natural Frequencies and Responses Loads

Only those natural frequencies near or less than 30 cps were used in the analysis. A summary of these natural frequencies for all major Category 1 structures is given in Table 3.7-3. The mode shapes and natural frequencies of the containment and internal structures are shown in Figure 3.7-7. For the coupled reactor building/RCS seismic analysis, the natural frequencies are summarized in Table 3.7-15.

A sample of a completed analysis for the containment and the internal structures is given in Figures 3.7-8 through 3.7-10. Results for the OBE are shown. Parameters computed in the analyses were inertial force, shear force, moment, acceleration and displacement.

Samples of the floor response spectra are given in Figures 3.7-11 through 3.7-29. These spectra were generated for the containment and auxiliary building and were incorporated into equipment specifications for use by equipment suppliers. Their use is discussed in Section 3.7.2.1.

3.7.2.3 Procedures Used to Lump Masses

3.7.2.3.1 Category 1 Structures, Systems and Components Other Than NSSS

The containment and the internal structures of concrete walls and slabs were represented in the lumped mass model as independent cantilever beams. The validity of modeling a cylindrical containment structure as a cantilever beam is discussed in Appendix E, BC-TOP-4, Revision 1. The lumped masses were computed from tributary structure dead loads and fixed equipment loads. For the containment 15 masses were considered sufficient to conservatively predict the behavior of the structure during seismic conditions. For the internal structures, the masses were lumped at 14 points. Some of the points had mass contributed from supported equipment. A component, system or piece of equipment was usually lumped into the supporting structure mass if its estimated weight was less than one-tenth that of its supporting mass. This equipment, component, or system was later analyzed using the response spectrum generated at the supporting level. The auxiliary building was modeled by lumping masses at the foundation and the concrete floors. The steel framework was lumped into the highest nodal point of the auxiliary building model. The intake structure was modeled similarly by lumping masses at the concrete slab elevations.

The modeling techniques used in dynamic analysis of piping are described in BP-TOP-1, Sections 3.0 through 3.4. An alternative to the Enveloping Response Spectrum Technique delineated in Section 3.3 of BP-TOP-1 is the Independent Support Motion (ISM) Response Spectrum Technique in which individual response spectra are applied to each support.

3.7.2.3.2 Nuclear Steam Supply System

The modeling of the NSSS for the seismic analysis is discussed in Sections 3.7.3.4.2.1.1 and 3.7.3.4.2.1.2.

3.7.2.4 Rocking and Translational Response Summary

Fixed base mathematical models were assumed in the dynamic analysis of the major Category 1 structures, and no rocking and translational response was obtained.

3.7.2.5 Methods Used to Couple Soil With Seismic System Structures

Finite element method was not used and therefore this section is not applicable. See Section 3.7.2.1 for the method used.

3.7.2.6 Development of Floor Response Spectra

The time history method of analysis was used to develop the floor or nodal response spectra for each structural system. A discussion of the technique of finding the nodal time history and then producing the spectrum may be found in Sections 4.2 and 5.2 of BC-TOP-4, Revision 1.

3.7.2.7 Differential Seismic Movement of Interconnected Components

3.7.2.7.1 Category 1 Structures, System and Components Other Than NSSS

BC-TOP-4, Revision 1, Section 5.3, describes the techniques used to compute seismic loadings in interconnected components. BP-TOP-1, Sections 4.2, 6.3.2 and 6.4 describe the techniques used to evaluate differential seismic movements in interconnected piping.

3.7.2.7.2 Nuclear Steam Supply System

Modeling of coupled, multisupported components of the NSSS is described in Sections 3.7.3.4.2.1.1 and 3.7.3.4.2.1.2. The stress and deformation criteria are given in Section 5.2.1.

3.7.2.8 Effects of Variations on Floor Response Spectra

The structural material properties that can affect any variations in seismic response are well known, and they would not cause any significant changes in response. For example, a variation of a few percent in the modulus of elasticity would not cause a significant shift in the natural periods of structural elements because natural frequencies are proportional to the square root of the modulus. For a discussion of spectral peak widening see BC-TOP-4, Revision 1, Section 5.2.

3.7.2.9 Use of Constant Vertical Load Factors

3.7.2.9.1 Category 1 Structures, Systems and Components Other Than NSSS

Vertical seismic analyses determining natural frequencies were made on Category 1 structural systems. For buildings other than the containment, the lowest natural frequency of vertical response for structural modes was above 33 Hz, and the structures were considered rigid in the vertical direction. In accordance with current practice, the horizontal ground response spectra were multiplied by two-thirds to give the vertical ground response spectra. For the containment, a time history analysis in the vertical direction was done. Spectral curves for vertical response at discrete elevations on the shell were determined.

Constant vertical load factors were not used for Category 1 structures, equipment or piping.

3.7.2.9.2 Nuclear Steam Supply System

Constant vertical load factors were not used for the seismic design of the NSSS.

3.7.2.10 Method Used to Account for Torsional Effects

The analysis techniques considered additional shear forces in resisting elements due to the eccentricity between the center of mass and center of rigidity. The torsional effects were obtained by hand calculations and the stresses were combined with the stresses due to horizontal and vertical analyses.

3.7.2.11 Comparison of Responses

A comparison of the results of a modal response spectrum analysis and a modal time history analysis at selected points for the containment, internal structures and auxiliary building is shown in Table 3.7-4. The synthetic ground time history had a spectrum which everywhere enveloped the spectrum used in the modal response spectrum analysis. Its application in the seismic analysis therefore produced conservative results. The ground time history spectrum curve is shown in Figure 3.7-4.

3.7.2.12 Methods for Seismic Analysis of Dams

This section does not apply to this plant since there are no dams used to impound bodies of water serving as heat sinks for the safe shutdown of the plant.

3.7.2.13 Methods to Determine Category 1 Structure Overturning Moments

Overturning moments were computed from the results of the modal response spectrum analysis. The moments of the containment and the internal structures were added. The eccentricity of the shear forces above the bottom of the slab, the effective decrease in weight due to hydrostatic forces, and the effective decrease in weight due to vertical seismic forces were all included in determining the factor of safety against overturning. Calculations showed that this factor of safety was greater than 1.5 for the DBE for the Category 1 structures considered.

Soil pressures were computed on the polygonal area approximating the perimeter of the containment and the neutral axis. The soil pressure was taken as varying linearly from zero at the neutral axis to a maximum at the outer edge. The soil pressures were determined to be within the allowable pressure given in Section 2.5.1.

3.7.2.14 Analysis Procedure for Damping

3.7.2.14.1 Category 1 Structures, Systems and Components Other Than NSSS

None of the Category 1 structural systems, other than the internal structures and containment shell, were modeled as coupled systems. The analysis of the coupled system of steam generators, nuclear reactor, internal structures, and containment shell is discussed in Section 3.7.2.15. For the generation of time histories at the support points of the NSSS, the damping value of the concrete structures was used since the concrete structures contributed most to the response of the model.

3.7.2.14.2 Nuclear Steam Supply System

Modeling and analysis of the coupled components in the NSSS is described in Sections 3.7.3.4.2.1.2.1 and 3.7.3.4.2.1.3.1.

3.7.2.15 Coupled Reactor Building/RCS Seismic Analysis

Seismic response spectra were developed for the reactor building shell, reactor building internal structure, and RCS attachment nozzles and connecting points using a coupled reactor building/RCS model.

Seismic analyses were performed using “state-of-the-art” methodologies and included the following:

1. Seismic ground motion based on R.G. 1.60 recommendations
2. Structural damping based on R.G. 1.61 recommendations
3. 3-dimensional (3-D) representation of the structures and the RCS
4. Soil structure interaction analysis

Because of the axial symmetry of the reactor building containment shell, the existing 2-D model is the same as the 3-D model. Thus, there is no difference between analysis results obtained using the 2-D model versus the 3-D model.

Although the reactor building containment shell is considered symmetrical, the interior structure of the reactor building exhibits some degree of asymmetry, which affects the overall dynamic properties, resulting in added torsional response. A revised 3-D model was generated for the reactor building internals.

Response spectra were generated at 71 locations, including 46 locations for the tributary piping attachment points with the RCS and 25 locations for the reactor building shell and internal structures.

The response spectra were generated for two earthquake levels, OBE and DBE, and for constant damping values of 0.5%, 1%, 2%, 3% and for the variable damping of Code Case N 411.

For the soil structure interaction analysis, the discussion in Section 3.7.1.6 states that the Seismic Category I structures, including the reactor building, are founded on bedrock. Therefore, a fixed base assumption is considered to be appropriate for the ANO-2 reactor building.

3.7.2.15.1 Methodology

Seismic Ground Motion:

The basic seismic input to the building structures was R.G. 1.60 ground motion spectra in two horizontal directions and one vertical direction. The horizontal spectra were normalized to 0.2 g for DBE and 0.1 g for OBE for both horizontal directions, and to 2/3 of the horizontal acceleration in the vertical direction. Uncorrelated acceleration time history functions based on enveloping the 2%, 5%, and 7% shaped R.G. 1.60 spectra were generated for each of the three directions.

Structural Damping:

The structural damping used in generating the original response spectra was 2% OBE and 5% DBE. The response spectra for RCS attached piping was originally generated for 0.5% and 1% damping for OBE and DBE, respectively. By following the requirements of ASME Code Case N-411, a significant reduction in response is achievable due to higher damping. For this coupled reactor building/RCS seismic analysis, the composite modal damping is as follows:

	OBE	DBE
Reactor building – shell	2%	5%
Reactor building – internal structures	4%	7%
RCS	2%	3%

Development of 3-D Model

For this coupled reactor building/RCS seismic analysis, the existing 2-D model of the reactor building was revised to create a 3-D stick model. The stiffness and mass properties of the new 3-D model were developed based on information contained in design bases calculations. The shear center and mass center for each floor elevation were based on design drawings showing the structural details of the walls and floors of the internal structure of the reactor building. This model includes the 3-D representation of the RCS attached at the appropriate elevations.

The new 3-D models are described as follows:

1. Reactor building containment shell stick model – Since the containment shell is axisymmetric, the 3-D reactor building containment shell model is the same as the current 2-D model.

2. Reactor building internal structure stick model – This dynamic model of the internal structures is a multi-branch 3-D stick model. The first stick represents the primary shield walls only. The second stick represents the secondary shield walls only without the steam generator pedestals. This 3-D model is based on the actual wall and floor stiffness and masses, allowing for differences between centers of mass and shear centers at each major floor elevation. This modeling captures the torsional response of the reactor building internal structure.

3. RCS stick model – This is a 3-D stick representation of the RCS incorporating steam generator dynamic properties. A composite 3-D lumped-mass ANSYS model of the reactor vessel, two steam generators, four reactor coolant pumps, and main coolant loop piping is included. In addition, representation of the reactor vessel and steam

generator assemblies used in this model include sufficient detail of the reactor internals and RSG internals to account for possible dynamic interaction between those internal components and the RCS. The RCS stick model is coupled to the reactor building internal structure stick model at appropriate support or restrained elevations. The number of masses and dynamic degrees of freedom are consistent with NRC guidance.

Seismic Analysis:

The seismic analyses consisted of a modal time history analysis, using ANSYS code reduced modal transient analysis option.

The following analyses were performed:

1. A frequency analysis to determine the coupled model natural frequencies and associated mode shapes. The resulting modal properties were used as a basis of comparison with the original models of the reactor building and the RCS.

2. Time-history analysis for both OBE and DBE using the R.G. 1.60 ground spectra as the control motion and R.G. 1.61 damping values for the structures. The 3-D stick model of the reactor building is subjected to simultaneous excitation in the three orthogonal global directions (N-S, E-W, vertical directions).

Upon completion of the dynamic analysis, acceleration and displacement time histories were generated at the main coupling points of the RCS. At each RCS attachment point, and for each earthquake level of OBE and DBE, three time histories of acceleration and displacement response corresponding to three orthogonal global directions were extracted.

Additionally, response spectra were generated for the 71 locations: 46 tributary piping attachment points with the RCS, and 25 locations for the reactor building shell and internal structures. These response spectra were developed using the results of the combined 3-D reactor building model coupled with the RCS model.

3.7.2.15.2 <u>Results</u>

Synthetic time histories were generated based on R.G. 1.60 ground response spectra for 2%, 5%, and 7% damping. Two separate response spectra records were created for the two horizontal directions, and one was created for the vertical direction. The time history was generated from a response spectrum using an iterative procedure. The synthetic time history function is presented in Figures 3.7-52 and 3.7-53 (one horizontal and one vertical component). Figures 3.7-54, 3.7-55, and 3.7-56 show the response spectra generated by the three time history components compared to the target response spectra.

The reactor building shell 3-D dynamic model is shown in Figure 3.7-57. The reactor building internal structure 3-D dynamic model is shown in Figure 3.7-58.

The 3-D model was analyzed with the RCS coupled to the reactor building internal structure and containment shell. A summary of the natural frequencies (modal properties) for the coupled analysis is presented in Table 3.7-15. As a result of this dynamic coupling, the steam generator seismic response shows higher amplification in N/S direction as compared with E/W direction.

3.7.3 SEISMIC SUBSYSTEM ANALYSIS

3.7.3.1 Determination of Number of Earthquake Cycles

3.7.3.1.1 Category 1 Structures, Systems and Components Other Than NSSS

Procedures to determine the number of earthquake cycles for piping during one seismic event are discussed in Section 6.2 of BP-TOP-1. Structures and equipment were designed on the basis of analytical results. In general, the design of structures and majority of the equipment was not fatigue controlled, since most of stress and strain changes would occur only a small number of times and/or would produce only minor stress-strain fluctuations. The occurrence of earthquake and Design Basis Accident (DBA) full design strains is expected to occur too infrequently and with too few cycles to require fatigue design of structures and equipment other than NSSS equipment.

3.7.3.1.2 Nuclear Steam Supply System

The number of maximum amplitude loading cycles specified for the seismic design of the NSSS components is given in Section 5.2.1.5.

3.7.3.2 Basis for Selection of Forcing Frequencies

Structural frequencies ("forcing frequencies") were not selected, but were calculated in accordance with Section 4.2.1 of BC-TOP-4, Revision 1. The seismic qualification of equipment and the design of the equipment supports was accomplished by using the results of one of the methods of seismic analysis outlined in Section 3.7.2.1.3.

3.7.3.3 Root Mean Square Basis

The term "root-mean-square-basis" was not used in the seismic analysis. The term used was "square root of the sum of the squares" and is referred to in Section 3.7.2.1.3 B.

3.7.3.4 Procedure for Combining Modal Responses

3.7.3.4.1 Category 1 Structures, Systems and Components Other Than NSSS

Sections 4.2, 5.3 and Appendix F of BC-TOP-4, Revision 1, describe the techniques used to combine modal responses for structures and equipment. Sections 5.1 and 5.2 of BP-TOP-1 describe the criteria used for piping systems.

3.7.3.4.2 Seismic System Analysis of Nuclear Steam Supply System

3.7.3.4.2.1 Reactor Coolant System

3.7.3.4.2.1.1 Introduction

The adequacy of seismic loadings used for the design of the major components of the Reactor Coolant System (RCS) were confirmed by the methods of dynamic analysis time history and response spectrum techniques. The major components are the reactor, the steam generators, the reactor coolant pumps, the reactor coolant piping and the pressurizer.

In order to account for possible dynamic coupling effects between the components, a composite coupled model was employed in the dynamic analysis of the reactor, the two steam generators, the four reactor coolant pumps and the interconnecting reactor coolant piping. The analysis of these dynamically coupled multisupported components utilized different time dependent input excitations applied simultaneously to each support. In addition, the representation of the reactor vessel assembly used in this coupled model included sufficient detail of the reactor internals to account for possible dynamic coupling from the RCS to the internals. The results of the analysis of the coupled components of the RCS include an appropriate time history forcing function for use in a separate analysis of a more detailed model of the reactor internals.

The analysis of the pressurizer employed a separate mathematical model and utilized response spectrum techniques.

A representation of the coupled components, of sufficient detail to account for possible dynamic coupling effects from the containment internal support structure to the RCS components, was supplied for use in performing the analysis of the containment internal support structure. The results of the analysis of the containment internal support structure included the time history forcing functions for use in the separate analysis of the more detailed model of the coupled components of the RCS. Response spectra were also developed from the containment internal support structure analysis for use in the pressurizer dynamic analysis.

For the time history analyses, dynamic responses to vertical seismic excitation were found for both the case of initial support displacement upward and the case of initial support displacement downward. The responses were combined to determine the most severe combinations produced by the effects of seismic excitations in each of the horizontal directions applied simultaneously with seismic excitation in either vertical direction. The square root of the sum of the squares method was used to combine the modal responses for the response spectrum modal analysis of the pressurizer.

Contributions from all significant modes of response were retained in the analyses.

The damping factors used in the seismic analyses of the major components of the RCS were selected from Table 3.7-6. Modal damping factors of two or three percent of critical and one to two percent of critical for the DBE and OBE, respectively, were used in the seismic analyses of the major components of the RCS.

3.7.3.4.2.1.2 Mathematical Models

In the descriptions of the mathematical models which follow, the spatial orientations are defined by the set of orthogonal axes where Y is in the vertical direction, and X and Z are in the horizontal plane, in the directions indicated on the appropriate figure. The mathematical representation of the section properties of the structural elements employs a 12 x 12 stiffness matrix for the three-dimensional space frame models, and employs a 6 x 6 stiffness matrix for the two-dimensional plane frame model. Elbows in piping runs include the in plane/out of plane bending flexibility factors as specified in the ASME Code, Section III.

3.7.3.4.2.1.2.1 Reactor Coolant System - Coupled Components

A schematic diagram of the composite mathematical model used in the analyses of the dynamically coupled components of the RCS is presented in Figure 3.7-30. This model includes 110 mass points with a total of 555 dynamic degrees of freedom. The mass points and corresponding dynamic degrees of freedom are distributed to provide appropriate

representations of the dynamic characteristics of the components, as follows: the reactor vessel, with internals, is represented by 18 mass points with a total of 75 dynamic degrees of freedom; each of the two steam generators are represented by 37 mass points with a total of 216 dynamic degrees of freedom, each of the four reactor coolant pumps are represented by two mass points with a total of five dynamic degrees of freedom, each pump suction and discharge branch of piping is represented by a mass point with three dynamic degrees of freedom, and each reactor vessel outlet pipe is represented by a mass point with two dynamic degrees of freedom. The representation of the reactor internals if formulated in conjunction with the analysis of the reactor internals discussed in Section 3.7.3.4.2.2, and is designed to simulate the dynamic characteristics of the models used in that analysis.

The mathematical model provides a three-dimensional representation of the dynamic response of the coupled components to seismic excitations in both the horizontal and vertical directions. The mass is distributed at the selected mass points and corresponding translational degrees of freedom are retained to include rotary inertial effects of the components. The total mass of the entire coupled system is dynamically active in each of the three coordinate directions.

3.7.3.4.2.1.2.2 Pressurizer

The mathematical model employed in the analysis of the pressurizer is shown schematically in Figure 3.7-31. This lumped parameter, planar model provides a multi-mass representation of the axially symmetric pressurizer and includes five mass points with a total of six dynamic degrees of freedom.

3.7.3.4.2.1.3 Calculations

3.7.3.4.2.1.3.1 General

As applied in the analysis, the simultaneous equations of motion for linear structural systems with viscous damping can be written, Reference 62:

$$M\ddot{X} + C\dot{X} + KX = M\ddot{Y} - K_{ms} X_s$$

where

- M = diagonal matrix of lumped masses
- C = square symmetric damping matrix
- K = square symmetric stiffness matrix which defines the mass point force to displacement relationship
- $\ddot{Y}$ = column matrix with elements equal to the absolute acceleration of the datum support in the coordinate direction of the related dynamic degree of freedom of the structural system
- K_{ms} = rectangular matrix of stiffness coefficients which defines the mass point force to nondatum support displacement relationship
- X_s = column matrix of displacements relative to the datum at nondatum supports
- X = column matrix of mass point displacements relative to the datum
- $\dot{X}$ = column matrix of mass point velocities relative to the datum
- $\ddot{X}$ = column matrix of mass point acceleration relative to the datum

In this form, the equations define the dynamic response of a multi-mass structural system subjected to time dependent support motion. In the analysis of systems with multiple supports, such as the coupled components of the RCS, the equations provide for different time dependent input motions at each of the supports. In this case, one of the supports of the system is designated the reference, or datum, from which the motions of all other points of the structural system are measured. The reactor vessel support is designated as the datum in the analyses of the coupled components of the RCS.

Normal mode theory, as described in Reference 62, is employed to reduce the equations of motion to a system of independent equations in terms of the normal modes for the time history and spectrum analyses of the RCS components. In the analyses, the dynamic responses of the major components are determined for seismic excitations in each of the three global coordinate directions. The dynamic responses to vertical seismic excitation are found for both the case of initial support displacement upward and the case of initial support displacement downward. These responses are combined to determine the most severe combinations produced by the effects of seismic excitations in each of the horizontal directions applied simultaneously with either seismic excitation in the vertical direction.

3.7.3.4.2.1.3.2 Frequency Analysis – (OSG)

An eigenvalue for the original steam generator analysis was performed utilizing the ICES STRUDL II computer code, Reference 19, to calculate the mode shapes and natural frequencies of the composite mathematical models. Modifications to the standard ICES STRUDL II program have been implemented by CE to include a Jacobi diagonalization procedure in the eigenvalue analysis, and to provide appropriate influence coefficients and stiffness matrices for use in the response and reaction calculations. For analyses with the replacement steam generators (RSGs) see Section 3.7.3.4.2.1.3.5.

A description of the ICES STRUDL II computer code is given in Section 3.7.3.4.2.1.6.

3.7.3.4.2.1.3.3 Mass Point Response Analysis – (OSG)

The time history of mass point responses to seismic excitation are computed using TMCALC, a CE code. This code performs a closed form integration of the equations of motion for singly or multiply supported dynamic systems, utilizing normal mode theory. For the multiply supported systems, the separate time histories of each support are imposed on the system simultaneously. The results are time history responses of the mass points.

A description of the TMCALC code is given is Section 3.7.3.4.2.1.6.

The mass point responses resulting from the spectrum analysis are found utilizing the ICES STRUDL II computer code. This code performs a normal mode response spectrum analysis resulting in modal inertial loads at each mass point. The mass point responses of the pressurizer are found using the response spectrum for the pressurizer support.

3.7.3.4.2.1.3.4 Seismic Reaction Analysis - (OSG)

The dynamically induced loads at all system design points due to the superimposed time history support excitations and mass point responses are calculated utilizing FORCE, a CE computer code. This code performs a complete loads analysis of the deformed structure at each incremental time step by computing internal and external system reactions (forces and moments) by superposition of the reactions due to the mass point displacements and the non-datum support displacements as follows:

$$R(t) = C_m X_m(t) + C_s X_s(t)$$

where

$R(t)$ = the matrix of all components of the reactions at the system design points

C_m = the matrix of mass point displacement influence coefficients

$X_m(t)$ = the column matrix of time history mass point displacements relative to the datum at each time step

C_s = the matrix of support displacement influence coefficients

$X_s(t)$ = the column matrix of time history support displacements relative to the datum at non-datum supports at each time step

The support and mass point displacements due to horizontal and vertical seismic excitations are added algebraically at each time step. The maximum component of each reaction for the entire time domain and its associated time of occurrence are selected.

A description of the FORCE code is given in Section 3.7.3.4.2.1.6.

The maximum reactions for the pressurizer, resulting from the response spectrum analysis, are found by applying the modal inertial loads for each mode, to the structural model using the STRUDL computer code. The design point reactions due to each modal loading are combined by STRUDL by summing the absolute values and by root sum square of the modal reactions.

3.7.3.4.2.1.3.5 Analysis of RCS with Replacement Steam Generator (RSG)

The original analysis was performed using the STRUDL computer code to define the structural properties of the RCS. The current analysis used the ANSYS computer code to define the structural properties of the RCS. The ANSYS model was developed by converting the STRUDL commands that produced the STRUDL structural model to equivalent ANSYS commands. The equivalence of the two models was confirmed by comparison of the predicted frequencies and mode shapes. The RCS model was updated to include the RSGs and detailed RV internals representation shown in Figure 3.7-30.

3.7.3.4.2.1.3.5.1 Frequency Analysis

An eigenvalue analysis was performed using the ANSYS computer code to calculate the mode shapes and natural frequencies of the RCS composite mathematical model. The calculated natural frequencies and dominant degrees of freedom for the RCS and the calculated modal frequencies and corresponding modal participation factors for the Replacement Pressurizer are shown in Table 3.7-7.

3.7.3.4.2.1.3.5.2 Response Analysis

The original OBE time history motions were used as input to the RCS supports. Motions were applied separately in the three orthogonal directions; X parallel to the hot leg, Y vertical, and Z perpendicular to the hot leg. Time history motions were applied at each RCS support location. The motions applied varied depending on the location in the building model to which the RCS support was attached. The response of the RCS for each direction was calculated using the method of modal superposition with a constant damping ratio of 1% for OBE. For DBE, twice the OBE time history input was used with a constant damping ratio of 2%.

3.7.3.4.2.1.4 Results

The reactions (forces and moments) at all design points in the system, obtained from the dynamic seismic analysis, are compared with the seismic loads in each component design specification. The results of this comparison are summarized in tabular form for the points of maximum calculated load in Table 3.7-8.

The maximum seismic loads calculated by the time history techniques are the result of a search and comparison over the entire time domain of each individual component of load due to the simultaneous application of the horizontal and either vertical excitation. The maximum calculated components of load for each design location do not in general occur at the same time, nor for the same combination of horizontal and vertical excitation, and therefore result in a conservative worst case.

The maximum seismic loads calculated by the response spectrum techniques are the result of combining the modal reactions due to the horizontal and the vertical excitation.

3.7.3.4.2.1.5 Conclusion

All seismic loads calculated by the dynamic seismic analyses are less than the corresponding loads in the component design specifications. These analyses were performed for OBE and DBE excitations and the results are compared with OBE and DBE design specification loads. It is concluded the seismic loadings specified for the design of the RCS components and supports are adequate.

3.7.3.4.2.1.6 Description of Computer Codes

3.7.3.4.2.1.6.1 ICES/STRUDL

The ICES/STRUDL-II computer program provides the ability to specify characteristics of problems - framed structures and three-dimensional solid structures, perform analyses - static and dynamic and reduce and combine results.

Analytic procedures in the pertinent portions of ICES/STRUDL-II apply to framed structures. Framed structures are two- or three-dimensional structures composed of slender, linear members which can be represented by properties along a centroidal axis. Such a structure is modeled with joints, including support joints, and members connecting the joints. A variety of force conditions on members or joints can be specified. The member stiffness matrix is computed from beam theory. The total stiffness matrix of the modeled structure is obtained by appropriately combining the individual member stiffnesses.

The stiffness analysis method of solution treats the joint displacements as unknowns. The solution procedure provides results for joints and members. Joint results include displacements and reactions and joint loads are calculated from member end forces. Member results are member end forces and distortions. The assumptions governing the beam element representation of the structure are as follows: linear, elastic, homogeneous, and isotropic behavior, small deformations, plane sections remain plane, and no coupling of axial, torque and bending.

The program is used to define the dynamic characteristics of the structural models used in the dynamic seismic analyses of the RCS components. The natural frequencies and mode shapes of the structural models and the influence coefficients which relate member end forces and moments and support reactions to unit displacements are calculated. The influence coefficients are calculated for each dynamic degree of freedom of each mass point and for each degree of freedom of each support point at which relative motion is imposed. In addition, stiffness coefficients are calculated which relate the forces corresponding to those joint degrees of freedom for which mass is specified to the imposed displacements corresponding to those (support) joint degrees of freedom at which relative motion will be specified during subsequent seismic response calculations. As appropriate, these data are stored for later use in response spectra or time history seismic response calculations.

ICES/STRUDL-II is a program which is in the public domain and has had sufficient use to justify its applicability and validity. The version of the program in use at CE was developed by the McDonnell Automation Company/Engineering Computer International and is run on the IBM-360 computer system.

3.7.3.4.2.1.6.2 TMCALC

The CE program TMCALC solves the differential equations of motion for a singly or multiply excited multi-degree-of-freedom linear structural system. The program accepts separate, independent, time varying inputs at each boundary point in the system at which motions due to a seismic event may be imposed, or where a load forcing function may be imposed. The input excitations are provided in digitized form and are assumed to vary linearly between input time steps. The solution of the equations of motion in normal mode coordinates employs a closed form integration process.

The inputs to TMCALC consist of:

A. Eigenvalues (natural frequencies) and eigenvectors (mode shapes).

B. A stiffness matrix which relates mass point degrees of freedom to boundary point degrees of freedom.

C. Mass and damping matrices.

D. Digitized time history records which define the excitation in terms of motions at the boundary points of the structural system or forces at mass points.

The output from TMCALC consists of digitized time history records of the absolute accelerations and relative displacements for each mass point and boundary point dynamic degree of freedom of the structural system. The program was developed by CE in 1970 and is used on the CDC 7600 computer at CE.

The program is used to calculate the dynamic response of structural models used in the dynamic seismic analysis of the RCS major components, and in the dynamic analysis of linear structural systems subjected to time varying load forcing functions, such as thrust from postulated pipe ruptures.

To demonstrate the applicability and validity of the TMCALC program, the solutions to test problems were obtained and shown to be substantially identical to the results obtained by hand calculation. One such problem is shown here for purposes of illustration. The satisfactory

agreement between the program results and the theoretical solution indicates the reliability of TMCALC. Figure 3.7-32 is a lumped mass, shear beam representation of a uniform beam with the given properties, subjected to different, arbitrary motions at each of the two supports, as shown. The closed form solution to the equation of motion for this structure can be found using standard integration techniques.

From this closed form solution for the equation of the multiply excited (see References 73 and 76) system shown in Figure 3.7-32, maximum values of relative displacement, velocity and acceleration were derived. These solutions are shown in Table 3.7-9 along with the corresponding results from program TMCALC. Differences can be seen to be less than one percent. The respective times at which these maxima occurred were identical.

3.7.3.4.2.1.6.3 FORCE

The computer program FORCE calculates the internal forces and moments at designated locations in a linear elastic structural system, at each time step, due to the time history of relative displacements of the system and boundary points. The program also selects the maximum value of each component of force or moment at each designated location, and the times at which they occur, over the entire duration of the specified dynamic event. The input to FORCE consists of the following:

A. A matrix of influence coefficients computed by the ICES/STRUDL-II program, which relate the displacements of the mass point and support point dynamic degrees of freedom to the reaction forces and moments at the designated locations.

B. The time history of the relative displacements of the mass point and support point dynamic degrees of freedom as calculated by the program TMCALC.

The program forms appropriate linear combinations of the relative displacements at each time step and performs a complete loads analysis of the deformed shape of the structure each time step over the entire duration of the specified dynamic event.

The program was developed by CE in 1970 and is used on the CDC 7600 computer.

The program is used to calculate the time dependent reactions in structural models subjected to dynamic excitation which are analyzed by the TMCALC program.

To demonstrate the validity of the FORCE program, results for test cases were obtained and shown to be substantially identical to those obtained for an equivalent analysis using the public domain program STRUDL. One such test case is shown here for purposes of illustration. Figure 3.7-33 is a lumped mass multiple degree of freedom model of a uniform beam which has been defined to have mass and differential boundary excitation. The arbitrary differential support motion and mass point responses chosen for this example are shown in Table 3.7-10. The matrix of influence coefficients and the arbitrary mass point and differential support point motions are input to the program to calculate the support reactions and internal shear forces and bending moments indicated in Figure 3.7-33. These results and those found by performing a stiffness analysis using the STRUDL program are shown in Table 3.7-11. Results can be seen to be substantially identical.

3.7.3.4.2.1.6.4 ANSYS

The ANSYS computer code, Reference 87, is a large-scale multi-purpose commercial finite element program that may be used for solving several classes of engineering analyses. The analysis capabilities of ANSYS include the ability to solve static and dynamic structural analyses, steady state and transient heat transfer problems, mode-frequency and buckling eigenvalue problems. The program contains many special features that allow nonlinearities or secondary effects to be included in the solution.

3.7.3.4.2.2 Reactor Internals and Core

The procedure for determining the response of the reactor internals and core to a seismic event had three basic steps. First, a response analysis of the reactor coolant system was performed to obtain the motion of the reactor vessel in the two orthogonal directions and the vertical direction. In the second step, the reactor vessel excitation was input to separate horizontal and vertical models of the internals and core. Separate horizontal and vertical models of the internals and core were formulated to more efficiently account for the structural and response differences in these directions. For the horizontal direction, the analysis of the coupled internals and core model provided reactor internals loads and the time history motions of the core plates and core shroud. These motions were then input, in the third step, to detailed models representing various rows of fuel assemblies across the core. The horizontal fuel assembly response and spacer grid impact loads were obtained from the detailed core model analyses.

For the vertical direction, reactor internals and fuel loads were obtained directly from the analysis of the coupled vertical internals and core model.

3.7.3.4.2.2.1 Analysis of the Reactor Internals and Core

3.7.3.4.2.2.1.1 Horizontal Analysis

The reactor coolant system seismic analysis, described in Section 3.7.3.4.2.1, provided horizontal Operating Basis Earthquake (OBE) and Design Basis Earthquake (DBE) acceleration time history motions of the reactor vessel at the vessel ledge and snubbers in the North-South and East-West directions. These time histories were 20 seconds in length.

The analysis of the reactor internals and core under horizontal seismic excitation was performed by nonlinear time history analysis. Coupled internals and core mathematical models were developed that describe the structural behavior of the internals plus core in the horizontal directions. Equations of the motion were formulated in terms of mass, damping and stiffness matrices and associated nodal acceleration, velocity, and displacement vectors.

The earthquake time histories were applied to the reactor vessel nodes. The seismic response of the internals was computed by direct integration of the equations of motion using a numerical step-by-step procedure incorporated in the CESHOCK computer program.

The mathematical models of the internals consist of lumped masses and elastic-beam elements to represent the beam-like behavior of the internals and nonlinear elements to simulate the effect of gaps between components. Typical component gaps represented by nonlinear elements are the core support barrel – reactor vessel snubber gap and the core shroud guide lug – fuel alignment plate gap. At appropriate locations within the internals and core, nodes were chosen to lump the weights of the structure. The criterion for choosing the number and location of mass concentrations was to provide accurate representation of the modes of

vibration of each component. Between the nodes, properties were calculated for moments of inertia, cross-sectional area, effective shear area and length. Stiffnesses for the complex internals structures such as flanges and grid beams were determined by finite element analyses. A sketch of the coupled internal and core model is shown in Figure 3.7-37.

Damping values used for the internals components were 4% of critical for the DBE and 2% of critical for the OBE in accordance with Regulatory Guide 1.61 for welded steel structures. Damping values for the fuel assemblies were based on measured values from full-scale fuel assembly testing.

Fuel assembly modeling in the coupled internals and core model accounted for the total number of assemblies in the core. Thus, the effects of the entire core on the response of the internals were included in the analysis. As shown in Figure 3.7-37, the fuel assemblies were combined into three groupings. The two outer groupings represented the 15 peripheral fuel assemblies on each side of the core. The center grouping represents the remaining 147 fuel assemblies. Individual fuel assemblies were modeled as uniform beams with rotational springs at each end to simulate the end conditions at the top and bottom of the core. The stiffness of each fuel grouping was determined by combining the individual fuel assembly stiffnesses as springs added in parallel. Nonlinear spring couplings between corresponding nodes on the outer rows of fuel assemblies and core shroud were used to permit fuel to core shroud impacting. Incorporated into these nonlinear springs was the spacer grid impact stiffness derived from test results.

3.7.3.4.2.2.1.2 <u>Vertical Analysis</u>

The response of the reactor internals and fuel in the vertical direction was determined by nonlinear analyses of the coupled vertical reactor internals and fuel model. The analyses were performed using the CESHOCK computer program. The input excitations to the model were the vertical OBE and the DBE acceleration time histories of the reactor vessel at the flange elevation.

The mathematical model of the reactor internals and core was developed using methods similar to those used for the horizontal model. A sketch of the vertical reactor internals and fuel model is shown in Figure 3.7-38. Model properties were calculated using cross-sectional structural properties and finite element models. The core was modeled by combining all fuel assemblies into a single grouping that includes the weight of the entire core. The vertical stiffness properties of the fuel grouping were obtained by combining the stiffness of each fuel assembly as springs in parallel. The fuel assembly grouping was subdivided into fuel rods and guide tubes with friction elements representing the interaction between the fuel rods and guide tubes at the spacer grid locations.

In addition to the friction elements, the model includes nonlinear elements that represent the CSB upper flange, the UGS flange, fuel assembly holddown forces provided by the upper end fitting springs and the expansion compensating ring. Damping values used for the internals components and fuel were 4% of critical for the DBE and 2% of critical for the OBE, in accordance with Regulatory Guide 1.61 for welded steel structures.

3.7.3.4.2.2.2 <u>Details of the Reactor Internals Models</u>

The salient details of the internals models described in Section 3.7.3.4.2.2.1 are discussed in the following paragraphs.

3.7.3.4.2.2.2.1 Hydrodynamic Effects

The dynamic analysis of reactor internals presents some special problems due to their immersion in a confined fluid. It has been shown both analytically and experimentally (Reference 57) that immersion of a body in a dense fluid medium lowers its natural frequency and significantly alters its vibratory response as compared to that in air. The effect is more pronounced where the confining boundaries of the fluid are in close proximity to the vibration body as is the case for the reactor internals. The method of accounting for the effects of a surrounding fluid on a vibrating system has been to ascribe to the system additional or "hydrodynamic mass".

This "hydrodynamic mass" decreases the frequencies of the system, but is not directly involved in the inertia force effects. The hydrodynamic mass of an immersed system is a function of the dimensions of the real mass and the space between the real mass and confining boundary.

Hydrodynamic mass effects for moving cylinders in a water annulus are discussed in References 57 and 64. The results of these references were applied to the internals structures to obtain the total (structural plus hydrodynamic) mass matrix which is then used in the evaluation of the natural frequencies and mode shapes for the model.

3.7.3.4.2.2.2.2 Core Support Barrel

The core support barrel was modeled as a beam with shear deformation. It has been shown (References 56 and 71) that the use of beam theory for cylindrical shells gives sufficiently accurate results when shear deformation is included.

3.7.3.4.2.2.2.3 Fuel Assemblies

See Section 3.7.3.4.2.2.6.3 for seismic analysis of fuel assemblies.

3.7.3.4.2.2.2.4 Support Barrel Flanges

To obtain accurate horizontal and vertical stiffnesses of the upper and lower core support barrel flanges and the upper guide structure support barrel upper flange, finite element analyses of these regions were performed. As shown in Figure 3.7-39, these areas were modeled with quadrilateral and triangular ring elements. Asymmetric loads, equivalent to lateral shear loads and bending moments, and symmetric axial loads were applied and the resulting displacements calculated. These results were then used to derive the equivalent member properties for the flanges.

3.7.3.4.2.2.2.5 CEA Shrouds

For the horizontal model, the CEA shrouds were treated as vibrating in unison and were modeled as guided cantilever beams in parallel. To account for the decreased lateral stiffness of the upper guide structure due to local bending of the fuel alignment plate, a short member with properties approximating the local bending stiffness of the fuel alignment was included at the bottom of the CEA shrouds. Since the stiffness of the upper guide structure support plate is large compared to that of the shrouds, the CEA shrouds were assumed to be rigidly connected to the upper guide structure support plate.

3.7.3.4.2.2.2.6 Upper Guide Structure Support Plate and Lower Support Structure Grid Beams

These grid beam structures were modeled as plane grids. Displacements due to vertical (out of plane) loads applied at the beam junctions were calculated through the use of the STRUDL computer code (Reference 19). Average stiffness values based on these results yielded an equivalent member cross section areas for the vertical model.

3.7.3.4.2.2.3 Linear Models for Reactor Internals

The dynamic characteristics of the reactor internals used to formulate the model for the RCS coupled analysis described in Section 3.7.3.4.2.1.2 were determined from linear models of the reactor internals.

Equivalent multi-mass mathematical models were developed to represent the reactor internals and core. The linear mathematical models of the internals were constructed in terms of lumped masses and elastic beam elements. At appropriate locations within the internals and core, points (nodes) were chosen to lump the weights of the structure. A sketch of the internals and core showing the relative node locations of the horizontal model is presented in Figure 3.7-34. Figures 3.7-35 and 3.7-36 show the idealized linear horizontal and vertical models. The criterion for choosing the number and location of mass concentration was to provide for accurate representation of the dynamically significant modes of vibration of each of the internal components. Between the nodes, properties were calculated for moments of inertia, cross-section areas, effective shear areas and lengths. Natural frequencies and mode shapes were determined using the models.

3.7.3.4.2.2.3.1 Natural Frequencies and Mode Shapes

The mass and beam element properties of the models were utilized in STAR, a computer program from the MRI/STARDYNE Analysis System programs (References 26 and 27) to obtain the natural frequencies and mode shapes. This system utilizes the "stiffness matrix" method of structural analysis. The natural frequencies and mode shapes were extracted from the system of equations:

$$(\underline{K} - W_n^2 \underline{M})\, ø_n = O$$

where

$\underline{K}$ = model stiffness matrix

$\underline{M}$ = Model mass matrix

W_n = Natural circular frequency for the n^{th} mode

$ø_n$ = Normal mode shape matrix for n^{th} mode

The mass matrix, $\underline{M}$, includes the hydrodynamic and structural masses.

3.7.3.4.2.2.4 Response Calculation Methods

3.7.3.4.2.2.4.1 Response Spectra Method

The response spectrum analysis was performed using the modal extraction data and the following relationships for each mode:

Nodal Accelerations

$$\ddot{\chi}_{in} = \gamma_n A_n \Phi_{in}$$

where

$\ddot{\chi}_{in}$ = Absolute acceleration at node "i" for mode "n"

γ_n = Modal participation factor

A_n = Modal acceleration from response spectrum

Φ_{in} = Mode shape factor at node "i" for mode "n"

Nodal Displacement

$$Y_{in} = \frac{\ddot{\chi}_{in}}{W_n^2}$$

where

Y_{in} = Displacement at node "i" for mode "n" relative to base

W_n = Natural circular frequency for n^{th} mode

Member Forces and Moments

$$F_n = \frac{(\gamma_n A_n)}{W_n^2} \overline{F}_n$$

where

F_n = Actual member force for mode "n"

$\overline{F}_n$ = Modal member force for mode "n"

The effect of the fluid environment was accounted for by defining the modal participation factor as follows:

$$\gamma_n = \frac{\sum_{i=1}^{M} W_{si} \Phi_{in}}{\sum_{i=1}^{M} W_{Ti} \Phi_{in}^2}$$

where

W_{si} = Structural weight of node "i"

W_{Ti} = Structural + hydrodynamic weight of node "i"

M = Number of masses

The square root of the sum of the squares method is normally used to combine the modal responses. However, since the modal frequencies were closely spaced, the responses of the closely spaced modes were combined by the sum of their absolute values. The modal damping factors were obtained by the method of "Mass Mode Weighting", which gives:

$$B_n = \frac{\sum M_i |\Phi_{in}| B_i}{\sum M_i |\Phi_{in}|}$$

where

B_n = Modal damping factor

M_i = Structural mass of mass node "i"

$|\Phi_{in}|$ = Absolute value of the mode shape at mass mode "i"

B_i = Damping associated with mass point "i"

3.7.3.4.2.2.4.2 Nonlinear Analysis

The nonlinear horizontal and vertical seismic loads for the internals were determined using the CESHOCK computer code (Reference 58). This computer code provides the numerical solution to transient dynamic problems by step by step integration of the differential equations of motion. The nonlinear input excitation for the model was lateral time history accelogram of the reactor vessel flange.

Since the CESHOCK code does not directly solve base excited systems, the acceleration time history of the reactor vessel flange was converted into an equivalent fixed base inertia force time history (Reference 77).

Input to the CESHOCK code consisted of initial conditions, nodal lumped masses, linear spring coefficients, mass moments of inertia, nonlinear spring curves and the acceleration time history. The output from the CESHOCK code consisted of displacements, translational and angular accelerations, impact forces, shears, and moments.

A brief description of the general methods used in the CESHOCK code to solve transient dynamic problems is presented below:

All of the dynamic systems capable of being solved by this program can be described by the differential equation:

$$Rx = U\ddot{x} + U^* \dot{x} + F$$

which is the equation of motion for a generalized spring-mass system,

where

R = Mass matrix

U = Stiffness matrix

U* = Damping matrix

F = Forcing vector

x = Generalized Displacement

$\dot{x}$ = Derivative with respect to time

By programming options, this equation can be used to represent an axial lumped, spring mass system equation:

$$M\ddot{Y} = A_x Y + A_x^* \dot{Y} + L$$

or a system with lateral motion Y and rotational motion θ defined by:

$$M\ddot{Y} = AY + B\theta + A^*\dot{Y} + B^*\dot{\theta} + L$$

$$J\ddot{\theta} = CY + D\theta + C^*Y + D^*\theta + M$$

where

$$A = \begin{bmatrix} \sum\limits_{j=1} A_{j1} & \bullet & \overset{\bullet}{\text{Symmetric}} & \bullet \\ -A_{21} & \sum\limits_{j=2} A_{j2} & \bullet & \bullet \\ -A_{31} & -A_{32} & \sum\limits_{j=3} A_{j3} & \bullet \\ \bullet & \bullet & \bullet & \bullet \end{bmatrix} \quad C = \begin{bmatrix} \sum\limits_{j=1} C_{ji} & \bullet & \overset{\bullet}{\text{Symmetric}} & \bullet \\ -C_{21} & \sum\limits_{j=2} C_{j2} & \bullet & \bullet \\ -C_{31} & -C_{32} & \sum\limits_{j=3} C_{j3} & \bullet \\ \bullet & \bullet & \bullet & \bullet \end{bmatrix}$$

$$B = \begin{bmatrix} \sum\limits_{j=1} b_{1j} & \bullet & \overset{\bullet}{\text{Symmetric}} & \bullet \\ -b_{21} & \sum\limits_{j=2} b_{2j} & \bullet & \bullet \\ -b_{31} & -b_{32} & \sum\limits_{j=3} b_{3j} & \bullet \\ \bullet & \bullet & \bullet & \bullet \end{bmatrix} \quad D = \begin{bmatrix} \sum\limits_{j=1} \left(d_{j1} - C_{j1} l_{j1}\right) & \bullet & \bullet & \bullet \\ -d_{21} & \sum\limits_{j=2} \left(d_{j2} - C_{j2} l_{j2}\right) & \bullet & \bullet \\ -d_{31} & -d_{32} & \sum\limits_{j=3} \left(d_{j3} - C_{j3} l_{j3}\right) & \bullet \\ \bullet & \bullet & \bullet & \bullet \end{bmatrix}$$

Given a coupling between two masses, i and j, the following properties are defined for the specific elements of the above matrices.

A_{ij} = Shear load at mass i caused by a positive unit deflection with no rotation at mass j.

For the axial system, the elements of A_x are defined as the load at mass i caused by a positive unit deflection at mass j. For lateral problems, the basic element used is the beam defined by the following stiffness coefficients.

B_{ij} = Bending moment at mass i caused by a positive unit deflection with no rotation at mass j.

C_{ij} = Shear load at mass i caused by a positive unit rotation with no deflection at mass j.

D_{ij} = Bending moment at mass i caused by a positive unit rotation with no deflection at mass j.

1_{ij} = Distance between the CGs of masses i and j.

m_i = Mass of node i, (lb-sec^2/in).

J_i = Polar moment of inertia of node i, (lb-in/sec^2)

References 46 and 54 give complete details for the derivation of these elements. The numerical integration is performed using either the Runge Kutta Gill method or Newmark's technique.

3.7.3.4.2.2.5 Results

3.7.3.4.2.2.5.1 Natural Frequencies

The most significant natural frequencies and mode shapes are presented in Figures 3.7-40 through 3.7-45 horizontal direction.

3.7.3.4.2.2.5.2 Response Loads Reactor Internals Nonlinear Analysis

The nonlinear horizontal and vertical seismic analyses determined OBE and DBE seismic loads on the reactor internals components. These loads were used in evaluating the structural integrity of the reactor internals described in Sections 4.2.2 and 4.4.2.

3.7.3.4.2.2.6 Seismic Analysis for Fuel Elements and Control Element Drive Mechanisms

3.7.3.4.2.2.6.1 Introduction

Dynamic analyses of the fuel assemblies were conducted to determine the adequacy of their seismic design under nonlinear conditions that exist when the gaps between fuel assemblies close and when the fuel lifts off the core support plate. These analyses were conducted in conjunction with the nonlinear seismic analysis of the reactor internals as discussed in Sections 3.7.3.4.2.2.1 through 3.7.3.4.2.2.5. The following section describes the mathematical model and analytical procedure used for the nonlinear impacting analyses of the reactor core.

3.7.3.4.2.2.6.2 Horizontal Core Analysis

The horizontal seismic analysis of the reactor internals and core, described in Section 3.7.3.4.2.2.1, provided horizontal OBE and DBE acceleration time history motions of the core boundary (the fuel alignment plate, core support plate, and the core shroud). Nonlinear models of the core were developed to represent the rows of fuel assemblies across the core. The core model representing a row of 15 fuel assemblies, the longest row, is shown in Figure 3.7-49. A core model representing the shortest row with 5 fuel assemblies was also developed and used in the analysis.

In the detailed core models, each fuel assembly is represented as a uniform beam with rotational springs at each end to simulate the end condition at the top and bottom of the core, Lumped masses are located at every spacer grid so that the significant modes of vibration of the fuel are represented to account for possible spacer grid impacting. Nonlinear spring couplings are used to simulate the gaps in the core. Each spacer grid is characterized by the dual load path model, which represents the load paths associated with both one-sided and through-grid impacts. One-sided loads are experienced when only one side of the spacer grid is loaded. This type of impact occurs when the peripheral fuel assembly hits the core shroud, or when two adjacent fuel assemblies strike one another. The second type of impact loading occurs typically when the fuel assemblies pile up on one side of the core causing the spacer grids to be subjected to a through-grid compressive loading. One-sided and through-grid loads on a spacer grid are shown in Figure 3.7-50. A grid model sketch with typical load distribution is shown in Figure 3.7-51.

3.7.3.4.2.2.6.3 Seismic Analysis for Fuel Assembly

The horizontal core analyses determined spacer grid impact loads and fuel assembly deflected shapes at times of peak response. Vertical loads on the fuel assembly components are determined from the vertical reactor internals and core analyses. These results are used in the evaluation of the structural integrity of the fuel assemblies, which is described in Section 4.2.1.

3.7.3.4.2.2.6.4 Reactor Vessel Head Area Components

The response loads of the CEDM components, the Head Lift Rig (HLR), and the ICI Flange Assembly and Support Post due to seismic effects were determined by analysis for the RCS subject to power uprate conditions. ANSYS finite element models (FEMs) of these components were developed, and linear response spectrum analyses were performed to calculate the response of each component to OBE and DBE inputs. These components were evaluated by comparison to the original loads used in the stress analyses.

A detailed discussion of the FEMs and evaluations of these components for seismic and pipe break excitation in combination with normal operation loads is given in Section 3.9.3.1.3.

3.7.3.5 Significant Dynamic Response Modes

3.7.3.5.1 Category 1 Structures, Systems and Components Other Than NSSS

Appendix F of BC-TOP-4, Revision 1, describes the analysis techniques used if the "peak of the spectra" method was used by the equipment suppliers. Such considerations are included in IEEE 344 as referenced in Appendix F of BC-TOP-4, Revision 1. For piping, this is covered in Section 2.3.2 and Appendix D of BP-TOP-1.

3.7.3.5.2 Nuclear Steam Supply System

The "peak of the spectra" method was not used in the NSSS seismic analysis.

3.7.3.6 Design Criteria and Analytical Procedures for Piping

3.7.3.6.1 Piping Other Than NSSS

Procedures and design criteria accounting for relative displacements between piping supports are provided in Sections 4.0, 6.3.2 and 6.4 of BP-TOP-1.

3.7.3.6.2 Nuclear Steam Supply System Piping

The treatment of relative motion of the NSSS supports is described in Sections 3.7.3.4.2.1.1 and 3.7.3.4.2.1.3.1.

3.7.3.7 Basis for Computing Combined Response

Section 5.1 of BP-TOP-1 provides the criteria used to combine the results of horizontal and vertical seismic responses for piping systems.

Sections 4.3, Equation 4-8, and 5.3 of BC-TOP-4, Revision 1, provides the criteria used to combine the results of horizontal and vertical seismic analyses for equipment. Section 3.7.2.1.3 of this report discusses seismic analyses of equipment.

3.7.3.8 Amplified Seismic Responses

A constant load factor was not used for the design of equipment. The natural frequencies of the equipment were computed and the spectrum response method was used to determine inertial forces in the horizontal and vertical directions. Amplification of vertical seismic response by slabs was considered in the seismic design of the equipment when required.

3.7.3.9 Use of Simplified Dynamic Analysis

Section 2.3.2 and Appendix D of BP-TOP-1 describe the basis for the simplified dynamic analysis technique used in lieu of response spectrum analysis technique for piping. Simplified dynamic analysis was not used for Category 1 structures, systems, or components.

3.7.3.10 Modal Period Variation

The procedures used to account for modal natural period variation in models of Category 1 structures are discussed in Section 3.7.2.8.

3.7.3.11 Torsional Effects of Eccentric Masses

The significant torsional effects of valves and other eccentric masses were taken into account in the seismic piping analysis by the techniques discussed in Section 3.2 of BP-TOP-1.

3.7.3.12 Piping Outside Containment

Sections 2.0 and 6.0 of BP-TOP-1 discuss the techniques and criteria used to analyze the Category 1 piping other than the buried type.

Section 6.0 of BC-TOP-4, Revision 1, discusses the techniques used to calculate the stresses from seismic loadings for buried piping. The buried Category 1 piping was designed to remain functional when subjected to seismic loads. This was accomplished by limiting the calculated stresses in the pipe material under all loading combinations, including earthquake, as discussed below.

The sum of the stresses produced by internal and/or external pressures, and those produced by seismic forces, did not exceed 2.4 S_h for the DBE or 1.2 S_h for OBE.

S_h indicates the allowable stresses prescribed in Tables I-7-1, I-7-2, and I-7-3 of Appendix I of the ASME Code. If ANSI B31.1.0, Power Piping was used, the allowable stresses were considered as indicated in Tables A-1 and A-2 of Appendix A of that code.

The stress allowables of 2.4 for DBE and 1.2 for OBE were based on the discussion given in Section 3.9.2.

3.7.3.13 Interaction of Other Piping With Category 1 Piping

Section 3.4 of BP-TOP-1 describes the techniques used to consider the interaction of Category 1 piping with non-Category 1 piping.

3.7.3.14 Field Location of Supports and Restraints

All Category 1 seismic supports and restraints, including those required for mechanical equipment and electrical components, are located after an appropriate seismic analysis determines the requirements. The required location and type of restraint is then sent to the restraint supplier for design details. These details are carefully reviewed to assure that the location, function and overall design is compatible with the seismic analysis.

Subsequent to installation, field engineers reviewed the installation to ensure compliance with the restraint detail and the assumptions in the analysis.

3.7.3.15 Seismic Analysis for Fuel Elements, Control Rod Assemblies and Control Rod Drives

The seismic analysis of the reactor internals is provided in Section 3.7.3.4.2.2.

3.7.4 SEISMIC INSTRUMENTATION PROGRAM

Three triaxial time-history accelerographs are installed on the Unit 1 reactor building. The location of these instruments coincides with two key elements in the Unit 2 dynamic model for seismic analysis. Therefore, data obtained from these instruments may be analyzed for both Units 1 and 2.

3.7.4.1 Comparison With Safety Guide 12

This seismic instrumentation system conforms to Safety Guide 12, "Instrumentation for Earthquakes," dated March 1971.

3.7.4.2 Location and Description of Instrumentation

The three strong motion triaxial accelerographs are mounted on the outside surface of the Unit 1 reactor building wall. These three instruments are placed at two elevations; one at Elevation 531 feet, 6 inches and the other two at Elevation 335 feet (top of base slab).

The seismic network control center provides two alarms to the control room based on measurements taken by two strong motion triaxial accelerographs located at the base slab provide alarms in the control room for Unit 1. One alarm is triggered when a setpoint of 0.01 g has been exceeded. This alarm will indicate that an earthquake has occurred and the seismic monitoring system is recording seismic data. The other alarm will provide an immediate indication if the predetermined vibratory ground motion acceleration value of 0.1 g for the OBE has been exceeded.

In addition to the above instrumentation, one strong motion peak-recording accelerograph mounted outside the containment on the Unit 2 containment base slab.

3.7.4.3 Control Room Operator Notification

An alarm in the Unit 1 control room will indicate to the operator that a seismic event has activated the seismic instrumentation and that the seismic event is being recorded. The actions to be taken in the event of this alarm are included in the plant operating procedures.

3.7.4.4 Comparison of Measured and Predicted Responses

Following an earthquake, the resulting measurements will be evaluated by qualified seismology and engineering personnel. If the analysis indicates the shock may have caused stresses exceeding design limits specified for OBE to structures, systems, or components, specific action will be taken as recommended by the evaluating personnel.

3.7.5 SEISMIC DESIGN CONTROL MEASURES

3.7.5.1 Category 1 Systems and Components Other Than NSSS

The seismic input data were provided to the suppliers of Category 1 equipment by means of detailed equipment specifications. One part of the specification contained input data in the form of floor response curves (Section 3.7.2.6). The specification designated the particular floor response spectrum curve(s) for the floor(s) on which the equipment or component is located.

The detailed equipment specifications required that the supplier submit test data and/or seismic analyses for review, as a condition of acceptance of the equipment for the intended function. The supplier was permitted to use (1) test reports of the particular component, or (2) reports of tests with applicable data from a previously tested comparable component which, during normal operating conditions has been subjected to equal or greater loadings, or (3) suitable analytical results.

The report from the supplier was reviewed for methods, procedures and results for compliance with the criteria. The submittal and review procedures were repeated, if necessary, when questions as to conformance with the criteria were raised.

3.7.5.2 Nuclear Steam Supply System

Purchase specifications for Seismic Category 1 components specify horizontal and vertical seismic acceleration values based on the floor response spectra at the equipment location. The vendors were required to demonstrate by calculations, operating experience data or testing, the capability of the equipment to withstand the seismic forces, and that the equipment would continue to operate after a DBE. The floor response spectra at the location of the equipment was supplied to the vendors. The vendors were also required to calculate the natural period of vibration of the equipment and see that the natural period did not fall within the critical frequency range of the floor response spectra. The calculations and/or test results received from the vendors were reviewed by cognizant engineering personnel for approval of the seismic qualification method used and verification that the equipment met the design conditions specified. The review and approval of vendor seismic qualification data followed the same procedure as approval of drawings and other design data.

3.7.6 SEISMIC EVALUATION OF CONCRETE MASONRY WALLS

IE Bulletin 80-11 requires that all concrete masonry walls within a Seismic Category 1 building be capable of withstanding loads associated with pipe support reactions during OBE and DBE seismic events. All such walls in Unit 2 are located in the Seismic Category 1 area of the auxiliary building. These walls were re-evaluated for the required loading conditions.

3.7.6.1 Description of Masonry Walls

3.7.6.1.1 Identification and Function of Walls

A field survey of all block walls in Seismic Category 1 buildings was conducted (1) to determine whether or not Seismic Category 1 systems (piping, electrical, HVAC and instrumentation) were attached to, or in the vicinity of, concrete block walls, and (2) to provide the data necessary for evaluation of any attachments found for adequacy of the attachments and ability of the walls to support the attached loads. Depending upon the type of attachment, different means were used to identify an item as Seismic Category 1. For conduits and electrical trays, tag numbers beginning with the letter "E" denote Seismic Category 1. For piping, tubing, and equipment, various drawings were used to identify items that are Seismic Category 1. These include piping area drawings, equipment location drawings, piping and instrument diagrams, and piping summary sheets. For heating and ventilating ducts, the type of support is noted. If the support system is braced, it is conservatively assumed to be Category 1.

A list of the walls, showing wall thickness, height, function, floor elevation, and type of attachments on the wall is given in Tables 3.7-12, 3.7-13 and 3.7-14. While the 60-day report included all walls within the Seismic Category 1 boundary of the auxiliary building, the 180-day report includes only those walls which support Seismic Category 1 pipes, Seismic Category 1 attachments other than pipe, or are in proximity to safety-related systems. Proximity is defined as within distance equal to the height of the wall for cantilevered walls and one-half the height plus the wall thickness for floor to ceiling walls. Consequently, fewer walls are included in the 180-day report than in the previous interim report. A total of 104 walls are classified as follows:

Table 3.7-12 - Walls supporting Seismic Category 1 pipes - 8

Table 3.7-13 - Walls supporting Seismic Category 1 attachments other than pipe - 19

Table 3.7-14 - Walls in the proximity of safety-related system - 77

Wall attachments generally are limited to small piping supports, electrical conduits and boxes, instrument lines, ventilation duct supports, and similar light objects. None of the walls identified are load bearing walls that support the building structure in the vertical direction or act as shear walls in the horizontal direction. In general, the walls fulfill a shielding or fire protection function.

3.7.6.1.2 Wall Configurations and Details

Most of the block walls are shielding walls constructed with heavyweight hollow concrete blocks in which all the cells are filled with grout, and in which continuous reinforcement is embedded in every other cell. The walls which do not have a shielding function are constructed with standard blocks in which only cells containing reinforcing steel, plumbing or other embedded items, are filled with grout.

Walls are constructed of a single wythe or of more than one wythe. Walls constructed of more than one wythe could, alternatively, be made of two wythes with center space filled with grout, or of two or more contiguous wythes with vertical joints packed with mortar.

The concrete block wall details are shown on the design drawings. Vertical reinforcing steel consists of one No. 5 bar at 16 inches spacing in the center of single wythe walls, and one No. 5 bar at 16 inches spacing near each face of multi wythe walls. Horizontal reinforcing steel consists of a bond beam with four No. 4 bars at 48 inches spacing in single wythe walls, and an identical bond beam at each face of multi wythe walls. Additional reinforcing is provided around

doorways and openings. At all block wall intersections with the lower concrete floors, every vertical reinforcing bar is anchored to the concrete with a deformed reinforcing bar dowel threaded into a 3/4-inch diameter concrete anchor. At block wall intersections with the upper concrete floors, a pair of continuous five-inch by three-inch angles with 3/4-inch anchors at 12-inch spacing, attached to floors, are used. At block wall intersections with concrete walls, every pair of horizontal bars is anchored to the concrete with a deformed reinforcing bar dowel threaded into a 5/8-inch diameter concrete anchor.

Concrete anchors are Phillips Red Head self-drilling concrete expansion anchors.

In addition to the above reinforcing steel, joint reinforcing consisting of extra heavy Dur-O-Wall truss steel bars is placed in alternate horizontal joints (16-inch spacing) of shielding walls and in every horizontal joint (8-inch spacing) of other walls. At shielding walls #3 steel tie bars hooked around vertical reinforcing bars are placed at staggered 32-inch spacing horizontally and 16-inch spacing vertically.

3.7.6.1.3 Materials of Construction

Materials specified for the wall construction are as follows:

Concrete blocks:	ASTM C90, Grade PI. Heavyweight units cured and oven dried density 135 pounds per cubic foot.
Mortar:	ASTM C476, Type PL, 2,000 psi compressive strength at 28 days.
Grout:	ASTM C476, 2,000 psi compressive strength at 28 days. For heavyweight units, grout dry density 147 pounds per cubic foot.
Reinforcing bars:	ASTM A615 Grade 60.
Horizontal joint reinforcement:	ASTM A82 Dur-O-Wall extra heavy truss type.

3.7.6.2 Construction Practices

3.7.6.2.1 General

For Unit 2, Bechtel Power Corporation was the general contractor for all work. The masonry construction work was awarded to a subcontractor who executed the work in accordance with specifications written by Bechtel Power Corporation for the supply and construction of concrete masonry walls.

Quality was assured in the general procedures employed by Bechtel in the selection of the subcontractor. Bechtel field engineering administered the subcontract to assure that the concrete block walls were erected in strict accordance to the drawings and specifications. The subcontractor provided material certificates, samples, testing, testing and inspection reports, and statements of conformance showing that all materials utilized in the installation met the requirements of the Concrete Masonry Specifications.

3.7.6.2.2 Workmanship

Blocks were laid plumb, true to line, with level and accurately spaced courses in locations shown. Blocks were kept plumb and level throughout; corners and reveals were kept plumb and true. Each course was solidly bedded in mortar. Joints were approximately 3/8-inch thick and extended the full depth of the face shells. Anchors, wall plugs, accessories, and other items required with the masonry were built in as the masonry work progressed. Spaces around built in items were solidly filled with mortar.

Masonry work was not performed when the temperature was below 40 °F. The ambient temperature was maintained above 40 °F in interior areas where masonry work was in progress and for 48 hours after erection had stopped.

3.7.6.2.3 Grout

Mortar overhangs and droppings were removed from cells, interior faces and foundations before grout filling the cells was poured. Grout was poured in lifts which did not exceed four feet. Each pour was thoroughly rodded to assure compaction and bond to the preceding pour. When work was required to be stopped for a period of 45 minutes or longer, the pour was stopped approximately 1-½ inches below the top of the last course and the surface of the grout was thoroughly roughened. When work resumed, the laitance was removed and the existing grout was dampened and coated with neat cement before additional grout was poured.

3.7.6.2.4 Inspection

General inspection was performed by the experienced Bechtel field engineering personnel to assure compliance with the requirements of the specification.

Continuous field inspection of all masonry work during laying and grouting was performed by the subcontractor to verify that the installation of reinforcing, placing of mortar and grout and other items were prepared and placed in accordance with the drawings and specifications.

3.7.6.2.5 Tests and Certificates

3.7.6.2.5.1 Tests

The subcontractor provided the following testing:

A. Sampling by an independent testing laboratory to assure that concrete masonry units conformed to the specifications.

B. Testing by an independent testing laboratory to assure that mortar and grout mix designs conformed to the specifications.

C. Testing of concrete anchors in accordance with the specification.

3.7.6.2.5.2 Certificates

The subcontractor submitted the following certificates for the materials utilized in the construction of the concrete masonry walls:

A. Certificates by an independent testing laboratory verifying that mortar and grout mix designs and concrete masonry units conformed to the specifications.

B. Mill test reports certifying that reinforcing bars and supports conformed to the specifications.

C. Statement of conformance certifying that the work met all of the requirements of the subcontract and the applicable specifications.

D. Field inspection reports of the work in progress.

3.7.6.3 Re-Evaluation Criteria and Commentary

3.7.6.3.1 Scope

The re-evaluation determines whether the concrete masonry walls and/or the safety-related equipment and systems associated with the walls perform their intended function under the loads and load combinations prescribed herein. Verification of wall adequacy includes a review of local transfer of load from block into wall, global response of wall, and transfer of wall reactions into supports. Anchor bolts and embedments for attachments to the walls are not considered to be within the scope of the evaluation.

The concrete masonry walls are evaluated for all applicable loads and load combinations. Calculated wall stresses are first compared against an allowable stress criteria. Wall stresses are maintained within the elastic range of the load carrying components. For the walls with calculated stresses exceeding the allowable limits, an appropriate bracing system is immediately implemented to bring them back to the allowable range.

3.7.6.3.1.1 Stress Criteria

A. Consideration of cracking for frequency determinations

B. Recognition of a potential plane of weakness at the collar joint

C. Stress increase factors for abnormal and extreme environmental loads

D. Realistic damping values

E. Interstory drift

3.7.6.3.1.2 Governing Code

The re-evaluation uses the method prescribed by the Uniform Building Code (UBC) and present state of the art techniques. Supplemental allowables, as specified herein, are used for cases not directly covered by the governing code.

3.7.6.3.1.3 Loads and Loads Combinations

The applicable factored load combinations for safety-related concrete structures are used to form the basis for the evaluation.

Load combinations which are used for structural analysis of block walls are as follows:

A. 1.5D + 1.8L

B. 1.25 (D + L + Ro + E)

C. 1.0 (D + L + E')

in which

D = Dead load of structure and equipment plus any other permanent loads contributing stress.

L = Live load on structure.

E = OBE loading.

E' = DBE loading.

Ro = Force on structure due to thermal expansion of pipes during operating conditions.

A load factor of 1.0 is used for all load combinations for anchors.

3.7.6.3.1.4 Materials

Material properties used in the re-evaluation are as follows:

Masonry ultimate compressive strength $(f'm)$	1,500 psi
Grout compressive strength $(f'c)$	2,000 psi
Mortar compressive strength	2,000 psi
Reinforcing bar yield strength	60,000 psi

Phillips Red-Head Self-Drilling Concrete anchor ultimate tensile strength

3/4" diameter	16,200 lbs
5/8" diameter	11,700 lbs

3.7.6.3.1.5 Design Allowables

Design allowables are taken from the applicable sections of the ANO-2 FSAR and the UBC.

However, for cases not covered by the code, such as the self-drilling concrete anchors, allowables are based on a safety factor of four for the OBE case, and a safety factor of three for DBE.

In-plane strain allowables for interstory drift effects for non-shear walls were established well below the level of strain required to initiate significant cracking. The allowable strain for a confined wall was based on the equivalent compression strut model discussed in Reference 65 and modified by a factor of safety of three against crushing. Test data (References 51, 60, 61, 65, 66, 67 and 68) were reviewed to determine cracking strains for confined masonry walls subjected to inplane displacements and confirms the predicted strain as given by the equivalent strut model.

Masonry

The allowable tension, compression, and shear stresses are as follows.

Masonry wall flexural compressive stress:	$0.33\ (f'm)$ = 500 psi
Masonry wall shear:	$1.1\sqrt{f'm}$ = 43 psi
Modulus of elasticity of the wall:	1,000 f'm

Collar Joint

A collar joint strength of zero has been conservatively assumed in the re-evaluation.

Core Concrete or Cell Grout

The allowable tensile stresses are $1.1\sqrt{f'm}$

Reinforcing Steel and Ties

The allowable tensile stresses are 20,000 psi as given in the UBC.

Anchorage

The allowable tension force on the self-drilling concrete anchors is as follows:

3/4" diameter	4.0 kips, 5.4 kips (DBE case only)
5/8" diameter	2.9 kips, 3.9 kips (DBE case only)

Since the OBE case is increased by 1.25 and the DBE case uses a factor of 1.0, all allowable loads are factored as stated below.

Code allowable stresses for masonry in compression, tension, shear and bond are increased by a factor of 1.67. In general, this provides a factor of safety against failure of $(3 \div 1.67) = 1.8$.

Reinforcing steel is allowed to approach 0.9 times the yield strength which is typical for reinforcing steel that is required to resist factored loads.

Design allowables for load combinations are as follows:

Masonry

The allowable masonry stresses given in Section 3.7.6.3.1.5.1 are increased as follows:

Stress	Increase Factor
Compression (flexural)	1.67
Shear and Bond:	1.67
Tension	
tension normal to bed joints:	1.67
tension parallel to the bed joints; in running bond:	1.67

Reinforcing Steel and Ties

The allowable steel stresses are 90 percent of minimum ASTM specified yield strength provided lap splice lengths and embedment (anchorage) can develop this stress level. Allowable bond stresses are increased by a factor of 1.67 in determining splice and anchorage lengths.

Anchorage

The allowable tension and shear forces on the self-drilling concrete anchors are not subject to increase.

3.7.6.3.1.5.1 Damping

In general, wall analysis is performed using damping values of three percent for OBE and five percent for DBE. These values are typically recognized as being conservative for reinforced masonry.

An exception is the analysis to determine concrete anchor tensile forces at some of the cantilever walls, where damping values used are four percent for OBE and seven percent for DBE. This is also conservative because the values are equal to or less than those specified for reinforced concrete structures in Regulatory Guide 1.61.

3.7.6.3.1.5.2 Modulus of Rupture

The extreme tensile fiber stress used in determining the lower bound uncracked moment capacity is $1.1\sqrt{f'm}$.

3.7.6.3.1.5.3 Non-Category 1 Masonry Walls

Concrete masonry walls not supporting safety systems but whose collapse could result in the loss of required function of safety-related equipment or systems, or the failure of the concerned walls due to the loss of the lateral support are evaluated the same as walls the support safety systems. Alternatively, the walls may be analytically checked to verify that they will not collapse when subjected to DBE loads.

3.7.6.3.1.6 Analysis and Design

3.7.6.3.1.6.1 Structural Response of Masonry Walls

The structural response of the masonry walls subjected to out of plane seismic inertia loads is based on a constant value of gross moment of inertia along the span of the wall for the elastic (uncracked) condition. If the wall is cracked, a better estimate of the moment of inertia is obtained by use of the ACI-318 formula for effective moment of inertia used in calculating immediate deflections. (Reference 50).

The effects of higher modes of vibration and variations in frequencies are considered on a case by case basis. The use of the average acceleration of the floors supporting the wall is considered sufficiently accurate for the purpose of this evaluation.

Equivalent Moment of Inertia (I_e)

To determine the out of plane frequencies of masonry walls, the uncracked behavior and capacities of the walls (Step 1) and, if applicable, the cracked behavior and capacities of the walls (Step 2) are considered.

Step 1 - Uncracked Condition

The equivalent moment of inertia of an uncracked wall (I_g) is obtained from a transformed section consisting of the block, mortar, cell grout and core concrete. Alternatively, the cell grout and core concrete, neglecting block and mortar on the tension side, may be used.

Step 2 - Cracked Condition

If the applied moment (M_a) due to all loads in a load combination exceeds the uncracked moment capacity (M_{cr}), the wall is considered to be cracked. In this event, the equivalent moment of inertia (I_e) is computed as follows:

$$I_e = \left(\frac{M_{cr}}{M_a}\right)^3 I_g + \left[1 - \left(\frac{M_{cr}}{M_a}\right)^3 \right] I_{cr}$$

$$M_{cr} = f_r \frac{(I_g)}{y}$$

where

M_{cr} = Uncracked moment capacity

M_a = Applied maximum moment on the wall

I_g = Moment of inertia of the uncracked gross section

I_{cr} = Moment of inertia of the cracked section

F_r = Modulus of rupture

y = Distance of neutral plane from tension face

In some instances the calculation of I_e is not necessary due to the shape of the curve and the position of either I_{cr} or I_g on the response spectrum curve. For example, if I_{cr} is at or very near the peak, the response at the frequency (f_{cr}) corresponding to I_{cr} may be used because it will result in a response which is higher than the response would be for I_e. Similarly, if I_g is on the left side of the response spectrum peak, the response at the frequency (f_g) corresponding to I_g may be used since it will result in a response which is higher than the response would be for I_e. However, the use of the more conservative peak value of the spectrum curve in lieu of an I_e analysis is optional, or an I_e analysis may be used if it will result in a lower response.

Alternatively, the use of the peak acceleration values from the response spectrum curve is acceptable in lieu of a frequency determination, and is a conservative approach.

In any case where the use of I_e may result in a higher response, an analysis using I_e is performed.

Modes of Vibration

The effect of modes of vibration higher than the fundamental modes is investigated. Modes analyses are performed on several walls to determine the frequencies, mode shapes and participation factors. The resulting forces and bending moments for the walls are computed using the SRSS procedure in response spectrum analyses. These resulting forces and moments are compared with those that are obtained by considering only the fundamental mode for the corresponding walls. The comparisons show that the differences are less than 0.5 percent. Therefore, only the fundamental mode is considered in this re-evaluation.

Frequency Variations

Uncertainties in structural frequencies of the masonry wall resulting from variations in mass, modulus of elasticity, material and section properties shall be taken into account by varying the modulus of elasticity as follows:

$$E = 800\ f'm \text{ to } 1200\ f'm$$

However, the modulus of elasticity varies with time. It is conservative to assume that five years after the date of completion, the modulus of elasticity is 20 percent higher than when the wall was built. Therefore, the nominal value of 1000 f'm is considered as the lower limit and 1200 f'm as the upper limit.

If the wall frequency using the nominal value of E is on the higher frequency side of the peak of the response spectrum, it is conservative to use the lower value of E. If the frequency of the wall using the nominal value of E is on the lower frequency side of the peak, the higher value of E may increase the required response acceleration for the wall analysis. All walls in this category have been checked against this uncertainty and are found to be adequate.

Accelerations

For a wall spanning between two floors, the effective acceleration is the average of the accelerations as given by the floor response spectra corresponding to the wall's natural frequency.

3.7.6.3.1.6.2 Structural Strength of Masonry Walls

Boundary Conditions

Boundary conditions are determined by considering one-way or two-way spans with hinged, fixed or free edges as appropriate. Conservative assumptions are used to simplify the analysis as long as due consideration is given to frequency variations.

The determination of the out of plane structural strength of masonry walls is highly sensitive to boundary conditions assumed for the analysis. Fixed end conditions are justified for walls (a) built into thicker walls or continuous across walls and slabs, (b) that have the strength to resist the fixed end moment, and (c) that have sufficient support rigidity to prevent rotation. Otherwise, the wall edge is simply supported or free depending on the shear carrying capability of the wall and support.

Distribution of Concentrated Out of Plane Loads

Distribution of concentrated loads are affected by the bearing area under the load, horizontal and vertical wall stiffness, boundary conditions and proximity of load to wall supports. Analytical procedures applied to plates based on elastic theory are used to determine the appropriate distribution of concentrated loads.

- Two-Way Action

  Where two-way bending is present in the wall, the localized moments per unit width under a concentrated load are determined by using appropriate analytical procedures for plates. Standard solutions and tabular values based on elastic theory contained in textbooks or other published documents are used if applicable for the case under investigation (considering load location and boundary conditions).

- One-Way Action

  For dominantly one-way bending, local moments are determined by using beam theory and an effective width equal to:

$$b = 6\,t + c$$

in which

b = he effective width

t = the wall thickness

c = the width of the load contact area.

However, the effective width computed by the above equation is limited in the evaluation to the value obtained from $b = 1.4e + c$, in which e is the distance from the concentrated load to the nearest support.

Interstory Drift Effects

Interstory drift values are derived from the original dynamic analysis. Strain allowables depending on the degree of confinement are applied from in plane drift effects on nonshear walls. The allowables are set at sufficiently conservative levels for in-plane effects alone such that a reasonable margin remains for out of plane loads. Out of plane drift effects are considered insignificant.

Stress Calculations

All stress calculations are performed by conventional methods prescribed by the Working Stress Design or other accepted principles of engineering mechanics.

Analytical Techniques

In general, classical methods for analyzing the walls are used in the evaluation. Design curves are developed using these methods and are used to qualify some of the block walls. However, numerical methods utilizing the computer for static or dynamic analyses are used on a case-by-case basis.

The density of the walls used in the analyses ranges from 141 to 146 pounds per cubic foot, depending on the block wall composition. The wall weight is generally increased by 10 percent to represent the weight of all attachments such as piping, piping supports, electrical conduits and boxes, instrumentation, and ventilation ducts. Actual weights of the attachments for some walls are calculated in lieu of the 10 percent increase. Reaction of the Seismic Category 1 pipe supports are considered as concentrated loads applied to the walls.

3.7.6.4 Results of the Evaluation

3.7.6.4.1 General

On the basis of the re-evaluation of the concrete masonry walls, it is concluded that all concerned concrete block walls are capable of withstanding the combined effects of the intended loads, such as wall inertia forces and pipe support reactions during the OBE and DBE without exceeding the allowable stress limits. Walls utilized as lateral support for the concerned walls are evaluated and the stresses are less than the allowable values. Collar joint strength is not used to transmit shear forces between wythes in the analysis.

Thermal effects on concrete block walls due to the ambient temperature in the surrounding areas are negligible and therefore were not taken into account in the re-evaluation.

3.7.6.4.2 Flexural Stresses

Design calculations show maximum masonry compressive stresses and maximum reinforcing steel tensile stresses resulting from the combined effects of wall inertia forces and pipe support loads during the OBE and DBE. All these stresses are less than the allowable values. Generally, the DBE stresses are the only stresses included in the calculations due to the fact that DBE usually governs. In some instances, OBE governs and is shown in the calculations in addition to the DBE case. Also, some walls indicate that the steel stress is negligible for the case in which the tensile stress in the masonry is less than the modulus of rupture. In this situation the masonry does not crack. In two walls, the stresses stay within the allowable limits after the appropriate bracing systems were implemented.

3.7.6.4.3 Wall Anchorage

All walls are anchored to supporting floors by dowels threaded into concrete expansion anchors. For walls extending continuously from floor to floor, the anchors do not have a significant function since lateral support is provided by shear transfer across the mortar joint between block units and the floor. For walls not extending to the floor above, i.e., cantilever walls, stability of the walls is directly related to the capability of the anchors to transmit tensile forces to the supporting concrete floor. Design calculations show anchor tensile forces at those walls which are cantilevered. At some of the cantilever walls the forces indicated are based on four percent damping factor for OBE (shown only if it is the governing case) and seven percent damping factor for DBE. All anchor tensile forces calculated are within the allowable limits.

3.7.6.4.4 Tie Bars

A tie bar investigation is performed to demonstrate that the tie bars have adequate strength to prevent separation of the wythes during vibration. This investigation is necessary since the bond of the collar joint between block and grout or mortar is assumed not to transfer tension or shear forces between the wythes.

All walls thicker than 12 inches are constructed of two or more wythes of concrete blocks, with the center space filled with mortar or grout. Between the wythes are tie bars spaced staggered at 32 inches horizontally and 16 inches vertically. Each end of the tie is hooked around the vertical reinforcement, and serves to prevent the wythes from separating. During seismic excitation the wythes may move together (in-phase) or in opposite directions (out-of-phase). In the case of in-phase motion, the tie bars will be subjected to a shearing force due to the slippage between the wythes. In the case of out-of-phase motion, the ties will be subjected to a tensile force as the wythes attempt to separate.

The analysis shows that the tie bars have adequate strength to resist the forces generated by both the in-phase and out-of-phase motion. The in-phase motion will produce both a shear force and bending moment in the tie due to slippage between the wythes. It is anticipated that some local crushing of the masonry at the rebar may occur. However, the stresses in the tie will stay within the allowable limits.

The out-of-phase motion will produce tensile forces in the tie bars. These tensile forces have been determined to be adequately resisted by the tie bar.

3.7.6.4.5 Effects of Large Openings

In order to determine whether or not calculated stresses using models without openings are representative, two selected walls were analyzed by finite element methods using the computer program STARDYNE. Configuration of the walls and their openings are modeled using plate elements. Supporting cross walls are considered in the analysis. The walls are modeled as being free to rotate at supports in the out-of-plane direction. Modal analysis was performed to determine the frequencies of the walls. The wall acceleration which corresponds to the fundamental frequency is used to determine the inertia force. Wall inertia force and pipe support loads are applied using the static option of STARDYNE to obtain element forces and moments from which masonry and reinforcing steel stresses are calculated.

Calculation 11406-350-4A shows a comparison of calculated maximum flexural stresses obtained by manual analysis using simplified wall models without openings and by finite element calculation using wall models with openings. Calculated frequencies are also compared. The results shown are for both OBE and DBE, and include effects of wall inertia forces and pipe support loads.

Frequencies calculated using the finite element method are generally higher than those calculated using manual analysis with beam models. This is attributed to the 4-side support condition in the computer models as compared to 2-side support condition in the simplified models.

Stresses calculated using the finite element method are generally lower than those calculated by manual analysis with beam models except for the localized stresses. Even though higher frequencies could result in greater accelerations, calculated stresses are reduced due to the two-way action.

The comparison shows that stresses calculated using simplified models without openings can be considered to be conservative.

3.7.6.4.6 <u>Dynamic Analysis</u>

A dynamic analysis is used to verify those walls which cannot be shown to be adequate by a simplified manual analysis or by a static computer analysis. The dynamic analysis is particularly useful for multi-wythe cantilever walls.

Since the shear capability at the collar joint is conservatively assumed to be zero between the grout or mortar and the block, the wall is analyzed as two separate flexural members tied together by tie bars. These ties are modeled as springs connected to the lumped masses of each flexural member. A modal analysis is performed using Bechtel program CE 917 to determine mode shapes, participation factors, and natural frequencies for the wall.

Bechtel program CE 918 is then used with the appropriate floor response spectrum as an input load to determine the resulting forces and moments in the wall.

The walls for which a dynamic analysis is performed are identified in the design calculations.

3.7.6.4.7 <u>Local Stresses at Attachments</u>

Through bolts have been used for all pipe supports. Also, since the loads are not of large magnitude, local stresses at attachments are not a concern.

3.7.6.4.8 Interstory Drift

Effects of building story interstory displacements resulting from seismic loads are calculated for the in-plane direction only, as out-of-plane stresses due to interstory displacements are not significant. For the in-plane direction, shear stress is calculated by

$$f_v = G \frac{\Delta}{h}$$

where

f_v = shear stress

G = modulus of rigidity = 400 $f'm$

Δ = interstory displacement

h = interstory height

For the in-plane direction, the maximum interstory displacement is predicted not to be more than 0.0006 inch per foot of height, resulting in a maximum shear stress of 30 psi, which is less than the allowable limit of 43 psi.

3.8 DESIGN OF CATEGORY 1 STRUCTURES

This section provides information on the design of Category 1 structures.

3.8.1 CONCRETE CONTAINMENT

The containment is a structure designed to house the primary nuclear system. It is part of the containment system whose functional requirement is the control of the release of radioactivity from the primary nuclear system. This section describes the structural design considerations, construction, testing, and surveillance for the prestressed concrete containment.

3.8.1.1 Description of the Containment

The general arrangement of the containment is shown in Figure 3.8-1. It consists of three basic parts: (1) a flat circular base slab, (2) a right circular cylinder, and (3) a sphere-torus dome. The containment is constructed of reinforced concrete prestressed by post-tensioned tendons in the cylinder and the dome. Special reinforcing details are provided at discontinuities. The design of the containment is described in Section 3.8.1.4.

The cylinder wall is prestressed by a system of horizontal and vertical tendons. The horizontal tendons are anchored at three buttresses equally spaced around the outside of the containment. The vertical tendons are anchored to the base slab at bottom and the ring girder at top. The dome is prestressed by three systems of dome tendons spaced at 120 degrees apart. The three-way dome tendons are anchored at the side of the ring girder. The tendons are installed in sheaths which are filled with a corrosion inhibitor. An access gallery is provided beneath the base slab for installation of the vertical tendons and inspection of bottom anchorage.

The interior of the containment is lined with steel plates welded together to form a leak tight barrier. The liner plate system is similar to that described in Part I of BC-TOP-1, Revision 1, (Reference 6). Since the base slab liner plate is covered with concrete, leak chase channels are provided at seam welds, to allow for leak testing during normal operation. Liner anchorage and other liner plate details are shown in Figures 3.8-7 and 3.8-8.

Large penetrations for equipment and personnel access, fuel transfer penetrations, piping and electrical penetrations are fabricated of steel, attached to the containment liner plate, and anchored into the concrete structure. Typical details of these penetrations are shown in Figure 3.8-9.

A large diameter equipment hatch is provided for transfer of material and equipment. Two personnel access locks are also provided. Each personnel lock is double door assembly with a quick acting valve system to equalize pressure when personnel are entering or leaving the containment. Hatch and lock doors are supplied with two compression seals with provisions for leak testing. One transfer tube is provided for fuel movement between the refueling canal in the containment and the spent fuel pool in the auxiliary building. The blind flange for isolating the transfer tube has concentric resilient seals with provisions for leak testing.

During outages, a temporary equipment hatch cover may be used in lieu of the permanent hatch cover. The temporary cover is designed to meet the requirements for reactor building closure during cold shutdown and refueling conditions.

Single barrier piping penetrations are provided for all piping passing through the walls of the containment. The closure for process piping is accomplished with a special head welded into the piping system and to the liner plate penetration nozzle. Piping carrying fluids at elevated temperatures is insulated. All electrical penetrations are of modular design with header plates of stainless steel (high voltage) or carbon steel (low voltage). Modules are bolted to header plates and have "O" ring pressure seals as described in greater detail in Section 8.3.1.1.13.

The details of locks, equipment hatch, transfer tube and penetrations are shown in Figure 3.8-9.

3.8.1.2 Applicable Codes, Standards and Specifications

Codes, specifications, industry standards, design criteria, Regulatory Guides, and Bechtel Topical Reports which constituted the basis for the design and construction of the containment are described in the following sections. Modifications to these codes, standards, etc. were made when necessary, to meet the specific requirements of the structure. These modifications are indicated in the sections where references to the codes, specifications, etc. are made.

3.8.1.2.1 Codes and Specifications

A. ACI 214-65 "Recommended Practices for Evaluation of Compression Test Results of Field Concrete"

B. ACI 301-66 "Specifications for Structural Concrete for Buildings"

C. ACI 306-66 "Recommended Practice for Cold Weather Concreting"

D. ACI 311-64 "Recommended Practice for Concrete Inspection"

E. ACI 315-65 Manual of Standard Practice for Detailing Reinforced Concrete Structures

F. ACI 318-63 "Building Code Requirements for Reinforced Concrete"

G. ACI 347-68 "Recommended Practice for Concrete Formwork"

H. ACI 605-59 "Recommended Practice for Hot Weather Concreting"

I. ACI 613-54 "Recommended Practice for Selecting Proportions for Concrete"

J. ACI 614-59 "Recommended Practices for Measuring Mixing, and Placing Concrete"

K. AISC Specification for the Design Fabrication and Erection of Structural Steel for Buildings, 1969, and Supplements No. 1 and 2, November, 1970 and December, 1971

L. ASME "Boiler and Pressure Vessel Code," Sections III, VIII, and IX-1968 Edition or later ASME code editions provided code used is reconciled.

Repair/Replacement associated with the containment liner plate shall be in accordance with ASME Section XI, IWA/IWE-4000.

M. American Welding Society (AWS) D1.1-92 or later approved Edition AWS D1.4-92 or later approved Edition	AWS D1.0 is no longer an active welding code and has been superseded by AWS D1.1. As an alternative to AWS requirements, Welding Procedure Specifications (WPS's), and/or Welder Performance Qualification (WPQ), meeting the ASME Section IX Code requirements may be utilized for structural steel applications provided all other applicable provisions of AWS D1.1 are met unrelated to WPS's and WPQ's
N. CFR	Code of Federal Regulations, Title 10-Atomic Energy, Part 50, "Licensing of Production and Utilization Facilities"
O. CFR	Code of Federal Regulations, Title 29 Labor, Part 1910, "Occupational Safety and Health Standards"

3.8.1.2.2 Industry Standards

Nationally recognized industry standards such as those published by the organizations listed below, were used whenever applicable to describe methods, procedures, and material properties. The specific standards used are identified in the applicable sections.

A. AASHO American Association of State Highway Officials

B. ACI American Concrete Institute

C. AISI American Iron and Steel Institute

D. ANSI American National Standards Institute

E. ASTM American Society for Testing and Materials

F. SNT Society of Nondestructive Testing

G. SSPC Steel Structures Painting Council

3.8.1.2.3 Design Criteria

A. ASCE - "Wind Forces on Structures," Paper No. 3269

B. AEC - "Nuclear Reactors and Earthquake," Publication TID 7024

3.8.1.2.4 Regulatory Guides

The following Regulatory Guides were used:

Regulatory Guide 1.10	"Mechanical (Cadweld) Splices in Reinforcing Bars of Category 1 Concrete Structures," Revision 1, 1/2/73, except as noted in Section 3.8.1.6.2
Regulatory Guide 1.15	"Testing of Reinforcing Bars for Concrete Structures," Revision 1, 12/28/72, except as noted in Section 3.8.1.6.2

Regulatory Guide 1.18 — "Structural Acceptance Test for Concrete Primary Reactor Containment," Revision 1, 12/28/72, except as noted in Section 3.8.1.7.1.

Regulatory Guide 1.19 — "Nondestructive Examination of Primary Containment Liner Welds," Revision 1, 8/11/72 of former Safety Guide 19, except as noted in Section 3.8.1.6.3.

Regulatory Guide 1.35 — "Inservice Surveillance of Ungrouted Tendons in Prestressed Concrete Containment Structures," 2/5/73.

Regulatory Guide 1.46 — "Protection Against Pipe Whip Inside Containment," May, 1973.

Regulatory Guide 1.55 — "Concrete Placement in Category 1 Structures," June 1973, except as noted in Section 3.8.1.6.1.6.

Exceptions to and interpretations of Regulatory Guides are given in the references sections.

3.8.1.2.5 Bechtel Topical Reports

BC-TOP-1 — "Containment Building, Liner Plate Design Report," Revision 1, December, 1972.

BC-TOP-4 — "Seismic Analysis of Structures and Equipment for Nuclear Power Plants," Revision 1, September 1972, and Addendum No. 1, April 1973.

BC-TOP-7 — "Full Scale Buttress Test for Prestressed Nuclear Containment Structures," Revision 0, August, 1971.

BC-TOP-8 — "Tendon End Anchor Reinforcement Test," Revision 0, November, 1971.

BN-TOP-1 — "Testing Criteria for Integrated Leak Rate Testing of Primary Containment Structures for Nuclear Power Plants," Revision 1, November 1972.

BN-TOP-2 — "Design for Pipe Break Effects," Revision 2.

BN-TOP-3 — "Performance and Sizing of Dry Pressure Containments," Revision 3.

3.8.1.2.6 Deleted

3.8.1.2.7 Structural Specifications

Structural specifications are prepared to cover the areas related to design and construction of the containment. These specifications emphasize important points of the industry standards for this containment and reduce options such as would otherwise be permitted by the industry standards. Unless specifically noted otherwise, these specifications do not deviate from the applicable industry standards. These specifications cover the following areas:

A. Concrete Material Properties

B. Placing and Curing of Concrete

C. Reinforcing Steel and Splices

D. Structural Steel

E. Post-Tensioning System

F. Liner Plate and Penetration Assemblies

3.8.1.3 Loads and Loading Combinations

3.8.1.3.1 Load Definitions

The design loads in the load combinations were identified as dead loads, live loads, prestressing loads, accident pressure loads, pipe rupture loads, thermal loads, seismic loads, wind and tornado loads, external pressure loads and missile loads.

A. Dead Loads

Dead loads considered were those produced by the weight of structures. The following specific weights were used:

1. Reinforced Concrete 150 lb/ft^3
2. Structural Steel 490 lb/ft^3

Dead loads were also assumed to be those produced by hydrostatic and soil loads.

B. Live Loads

Equipment loads were those specified by the equipment manufacturers. Snow load was considered to be 20 psf.

C. Prestressing Loads

Prestressing loads were considered in all loading combinations.

D. Accident Pressure Loads

The minimum design pressure of the containment is greater than the calculated peak pressure occurring as the result of any rupture of the Reactor Coolant System (RCS). The basis for the containment design pressure of 59 psig is presented in Section 6.2.1.

E. Pipe Rupture Loads

The local forces or pressures on structures or penetrations caused by the rupture of any pipe were considered. Pipe rupture effects are further discussed in Section 3.6.

F. Thermal Loads

The conditions considered in determining thermal stresses in the containment were temperature gradients through the containment wall and the thermal expansion and contraction of liner plate, piping and equipment.

G. Seismic Loads

Seismic loads for the Design Basis Earthquake (DBE) and the Operating Basis Earthquake (OBE) were considered. A more detailed discussion is presented in Section 3.7.1.

H. Wind and Tornado Loads

Wind and tornado loads were considered. A more detailed discussion is presented in Section 3.3.1.

I. External Pressure Loads

An external pressure of 5.0 psi on the containment was considered. A more detailed discussion is presented in Section 6.2.1.

J. Missile Loads

External and internal missile loads were considered. A more detailed discussion is presented in Section 3.5.2.

The following terms are used in the loading combination equations:

C = Required capacity of the containment to resist factored loads
D = Dead loads
E = Operating basis earthquake loads
E' = Design basis earthquake loads
F = Prestress loads
H = Pipe expansion loads
L = Live loads
P = LOCA pressure loads
R = Pipe rupture loads
T_A = LOCA thermal loads
T_O = Operating thermal loads
W' = Tornado wind and tornado missile loads
ø = Capacity reduction factors

3.8.1.3.2 Capacity Reduction Factors

The capacities of all load carrying structural elements are reduced for the factored loading case by capacity reduction factors (ø) as given below. These factors provide for the possibility that small adverse variations in material strengths, workmanship, dimensions, and degree of supervision, while individually within the required tolerances and the limits of good practice, occasionally may combine to result in under-capacity.

ø = 0.90 for concrete in flexure.
ø = 0.85 for shear, bond, and anchorage in concrete.
ø = 0.90 for reinforcing steel in direct tension.
ø = 0.90 for welded or mechanical splices of reinforced steel.
ø = 0.85 for lap splices of reinforcing steel.
ø = 0.95 for prestressed tendons in direct tension

3.8.1.3.3 Loading Combinations

The two loading cases considered in the design of the containment were identified as the design loading case and the factored loading case. Both were used to analyze localized areas of the containment such as penetrations and shell discontinuities, as well as the containment as an entire structure.

A. Design Loading Case:

For the design loading case, the containment design is the basic working stress design. The containment is designed for the following loading combinations:

1. $D + L + F + T_O$

2. $D + L + F + P + T_A$

B. Factored Loading Case:

For the factored loading case, the working stress design method was also used, but with allowable stresses as specified in Section 3.8.1.3.4. The final design of the containment satisfied the following load combinations and factors:

1. $C = 1/ø\ [(1.0 + 0.05)\ D + 1.5P + 1.0T_A + 1.0F]$

2. $C = 1/ø\ [(1.0 + 0.05)\ D + 1.25P + 1.0T_A + 1.25H + 1.25E + 1.0F]$

3. $C = 1/ø\ [(1.0 + 0.05)\ D + 1.25H + 1.0R + 1.0F + 1.25E + 1.0T_O]$

4. $C = 1/ø\ [(1.0 + 0.05)\ D + 1.0F + 1.25H + 1.0W' + 1.0T_O]$

5. $C = 1/ø\ [(1.0 + 0.05)\ D + 1.0P + 1.0T_A + 1.0H + 1.0E' + 1.0F]$

6. $C = 1/ø\ [(1.0 + 0.05)\ D + 1.0H + 1.0R + 1.0E' + 1.0F + 1.0T_O]$

3.8.1.3.4 Design Approach

Safety of the structure under extraordinary circumstances and performance of the containment at various loading stages were the main considerations in establishing the structural design criteria. The two basic criteria are:

A. The integrity of the liner plate is guaranteed under all loading conditions and,

B. The structure has a low strain, essentially elastic response such that its behavior is predictable under all design loadings.

The containment was designed to meet the performance and strength requirements under the following conditions:

A. Prior to prestressing

B. At transfer of prestress

C. Under sustained prestress

D. At design loading case

E. At factored loading case

3.8.1.3.4.1 Loads Prior to Prestessing

Under these loading conditions, the structure was designed and analyzed as a conventionally reinforced concrete structure. It was designed for dead loads and live loads including construction loads. Allowable stresses are in accordance with the ACI 318-63 Code.

3.8.1.3.4.2 Loads at Transfer of Prestress

The containment was checked for prestress loads and the stresses were compared with those allowed by the ACI 318-63 Code with the following exceptions: ACI 318-63, Section 26 allows a concrete compressive stress of 0.60 f'_{ci} at initial transfer. In order to limit creep deformation, the membrane-compression stress was limited to 0.30 f'_{ci} whereas in combination with flexural compression the maximum allowable stress was limited to 0.60 f'_{ci} per the ACI 318-63 code.

For local stress concentrations with nonlinear stress distributions as predicted by the finite element analysis, a concrete compressive stress of 0.75 f'_{ci} was permitted when local reinforcing was included to distribute and control the localized stresses. These high local stresses are present in every structure, but they are seldom identified because of simplifications made in design analysis. These high stresses were allowed because they occur in a very small percentage of the cross section, are confined by material at lower stresses, and would have to be considerably greater than the values allowed before significant local plastic yielding would result.

Membrane tension and flexural tension were permitted provided they did not jeopardize the integrity of the liner plate. Predicted membrane tension was permitted during the post-tensioning sequence, but the average concrete tension stress was limited to 1.0 $\sqrt{f'_{ci}}$. When there was flexural tension, but no membrane tension, the section was designed in accordance with Section 2605 (a) of the ACI 318-63 Code. The effects of the prestressing sequence were considered. Shear criteria is in accordance with Chapter 26 of the ACI 318-63 Code, as modified by the equations shown in Section 3.8.1.3.4.5.

3.8.1.3.4.3 Loads Under Sustained Prestress

The allowable stresses for this case were the same as stated in Section 3.8.1.3.4.2. In addition, the allowable tensile stress in non-prestressed reinforcing was limited to 0.5 F_y (where F_y is equal to the yield stress of the steel) and no membrane concrete tensile stresses were permitted. The ACI 318-63 Code limits the concrete compression to 0.45 f'_c for sustained prestress load. Values of 0.30 f'_c and 0.60 f'_c are used as described above, which bracket the ACI allowable value. However, with the same limits for concrete stress at transfer of prestress, the predicted stresses under sustained load are reduced due to creep.

3.8.1.3.4.4 At Design Loading Case

Under the design loading case, the same performance limits as in Section 3.8.1.3.4.2 are applied with the following exceptions:

A. If the net membrane compression is below 100 psi, it is neglected and a cracked section is assumed in the computation of flexural nonprestressed reinforcing steel. Flexural tensile stresses in nonprestressed reinforcing of 0.5 F_y is allowed.

B. When maximum concrete flexural stress does not exceed 6.0 $\sqrt{f'_c}$ and the extent of the tension zone is no more than one-third the depth of the section, non-prestressed reinforcing is provided to carry the entire force in the tension block. Otherwise, the non-prestressed reinforcing steel is designed assuming a cracked section. The allowable tensile stress in bonded reinforcing steel is 0.5 F_y.

C. The problem of shear and diagonal tension as a prestressed concrete structure is considered in two parts; membrane principal tension and flexural principal tension.

   Since sufficient prestressing is used to eliminate membrane tensile stress, membrane principal tension is not critical at design loads. Membrane principal tension due to combined membrane tension and membrane shear is considered in Section 3.8.1.3.4.5.

   Flexural principal tension is the tension associated with bending in planes perpendicular to the surface of the shell and shear stress normal to the shell (radial shear stress). The ACI 318-63 code provisions of Chapter 26 for shear are considered adequate for the design purpose with appropriate modifications as discussed in Section 3.8.1.3.4.5 using a load factor of 1.5 for shear loads.

3.8.1.3.4.5 At Factored Loading Case

The containment shell is checked for the factored loading case as described in Section 3.8.1.3.3.

The stress is prestressing steel and bonded reinforcing steel is limited to F_y, where F_y is the guaranteed minimum yield stress given in the appropriate ASTM specifications. The membrane compressive stress in concrete is limited to 0.85 f'_c. In combination with flexural compression in concrete, the predicted stress is allowed to reach a limit of f'_c, (90-day ultimate compressive stress). The peak predicted strain in concrete due to secondary moments, membrane loads and thermal loads is limited to 0.003 inch/inch.

The strain in the liner is limited to 0.005 inch/inch.

Membrane principal tension in concrete is calculated due to combined membrane tension and membrane shear, excluding flexural tension due to bending moments or thermal gradients. When the value of principal membrane tensile stress exceeds $2\sqrt{f'_c}$, the combination of bonded reinforcing steel and prestressing steel resists the calculated value of principal membrane tension without exceeding the above mentioned stress limitation of F_y.

When the value of principal membrane tension in concrete does not exceed $3\sqrt{f'_c}$ and when the principal concrete tension due to combined membrane tension, membrane shear, and flexural tension caused by bending moments or thermal gradients exceeds $6\sqrt{f'_c}$, bonded reinforcing steel is provided.

The allowable tensile stress in the reinforcing steel is F_y.

The following criteria are used for shear design. A load factor of 1.5 is applied to predicted shear loads.

Shear stress limits and shear reinforcing for radial shear are in accordance with Chapter 26 of the ACI 318-63 Code with the following exceptions:

Formula 26-12 of the Code is replaced by:

$$V_{ci} = Kb'd\sqrt{f'_c} + M_{cr}\frac{V}{M'} + V_i$$

where

$$K = \left[1.75 - \frac{0.036}{np'} + 4.0np'\right]$$

But not less than 0.6 for $p' \geq 0.003$

For $p' < 0.003$, the value of K is zero.

$$M_{cr} = \frac{I}{Y}\left(6\sqrt{f'_c} + f_{pe} + f_n + f_i\right)$$

f_{pe} = Compressive stress in concrete due to prestress applied normal to the cross section after losses (including the stress due to any secondary moment) at the extreme fiber of the section at which tensile stresses are caused by live loads.

F_n = Stress due to applied axial loads (f_n shall be negative for tensile stress and positive for compressive stress).

F_r = Stress due to initial loads, at the extreme fiber of a section at which tensile stresses are caused by applied loads (including the stress due to any secondary moment). f_i shall be negative for tension and positive for compression.

n = $505/\sqrt{f'_c}$

P' = $\frac{A'_s}{bd}$

V = Shear at the section under consideration due to applied loads.

M' = Moment at a distance d/2 from the section under consideration, measured in the direction of decreasing moment, due to applied loads.

Vi = Shear due to initial loads (positive when initial shear is in the same direction as the shear due to applied loads).

Lower limit placed by ACI 318-63 on V_{ci} as 1.7 b'd $\sqrt{f'_c}$ is not applied.

Formula 26-13 of the Code is replaced by:

$$V_{cw} = 3.5\ b'd\ \sqrt{f'_c} \qquad \sqrt{\frac{1 + f_{pe} + f_n}{3.5\sqrt{f'_c}}}$$

The term f_n is as defined above. All other notations are in accordance with Chapter 26, ACI 318-63.

When the above mentioned equations show that the allowable shear in concrete is zero, radial shear ties are provided to resist all the calculated shear.

3.8.1.4 <u>Design and Analysis Procedures</u>

The containment is analyzed for various loading combinations, considering the values of individual loads that generate the most significant stress condition for each component and member of the structure.

The critical areas for analysis are the base slab, the intersection between cylinder wall and base slab, the ring girder, the liner plate, the tendon anchorage zones and the penetration openings.

Classical theory and numerical methods are applied as necessary for the analysis of structural elements. They are described in Section 3.8.1.4.1 and in Section 5.2.1.5 of the Arkansas Nuclear One - Unit 1 SAR.

The design methods of the containment incorporate several phases as described herein. Analysis and design of tendon anchorage zones and reinforcement in buttresses are discussed in BC-TOP-7 (Reference 18), and BC-TOP-8 (Reference 39). The methods used to provide reinforcing steel are discussed in Section 3.8.1.4.1. The methods of analyzing the effects of penetrations, the thickening of walls, reinforcing and embedments, etc., are discussed in Section 3.8.1.4.1.2. The design of the liner and its anchorage system is covered in BC-TOP-1, Revision 1 (Reference 6), and Section 3.8.1.4.2. Information on analyses for computation of seismic loads is provided in Section 3.7.

3.8.1.4.1 <u>Analytical Techniques</u>

The analysis of the containment consisted of five primary analytical models. Four models use non-axisymmetric three-dimensional finite element modeling techniques for the cylindrical shell, dome, basemat, and equipment hatch. The fifth model is an axisymmetric finite element representation of the containment structure to provide an overall analysis and address localized effects in the transition zones of the containment for the ring girder and the haunch area connecting the basemat to the cylindrical shell. The axisymmetric model did not account for the buttresses, penetrations, brackets, and anchors, however, these items were considered in the non-axisymmetric analysis models. The axisymmetric finite element analysis assumed the structure as symmetrical about the axis and included load cases of dead, live, temperature, pressure, and prestress loads. The non-axisymmetric analysis included these loads plus lateral loads such as earthquakes and tornadoes that were allowed to vary depending upon condition and localized containment geometry.

3.8.1.4.1.1 AxisymmetricAnalysis

The containment is considered to be an axisymmetric structure for an overall analysis and to specifically address the transition areas of the structure. Although there are deviations from this ideal shape, the deviations are addressed by the combined five analytical models which provide a complete structure analysis evaluation of the pressure uprated condition of 59 psig.

The single axisymmetric model was used to look at the transition areas of the containment at the ring girder between the dome and cylindrical shell, and the haunch between the basemat and the cylindrical shell. The axisymmetric analysis was used in these areas due to the limitations of the plate elements used in the non-axisymmetric models.

The tendons are modeled by a combination of applied pseudo pressure and nodal force loads representing the hoop and vertical tendons in the cylindrical shell and the three overlapping tendon groups in the dome.

The liner plate was simulated by a layer of elements attached to the interior surfaces of the concrete structure.

The finite element mesh of the structure was extended into the foundation to account for the elastic nature of the foundation materials and its effect on the behavior of the base slab.

3.8.1.4.1.2 Nonaxisymmetric Analysis

Non-axisymmetric three dimensional computer models were constructed for the cylindrical shell, dome, basemat, and the equipment hatch to analyze the containment for 59 psig design pressure. Each of the analyses models the liner plate being bonded to the inside face of the element and the temperature is varied to introduce thermal forces into the analyzed element. A temperature gradient is introduced across the shell element to depict the operating and accident temperature effects into the model. The evaluation of all the loading combinations insures the most critical condition is analyzed for design.

The cylindrical shell model is a three-dimensional model that incorporates the basemat, cylindrical shell, buttresses, dome, and internal D ring using shell elements. Also included in the model are brick elements for the reactor and steam generator pedestals along with the rock foundation. The shell tendon and dome prestress loads were modeled using overlapping elements with pseudothermal methods. The cylindrical shell model is used to check the adequacy of the cylindrical shell with the dome, basemat, and the internals included into the model for improved accuracy.

The dome analysis is a three dimensional model that includes the dome, cylindrical shell, and buttresses using shell elements with fixed based boundary conditions along the bottom row of elements around the full circumference of the cylindrical shell. The tendon prestress loads were modeled using the same overlapping pseudo thermal element method used in the cylindrical shell model. The dome tendon prestress shell loads were simulated by applying vectored nodal forces normal to the tendon locations. The dome model is used in determining the adequacy of the dome area only and excludes the basemat and internal structure due to their remote location relative to the dome.

The basemat model is effectively the same three-dimensional analysis model as that used for the cylindrical shell that includes the dome, cylindrical shell, buttresses, internal structure, basemat, and foundation. The difference between the two analyses is that the basemat and foundation elements were modified to better analyze the overturning condition in the basemat. All loading conditions in this model are statically analyzed, including the dynamic seismic conditions which are considered as a pseudo static load using the dynamic results from the cylindrical shell analysis.

The equipment hatch analysis model is a three dimensional model using brick elements combined with plate and truss elements to represent liner plate and tendons in the equipment hatch area, respectively. The remaining cylindrical shell and dome are modeled the same as the cylindrical shell analysis, but have fixed base boundary conditions along the bottom circumference (i.e., no basemat). The tendon prestress loads around the opening were applied using pseudo thermal methods on interlaced truss elements.

3.8.1.4.1.3 Load Combinations and Stress Analysis

After the five finite element analyses were performed, the resulting forces and moments were converted to stress utilizing a post processor computer program that uses ASME Section III, Div, 2 criteria which is different than the ACI 318-63 Code of Record for the containment. The differences in the codes were reconciled and ACI 318-63 remains the code of record.

The calculations for out of plane shear in the base slab uses the equation 17-2 found in ACI 318-63 section 1701 (d). This section states that the limit of M not less than Vd does not apply when using M′=M-N(4t-d)/8 in section (e) for members subjected to axial load in addition to shear and flexure. This does not address the extra capacity for shear when the concrete is in compression. The wall and basemat juncture has compression from the tendons in this area. Section (e) of ACI 318-63 would apply, however, the code is not clear about the shear limit. The later 1992 ACI code and ASME Section III, Div. 2 code specifically points this omission out. The limit for M was not used in this analysis and the additional shear capacity from the compression is included.

Radial shear (through thickness shear) is considered using the criteria stated in Section 3.8.1.3.4.5 of the SAR. The criteria for tangential shear was developed by combining ASME Section III, Div. 2 criteria for tangential shear with the Unit 2 shear criteria in Section 3.8.1.3.4.5 of the SAR.

A. Seismic Loadings

The analysis of seismic loadings on the containment was performed using the methods outlined in Section 3.7. The computer models simulate the accelerations and loadings as closely as possible to assure the seismic input is not changed.

B. Wind and Tornado Loadings

Wind and tornado loadings were not considered in this analysis of the containment. The wind loads are negligible and do not appear in the loading combinations in Section 3.8.1.3.3. The factored loading combination #4 in 3.8.1.3.3 containing tornado loads was not included in this analysis because none of the other loads in the formula changed from the original analysis.

C. Buttress and Tendon Anchorage Zones

The containment has three buttresses. At each buttress, two out of any group of three adjacent hoop tendons are anchored on opposite faces of the buttress, with the third tendon continuing past the buttress.

Between the opposite anchorages in the buttress, the compressive forces exerted by the anchored tendons are twice as large as elsewhere on the buttress. This value, combined with the effect of the tendon which continues past the buttress, is 1.5 times the prestressing forces acting in the containment wall. The thickness of the buttress is approximately 1.5 times the thickness of the wall. Hence, the hoop stresses and strains, as well as the radial displacements, may be considered as being nearly constant all around the structure.

The vertical stresses and strains, caused by the vertical post-tensioning, become constant a short distance away from the anchorages because of the stiffness of the cylindrical walls. The effects of the buttresses on the overall behavior of the containment are negligible under dead and prestressing loads. The stresses and strains remain nearly axisymmetric despite the presence of the buttresses.

The design of the tendon anchorage zones was based on two test programs conducted by Bechtel to demonstrate the adequacy of several reinforcing patterns for use in anchorage zone concrete in the base slab, buttresses and ring girder. These tests were undertaken to develop a more efficient design to reduce reinforcement congestion and thereby facilitate the placement of high quality concrete around the tendon anchorages. The test programs were as follows:

1. A full scale model of a simulated containment buttress containing several patterns of reinforcement and types of tendon anchorages was constructed and tested. A detailed description of the test is presented in Bechtel Topical Report BC-TOP-7 (Reference 18).

2. Two large concrete test blocks containing two patterns of reinforcement with different proportions of reinforcing bars were constructed and tested. A detailed description of the test is presented in Bechtel Topical Report BC-TOP-8 (Reference 39).

The test results demonstrated satisfactory performance of the test anchorages. The design of the tendon anchorage zones was based on the results and recommendations of these tests.

D. Large Penetration Openings

Large penetrations were defined as those having an inside diameter equal to or greater than 2.5 times the containment wall thickness. The equipment hatch and personnel airlock fall into this category. The equipment hatch opening was evaluated using a finite element model addressed above. The personnel airlock was analyzed as an opening in a cylindrical shell with forces and moments acting upon it the same as the small penetrations described below. Both penetrations were found to be adequate.

E. Small Penetration Openings

Small penetration openings were defined as those having an inside diameter less than 2.5 times the containment wall thickness.

The stresses at the openings due to applied moments and forces were determined using the methods outlined in References 47 and 48.

The main steam, main feedwater, and the emergency escape lock were analyzed. The results of these analyses showed the stresses to be within the allowable limits. The remaining penetrations were found to be reinforced identically to the Unit 1 penetrations and were not analyzed because these penetrations are typically designed for plastic pipe forces and Unit 1 is designed to 59 psig.

3.8.1.4.2 Steel Liner Plate and Penetrations

The steel liner plate and penetrations were designed to serve as the leakage barrier for the containment. Typical details for the liner plate and penetrations are shown in Figures 3.8-7 through 3.8-9.

The design of the liner plate considered the composite action of the liner and the concrete structure and included the transient effects on the liner due to temperature changes during construction, normal operation, and the Loss of Coolant Accident (LOCA). The changes in strains to be experienced by the liner due to these effects, and those at the pressure testing of the containment, were considered.

The stability of the liner was achieved by anchoring it to the concrete structure. At all penetrations, the liner was thickened to reduce stress concentration. The thickened plate was also anchored to the concrete.

Embedded plates were provided in the liner to transfer concentrated loads to the wall, slab, and dome of the containment. Examples of these concentrated loads are polar crane brackets and floor beam brackets. A typical bracket detail is shown in Figure 3.8-8.

All components of the liner which must resist the full design pressure, such as the equipment hatch, personnel locks, and penetrations, were designed to meet the requirements of the applicable subsection of Section III, Nuclear Vessels, of the ASME Code.

Flued head design was used for all containment penetration connections, except for 2P-53 which has closed flanges on both ends to allow for temporary access to containment. 2P-53 does not require a flued head as process piping does not pass through this penetration.

Penetration connections are butt welds without backing bars. All welds were radiographed. Table 3.8-1 gives pipe sizes and materials for all penetrations. Table 3.8-2 shows results of radiographic examinations and corrective measures for defects.

The Topical Report BC-TOP-1, Revision 1, Reference 6, constitutes the basic approach used in the design of the liner plate.

There is a minor difference in the design of the Unit 2 liner plate from that presented in the topical report. The 1/4-inch liner plate material is ASTM A-516, Grade 60, with a specified yield stress of 32,000 psi, instead of ASTM A-442, which has a specified yield stress of 30,000 psi.

3.8.1.4.3 Computer Programs Used in the Analysis

Computer programs used in the original analysis of the containment are presented in Table 3.8-3.

3.8.1.5 Structural Acceptance Criteria

The fundamental acceptance criteria for the completed containment is the successful completion of the initial and uprate structural integrity test, which measured responses within the limits predicted by analyses. The limits are predicted based on test load combinations and code allowable values for stress, strain, or gross deformation for the range of material properties and construction tolerances. In this way the margins of safety associated with the design and construction of the containment are, as a minimum, the accepted margins associated with nationally recognized codes of practice.

The structural integrity test yields information on both the overall response of the containment and the response of localized areas, such as major penetrations or buttresses, which are important to its design functions.

The design and analysis methods, as well as the type of construction and construction materials, were chosen to allow assessment of the structure's capability throughout its service life. Additionally, surveillance testing provided further assurances of the structure's continuing ability to meet its design functions.

During the 2R14 Steam Generator Replacement Outage the containment design pressure was increased from 54 psig to 59 psig. An uprate Structural Integrity Test (SIT) was performed to demonstrate the acceptability of the containment at the 59 psig pressure.

The values of calculated stress and strains for critical sections of the containment and equipment hatch are found in the containment uprate calculations. The test information documented in BC-TOP-8 permits the assessment of the margins of safety for anchorage zones.

3.8.1.6 Materials, Quality Control, and Special Construction Techniques

The containment is constructed of concrete and steel using proven methods common to heavy, industrial construction. The basic categories for steel are reinforcement, prestressing system, and liner plate. The range of properties for design was generally identified by standard industry specifications.

3.8.1.6.1 Concrete

The 90-day compressive strength of the concrete used is 5,750 psi for walls and dome and 4,000 psi for all other portions of the containments. Structural concrete is batched and placed in accordance with "Specifications for Structural Concrete for Buildings" (ACI-301-66) and "Building Code Requirements for Reinforced Concrete" (ACI 318-63) with the additional specific information and exceptions as noted below.

3.8.1.6.1.1 Cement

Cement is Type II conforming to the "Specification for Portland Cement" (ASTM C 150-70). The cement does not contain more than 0.60 percent by weight of alkalies calculated as Na_2O plus 0.658 K_2O. Certified copies of mill test reports showing the chemical composition and physical properties are obtained for each load of cement delivered. The limitation of the alkali content of the cement may be waived provided that the aggregates pass required laboratory tests and have no history of alkali aggregate incompatibility.

Cement used in the repair of the containment construction opening following replacement of the original steam generators is Type II low alkali cement per ASTM C 150-98. Tensile strength tests per the requirements of ASTM C 190 (see below) were not performed since this standard has been withdrawn. Fly ash was provided per ASTM C 618-99, Class C, with loss on ignition not exceeding 6 percent and was tested per ASTM C 311-98.

In addition to the tests required by the cement manufacturers, the following tests are performed:

ASTM C 114 - Chemical Analysis
ASTM C 115 - Fineness of Portland Cement (Turbidimeter) or
ASTM C 204 - Fineness of Portland Cement (Air Permeability)
ASTM C 151 - Autoclave Expansion
ASTM C 191 - Time of Set (Vicat Needle) or
ASTM C 266 - Time of Set (Gillmore Needle)
ASTM C 109 - Compressive Strength
ASTM C 190 - Tensile Strength

The purpose of the above tests is to ascertain conformance with ASTM Specification C 150. In addition, tests ASTM C 191 or ASTM C 266 and ASTM C 109 are repeated periodically during construction to check storage environmental effects on cement characteristics. The tests supplement visual inspection of material storage procedures.

3.8.1.6.1.2 Aggregates

All aggregates conform to the "Standard Specifications for Concrete Aggregate" (ASTM C 33-69). In addition to the specified gradation, the fine aggregate (sand) has a fineness modulus of not less than 2.5 or more than 3.0 during normal operations; at least nine of 10 test samples should not vary fineness modulus more than 0.20 from the average. Coarse aggregate may be rejected if the loss when subjected to the Los Angeles abrasion test, ASTM C 131-69 using grading A, exceeds 40 percent by weight at 500 revolutions.

Acceptance of aggregates is based on the following tests:

ASTM Test No	Name of Test	Basis ForTest
C 131	Los Angeles Abrasion	ASTM Spec C-33
C 142	Clay Lumps and Friables Particles	ASTM Spec C-33
C 117	Material Finer than No. 200 Sieve	ASTM Spec C-33
C 87	Mortar Making Properties	ASTM Spec C-33

ASTM Test No	Name of Test	Basis ForTest
C 40	Organic Impurities	ASTM Spec C-33
C 289	Potential Reactivity (Chemical)	ASTM Spec C-33
C 136	Sieve Analysis	ASTM Spec C-33
C 88	Soundness	ASTM Spec C-33
C 127	Specific Gravity and Absorption	ASTM Spec C-33
C 128	Specific Gravity and Absorption	ASTM Spec C-33
C 295	Petrographic	ASTM Spec C-33

In addition to the foregoing initial tests, a daily inspection control program was carried on during construction to ascertain consistency in potentially variable characteristics such as gradation and organic content.

All aggregates used in the repair of the containment construction opening following replacement of the original steam generators conform to the “Standard Specifications for Concrete Aggregate” (ASTM C 33-99). In addition to the specified gradation, the fine aggregate (sand) has a fineness modulus of not less than 2.5 or more than 3.0. In addition to the foregoing initial tests, a daily inspection control program was carried on during concrete production to ascertain consistency in potentially variable characteristics such as gradation and organic content.

3.8.1.6.1.3 Water

Water used in mixing concrete is free of injurious amounts of oil, acid, alkali, organic matter or other deleterious substances as determined by American Association of State Highway Officials (AASHO) Methods of Sampling and Testing, Designation T26-51.

Water used in the concrete mix for the repair of the containment construction opening following replacement of the original steam generators complied with American Association of State Highway and Transportation Officials (AASHTO) T-26 for its effect on cement compressive strength per ASTM C 109-99, setting time per ASTM C 191-99, and autoclave expansion per ASTM C 151-98.

3.8.1.6.1.4 Admixtures

The concrete also contains an air entraining admixture, a water-reducing admixture and a pozzolan. The air entraining admixture is in accordance with the "Specification for Air Entraining Admixture for Concrete" (ASTM C 260-69). It is capable of entraining three to six percent air, is completely water soluble, and is completely dissolved when it enters the batch. The water reducing and retarding admixture conforms to the "Standard Specification for Chemical Admixtures for Concrete" (ASTM C 494-68), Types A and D. Type ambient air temperature is 70 °F and above. Pozzolans conform to "Specifications for Fly Ash and Raw or Calcined Natural Pozzolans for Use in Portland Cement Concrete" (ASTM C 618-68).

The air entraining admixture used in the repair of the containment construction opening following replacement of the original steam generators conforms to ASTM C 260-98. The high range water reducing admixture conforms to ASTM C 494-98, Type F.

3.8.1.6.1.5 Concrete Testing

During construction concrete is sampled and tested for slump, air content, temperature, and unit weight prior to casting compressive strength cylinders.

Compressive strength cylinders are cast from representative samples taken in accordance with "Sampling Fresh Concrete" (ASTM C 172-68), Paragraph 3. Cylinders are made, cured and tested in accordance with the "Standard Method for Making and Curing Compression and Flexure Tests in the Field" (ASTM C 31-69) and the "Standard Test for Compressive Strength of Molded Concrete Cylinders" (ASTM C 39-66).

Cylinders improperly made or cured are discarded. Not less than six specimens are made for each test. Three cylinders are tested at 28 days, at least one cylinder is tested at seven days and at least two cylinders are tested at 90 days when 90-day compressive strengths were specified. Three correlation cylinders are taken at the point of deposition in the forms from the same batch sampled at the batching plant to verify the strength results. These cylinders are tested at 28 days.

For structural concrete, six cylinders are made for each 100 yards of concrete placed or fraction thereof for each mix design of concrete places in any one day.

When a correlation of test data is established for each mix, as approved by the contractor, the 90-day test cylinders are discontinued except for prestressed concrete.

Cause for concrete rejection was established in accordance with the "Building Requirements for Reinforced Concrete" (ACI 318-63), Paragraph 504.

During placement of concrete for repair of the containment construction opening following replacement of the original steam generators, samples were taken in accordance with ASTM C 172-97 at the beginning, middle, and at the end of the pour. These samples were used to perform slump tests in accordance with ASTM C 143-98, temperature tests in accordance with ASTM C 1064-86, air content tests in accordance with ASTM C 231-97, and unit weight tests in accordance with ASTM C 31-98 and ASTM C 172-97.

Three sets of 12 cylinders each were made for the compressive strength tests. Two cylinders from each set were tested at 1, 7, and 28 days and 6 cylinders were spared. Note: If the 7-day test showed that the required strength of 5750 psi had been met, the 28 day test was deleted and the spare cylinders discarded. The cylinders were tested in accordance with ASTM C 39-96.

3.8.1.6.1.6 Concrete Placement

Concrete placement in the containment is in accordance with Regulatory Guide 1.55 with the following exception:

Regulatory Positions 2 and 3 of the Regulatory Guide state the presumed functional responsibilities of the "Designer" and the "Constructor". Under the designer's role are listed the responsibilities for checking shop drawings and locations of construction joints. On this job, the former is fully delegated to the Bechtel field, although the design engineering office may check significant portions and may advise the field accordingly. The responsibility for construction joint location is partly delegated to the field in the sense that the field has to follow the

guidelines set out in the design drawings prepared by "Engineering". In interface areas, a delegation of the design engineering office's responsibility to the field office is within the definition of the terms "responsibility" and "delegated responsibility" as discussed in Paragraph 1.3 of the proposed ANSI N45.2.5 - 1972 referenced in the Appendix to the Regulatory Guide. Delegation of the responsibilities for checking the reinforcing drawings to the field engineering group is justified by the following:

A. The Bechtel field engineering group is segregated from the field supervision group, although both are located at the jobsite and eventually report to the project superintendent.

B. The field engineering group is staffed for the most part by graduate engineers who have been trained in the use of the ACI code and understand the design implication of the proper location, splicing and embedment of reinforcing steel.

C. The field inspection of the actual rebar as placed in the forms is conducted using the engineering drawings as the primary source document. This assures a check on any errors which may have passed the critical eye of the field engineer in checking the shop detail or erection drawings.

D. It is standard practice in the civil engineering profession that engineering requirement drawings for reinforcing are converted to shop detail and erection drawings in accordance with ACI standards applied by steel detailers at the reinforcing steel vendor's shop. Most contractors installing reinforcing steel rely upon their superintendent and foreman for correct interpretation of these detail drawings in erecting the reinforcing steel. While this is also true of Bechtel field operation, we do have the additional help and guidance of the field engineers both during the installation phase and finally at the inspection phase prior to final sign off on the report card.

E. The field engineers have the added benefit of being able to plan and witness the actual installation and can, therefore, better foresee any difficulties in meeting the intended design requirements. Their assessment of the situation is further assisted by regular telephone communication with the design engineers who also periodically visit the jobsite.

   The above procedure of delegation of the design engineering office's responsibility to field personnel and periodic monitoring by the engineering office provides an assurance of correctness and conformance of the shop drawings to the design drawings, and therefore, meets the intent of Regulatory Guide 1.55.

The following codes and specifications are used:

A. ACI 301-66 - "Specifications for Structural Concrete for Buildings" is used except as noted below:

   1. The following requirements apply in place of the requirements specified in Paragraph 405 (a):

      Forms for columns, walls, sides of beams, slabs and girders and other parts not supporting the weight of the concrete are removed as soon as practicable in order to avoid delay in curing and repairing surface imperfections. Wood forms or

insulated steel forms for members 2-1/2 feet or greater in thickness are stripped within 24 hours or the forms are kept in place for a minimum of seven days. If forms are stripped within 24 hours, the surface is cured by moist curing or membrane curing as specified in Chapter 12.

2. The following requirements apply in place of Paragraph 1404 (a): Slump is specified for particular locations and degree of congestion rather than holding a 2-inch maximum. A margin for maximum slump above the stated maximum average value is included in job standards.

3. The following requirement applies in place of Paragraph 1405 (a): The minimum curing period is seven days for heavily reinforced massive sections.

4. Section 1602, Paragraph (a) 4.a the last sentence concerning the taking of samples at the discharge end of the pump line does not apply.

B. ACI 306-66 - "Recommended Practice for Cold Weather Concreting" is used without exception.

C. ACI 318-63 - "Building Code Requirements for Reinforced Concrete" is used without exception.

D. ACI 347-68 - "Recommended Practice for Concrete Formwork" is used except as modified based on the specific construction procedure used.

E. ACI 605-59 - "Recommended Practice for Hot-Weather Concreting" is used without exception.

F. ACI SP. 2-67 - "Manual Of Concrete Inspection" is used without exception.

G. ASTM C94-69 - "Ready-Mixed Concrete" is used without exception.

Placement of concrete for repair of the containment construction opening following replacement of the original steam generators was done in accordance with ACI 301-96 and ACI 304R-89. Concrete was consolidated by mechanical, internal type vibrators in accordance with ACI 309R-96.

The rate of the concrete pour was limited to no more than three feet per hour. Placement of concrete in hot or cold weather was performed in accordance with ACI 305R-91 or ACI 306R-88, respectively. Concrete placement inspection activities were performed in accordance with Bechtel's Quality Assurance Program and ANSI N45.2.5.

3.8.1.6.2 Reinforcing Steel

Reinforcing bars for concrete are deformed bars meeting the requirements of the "Specification for Deformed and Plain Billet Steel Bars for Concrete Reinforcement" (ASTM A-615-68), Grade 60. Placing and splicing of bars is in accordance with the "Building Code Requirements for Reinforced Concrete" (ACI-318-63). Mill tests reports, in accordance with ASTM A-615, are obtained from the reinforcing steel supplier to substantiate specification requirements.

In addition, user tests are performed on specimens to supplement the standard mill tests. The testing of reinforcing steel including the tonnage of bars of a given size and grade which is represented by a given number of test specimens is in accordance with Regulatory Guide 1.15 with the following exception: ASTM A-615-68 is used in lieu of A-615-72. Hence, for #14 and #18 reinforcing bars, reduced diameter test specimens are used and bend tests are not required.

Bars #11 and smaller are generally lap spliced in accordance with ACI 318-63. Where lap splicing was not used, reinforcing bars were cadweld spliced. Bars #14 and #18 are cadweld spliced exclusively. Splicing of reinforcing bars by welding was not done during containment construction. Splicing of reinforcing bars by use of Dywidag splices was not done in the containment.

Cadweld splicing during construction of the containment was performed in accordance with Regulatory Guide 1.10, Revision 1, 1/2/73, with the following exceptions to the Regulatory Guide:

Section C.1. Crew Qualification. The Regulatory Guide requires requalification of each member of the splicing crew (or each crew if the members work as a unit), if the specific splice position, e.g. horizontal, vertical, diagonal, has not been used for a period of three months or more. The project procedure conforms to the Safety Guide 10, 3/10/71 which does not require the specified member or crew requalification. The project specification was issued for construction prior to the publication of Regulatory Guide 1.10. The specified procedure was based on extensive experience of the crew which had satisfactorily completed similar work on Unit 1.

Section C.5. Procedure for Substandard Tensile Test Results, Paragraph a. The Regulatory Guide requires that if two or more splices from any of the six additional splice samples fail to meet the tensile test specification of Paragraph 3a, the balance of the 100 production splices under investigation should be rejected and replaced.

The intent of the Regulatory Guide is met in the project specification by requiring that if two or more splices from any of the six additional splice samples fail to meet the tensile test specification of Paragraph 3a, the Project Engineer will evaluate and assess the acceptability of the reduced average tensile strength with respect to the required strength at the location from which the samples were taken. There were no substandard tensile test splices for the work done. In the event of any such splices on remaining work, Regulatory Guide 1.10 will form the basis for the Project Engineer's evaluation.

Reinforcing bars (limited to #3 through #11) used in the repair of the containment construction opening following replacement of the original steam generators conform to ASTM A 615-96, Grade 60. Mechanical property tests for yield strength, tensile strength, and percentage elongation as well as bend tests required by ASTM A 615-96 were performed per ASTM A 370-97. Placement of rebar was in accordance with ACI 301-96. Splicing of the new rebar to the existing rebar was accomplished using Cadwelds or welding. Testing of Cadweld splices during the containment opening restoration was performed in the same manner as was done during construction of the containment except that only sister splices were tested.

3.8.1.6.3 Liner Plate and Penetrations

The containment is lined with welded steel plate conforming to the requirements of the ASTM A-516, Grade 60, to ensure low leakage. The A-516, Grade 60 material was chosen on the basis that it has sufficient strength, as well as ductility, to resist the expected strains from design criteria loading and, at the same time, preserve the required leak tightness of the containment. It is readily weldable by all commercially available arc and gas welding processes.

The liner plate is considered as a leak tight membrane. Applicable portions of the ASME Code are referenced in setting the standards for materials, fabrication, inspection, and testing of the liner plate. Mill test results performed according to the requirements of ASTM A-516 are obtained for the liner plate material. In addition, all floor liner plate sections greater than ¼-inch thick used with Cadweld connectors or other anchorages were ultrasonically examined. All welding procedures, welders, and welding operators used in the fabrication and erection of the steel liner plate and penetration sleeves are qualified by tests in accordance with Section IX of the ASME Code.

Nondestructive examination of primary containment liner welds is conducted in accordance with the procedures established for Unit 1 and complies with the procedures described in Regulatory Guide 1.19 except at noted:

A. Reference: Paragraph C.1.a. For each welder, one spot (not less than 12 inches in length) in the first 10 feet of weld and in each additional 25-foot increment thereafter is radiographed in accordance with the methods and techniques described in UW-51 of the ASME B&PV Code, Section VIII.

B. Reference: Paragraph C.1.b. Where nonradiographable welds are used, a minimum of 10 percent of all such welding (which includes at least one-third of the locations where there are welded backing strip splices and intersections of joints) is examined by magnetic particle or liquid penetrant examination. Welding which does not satisfy acceptance standards is repaired and retested to the same extent as stipulated for radiography.

C. Reference: Paragraph C.1.c. The leak detection solution used for vacuum box testing is checked against a standard sample with a known leak path to verify the bubble formation property of the solution.

D. Reference: Paragraph C.1.d. Leak chase system channels are pressurized to a test pressure of 80 psi which exceeds containment design pressure of 59 psi. All channel to liner welds are soap bubble tested and checked for any pressure decay within 15 minutes.

E. Reference: Paragraph C.2. All welds are examined in accordance with the methods and techniques noted in Items A through D above.

F. Reference: Paragraph C.5. Locations for spot radiograph examination are selected at random.

The tolerances for erection of liner plate and the penetration assemblies were determined based upon the structural geometry, liner stability, concrete capability and the construction methods.

During replacement of the original steam generators, a containment construction opening was created. As part of the process for creating this construction opening, a 21′-6″ x 27′-9″ section of the containment liner was removed. Following completion of the steam generator replacement, this section of liner plate was reinstalled. Welding, magnetic particle, radiographic weld examination, and vacuum box leak testing of the new liner plate welds was performed in accordance with the Bechtel Special Processes Manual (which was based on ANO's commitments to the requirements of ASME Section VIII, Division 1 and Subsection IWE of ASME Section XI) to insure weld acceptability and leak-tightness. Leak testing in accordance with 10 CFR 50, Appendix J was also performed.

3.8.1.6.4 Post-Tensioning System

The prestressed, post-tensioning system selected for the containment is an Prescon BBRV buttonhead system.

A. Tendons

The tendons are composed of stress relieved wires of 1/4-inch diameter with a tensile strength of 240,000 psi in accordance with ASTM A-421, Type BA. The pertinent features of the tendons are as follows:

Number of wires	186
Ultimate tensile capacity (kips)	2192
End anchorage	Buttonheads

Sampling and testing of the tendon material conform to ASTM A-421.

B. Anchorages

The end anchors used are capable of developing 100 percent of the minimum tensile strength of the tendons. Furthermore, the end anchors are capable of maintaining integrity for 500 cycles of loads corresponding to an average axial stress variation between 0.7 and 0.75 F'_c, at a repetition rate of one cycle in 0.1 second. This requirement sets the minimum acceptable limits on fatigue effects on the end anchor and tendon performance in response to earthquake loads.

The anchorage assemblies, including the bearing plates, are capable of transmitting the ultimate loads of the tendons into the structure without brittle fracture at an anticipated lowest service temperature of 0.0 °F.

C. Sheathing

Sheaths for the tendons are classified as concrete forms and are not subjected to any Standard Codes. They provide a void in the concrete in which the tendons are installed, stressed and greased after the concrete is placed.

The sheaths are fabricated from 24-gauge, cold rolled, galvanized carbon steel, and have an internal diameter of five inches. Couplers are provided at all field splices.

Before installation of the tendons, the sheathing is cleaned to remove all water and debris.

Splash caps at the ends of all sheaths, to prevent concrete and laitance from entering into the sheaths during construction, are provided.

D. Corrosion Protection

Suitable atmospheric corrosion protection is maintained for the tendons from the point of manufacture to the installed locations. The atmospheric corrosion protection provides assurance that the tendon integrity is not impaired due to exposure to the environment.

Prior to shipment, a thin film of petroleum oil based rust inhibitor is applied to the tendons in accordance with the manufacturer's instructions. After the tendons are installed and stressed, the interior of the sheathing is pumped full of a modified, thixotropic, refined petroleum oil based product to provide corrosion protection. The tendons and anchors are also encapsulated by gasketed end caps which are filled with the corrosion protection material and sealed against the bearing plates.

E. Prestressing Sequences

The criteria of prestressing sequence are based on the design requirements to limit the membrane tension in concrete and to minimize unbalanced loads of differential stresses in the structure. Prestressing begins after the concrete in the wall and the dome has reached the specified F'_c (5,750 psi).

As part of the creation of the containment construction opening for replacement of the original steam generators, the tendons in the area of the opening, where concrete removal was to take place, were removed to preclude damaging them. Eighteen horizontal tendons (212H20 through 212H28 and 232H21 through 232H29) and six vertical tendons (2V82 through 2V87) were removed. The replacement horizontal tendons were 186 wire (1/4″ diameter wires) ASTM A421, Type BA, with relaxation losses not exceeding those for the original tendons. The tendons were re-tensioned to a force level which ensures that the 40 year minimum effective prestress levels exceed 742.2 kip/ft in the hoop direction and 429 kip/ft in the vertical direction. This ensured that the replaced portion of the post-tensioning system was compatible with the existing one.

The evaluation of tendon prestress for the period of extended operation associated with license renewal is discussed in Section 18.2.4.

3.8.1.7 Testing and Inservice Surveillance Requirements

Testing and inservice surveillance requirements for the containment include the following:

A. Preoperational Structural Integrity Test.

B. Preoperational Integrated Leak Rate Test.

C. Inservice Tendon Surveillance.

3.8.1.7.1 Preoperational Structural Integrity Test

Prior to initial fuel loading, the containment was subjected to a pressure of 115 percent of the design pressure. The results of this test demonstrated that the containment is capable of resisting the postulated accident pressure. In addition, by measuring the structural response and comparing the results with analytical predictions, the test also served to verify the anticipated structural behavior.

The structural initial integrity test was conducted in accordance with Regulatory Guide 1.18 with the following exceptions:

A. Reference: Paragraph C.2 of Regulatory Guide 1.18. The test procedure was in accordance with the regulatory guide subject to the following clarification: It was intended to select the number and distribution of measuring points for monitoring radial deflection so that the as-built condition can be considered in the assessment of roundup, buttress shell interaction, and general shell response. However, to obtain the most significant data, the measuring point locations may have been changed to those where the as-built containment is at the limit of tolerances if such points exist. Accordingly, an arbitrary selection of measurement points was not intended.

B. Reference: Paragraph C.3 of Regulatory Guide 1.18. Measurement of tangential deflections was not planned. The magnitude of the expected local tangential deformation under the test pressure conditions is so negligibly small that, combined with the difficulty in obtaining fixed reference lines for local measurements, it was impractical to attempt measurement of local tangential defections.

C. Reference: Paragraph C.9 of Regulatory Guide 1.18. The structural integrity testing was scheduled when extremely inclement weather was not forecast. If, despite the forecast, snow, heavy rain, or strong wind should have occured during the test, the test results would have been considered valid unless there had been evidence to indicate otherwise.

Following completion of the repair of the containment construction opening after replacement of the original steam generators, the restored containment was subjected to a post-repair/pre-service “containment pressure test” per Article IWL-5000 of ASME Section XI, a Structural Integrity Test (SIT), and an Integrated Leak Rate Test (ILRT) (per Article IWE-5000 of ASME Section XI). The examinations for the liner plate and post-tensioning system and the pressure test together satisfy all applicable requirements of ASME Section XI for pre-service post-repair/restoration examination/testing.

The uprate structural integrity test for the containment uprate was conducted in accordance with Regulatory Guide 1.18 with the following exceptions:

A. Reference: Paragraph C.1 or RG 1.18

   The uprate test procedure has three monitoring points during pressurization /depressurization of the building during the test. These include initial measurements at atmospheric pressure prior to commencing the test, at 62.1 psig (the initial test pressure), and at 1.15Pd (68 psig). Measurements will be taken again at 62.1 psig during depressurization and at atmospheric pressure if the ILRT is conducted at 68 psig. Should ILRT be conducted at Pa (58 psig) measurements will be taken at 58 psig and at atmospheric pressure during depressurization of the containment building.

B. Reference: Paragraph C.2 RG 1.18

The uprate test procedure was conducted in accordance with the regulatory guide following the same clarifications as given above for the initial test except for the following. The uprate test uses only two meridians of the three meridians that were instrumented during the initial test, meridians 00/1800 and 600/2400. The deflections monitored during the initial test demonstrated that the third meridian deflections were very similar to those of the other two and did not yield additional significant information on the performance of the building.

C. Reference: Paragraph C.3 RG 1.18

The uprate test procedure did not plan for tangential deflections as indicated in the initial test above. The instrumentation locations during the uprate test around the equipment hatch include only two points above and two points to the north of the equipment hatch. The movements of the equipment hatch during the uprate test can adequately be predicted based on the information gathered during the initial test and these monitored points. The points that are monitored are located at the initial test locations.

D. Reference: Paragraph C9 RG 1.18

The same exceptions noted above for the initial test are taken for the uprate test.

E. Reference: Paragraph C12 RG 1.186

The information requested in paragraph C12 to be put into the PSAR will be included in the Final Structural Integrity Test Report and included as permanent plant documentation.

3.8.1.7.2 <u>Preoperational Integrated Leakage Rate Testing</u>

Preoperational integrated leakage rate testing of the containment was conducted in accordance with the procedures described in the Bechtel Power Corporation Topical Report BN-TOP-1, "Testing Criteria for Integrated Leakage Rate Testing of Primary Containment Structures for Nuclear Power Plants", Revision 1, November 1, 1972 (see 2CAN037824).

3.8.1.7.3 <u>Inservice Tendon Surveillance</u>

The objective of the inservice tendon surveillance program during the lifetime of the plant is to provide a systematic means of assessing the continued quality of the post-tensioning system. The program is intended to furnish sufficient inservice historical evidence to provide a measure of confidence in the condition and the functional capability of the system, as well as an opportunity for timely corrective measures should adverse conditions, such as excessive corrosion, be detected.

The inservice tendon surveillance program will be conducted in accordance with the requirements of ASME B&PV Code Section XI Subsection IWL as modified by 10 CFR 50.55a.

3.8.2 STEEL CONTAINMENT SYSTEM

Not applicable to Unit 2, which uses a concrete containment structure.

3.8.3 CONCRETE AND STRUCTURAL STEEL INTERNAL STRUCTURES OF CONTAINMENT

3.8.3.1 <u>Description of the Internal Structures</u>

The internal structures located in the containment consist of the primary shield, secondary shield, refueling canal, removable missile shield above the reactor vessel, floor slabs, gratings and platforms, and steam generator and polar crane supports.

3.8.3.1.1 <u>Primary Shield</u>

The primary shield is a heavily reinforced concrete structure which houses the reactor, provides the primary radiation shielding and pressure barrier and is an integral part of the internal structures.

The massive primary shield walls, which are anchored into the containment base slab, provide a support for the secondary shield walls above the reactor cavity. In plan the primary shield walls are forming a monolithical ring, housing the reactor vessel. Large penetrations in the primary shield walls are provided for the primary loop piping.

The arrangement of the primary shield walls is shown in Figures 3.8-13 through 3.8-15.

3.8.3.1.2 <u>Secondary Shield</u>

The secondary shield is a heavily reinforced concrete structure enclosing the primary shield at the lower levels and the steam generator cavities and the refueling canal walls at the higher levels. The massive secondary shield walls are anchored into the base slab of the containment, in a manner similar to the primary shield walls, in order to allow for load transfer to the foundations. Each of the two enclosed secondary shield cavities houses a steam generator and two reactor coolant pumps. In addition one of the cavities also houses the pressurizer.

Steel embedments in the secondary shield walls transmit loads from various equipment, pipe supports and platforms to the walls.

The arrangement of the secondary shield walls is shown in Figure 3.8-13.

3.8.3.1.3 <u>Refueling Canal</u>

The refueling canal is a reinforced concrete structure which is flooded during the reactor refueling operation. The canal walls are formed by the steam generator cavity walls and by an extension of the primary shield walls. Hydrostatic and other loads from the refueling canal are transferred through these walls to the containment base slab.

The refueling canal is lined with stainless steel plate and is connected with the spent fuel pool in the auxiliary building through the fuel transfer tube.

3.8.3.1.4 <u>Missile Shield</u>

The missile shield is a thick reinforced concrete slab supported by the secondary shield walls and is located above the reactor to provide protection against postulated CRDM missiles. The slab is movable to allow access to the refueling canal and reactor vessel.

3.8.3.1.5 Floor Slabs, Grating and Platform

Concrete floor slabs, structural steel floors, and platforms are provided inside and outside of the secondary shield walls as required. Support for these structures is provided by the secondary shield walls or by concrete or structural steel columns, transmitting loads to the containment base slab. A limited amount of grating supports is attached to the liner plate, which transmits loads to the containment wall concrete through the vertical liner plate stiffeners.

3.8.3.1.6 Steam Generator and Polar Crane Supports

The steam generator is mounted on a thick, heavily reinforced concrete slab. The slab is supported vertically by a massive reinforced concrete pedestal transmitting loads from the steam generator base to the containment base slab, and is supported laterally by the primary and secondary shield walls. The steam generator pedestal is shown in Figure 3.8-13.

The polar crane is supported by crane girders mounted on crane brackets evenly spaced around the inside face of the containment wall. The crane brackets are made of welded steel plates and embedded in the containment wall concrete. Details of this support are presented in Figure 3.8-8.

3.8.3.2 Applicable Codes, Standards and Specifications

The applicable codes, specifications, industry standards, design criteria, Regulatory Guides, and Bechtel Topical Reports used in the structural design of the internal structures are covered in Section 3.8.1.2 with the following exceptions:

A. Codes and Specifications in addition, considered the use of AWS D12.1-61 Code - "Recommended Practices for Welding Reinforcing Steel, Metal Inserts and Connections in Reinforced Concrete Construction."

B. Regulatory Guides 1.18, 1.19, and 1.35 listed in Section 3.8.1.2.4 do not apply to the design of the internal structures.

C. Bechtel Topical Reports BC-TOP-1, Revision 1, BC-TOP-7, BC-TOP-8, and BN-TOP-1 listed in Section 3.8.1.2.5 do not apply to the design of the internal structures.

D. Discussion on structural specifications in Section 3.8.1.2.7 applies, however, specifications for the internal structures were prepared to cover the following areas:

   1. Concrete Material Properties

   2. Placing and Curing of Concrete

   3. Reinforcing Steel and splices

   4. Structural Steel

   5. Refueling Canal Liner Plate

3.8.3.3 Loads and Loading Combinations

3.8.3.3.1 Load Definitions

The design loads in the loading combinations were identified as dead loads, live loads, pipe rupture loads, thermal loads, seismic loads and missile loads.

A. Dead Loads

For dead loads, the following specific weights were used:

1. Reinforced Concrete 150 pounds/feet^3

2. Structural Steel 490 pounds/feet^3

B. Live Loads

Floor live loads were considered to be 100 psf for grating floors and 250 psf for reinforced concrete floors.

C. Pipe Rupture Loads

Forces or pressures on structures caused by pipe rupture were considered. Pipe rupture effects are further discussed in Section 3.6.

D. Thermal Loads

The conditions considered in determining stresses due to thermal loads were temperature gradients through the primary and secondary shield walls, and forces on internal structures due to the thermal expansion of piping and equipment.

E. Seismic Loads

Seismic loads for the DBE and the OBE were considered. A more detailed discussion is presented in Section 3.7.1.

F. Missile Loads

Internal missile loads were considered in the design. A more detailed discussion is presented in Section 3.5.2.

G. Accident Pressure Loads

Loads generated inside the steam generator and reactor cavities due to a LOCA.

3.8.3.3.2 Loading Combinations

The two loading cases considered in the design of the internal structures were identified as (1) the normal condition and (2) the accident condition.

The following variables are used in the loading combination equations:

U = Required ultimate load capacity.

D = Dead load of structure and equipment plus any other permanent loads contributing stresses, such as hydrostatic loads. An allowance was also made for future permanent loads.

L = Live load and piping load.

R = Force or pressure on structure due to rupture of any one pipe.

T_o = Thermal loads due to temperature gradient through-wall under normal conditions.

H_o = Force on structure due to thermal expansion of pipes under normal conditions.

T_A = Thermal loads due to temperature gradient through wall under accident conditions.

H_A = Force on structure due to thermal expansion of pipes under accident conditions.

E = Operating Basis Earthquake loads resulting from ground surface acceleration of 0.1 g.

E' = Design Basis Earthquake loads resulting from ground surface acceleration of 0.2 g.

P_A = LOCA Pressure Load

F_s = Allowable working stress in structural steel.

F_y = Yield stress of structural steel.

3.8.3.3.2.1 Normal Condition

A. Concrete Structures

Design of concrete structures was in accordance with the following loading combinations:

1. $U = 1.5D + 1.8L$
2. $U = 1.25\ (D + L + H_o + E) + 1.0\ T_o$
3. $U = 0.9\ D + 1.25\ (H_o + E) + 1.0\ T_o$

In addition, for ductile moment resisting concrete space frames and for shear walls the following loading combinations were used:

4. $U = 1.4\ (D + L + E) + 1.0\ T_o + 1.25\ H_o$
5. $U = 0.9\ D + 1.25\ E + 1.0\ T_o + 1.25\ H_o$

For structural elements carrying mainly earthquake forces, such as equipment supports, the following loading combinations were used:

6. $U = 1.0\ D + 1.0\ L + 1.8\ E + 1.0\ T_o + 1.25\ H_o$

B. Structural Steel

Steel structures were designed in accordance with the following loading combinations without exceeding the specified stresses:

1. D + L   Stress Limit = F_s
2. D + L + T_o + H_o + E   Stress Limit = 1.25F_s

In addition, for structural elements, carrying mainly earthquake forces, such as struts and bracings, the following loading combination was used.

3. D + L + T_o + H_o + E   Stress Limit = F_s

3.8.3.3.2.2 <u>Accident Condition</u>

A. Concrete Structures

Design of concrete structures was in accordance with the following loading combinations:

1. U = 1.05 D + 1.05 L + 1.25 E + 1.0 T_A + 1.0 H_A + 1.0 R + 1.0 P_A
2. U = 0.95 D + 1.25 E + 1.0 T_A + 1.0 H_A + 1.0 R + 1.0 P_A
3. U = 1.0 D + 1.0 L + 1.0 E' + 1.0 T_O + 1.25 H_O + 1.0 R
4. U = 1.0 D + 1.0 L + 1.0 E' + 1.0 T_A + 1.0 H_A + 1.0 R + 1.0 P_A

B. Structural Steel

Steel structures were designed in accordance with the following loading combinations without exceeding the specified stress limits:

1. D + L + R + T_O + H_O + E'   Stress limit = 1.5F_S
2. D + L + R + T_A + H_A + E'   Stress limit = 1.5F_S

For the accident condition loading combinations, the maximum allowable stress in bending and tension is limited to 0.9F_y and the maximum allowable stress in shear is limited to 0.5F_y.

3.8.3.4 <u>Design and Analysis Procedures</u>

3.8.3.4.1 <u>General Considerations</u>

The internal structures were designed to provide structural support and radiation shielding for the RCS, auxiliary systems and engineered safety features. The internal structures were designed as an integral unit with all structural components interconnected to allow transmittal of all vertical and horizontal design loads to the containment base slab.

The structural components were designed using both reinforced and structural steel as appropriate. All design aspects were integrated with the design criteria of the Nuclear Steam System (NSS) supplier and included particular attention to the combined thermal and dynamic effects. Design loads and loading combinations for the internal structures are listed and described in Section 3.8.3.3.

The basic techniques of analyzing the internal structures can be classified into two groups: (1) conventional methods involving simplifying assumptions such as those found in beam theory, and (2) plate theories using various degrees of approximation.

Design considerations implemented in the design of the internal structures are presented in the following discussion.

Loads and deformations resulting from a LOCA and the associated effects on any one of the basic systems were restricted so that propagation of the failure to any other system is prevented. In addition, a failure in one loop of the Nuclear Steam Supply System (NSSS) is restricted so that propagation of the failure to the other loop is prevented. All components of engineered safety features are protected by barriers from missiles which might be generated from the primary system.

Full recognition was given to the time increments associated with postulated failure conditions, and yield capacities were appropriately increased when a transient analysis demonstrated that the rapid strain rate justified this approach.

Pressure buildup in locally confined areas such as the reactor cavity or the steam generator cavities are discussed in Sections 3.8.3.4.2 and 3.8.3.4.3, respectively.

The structures were, in general, proportioned to maintain elastic behavior when subject to various combinations of dead loads, thermal loads, seismic and accident loads. The upper limit of elastic behavior was considered to be the yield strength of the effective load carrying structural material. The yield strength, F_y, for steel (including reinforcing steel) was considered to be the guaranteed minimum in appropriate ASTM specifications. The yield strength for reinforced concrete structures was considered to be the ultimate resisting capacity as calculated from the "Ultimate Strength Design" portion of the ACI-318-6 Code.

Reinforced concrete structures were designed for ductile behavior that is with reinforcing steel stresses controlling. The design was in accordance with the "Ultimate Strength Design" portion of the ACI 318-63 Code, except that in localized areas, increased bearing stresses were permitted in accordance with the ACI 318-71 Code.

Under seismic loading, no plastic analysis was considered. Local yielding or erosion of barriers was considered permissible due to pipe rupture loading or missile impact, provided there was no general failure.

Structural steel was designed in accordance with basic working stress design methods. Increased allowable stressed were used for the accident condition.

The final designs of the interior structures and equipment supports were reviewed to assure that they can withstand applicable design pressure loads, jet forces, pipe reactions, and earthquake loads without loss of function. The deflections or deformations of the structures and supports were checked to ensure that the functions of the containment and safety feature systems were not impaired.

3.8.3.4.1.1 Effect of Radiation Generated Heat

The effect of radiation generated heat on the internal structures has been considered in the design of the primary and secondary shield walls. The shield wall thicknesses were determined on the basis of the radiation shielding requirements, much higher than those required for structural purposes. This additional thickness provides reserve strength greater than required to offset minor damages to the structures due to a LOCA. Since high temperatures are damaging to concrete, provisions are made to maintain a constant temperature through ventilation. The ventilation within the containment has been designed to cool the area surrounding the shield walls in order to prevent any appreciable loss of structural strength due to gamma and neutron heating.

The maximum concrete temperatures were considered as follows:

A. For normal conditions 150 °F, except that in local areas 200 °F was allowed.

B. For accident conditions 350 °F for the interior surface, except that in local areas 650 °F from steam and/or water jets was allowed.

3.8.3.4.1.2 Range of Design Variables

The range of design variables that influenced the results of the analyses is identified as follows:

A. Accuracy of design loads

B. Variations from assumed load distributions

C. Future changes in type or magnitude of loads

D. Frequency of loading and impact

E. Accuracy of analysis

F. Design accuracy of member sizing and proportioning

G. Reliability of specified material strengths

H. Construction dimensional variations

I. Service of structure

For the working stress design methods, the effects of the design variables, were included in the values of the allowable stresses. For the ultimate strength design method, the effects of these design variables were accounted for in the load factors and capacity reduction factors.

3.8.3.4.1.3 Computer Programs Used in the Analysis

Computer programs used in the original analysis of internal structures are presented in Table 3.8-3.

3.8.3.4.2 Primary Shield

The primary shield was designed for loads and loading combinations in accordance with Section 3.8.3.3.

The reactor cavity was designed to withstand uplift forces and a differential pressure across the cavity wall resulting from an assumed a hypothetical hot leg slot failure. The area of slot was considered equivalent to twice the cross-sectional area of the pipe.

For a discussion of loads generated by postulated pipe ruptures, see Section 6.2.1. Provisions were incorporated in the reactor cavity design to safely withstand the calculated differential pressure so as to maintain the integrity of the reactor cavity. The maximum stress level in the rebar under this loading condition is limited to 0.9 times the yield capacity of the steel reinforcing.

A critical section in the design of the primary shield is shown in Figure 3.8-15 in the lower right hand area of Section A. This area shows the concrete supports and reinforcement for the base of the reactor vessel support columns. Equation A.4 of Section 3.8.3.3.2.2 was the critical design load combination for this section.

The primary shield was analyzed as a cylindrical pressure vessel utilizing "CE 316-FINEL" computer program. The analysis was based on ultimate strength design in accordance with ACI 318-63 Code. No exceptions to the code have been taken in design of the primary shield.

3.8.3.4.3 Steam Generator Cavities

The steam generator cavities are designed for a differential pressure across the cavity walls resulting from a hypothetical hot leg slot failure. The area of the slot was considered equivalent to twice the cross-sectional area of pipe. The cavities are also designed for jet forces on localized areas of the walls resulting from the impingement of escaping fluid.

A critical section in the design of secondary shield is shown in C-2157 referenced in SAR Table 1.7-2 (see area "A"). Equation A.4 of Section 3.8.3.3.2.2 was the critical design load combination for this section. The secondary shield was analyzed as a series of 10'-0" deep ring beams utilizing "CE 309-STRESS" and "CE-901 STRUDL" computer programs. The analysis was based on ultimate strength design in accordance with ACI 318-63 Code. No exceptions to the code have been taken in design of the secondary shield.

3.8.3.4.4 Refueling Canal

For the refueling condition, the walls are designed for the hydrostatic head due to 39.5 feet of water. The pressure loads due to postulated pipe rupture and hydrostatic head were not considered to occur simultaneously.

3.8.3.4.5 Reactor Coolant System Equipment Supports

The steel and concrete supports for the reactor, the reactor coolant pumps, the steam generators, and the pressurizer were designed for loads supplied by Combustion Engineering (CE) and Westinghouse (WEC) (for sketch of supports see Figure 3.8-13a). These loads included the maximum forces on a support due to accident loads, e.g., pipe rupture, with a dynamic load factor of 2, operating loads, and DBE seismic loads. The directions of the seismic forces were chosen to give the largest load at each support.

The loads were combined using the maximum DBE forces and the maximum accident forces simultaneously. This gave the worst possible design condition that could occur for each support.

The pressurizer support and the reactor coolant pump supports were analyzed by conventional design techniques using the loads as described above.

The reactor and steam generator supports were analyzed by a combination of conventional design techniques and computer programs. The reactor vessel support was analyzed by the "CE 316-FINEL" computer program as described in Section 3.8.3.4.2.

The steam generator upper supports were analyzed by the "CE-901 STRUDL" computer program as described in Section 3.8.4.3. The lower steam generator support is described in Section 3.8.3.1.6 and was analyzed by the "CE-309-STRESS" computer program.

A combination of cold gaps, keyways, and snubbers were provided between the above mentioned equipment and their supports so that minimal thermal loads from the expansion of the equipment will be transmitted to the supports.

In all cases the steel and concrete supports were designed in compliance with the AISC-1969 specification and the ACI 318-63 code, except that in localized areas an increased concrete bearing stress was permitted in accordance with the ACI-318-1971 Code.

3.8.3.5 Structural Acceptance Criteria

Internal structures were designed for structural acceptance criteria as outlined in Sections 3.8.3.2 and 3.8.3.3.2.

The limiting values of stress, strain, and gross deformations were established as follows:

A. to maintain the structural integrity when subjected to the most severe load combinations; and,

B. to prevent structural deformations from displacing the equipment to the extent that the equipment suffers a loss of function.

The calculated results for representative structural members of the internal structures shown in Table 3.8-6, indicate the margins of safety provided in the design.

3.8.3.6 Materials, Quality Control and Special Construction Techniques

The internal structures are constructed of concrete and steel using proven methods common to heavy industrial construction.

The range of material properties used for the design were generally identified by standard industry specifications.

3.8.3.6.1 Concrete

Concrete generally conforms to the requirements discussed in Section 3.8.1.6.1, except that a 3,000 psi concrete compressive strength at 28 days and 5,500 psi concrete compressive strength at 90 days are used in the design of the internal structures.

3.8.3.6.2 Steel

The two basic categories of steel used in the internal structures are reinforcing steel and structural steel. A discussion for each category follows.

3.8.3.6.2.1 Reinforcing Steel

Reinforcing steel is described in Section 3.8.1.6.2 with one following exception. Because of construction requirements it was necessary to splice nine #18 reinforcing bars with butt welds around the reactor cavity access opening. A special welding procedure conforming to the requirements of AWS D 12.1-61 was used.

3.8.3.6.2.2 Structural and Miscellaneous Steel

Structural and miscellaneous steel generally conform to the following ASTM specifications:

Rolled shaped, Bars and Plates	A36-69 or A441-70a
High Strength Bolts	A325-70a or A490-67
Other Bolts	A307-68
Stainless Steel	A167, Type 304L

Other types of steel were used in small quantities in the internal structures as required.

Mill test reports are obtained for structural steel materials used.

3.8.3.7 Testing and Inservice Surveillance Requirements

A formal program of testing and inservice surveillance is not planned for the internal structures. The internal structures are not directly related to the functioning of the containment concept; hence, no testing or surveillance is required.

3.8.4 OTHER CATEGORY 1 STRUCTURES

3.8.4.1 Description of the Structures

Seismic Category 1 structures, other than the containment and the internal structures, are:

A. The Auxiliary Building (portions of reinforced concrete)

B. The Intake Structure

C. The Emergency Diesel Fuel Storage Vault

D. The Emergency Cooling Pond Pipe Inlet and Pipe Outlet Structures

E. The Electrical Manholes (Seismic Category 1)

F. Condensate Tank Foundation (T41B)

G. Condensate Storage Tank (T41B) Pipe Trenches

H. Post Accident Sampling System Building

Relative locations of all Seismic Category 1 structures are shown in Figure 3.5-1.

3.8.4.1.1 Auxiliary Building

The auxiliary building is located between the Unit 2 Category 1 prestressed concrete containment, the Unit 2 Category 2 steel framed turbine building, and the Unit 1 Category 1 auxiliary building. A complete separation has been provided between the Unit 2 auxiliary building and the adjacent concrete Category 1 structures.

The auxiliary building is essentially an opposite hand duplicate of the Unit 1 auxiliary building and consists of a reinforced concrete structure and a structural steel superstructure.

The reinforced concrete portion is a multilevel structure with floors and slabs transmitting loads to the foundation. The structure is founded on rock. The base mat was designed to resist the hydrostatic loads of the Probable Maximum Flood (PMF). Typical plan and sections of the auxiliary building reinforced concrete structure are shown in Figure 3.8-19. Typical details are shown in Figure 3.8-26.

The boron management holdup tank vaults, which is a monolithic Category 1 appendix to the auxiliary building below grade level, is anchored through its base to the foundation rock to counter uplift forces during high water levels. A plan and a section of this reinforced concrete structure is shown in Figure 3.8-20.

The massive reinforced concrete spent fuel pool is monolithically tied to the remaining part of the auxiliary building. The spent fuel pool is designed to withstand 212 °F temperatures inside the pool without failure and the walls are inherently resistant to missiles. Reinforcing steel which is provided in the spent fuel pool walls will also limit concrete cracking during the expected thermal stresses.

The emergency diesel generator rooms are located in the auxiliary building and are well above the PMF elevation. The two generator units are supported by 42-inch thick reinforced concrete slabs. The Auxiliary Building Extension is located at the north end of the Unit 2 Auxiliary Building. The 335 feet and 354 feet elevations of the Auxiliary Building Extension are not protected from external flooding.

The structural steel superstructure has a framing system supporting the roof and metal siding. The fuel loading crane is supported by steel frames straddling the fuel pool bay. This portion of the Auxiliary Building is Category 2, but is designed to withstand the Design Basis Earthquake. During a tornado, portions of siding and roof deck may be blown off, but the steel frame is designed to assure that it will not collapse or distort so as to allow the bridge crane to fall. Steel frames supporting the roof and crane are checked to assure that stresses do not exceed 90 percent of minimum yield stress if one-third of the siding remains in place. The assumption that only one-third siding remains in place is considered reasonable, since the applied forces are 185 psf on the windward side and 110 psf on the leeward side and the normal allowable design pressure is on the order of 25 psf.

In moving the spent fuel cask from the cask washdown area to the railroad spur opening, the loaded fuel handling crane will pass over the relay panel room ceiling. A more detailed description of the spent fuel cask handling is provided in Section 9.1.4.2.10.

3.8.4.1.2 Intake Structure

The intake structure is located in the southeast corner of the plant site. It is a reinforced concrete Category 1 structure and is considered as an extension of the Unit 1 intake structure. There is no separation between the two structures and both are founded on rock. The structure provides a support for a gantry crane to service the equipment. A floor plan arrangement and a section are shown in Figures 3.8-21 and 3.8-22.

3.8.4.1.3 Emergency Diesel Fuel Storage Vault

The Unit 2 emergency diesel fuel storage vault is located to the west of the containment and is an extension of the Unit 1 diesel fuel storage vault to which it is attached monolithically.

The emergency diesel fuel storage vault is an underground, reinforced concrete structure with only the cover slab and an access shaft projecting above grade level. The structure is founded on rock and rock anchors are used to counter the uplift forces during flood. A thick base mat is designed to resist the hydrostatic loads during the PMF. A floor plan arrangement and a section are shown in Figures 3.8-23 and 3.8-24.

3.8.4.1.4 Pipe Inlet and Pipe Outlet Structures at the Emergency Cooling Pond

The pipe inlet and outlet structures are located on the west tips of the kidney shaped emergency cooling pond in a northwest direction from the containment. They are relatively small, reinforced concrete structures and are partially underground, founded on natural soil and surrounded by backfill materials. Plant arrangements and sections are shown in Figure 3.8-25.

3.8.4.1.5 Electrical Manholes

The Seismic Category 1 electrical manholes are placed at various locations within the plant site. They are relatively small, reinforced concrete structures founded either on natural soil or backfill materials. They are surrounded by backfill material and located partially underground. An access opening in the top slab, at grade level, is provided with a missile resistant reinforced concrete cover. A plan arrangement and a section are shown in Figures 3.8-23 and 3.8-24. A detail of the cover is shown in Figure 3.5-8.

3.8.4.1.6 Condensate Storage Tank (T41B) Pipe Trenches

The pipe trenches are reinforced concrete trenches running from the Condensate Storage Tank (T41B) to both Unit-1 and Unit-2 Auxiliary Building walls. Like the electrical manholes, they are surrounded by backfill material and situated on natural soil or backfill material. They project partially out of the ground and are covered by a missile resistant reinforced concrete cover. A section through the trench is shown in Figure 3.8-34.

3.8.4.1.7 Condensate Storage Tank (T41B) Foundation

The Condensate Storage Tank (T41B) Foundation is located west of the Unit-1 Auxiliary Building approximately 150 feet. It is a 2½ foot thick by 52 foot reinforced concrete octagon mat supported on 42" diameter drilled concrete piers. Two 11.5 x 12.5 x 8.5 feet deep valve pits are located partially underneath and on opposite sides of the foundation. A 5 foot high reinforced concrete wall designed for missile protection surrounds the tank. A general layout of the foundation is shown in Figure 3.8-35.

3.8.4.2 Applicable Codes, Standards and Specifications

Codes, specifications, industry standards, design criteria, Regulatory Guides, and Bechtel Topical Reports which constituted the basis for the design and construction of the Other Category 1 Structures, are described in the following sections. Modifications to these codes, standards, etc. were made when necessary, to meet the specific requirements of the structure. These modifications are indicated in the sections where references to the codes, standards, etc. are made.

3.8.4.2.1 Codes and Specifications

The applicable codes and specifications used in the design of the Other Category 1 Structures are covered in Section 3.8.1.2.1, with the following exception: Item L., "ASME Boiler and Pressure Vessel Code," Sections III, VIII and IX - 1968 Edition, does not apply.

3.8.4.2.2 Industry Standards

Nationally recognized industry standards such as those published by the organizations listed below, were used whenever applicable to describe methods, procedures, and material properties. The specific standards used are identified in the applicable sections.

A. AASHO - American Association of State Highway Officials

B. ACI - American Concrete Institute

C. AISI - American Iron and Steel Institute

D. ANSI - American National Standards Institute

E. ASTM - American Society for Testing and Materials

F. SNT - Society of Nondestructive Testing

G. SSPC - Steel Structures Painting Council

3.8.4.2.3 Design Criteria

A. ASCE "Wind Forces on Structures," Paper No. 3269.

B. "Nuclear Reactors and Earthquake," Publication TID 7024.

3.8.4.2.4 Regulatory Guides

The following regulatory guides were used:

Regulatory Guide 1.15 "Testing of Reinforcing Bars for Concrete Structures," December 1972, as noted in Section 3.8.1.6.2.

Regulatory Guide 1.55 "Concrete Placement in Category 1 Structures," June 1973 except as noted in Section 3.8.1.6.1.6.

3.8.4.2.5 Bechtel Topical Reports

The following document was used to the extent referenced in 3.7:

BC-TOP-4 "Seismic Analysis of Structures and Equipment for Nuclear Power Plants," Revision 1, September 1972, and Addendum No. 1, April 1973.

3.8.4.2.6 Structural Specifications

Structural specifications are prepared to cover the areas related to design and construction of other Category 1 structures. These specifications emphasize important points of the industry standards for the other Category 1 structures and reduce options such as would otherwise be permitted by the industry standards. Unless specifically noted otherwise, these specifications do not deviate from the applicable industry standards.

These specifications cover the following areas:

A. Concrete Material Properties

B. Placing and Curing of Concrete

C. Reinforcing Steel and Splices

D. Structural Steel

E. Spent Fuel Pool Liner Plate

3.8.4.3 Loads and Loading Combinations

3.8.4.3.1 Load Definitions

The design loads in the load combinations were identified as dead loads, live loads, accident pressure loads, pipe rupture loads, thermal loads, seismic loads, wind and tornado loads, hydrostatic loads and missile loads.

A. Dead Loads

For dead loads, the following specific weights were used:

1. Reinforced Concrete 150 lb/ft^3

2. Structural Steel 490 lb/ft^3

B. Live Loads

Floor live loads were considered to be 100 psf for grating floors and 250 psf for reinforced concrete floors.

Snow load was considered to be 20 psf.

C. Pipe Rupture Loads

Forces or pressures on structures caused by pipe rupture were considered. Pipe rupture effects are further discussed in Section 3.6.

D. Thermal Loads

Temperature gradient through the spent fuel pool wall considered a maximum temperature of 212 °F on the inside face of the spent fuel pool wall.

E. Seismic Loads

Seismic loads for the DBE and the OBE were considered. A more detailed discussion is presented in Section 3.7.1.

F. Wind and Tornado Loads

Wind and tornado loads were considered. A more detailed discussion if presented in Section 3.3.1.

G. Hydrostatic Loads

Buoyant forces resulting from the displacement of ground or flood water by the structure and lateral hydrostatic forces were considered. A more detailed discussion is presented in Section 3.4.3.

H. Missile Loads

External and internal missile loads were considered. A more detailed discussion is presented in Sections 3.5.2 and 3.5.3.

3.8.4.3.2 Loading Combinations

The loading cases considered in the design of the Other Category 1 Structures were identified as (1) the normal condition and (2) the accident condition.

The following variables are used in the loading combination equations:

U = Required ultimate load capacity.

D = Dead load of structure and equipment plus any other permanent loads contributing stresses, such as hydrostatic loads.

L = Live load and piping load.

R = Force or pressure on structure due to rupture of any one pipe.

T_o = Thermal loads due to temperature gradient through-wall under normal conditions.

H_o = Force on structure due to thermal expansion of pipes under normal conditions.

T_A = Thermal loads due to temperature gradient through wall under accident conditions.

H_A = Force on structure due to thermal expansion of pipes under accident conditions.

E = Operating Basis Earthquake loads resulting from ground surface acceleration of 0.1 g.

E' = Design Basis Earthquake loads resulting from ground surface acceleration of 0.2 g.

A = Hydrostatic load due to probable maximum flood.

W = Wind load.

W' = Tornado wind load.

F_s = Allowable working stress in structural steel.

F_y = Yield stress of structural steel.

3.8.4.3.2.1 <u>Normal Condition</u>

A. Concrete Structures

Design of concrete structures was in accordance with the following loading combinations:

1. $U = 1.5D + 1.8L$
2. $U = 1.25\ (D + L + H_o + E) + 1.0\ T_o$
3. $U = 1.25\ (D + L + H_o + W) + 1.0\ T_o$
4. $U = 0.9\ D + 1.25\ (H_o + E) + 1.0\ T_o$
5. $U = 0.9\ D + 1.25\ (H_o + W) + 1.0\ T_o$

In addition, for ductile moment resisting concrete space frames and for shear walls, the following loading combinations were used:

6. $U = 1.4\ (D + L + E) + 1.0\ T_o + 1.25\ H_o$
7. $U = 0.9\ D + 1.25\ E - 1.0\ T_o + 1.25\ H_o$

For structural elements carrying mainly earthquake forces, such as equipment supports, the following loading combination was used:

8. $U = 1.0\ D + 1.0\ L + 1.8\ E + 1.0\ T_o + 1.25\ H_o$

B. Structural Steel

Steel structures were designed in accordance with the following loading combinations without exceeding the specified stresses:

1. D + L - Stress Limit = F_s

2. $D + L + T_o + H_o + E$ - Stress Limit = $1.25F_s$

3. $D + L + T_o + H_o + W$ - Stress Limit = $1.33F_s$

In addition, for structural elements, carrying mainly earthquake forces, such as struts and bracings, the following loading combination was used:

4. $D + L + T_o + H_o + E$ - Stress Limit = F_s

3.8.4.3.2.2 Accident Condition

A. Concrete Structures

Design of concrete structures was in accordance with the following loading combinations:

1. $U = 1.05\ D + 1.05\ L + 1.25\ E + 1.0\ T_A + 1.0\ H_A + 1.0\ R$

2. $U = 0.95\ D + 1.25\ E + 1.0\ T_A + 1.0\ H_A + 1.0\ R$

3. $U = 1.0\ D + 1.0\ L + 1.0\ E' + 1.0\ T_o + 1.25\ H_o + 1.0\ R$

4. $U = 1.0\ D + 1.0\ L + 1.0\ E' + 1.0\ T_A + 1.0\ H_A + 1.0\ R$

5. $U = 1.0\ D + 1.0\ L + 1.0\ A + 1.0\ T_o + 1.25\ H_o$

6. $U = 1.0\ D + 1.0\ L + 1.0\ W' + 1.0\ T_o + 1.25\ H_o$

B. Structural Steel

Steel structures were designed in accordance with the following loading combination without exceeding the specified stress limits:

1. $D + L + R + T_o + H_o + E'$ Stress Limit = $1.5\ F_s$

2. $D + L + R + T_A + H_A = E'$ Stress Limit = $1.5\ F_s$

3. $D + L + A + T_o + H_o$ Stress Limit = $1.5\ F_s$

4. $D + L + T_o + H_o + W'$ Stress Limit = $1.5\ F_s$

For the accident loading combinations, the maximum allowable stress in bending and tension is limited to $0.9\ F_y$ and the maximum allowable stress in shear is limited to $0.5\ F_y$.

3.8.4.4 Design and Analysis Procedure

The analysis procedures including assumptions of load distribution and boundary conditions for the Other Category 1 Structures, listed in Section 3.8.4.1 were based on conventional methods. The basic analytical techniques may be classified in two groups: (1) methods involving simplifying assumptions such as those found in beam theory, and (2) those based on plate

theories of different degree of approximation. The structures were expected to behave under loads as structural units and were provided with connections capable of transmitting axial and lateral loads by diaphragm action to their foundations.

The structures were, in general, proportioned to maintain elastic behavior when subject to various combinations of dead, live, thermal, seismic, tornado and accident loads. The upper limit of elastic behavior was considered to be the yield strength, F_y, for steel (including reinforcing steel) was considered to be the guaranteed minimum in appropriate ASTM specifications. The yield strength for reinforced concrete structures was considered to be the ultimate resisting capacity as calculated from "Ultimate Strength Design" portion of the ACI-318-63 code.

Reinforced concrete structures were designed for ductile behavior, that is, with reinforcing steel stresses controlling. "The Ultimate Strength Design" portion of the ACI 318-63 code was used.

Under seismic loading, no plastic analysis was considered. Local yielding or erosion of barriers was considered permissible due to pipe rupture loading or missile impact, provided there was no general failure.
Structural steel was designed in accordance with basic Working Stress Design Methods. Increased allowable stresses were used for the accident condition.

The range of design variables that influenced the results of the analyses is considered as follows:

A. Accuracy of design loads
B. Variations from assumed load distributions
C. Future changes in type or magnitude of loads
D. Frequency of loading and impact
E. Accuracy of analysis
F. Design accuracy of member sizing and proportioning
G. Reliability of specified material strengths
H. Construction dimensional variations
I. Service of structure

For the working stress design methods, the effects of the design variables were included in the values of the allowable stresses. For the ultimate strength design method, the effects of these design variables were accounted for in the use of load factors and capacity reduction factors.

Seismic Category 2 structures whose collapse could result in loss of required function of Seismic Category 1 structures, equipment or systems were either:

A. analyzed for the loading combination given in Section 3.8.4.3.2; or,

B. structurally separated from the Category 1 structures to assure that interaction does not occur.

Computer programs used in the original analysis of the Other Category 1 Structures are presented in Table 3.8-3.

3.8.4.5 Structural Acceptance Criteria

The Other Category 1 Structures were designed for structural acceptance criteria as outlined in Sections 3.8.4.2 and 3.8.4.3.2.

The criteria to limit values of stress, stain and gross deformations for the Other Category 1 Structures were established as follows:

A. To maintain structural integrity when subjected to the most severe load combinations, and

B. To prevent structural deformations from displacing the Category 1 equipment to the extent that it suffers a loss of function.

The calculated results for representative structural members of the Other Category 1 Structures, shown in Table 3.8-7, indicate the margins of safety provided in the design.

3.8.4.6 Materials Quality Control and Special Construction Techniques

The Other Category 1 Structures are constructed of concrete and steel using proven methods common to heavy industrial construction. The range of material properties for design was generally identified by standard industry specification.

3.8.4.6.1 Concrete

Concrete generally conformed to the requirements discussed in Section 3.8.1.6.1, except that a 3,000 psi concrete compressive strength at 28 days was used for the Other Category 1 Structures.

3.8.4.6.2 Steel

The two basic categories of steel used in the Other Category 1 Structures are reinforcing and structural steel. A discussion for each category follows.

3.8.4.6.2.1 Reinforcing Steel

Reinforcing steel generally conformed to the requirements discussed in Section 3.8.1.6.2, except that #14 and #18 reinforcing bars were not used.

Reinforcing steel was lap spliced in accordance with ACI 318-63, except at local areas around temporary construction openings where "Dywidag" threaded bars were used as dowels lapped with the normal reinforcing steel. The dowels were spliced with "Dywidag" mechanical connectors at the perimeter of the openings. Splicing of reinforcing steel by welding or by use of cadwelds was not done.

Dywidag mechanical connectors were used for the following reasons:

A. The Grade 60 reinforcing steel specified is generally difficult to weld properly. Welding procedures are available but are generally more complicated than those used for welding low carbon steels and involve both preheating of the steel as well as post-weld heat treatment.

B. Both conventional lap splices and welded splices require the reinforcing to project into the construction opening in order for the splice to be completed at the time the temporary construction opening is closed. The protruding rebars therefore require a larger temporary construction opening in the concrete slab or wall to allow for equipment access. In addition to the larger opening size there is the potential danger of damage to the reinforcing in the event the projecting rebars are accidentally bent during construction. Some openings may remain open for a period of a year or more.

Installation of the Dywidag connectors was done in accordance with the manufacturer's instruction except that the joint nuts were tightened and manually torqued using a 24-inch wrench instead of a torque wrench. Drawings were prepared for each opening showing the connector size and spacing. Visual inspection was made for verification and conformance with the placement drawings. Field inspection reports were prepared for each opening.

The method used in making a splice is straightforward and required only normal techniques with which an ironworker is familiar.

Two types of tests were used in connection with the connectors. First a user's test was made on the threaded rebar at a frequency of two tests per order or two tests per mill heat number.

The second test consisted of testing completed test assemblies at the rate of one test per 100 installed splices. The manufacturer's procedures were followed in making the splices except that a 24-inch wrench was used to manually torque the joint nut instead of using a torque wrench. This is the same procedure as for the splices in the structures.

A lower test frequency than that used for cadwelds is justified due to a less complicated installation procedure and the ability to visually inspect splices to determine compliance with the manufacturer's criteria since the splice is completed in stages when employed in temporary construction openings.

The test results show that the minimum ultimate strength of this completed test splice was in excess of 100 ksi which exceeds the minimum specified ultimate strength of 90 ksi for the Grade 60 reinforcing steel furnished for the project.

Dowels for plugs in temporary opening, including the "Dywidag" splice, were at least one size larger than the designed wall or slab reinforcing steel. On this basis the minimum connector called for was a #10 while the maximum main reinforcement was a #9. Therefore an allowance for minor installation variations has been made.

In most cases the tensile capacity of the connector has not been considered in the design of the closure. The wall or slab closure in general has been considered as a point simply supported either for one- or two-way action as the condition required.

For the case where only shear is transferred by the connectors, the maximum shear stress in the rebar is well below the allowable value for this material. Where tensile stresses are transmitted through the connector, the connector has an additional safety factor of 27 percent or more by virtue of the larger size connector assembly used in place of the designed reinforcement.

The wall at column line 1 between column lines A2 and B2 was determined to have the worst case stress conditions for connections.

A. The height of the temporary construction opening is approximately half the height of the wall and the connectors provide continuity for the vertical and horizontal wall spans.

B. The wall is an external wall subjected to tornado wind loadings and is a shear wall resisting earthquake loads.

All of the load combinations shown in Section 3.8 were evaluated to determine which combination would give the highest stresses in the connector. The controlling load combination was Equation 6 in Section 3.8.4.3.2.2.A which has the tornado wind as the major load. After the temporary construction opening is closed, the wall will act as a unit. The wall is continuous at its bottom and sides, but is not continuous at the top support. To simulate as close as possible the as-built conditions, a flat plate analysis was used assuming that the wall is simply supported on the top and fixed on the other three sides as shown in Figure 3.8-32.

The location of the maximum stresses and stress gradations in the concrete, the connectors, and the reinforcing steel in the wall are shown on Figure 3.8-32 and Tables 3.8-9 and 3.8-10.

The moment and reaction gradations are obtained from Figures 10 and 17 of "Moments and Reactions for Rectangular Plates" by W.T. Moody, a Water Resources Technical Publication Engineering Monograph, No. 27, dated July 1963.

Floor Slab Temporary Construction Opening

The temporary construction openings in slabs were designed as one-way simply supported slabs, supported on seats in the direction of the span. The mechanical connectors were used around the perimeter of the opening. Because of the design assumptions, there theoretically would be no stress in the connectors. Therefore, the connectors are not required for structural reasons.

In the case of the largest slab temporary construction opening shown on Figure 3.8-30 between column lines 1 and 2, A2 and B2, the 4-foot splice length can resist the developed negative moment if the support is assumed fixed. The stress level in a #10 bar developed by the negative moment is about 25,000 psi.

The method of transferring tensile stresses from the reinforcing steel to the thread bar connector, and back to the reinforcing steel is by the use of a lap splice between reinforcing steel and the thread bar of the connectors as shown in Figure 3.8-33. The bond length used for developing the connector in walls was the tension lap length required by ACI Standard 318-63 for ultimate strength design based on the reinforcing steel bar diameter. In the case of floor openings, where the closure was designed as a simply supported slab, a nominal splice length of four feet was used. The use of the sample bond values for the thread bar as for the reinforcing steel is justified by the comparison of data supplied by the manufacturer and the deformation requirements set forth in ASTM A615-68.

The Columbia University test data on the #11 bar shows a minimum yield point load of 101,000 pounds which is larger than the required yield point load of 93,600 pounds. The 46,800 pounds is a load for a 15-minute hold time during the test and not the ultimate strength

which was 145,000 pounds. In order to show the sensitivity of the connector strengths to different torque values used to tighten the jam nuts, a test program was conducted using complete assemblies (three tests per torque value) torqued to 100, 500, 700 and 1000 foot-pounds. Three assemblies were also torqued manually with a 24-inch wrench in the same manner as the production assemblies. Test results including slippage, yield strength, tensile strength, and location of fracture of the test assembly are shown in the test slippage data which was forwarded to the staff by letter from J.D. Phillips to J. Stolz dated May 5, 1976, (2CAN057601).

Since #10 connectors were not readily available at the time of the tests, only #11 connectors were used in the initial test program. The test data on #10 connectors was submitted August 5, 1976 (2CAN087605).

The tests discussed above are the user's tensile tests on the thread bar. The mill test reports submitted are a part of the documentation for the Columbia University test. The user test reports performed to date were forwarded with the test slippage data noted above.

The test results of the production splice assemblies were included in the user's threaded rebar tensile test reports described above. These reports show the test tensile strength of threaded bars as well as assemblies and the failure location. The minimum required tensile strength was also included in the reports as a splice acceptance criterion.

The reinforcing steel used in the mechanical splices fully conformed to the requirements of ASTM A615-68, Grade 60, as described in Section 3.8.1.6.2. The manufacturer's documentation included certified mill test reports and certified splice test reports. In addition to the manufacturer's documentation, user's tests were also conducted. The testing frequency required was one tensile test of a splice assembly for each 100 splices or at least two splice tests for each shipment or mill rolling heat. The results of the user's tests confirmed that the tensile strengths of these splices equaled or exceeded 125 percent minimum yield strengths specified for the reinforcement.

3.8.4.6.2.2 Structural and Miscellaneous Steel

Structural and miscellaneous steel generally conformed to the following ASTM specifications:

Rolled shaped, bars and plates	A36-69 or A441-70a
High strength bolts	A325-70a or A490-67
Other bolts	A307-68
Stainless steel	A167, Type 304L

Other types of steel are used in small quantities in the Other Category 1 Structures as required.

Mill test reports are obtained for structural steel materials used.

3.8.4.7 Testing and Inservice Surveillance Requirements

Testing and inservice surveillance are not required for Category 1 structures other than the containment and no formal program of testing and inservice surveillance is planned.

3.8.5 FOUNDATIONS AND CONCRETE SUPPORTS

3.8.5.1 Descriptions of the Foundations and Supports

All Category 1 Structures except the emergency cooling pond inlet and outlet structures and Category 1 electrical manholes are founded on competent un-weathered bedrock. The properties of the bedrock materials are discussed in Sections 2.5.4.10 and 2.5.4.11. The emergency cooling pond inlet and outlet structures are founded on natural soil and the Category 1 electrical manholes are founded on natural soils or backfill materials.

3.8.5.1.1 Containment Foundation

The containment foundation is a thick heavily reinforced concrete circular slab bearing directly on rock. At the perimeter the slab provides (1) a fixed support for the containment cylinder wall allowing for a load transfer from the wall to the base slab and (2) an anchorage area for the vertical tendons.

A complete separation has been provided between the containment base slab and the adjacent auxiliary building foundation slab. The general arrangement of the containment, including its base slab, are discussed in Section 3.8.1.1 and shown in Figures 3.8-1, 3.8-2, 3.8-4, 3.8-5 and 3.8-19.

3.8.5.1.2 Internal Structures Foundations and Supports

The foundation for the internal structures is provided by the reinforced concrete containment base slab. The walls and columns of the internal structures are anchored to the base slab and allow for a load transfer from the structure to the base.

The general arrangement of the supports for the internal structures, including the support structure for the equipment are discussed in Sections 3.8.3.1.1, 3.8.3.1.2, 3.8.3.1.6 and shown in Figure 3.8-15. The support structures for the major NSSS equipment are also further discussed in Section 5.5.14.

3.8.5.1.3 Other Category 1 Structures Foundations

3.8.5.1.3.1 Auxiliary Building, Intake Structure and Emergency Diesel Fuel Storage Vaults

The foundations for these structures are provided by thick, reinforced concrete slabs. Fixed connections with the walls and columns of these structures allow for a load transfer into the base. The foundations of these three structures bear directly on rock. Each structure is physically separated from the other. The emergency diesel fuel storage vault structure's foundation and part of the auxiliary building that houses the boron management holdup tanks are provided with rock anchors to transmit uplift forces during flood into the foundation rock. The general arrangement of the structures, including their foundations are discussed in sections and shown in figures as follows:

A. Auxiliary building in Section 3.8.4.1.1 and Figures 3.8-19 and 3.8-20.

B. Intake structure in Section 3.8.4.1.2 and Figure 3.8-22.

C. Emergency diesel storage vault in Section 3.8.4.1.3 and Figure 3.8-24.

3.8.5.1.3.2 Emergency Cooling Pond Inlet and Outlet Structures, Category 1 Electrical Manholes and the Condensate Storage Tank (T41B) Pipe Trenches

The reinforced concrete foundations of these structures provide a fixed support for the walls transmitting loads to them. These structures are relatively small and the relatively light loads are transmitted to the natural soils or backfill materials. Their foundations are completely independent of each other and of foundations for other structures. The general arrangement of the supports for these structures is discussed in sections and shown in figures as follows:

A. Emergency cooling pond inlet and outlet structures in Section 3.8.4.1.4 and Figure 3.8-25.

B. Electrical manholes in Section 3.8.4.1.5 and Figure 3.8-24.

C. Condensate Storage Tank (T41B) Pipe Trenches in Section 3.8.4.1.6 and Figure 3.8-34.

3.8.5.1.3.3 Foundation for the Refueling Water Tank

The foundation for the refueling water tank, which is Seismic Category 1 component, is provided by a thick reinforced concrete cover slab of the boron management holdup tank vaults of the auxiliary building. Loads from the cover slab are transmitted through walls into the vaults' base slab, bearing directly on rock. Anchors extending from the base slab are designed to transmit uplift forces during a flood into the foundation rock.

The general arrangement is shown in Figure 3.8-20.

3.8.5.1.3.4 Condensate Storage Tank (T41B) Foundation

The CST foundation is a thick concrete slab supported by drilled piers which bear directly on rock. The piers were sized for the bearing capacity of 38 ksf of the rock. The general arrangement of this foundation is discussed in Section 3.8.4.1.7 and shown in Figure 3.8-35.

3.8.5.2 Applicable Codes, Standards and Specifications

Applicable codes, standards and specifications which constituted the basis for the design and construction of the foundations and supports were as discussed in Section 3.8.1.2 for the containment, in Section 3.8.3.2 for the internal structures and in Section 3.8.4.2 for the Other Category 1 Structures.

3.8.5.3 Loads and Loading Combinations

Loads and loading combinations which constituted the basis for the design of foundations and concrete supports were as discussed in Section 3.8.1.3 for the containment, in Section 3.8.3.3 for the internal structures and in Section 3.8.4.3 for the Other Category 1 Structures.

Expected settlement of Category 1 Structures founded on rock is discussed in Section 2.5.4.10.

Structures founded on natural soil or backfill materials are completely independent of each other and produce relatively light loading on the foundation soil. They were not expected to produce any significant settlement.

3.8.5.4 Design and Analysis Procedures

Design and analysis procedures used in the design of foundations and supports were as discussed in Section 3.8.1.4 for the containment, in Section 3.8.3.4 for the internal structures, which include the major concrete support structures, and in Section 3.8.4.4 for the Other Category 1 Structures.

Computer programs used in the original design of the Category 1 Structures and their foundations and concrete supports are presented in Table 3.8-3.

3.8.5.5 Structural Acceptance Criteria

The foundations of all Category 1 structures meet the same structural acceptance criteria as discussed in Sections 3.8.1.5, 3.8.3.5, and 3.8.4.5. The limiting conditions for the foundation medium together with a comparison between actual capacity and estimated structure loads are found in Sections 2.5.4.10 and 2.5.4.11. Calculated results of foundation loads are given in Table 3.8-6.

A minimum factor of safety of 1.5 against overturning was maintained for all structures and supports. Overturning moments were determined from the dynamic analysis of the structures or were established using the following simplified method. The mass and center of gravity of the structure were calculated based on dead loads. A horizontal acceleration was applied to the mass. This acceleration was based on the natural frequency of the structure as determined in the dynamic analysis, or was based on the peak of the appropriate response spectrum curve. The resisting moment to overturning was calculated using the dead load of the structure and included the effects of vertical seismic acceleration.

The foundation bearing pressures shown in Table 3.8-8, when compared with the allowable bearing pressures, show that the un-weathered shale foundation medium can safely support the pressures caused by overturning moments.

Category 1 electrical manholes and the emergency cooling pond inlet and outlet structures are surrounded by backfill material. Since the lateral forces for these structures are resisted by passive earth pressures, the effects of overturning moments on the foundation medium were not considered.

The calculated results for representative portions of the containment and other Category 1 structures and foundations, shown in Tables 3.8-4, 3.8-6, and 3.8-8, indicate the margins of safety provided in the design.

3.8.5.6 Materials Quality Control and Special Construction Techniques

The foundations and concrete supports are constructed of reinforced concrete using proven methods common to heavy industrial construction. The same discussion applies as is provided for the structures themselves in Sections 3.8.1.6, 3.8.3.6 and 3.8.4.6.

3.8.5.7 Testing and Inservice Surveillance Requirements

Testing and inservice surveillance are not required and are not planned for foundations of structures or for concrete supports. A discussion of the test program which serves as the basis for the Soils Investigation and Foundation Report may be found in Section 2.5, Geology and Seismology.

3.9 MECHANICAL SYSTEMS AND COMPONENTS

3.9.1 DYNAMIC SYSTEM ANALYSIS AND TESTING

3.9.1.1 Vibration Operational Testing

Safety-related piping systems have been designed in accordance with the ASME Code, Section III.

In order to comply with the Code, each system has been designed to minimize dynamic effects but, due to the complexities of analyzing these effects, an initial test program was also implemented.

[The remainder of the section (Section 3.9.1.1) is historical information; it was written for submittal in the FSAR to describe the testing to be conducted during initial startup.]

The initial test program for the Class 1, 2, and 3 piping systems will simulate actual operating modes to demonstrate that the appurtenances comprising these systems will meet functional design requirements.

Piping systems will be checked in three sequential series of tests and inspections. Construction acceptance, the first step, entails inspection of components for correct installation according to codes, specifications and drawings. During this phase, pipe and equipment supports will be checked for correct assembly and setting based on calculations. The cold locations of Reactor Coolant System (RCS) components such as steam generators and reactor coolant pumps will be recorded.

During the second step of testing, plant heatup, the plant will be heated to normal operating temperatures. During the heatup, expansion data will be recorded and all systems will be observed periodically to verify proper expansion.

During the third step of testing - performance testing - systems will be operated and performance of the pumps, valves, controls, and auxiliary equipment checked. This phase of testing will include transient test, such as reactor coolant pump trips, reactor trip and relief valve testing. During this phase of testing, the piping and piping restraints will be observed for vibration and expansion response. Automatic safety devices, control devices and other major equipment will be observed for indications of overstress, excess vibration, overheating and noise. Also, to verify the piping design for water hammer, each system test will include valve operation during transient system modes.

Vibratory dynamic loadings can be placed in two categories: transient induced vibrations, and steady state vibrations. The first is a dynamic system response to a transient time dependent forcing function, e.g. fast valve closure, while the second is a constant vibration, usually flow induced.

A. Transient Response

   Dynamic events falling into this category are anticipated operational occurrences. The systems and the transients to be included in the initial test program are:

   1. Main Steam Turbine Stop Valve Trip

   2. Main Steam Relief Valve Blowdown

For those types of transients listed above, a time dependent dynamic analysis is performed on the system. The stresses thus obtained are combined with system stresses resulting from other operating conditions in accordance with Table 3.9-2.

Since a comprehensive dynamic analysis has been performed on these systems, movements in excess of those calculated are not anticipated.

B. Steady State Vibration

System vibrations resulting from flow disturbances fall into this category. Positive displacement pumps may cause such flow variations and vibrations and as such are reviewed. Therefore, the charging system will be checked.

Since the exact nature of the flow disturbances is not known prior to pump operation, no analysis is performed. If system vibration is evident during initial operation, the maximum amplitudes will be measured. The acceptance criteria is that the maximum measured amplitudes shall not induce a stress in the piping system greater than one-half the endurance limit as defined in ASME Section III, 1971.

If required, additional restraints will be provided to reduce stresses to acceptable levels.

The testing required to demonstrate satisfactory response to steady state and transient operation is described in the test summaries of Chapter 14. No additional tests are planned to verify pipe break assumptions for high and moderate energy systems outside the containment, inasmuch as such an evaluation would have to include seismic stress levels which cannot be verified by testing.

3.9.1.2 <u>This Text Has Been Deleted</u>

See Section 3.9.3.3.

3.9.1.3 <u>Dynamic Testing Procedures</u>

The methods employed to ensure the design adequacy of the NSSS are described in Section 3.7.

The valves in the plant that are necessary for a safe shutdown and that are subjected to the severest of operating conditions are the active, Category 1, reactor coolant pressure boundary valves, as defined in 10 CFR 50. Unit 2 has 14 motor-operated valves that meet this definition and receive an ES signal. They are required to actuate upon an engineered safety features actuation signal and to either isolate the containment or to open an engineered safety features system flow path. These valves are described in Table 3.9-6. (The list originally included the RCP controlled bleedoff isolation valve, which was subsequently determined not to be part of the RCPB. Although classified as active RCPB valves, check valves in the RCPB and the hot leg injection valves on the HPSI headers are not included in this list because they do not receive an ES signal; see Section 5.2.)

A summary of these valves is as follows:

Valve	Size	Quantity	System
High Pressure Safety Injection	2"	8	Safety Injection System (SIS)
Low Pressure Safety Injection	6"	4	SIS
Letdown Isolation	2"	2	Chemical & Volume Control System (CVCS)

All of these valves received extensive preoperational testing prior to initial fuel loading. (The original HPSI and LPSI valves have been replaced.) The electric motor operators for these valves are all of the Limitorque SMB series and have a history of qualification testing used to verify their reliability and operability. It is to be noted that while they are all designed to RCS pressures and temperatures, their actual operating conditions are lower and, in the case of the Low Pressure Safety Injection (LPSI) valves, an order of magnitude lower. Extensive testing has been carried out by the valve operator manufacturer and by an independent institute. The testing has been done over a number of years and the most recent testing (at the time of license application) in the summer of 1972 bears out the operability confirmed initially.

A. Manufacturer's Electric Motor Operator Qualification Testing

1. Shock and Vibration Testing

In August 1970, a Limitorque SMB Series operator was mounted on a test stand having a threaded valve stem driven by the operator simulating opening and closing a valve. The operator was electrically connected so as to stop at the full open position by means of a geared limit switch. The operator had a 4-train geared limit switch installed and all contacts not being used for motor control were wired to electric indicating lights at a remote panel.

The unit successfully completed a 5.3 G shock level at 32 Hz with no discrepancies noted. An exploratory scan of 5 to 35 Hz was made and no critical resonant frequencies were noted on the operator. The unit was shocked and vibrated in each of three different axes a total of two minutes on, one minute off, three times per axis. The unit was operated electrically to both the full open and full close position and all torque switches and limit switches functioned properly. None of the auxiliary limit switches wired to indicating lights ever flickered or indicated they were opening. All electrical and mechanical devices on the operator worked successfully.

2. Heat Testing

In January 1969, a completely assembled and operational SMB series operator was placed in an oven where the temperature was maintained at approximately 325 °F for a duration of 12 hours. The unit was electrically operated every 30 minutes for a period of approximately two minutes per cycle and the geared limit switches were used to stop the actuator at the full open and full closed position of travel. Indicating light circuits were also wired to the geared limit switches.

The test was successful in every respect. There were no malfunctions of the operator. And, upon inspection of the component parts used, there was no noticeable deterioration or wear.

3. Live Steam Testing

In January 1969, a complete SMB series operator was set up for electrical operation and live steam was piped into the conduit taps on the top of the limit switch compartment. One of the bottom conduit taps was left open to drain any condensate. The operator was set up on a timer basis for operation over a period of approximately nine hours and operating every 30 minutes for two minutes per cycle. During this test, the live steam in the switch compartment seemed to have no effect whatever on the function of the limit switches in their control of the operator at the full open and full closed position of travel. In addition, the limit switches were wired up to indicating lights which operated satisfactorily.

The test was successful and there was no noticeable effect on the function of any of the parts in the limit switch compartment.

4. Life Cycle Testing

In January 1969, the operator was mounted on a stand inside a test chamber and a 150-cycle load test was made on the unit. This test cycle consisted of stroking a 2 3/8-inch diameter valve stem at a speed of six inches per minute for a total of approximately 12 inches in two minutes. The valve stem in the full closed position produced a thrust of 16,500 pounds on a rigid plate securely bolted to the test chamber. The unit was wired for torque seating control in the closing direction and position limiting control in the open direction.

After the life cycle testing was completed, the unit was inspected and found to be in excellent condition. There was no noticeable wear on any of the parts.

5. Simulated Accident Environment Testing

An electric motor operator was tested under conditions which simulated the temperature humidity and chemical environments that could be expected to exist in the containment following some postulated accident such as the rupture of a major reactor coolant pipe.

The operator was placed in an Autoclave type chamber and subjected to 90 psig saturated steam. At specified intervals the operator was cycled to assure proper operation. Forty minutes after the introduction of steam a 1.5 percent boric acid solution was sprayed on the operator assembly. The operator continued to operate satisfactorily. Later, the steam pressure was periodically reduced to simulate post-accident conditions. The boric acid spray was allowed to continue for four hours. The steam pressure was eventually reduced to 15 psig. The test continued for seven days.

During this time the operation of the operator became erratic. The corrosive effects of the steam and boric acid spray caused electrical contact malfunctions which were bypassed by the use of an appropriate jumper. The valve continued to cycle during the 7-day period.

A design change was made to the limit switch in order to correct the erratic operation. It was tested under similar accident conditions and found to operate satisfactorily. This design change has been incorporated into all subsequent applicable models of this operation.

B. Independent Testing - Franklin Institute Tests

More recent tests of the Limitorque SMB series operator were conducted during the summer of 1972 by the Franklin Institute Research Laboratories. In these tests the operator was exposed to gamma radiation (200 megarads), a steam/chemical environment (for 12 days), a steam environment at temperatures going as high as 340 °F during the first day (test consisted of a 30-day exposure) and a seismic test similar to those in August, 1970. During all of these tests, as appropriate, the operator was periodically cycled and found to operate satisfactorily (References 32 and 33).

C. Valve Purchase Specification

In addition to a proven record as verified by the previous testing, the valve vendor must also comply with the purchase specification requirements. The purchase specifications for these valves require that they be hydrostatically tested, leak tested and cycled from the extremes of allowed movement of opened or closed. The hydrostatic test is in accordance with the ASME Boiler and Pressure Vessel Code. The seat leakage test is in accordance with the edition of MSS-SP-61 which was in effect when the valves were purchased as modified by the purchase specifications. Valves will not show a leakage greater than 2 cubic centimeters per hour per inch of diameter of nominal valve size, or permanent deformation when the valves are submitted to two times design pressure, except that the stress developed at test pressure shall not exceed 90 percent of the specified minimum yield strength based on the minimum specified wall thickness.

The valve vendor is also required to submit calculations which show that when the valve assembly is subjected to a 3g horizontal force and a 3g vertical force that stresses incurred are within the code allowable stresses. We have also verified that the first natural frequency is above 20 cps for all 14 original valves.

D. Preoperational Testing

Testing procedures for valves that require operation to meet Engineered Safety Features (ESF) requirements were quite extensive during the preoperational testing program. These tests demonstrate proper installation, strength and functional performance of valves. Subsequent to satisfactory preoperational testing, surveillance testing requirements were established to assure continued satisfactory operation of these valves. Furthermore, if maintenance or repair of these valves is required, appropriate functional testing will be accomplished to assure proper operation subsequent to the maintenance or repair.

[The description of Items 1 through 4 below is historical information; it was written for submittal in the FSAR to describe these preoperational tests.]

1. System Electrical Test

   The purpose of these tests is to verify electrical characteristics of valve operators in performing their function. Preliminary checkout of the operator valve assembly requires that the valve be free to move. If the motor operated valve travels in the wrong direction from its mid-travel position, its breaker must be tripped immediately as there would be no torque limit protection. The valve can be operated manually with a handwheel to ascertain its freedom of movement.

   The phase rotation of the operator is checked. During valve operation, verification that the valve travel and motor are stopped is done by closing the torque limit switch. Similarly the opening of the valve is terminated by the opening of the limit switch.

   In checking the valve for ESF actuation, the valve is placed in the position opposite to its ESF position and then an ESF actuation signal is simulated.

   Then the control room switch is turned to the opposite position of ESF operation and the valve is verified as remaining in its ESF position. Similarly, turning the circuit breaker panel switch to the opposite position of ESF operation has no effect on the valve.

   Acceptance criteria for these electrical tests are:

   a. Valves must open, close, and travel in the proper direction in response to control and engineered safety features signals.

   b. The valve open and closed indicating lights must indicate correctly.

   c. Valve motor resistance to ground readings must be within specification.

   d. The specified valve travel time is within specification requirements.

2. System Engineered Safety Features

   The purpose of these tests is to demonstrate actual valve performance for its intended ESF use. Initially all valves are placed in their non ESF position prior to simulating an ESF signal. Upon initiation of an ESF signal the tests for the subject valve demonstrate containment isolation and also emergency injection flow capacity to the RCS from the Low Pressure Safety Injection (LPSI) system and the High Pressure Safety Injection (HPSI) system.

3. System Functional Testing

   The purpose of this testing is to verify that the valves perform as intended for normal operation. Cycling the valves under conditions of specified differential pressure and/or flow that may be encountered during plant operation will verify that the valve motor does not exceed maximum operating current and cycle time.

4. Integrated ESF Actuation Test

   The purpose of this test, for which these valves are used to perform is to demonstrate the full operational sequence that would bring the Emergency Core Cooling Systems (ECCSs) and the containment pressure reducing systems into action, including the transfer to alternate power sources.

   General acceptance criteria for this test are:

   a. The ESF systems operate as described in the FSAR.

   b. Upon actuation of the ESF signal, HPSI and LPSI to the RCS are supplied in accordance with FSAR requirements.

   c. Upon loss of normal station power, the ESF systems continue to perform their designed functions without interruption.

   Following completion of the preoperational test program and issuance of an operating license for the facility these valves are functionally tested as required by the Technical Specifications.

It should be noted that the maximum acceleration for the specific piping systems at the locations of these valves will be less, by design, than the maximum g-force in either the horizontal or vertical direction that the fifteen valves are required to withstand during testing. The entire scope of testing verifies the valves' operability from conditions of extreme duress to normal operation. The results of the earliest environmental, vibratory, and load testing have been verified in later testing by independent research (References 32 and 33).

For other Category 1 mechanical equipment, the manufacturer was required to determine the natural frequency of the equipment, including the supports. The adequacy of the "g" value specified in the component specification was then confirmed.

The static "g" values supplied for principal Category 1 equipment are listed in Table 3.9-1.

In shock and vibration testing of active valve electric motor operators, loads were not applied simultaneously in vertical and horizontal directions because the operators are characterized by Items A, B and C below:

A. The nature of the equipment is such that the resonance frequencies can be validly identified by sine sweep testing;

B. Not more than one of the resonance frequencies is below 33 Hz; and,

C. The absence of significant directional coupling (from the standpoint of response or failure mode) can be determined by inspection or by comparison with tests of similar equipment.

Electrical motor operators and valves were mounted to the test table using the same support points by which they are mounted in the plant. More specifically, valves were mounted from pipe stubs attached to the ends of the valves and motor operators were mounted to the table using the same hardware at the same locations as were used in plant installation.

3.9.1.4 Dynamic System Analysis for Reactor Internals

3.9.1.4.1 Introduction

The flow induced vibration of the core support barrel system, during normal operation, was characterized as a forced response to both deterministic (periodic and transient) and random pressure fluctuations in the coolant. Methods were developed to predict the various components of the hydraulic forcing function and the response of the reactor internals to such excitation. An analytical method based on a theoretical solution of the appropriate governing hydrodynamic differential equations for a mathematically tractable geometry was used to develop the periodic hydraulic forcing function.

The response of the core support barrel system to the normal operating loads was combined with the seismic and LOCA analyses for comparison with the criteria specified in Section 4.2.2.

The effect of cross and parallel flow on the tubular Control Element Assembly (CEA) shrouds and fuel elements has been evaluated analytically by conservative application of techniques and parameters presented in the literature.

3.9.1.4.2 Periodic Forcing Function

An analysis based on an idealized hydrodynamic model was employed to obtain a basic understanding of the relationship between reactor coolant pump pulsations in the inlet ducts and the periodic pressure fluctuations on the core support barrel. The idealized model represented the annulus of coolant between the core support barrel and the reactor vessel. In deriving the governing hydrodynamic differential equation for the above model, the fluid was taken to be compressible and inviscid. Linearized versions of the equations of motion and continuity were used. The excitation of the hydraulic model was assumed harmonic with the frequencies of excitation corresponding to the pump rotational speed, 20 Hz, its first harmonic, 40 Hz, the blade passing frequency, 100 Hz, and its first harmonic, 200 Hz. The result of the hydraulic analysis was a system of equations which defined the force response, natural frequencies and natural modes of the hydrodynamic mode. The forced response equations defined the spatial distribution of pressure on the core support barrel system as a function of time, space and excitation and natural hydraulic frequencies.

3.9.1.4.3 Random Forcing Function

The random hydraulic forcing function was developed by analytical and experimental methods. An analytical expression was developed to define the turbulent pressure fluctuation for fully developed flow. This expression was modified, based upon the result of scale model testing, to account for the fact that flow in the downcomer is not fully developed. In addition, experimentally adjusted analytical expressions were developed to define the peak value of the pressure spectral density associated with the turbulence and the maximum area of coherence, in terms of the boundary layer displacement, across which the random pressure fluctuations are in phase.

3.9.1.4.4 Mathematical Model

A finite element model of the core support barrel system was developed, as shown in Figure 3.9-1. Frequencies and mode shapes of the core support barrel in air were obtained using the ASHSD program (Reference 49). Evaluation of the reduction of these frequencies for the system immersed in coolant was made by means of the "virtual mass" method outlined in Reference 49.

3.9.1.4.5 Response Analysis

3.9.1.4.5.1 Deterministic Response

The normal mode method was used to obtain the structural response of the core support barrel system to deterministic forcing functions. Generalized masses based on mode shapes and the mass matrix from the shell finite element computer program were calculated for each core support barrel mode of vibration. Modal force participation factors, based on the mode shapes and the predicted periodic forcing functions, were calculated for each mode and forcing function. The generalized coordinate response for each mode was then obtained through solution of the corresponding independent second order, single degree of freedom equation. Utilizing displacement and stress mode shapes from the shell finite element computer program, the structural response of the core support barrel for each mode was obtained by means of the appropriate coordinate transformations. Response to the composite forcing function was obtained through summation of the component modes.

The results of these calculations show that the maximum stress is well below the design allowable fatigue stress specified by the ASME Code, Section III.

The effect of crossflow on the tubular CEA shrouds and fuel elements was determined using analytical procedure outlined in Reference 70. This evaluation involved determination of the von Karmen vortex shedding frequencies and the tube natural frequencies, a comparison of the tube and shedding frequencies, and determination of the tube vibration amplitude and stress. The effect of paralleled flow was evaluated using the empirical relation in Reference 74. The stability criterion, presented in Reference 52, for predicting the critical flow velocity above which severe tube vibrations can result, was applied to the CEA shrouds and fuel elements.

The above analysis shows the CEA shroud and fuel elements to be structurally stable in the reactor flow and to have structural responses, due to cross and paralleled flow, which are well within design allowables.

3.9.1.4.5.2 Random Response

The random response analysis considered the response of the core support barrel system to the turbulent downcomer flow during steady state operation. The random forcing function was assumed to be a wideband stationary random process with a pressure spectral density equal to the peak value associated with the turbulence. The rms vibration level of the core support barrel system in terms of a beam mode was obtained based upon a damped, single degree of freedom analysis assuming the rms random pressure fluctuations to be spatially invariant. The maximum rms response calculated was considerably less than the design operating clearances available at the snubbers.

3.9.1.4.6 Precritical Vibration Monitoring Program

The Maine Yankee and Fort Calhoun Precritical Vibration Monitoring Programs (PVMP) together constitute the prototype PVMP for Unit 2. In accordance with Regulatory Guide 1.20, prototype prediction, measurement and inspection programs were developed and performed for the Maine Yankee and Fort Calhoun reactor internals. Theoretical prediction analyses were performed for Maine Yankee (Reference 3) and Fort Calhoun (Reference 2) to estimate the amplitude, time and spatial dependency of the steady state and transient hydraulic and structural responses to be encountered during precritical testing. The precritical vibration

monitoring programs for Maine Yankee and Fort Calhoun have been completed successfully (References 24 and 28, respectively). It was concluded from these programs that flow induced vibrations of the Maine Yankee and Fort Calhoun reactor internals are well within design allowables and are acceptable for all normal, steady state and transient flow modes of reactor coolant pump operation.

Comparisons of the measured and predicted responses for Maine Yankee and Fort Calhoun demonstrate that the theoretical prediction methods used provide conservative estimates of the total steady state responses of the core support barrel, thermal shield system.

Presented in Table 3.9-5 is a summary of the significant hydraulic and structural design parameters for each of the three reactor designs.

The effect of these structural and hydraulic parameters on the flow induced vibratory response of the reactor internals is evaluated and summarized in Reference 5. In general, this reference, which is a summary of the flow induced vibration analysis for Unit 2, demonstrates that: 1) the predicted structural response of the Unit 2 reactor internals are well within design allowables and are acceptable for all normal, steady state and transient flow modes of primary coolant pump operation; and, 2) the prototype precritical vibration monitoring programs for Maine Yankee and Fort Calhoun adequately account for the specific design features for Unit 2 which are shared by the two prototype reactor designs.

AP&L implemented a PVMP for Unit 2 in accordance with the requirements of Regulatory Guide 1.20 as it relates to other than prototype units. The reactor vessel internals were subjected during the preoperational and functional testing program to all significant flow modes of normal reactor operation for a sufficient period of time to determine whether the reactor vessel internals exhibited any unexpected vibration problems.

After completion of the preoperational and functional tests, the reactor vessel internals were subjected to visual examination to detect any evidence of unanticipated or excessive vibrations. These examinations were conducted at all major points of contact for load transmission such as the core barrel flange and snubbers.

3.9.1.5 Correlation of Test and Analytical Results

As discussed in Section 3.9.1.4, the Maine Yankee and Fort Calhoun Programs are established as the prototype. The correlations of the results from those precritical vibration monitoring programs with the analytical responses derived from mathematical models are described in References 2, 3, 24, and 28.

Reference 5 presents the results of the Unit 2 reactor internals vibration analyses and provides a comparison of these results to the results of the Maine Yankee and Fort Calhoun analyses and measurements. Reference 1 provides additional information on the analytical methodology, summaries of the prototype PVMPs conducted on Maine Yankee and Fort Calhoun, additional confirmatory data from neutron noise monitoring programs conducted by CE, and additional comparisons of Unit 2 to the prototype plants. The information presented in References 1 and 5 provides a high degree of assurance that the structural responses of the Unit 2 reactor internals is well within design allowable criteria for all normal, steady state and transient flow modes of reactor coolant pump operation.

3.9.1.6 Analysis Methods Under LOCA Loadings

3.9.1.6.1 Introduction

Dynamic analyses were performed to determine the structural response of the reactor vessel internals to the transient LOCA loading and to verify the adequacy of their structural design. The analyses determined the shell, beam and rigid body motions of the internals using established computerized structural response techniques. The time and space dependent pressure loads used in the analyses were obtained from LOCA blowdown analyses performed with the water hammer and CEFLASH computer codes. This method is discussed in Reference 43. The pressure time histories were determined for each node in the hydraulic model for inlet and outlet breaks. The loads resulting from the LOCA analyses of the internals, when combined with normal operating and seismic loads, are subject to the requirements of Sections 4.2.1 and 4.2.2.

The LOCA blowdown analyses have been re-performed to account for the power uprate and the replacement of the steam generators, using the CEFLASH-4B computer code. A detailed description of this code, along with the NRC approval of its use, is provided in Reference 86. The leak before break methodology was adopted for these analyses. Since this methodology limits the scope of the evaluation to breaks in the RCS tributary lines, blowdown analyses were performed for these breaks, rather than the vessel inlet and outlet breaks assumed in the original analysis.

3.9.1.6.2 Method of Analysis

3.9.1.6.2.1 General

The dynamic LOCA analyses of the reactor internals and core consisted basically of three parts. In the first part, the time dependent beam and shell response of the core support barrel to a transient LOCA loading were calculated using the finite element computer code, ASHSD (Reference 49). In performing the dynamic analyses of the core support barrel, the shell and beam responses were considered separately to account for differing boundary conditions. For the load harmonics which give rise to shell responses, the boundary condition at the upper flange of the Core Support Barrel (CSB) was a rigid restraint in all directions. At the lower flange of the CSB, the boundary condition was a simple support in the radial direction, which represented the effects of the lower support structure stiffness on the CSB. For the load harmonic which gives rise to beam response in the barrel, the upper flange boundary condition was identical to the shell response. For the lower end of the CSB two cases were considered. In the first case, the lower end of the CSB was unrestrained. A rigid radial restraint at the snubber elevation was applied in the second case to simulate a closed snubber gap.

In the second part, the CSB potential for buckling when loaded by a net external radial pressure resulting from an outlet line break was evaluated with the finite element computer code, SAMMSOR-DYNASOR (Reference 77). The initial imperfection was applied to the core support barrel by means of a pseudoload, for each circumferential harmonic considered. The actual transient loading in terms of its harmonics was applied to the initially "imperfect" geometry of the CSB and the response obtained for each of the imperfection harmonics.

In the third part, the dynamic structural response of the reactor internals to vertical and horizontal loads resulting from inlet and outlet breaks was determined with the SHOCK code (Reference 58). Separate mathematical models that incorporated structural nonlinearities were developed for the vertical and horizontal directions. The horizontal loads applied to the core

support barrel during an inlet break were obtained by representing the pressure time history as a Fourier expansion and considering the harmonic which excites the beam mode of vibration. Horizontal loads on the CEA shroud tubes were determined directly from the blowdown pressure time history. Vertical loads for the inlet and outlet breaks were also determined directly from the pressure time history.

3.9.1.6.2.2 Mathematical Models

A. Core Support Barrel

For the dynamic response and buckling analyses of the core support barrel, similar finite element models were developed. The core support barrel was modeled as a series of shell elements joined at their nodal point circles as shown in Figures 3.9-1 and 3.9-2 for the ASHSD and SAMMSOR-DYNASOR models, respectively. The length of the elements in each model was selected to be a fraction of the shell attenuation length. Since rapid changes in the stress pattern occur in the regions of structural discontinuity, the nodal point circles were more closely spaced in such regions. The finite element representation of the CSB included the upper and lower flanges and sections of different wall thickness.

B. Internals

The reactor internals model was developed in terms of spring mass systems for both vertical and lateral directions as shown in Figures 3.9-3 and 3.9-4. For both models, the stiffness values were generally evaluated using beam characteristic equations. In complex areas such as the CSB flanges, upper guide structure, support barrel flange and lower support structure grid beams, the beam properties were derived from finite element analyses. The lumped mass weights were generally based upon the mass distribution of the uniform support structures, but included at appropriate nodes were local masses such as snubber blocks and fuel end fittings. To simulate the effect associated with the internals oscillating laterally in the water filled vessel, a virtual or hydrodynamic mass was calculated and added to the structural mass. More details of the spring lumped mass system modeling techniques, component finite element analyses and the hydrodynamic mass effect described above are presented in Section 3.7.3.

In the horizontal model, the CSB reactor vessel snubber clearance was simulated by a nonlinear spring, which accounted for the loads generated when snubbing occurred. In the vertical model, nonlinear springs in the form of compression only springs were used to simulate preload and interface conditions such as those between the fuel and core support plate, the core shroud and fuel alignment plate, and between the upper guide structure flange and core support barrel upper flange. The effect of hydraulic drag in the vertical model is simulated by a force time history applied to the fuel rods nodes.

3.9.1.6.2.3 Response Calculations

A. Dynamic Response of Core Support Barrel

The finite element computer code, ASHSD, was used to calculate the dynamic response of the core support barrel to transient LOCA loading resulting from an inlet break. A damped equation of motion was formulated for each degree of freedom of

the system. Four degrees of freedom, radial displacement, circumferential displacement, vertical displacement and meridional rotation were taken into account in the analysis. The differential equations of motion were solved numerically using a step-by-step integration procedure.

The ASHSD code computed the nodal point displacement, resultant shell forces, and shell stress as function of time. The maximum principal stresses at the internal and external surfaces of the core support barrel were determined from the bending and membrane components during each phase of transient loading. The results were compared to the stress and deformation criteria of Section 4.2.2 and were found to be within the specified limits.

The finite element code SAMMSOR-DYNASOR was used to perform a dynamic buckling analysis of the core support barrel when subjected to radial pressure loads from an outlet break. Stiffness and mass matrices for shells of revolution were generated utilizing the SAMMSOR part of the code. The equation of motion of the shell were solved in DYNASOR using the Houbolt numerical procedure.

The loading history was subdivided into line segments appropriately selected so as to closely approximate the actual time history. Using the DYNASOR program, the radial displacement was calculated at the desired time for each element in the model and for the selected circumferential harmonics.

In order to satisfy the dynamic stability requirement of the ASME Code, Section III, an overload analysis was also performed for the CSB. The maximum applied pressure load was below the permissible value of 75 percent of the dynamic instability load.

B. Dynamic Response of Internals

The reactor vessel internals pipe break analysis was updated to determine the response of the reactor internals and fuel to the excitation caused by a postulated branch line break (BLPB) considering both the replacement steam generators and the power uprate planned for Cycle 16.

During a pipe break the reactor internals are subjected to two forms of excitation:

Transient pressure forces acting directly on internal components, and

Vibratory motion of the reactor vessel

The transient pressure forces were calculated by the LOCA blowdown analysis (see Section 3.9.1.6.1) while the reactor vessel motions were obtained from the reactor coolant system pipe break analysis (see Section 3.9.1.7.1).

As was the case for the reactor vessel internals seismic analysis (see Section 3.7.3.4.2.2), separate analyses were performed in the horizontal and vertical directions due to the structural and response differences in these directions.

<u>Horizontal Analysis of the Reactor Internals and Core</u>

The coupled core and internals CESHOCK model used for the pipe break analyses was similar to that used for the seismic analysis. However, additional detail was added to the CEA shroud representation and reactor vessel flange region. A sketch of

the horizontal pipe break reactor internals and core model is shown in Figure 3.9-3. The additional detail for the CEA shroud was added in order to represent the direct transient pressure loading on the CEA shrouds that occur during a hot leg tributary line pipe break. The added detail in the reactor vessel flange region was added to account for possible interaction between the CSB upper flange, UGS flange, and vessel ledge. Nonlinear, hysteresis, and friction elements were used to represent this interface region. A critical damping ratio of 4% was used for the reactor internals components in accordance with Regulatory Guide 1.61 for welded steel structures. The fuel assembly damping values were based on test data from full-scale fuel assembly tests.

The input excitation for a primary side inlet break includes transient pressure loads on CSB and reactor vessel acceleration time histories at the vessel flange and snubber. For a primary side outlet break, the input excitation included transient pressure forces on the CSB and CEA shrouds and the reactor vessel motions. Analyses were performed in two directions, parallel to the outlet nozzles (X direction) and perpendicular to the outlet nozzles (Z direction).

Vertical Analysis of the Reactor Internals and Core

The methodology for the vertical analysis of the reactor internals and core was similar to that used for the vertical seismic analysis. The coupled reactor internals and fuel CESHOCK model is shown in Figure 3.9-4. The input excitation included both pressure forces on the internals and fuel and vessel motions. A critical damping ratio of 4% was used for the reactor internals and the fuel in accordance with the Regulatory Guide 1.61 for welded steel structures.

Nonlinear horizontal and vertical pipe break analyses were performed for the following limiting pipe breaks:

	Vertical Analyses	Horizontal Analyses
Main Steam Line Terminal End Break	0 - 0.4 sec	Not Done
Feedwater Line Terminal End Break	0 - 0.4 sec	Not Done
Safety Injection Line Break	0 - 0.4 sec	0 - 0.4 sec (X & Z direction)
Surge Line Terminal End Break	0 - 0.4 sec	0 - 0.4 sec (X direction)
Surge Line Intermediate Break	0 - 0.4 sec	0 - 0.4 sec (X direction)
Shutdown Cooling Line Break	0 - 0.4 sec	0 - 0.4 sec (X direction)

These analyses determined loads on the reactor internals components that were used in evaluating the structural integrity of the reactor internals (see Sections 3.9.3, 4.2.2, and 4.4.2).

The vertical and horizontal LOCA results were compared to the stress and deformation criteria presented in Sections 4.2.1 and 4.4.2 and found to be within the specified limits.

3.9.1.6.2.4 LOCA Hydraulic Blowdown Analyses for Fuel Assemblies

3.9.1.6.2.4.1 Analytical Methods

The names of the computer codes used by CE to calculate blowdown loads are WATERHAMMER and CEFLASH-4. Detailed descriptions of these codes are given in References 7, 55, and 72. The application of these codes to blowdown loads is described in Reference 43 which has received NRC approval via Reference 59. The LOCA blowdown analyses have been re-performed to account for the power uprate and the replacement of the steam generators, using the CEFLASH-4B computer code.

Thermal hydraulics calculations are used to provide the steady state input description of the system. This input consists of fluid inventories, pressures, temperatures and flow rates throughout the system (reactor vessel, piping, steam generators and pressurizer). A description of the analytical models used to represent the thermal hydraulic characteristics of the various portions of the primary system is given in Reference 43.

3.9.1.6.2.4.2 Horizontal Core Analysis

The methodology for the pipe break analysis of the core is the same as that for the seismic analysis. The detailed core models are the same. The input excitations were the motions of the core boundary from the coupled reactor internals and core analysis.

Only the 15-row model was used for the BLPB analyses because it was found that there was essentially no fuel assembly impacting in the 15-row pipe break analyses.

The horizontal core analysis determined spacer grid impact loads and fuel assembly displacement shapes at times of peak response. Vertical loads on fuel assembly components were obtained from the vertical reactor internals and core analyses. These results were used in the evaluation of the structural integrity of the fuel assemblies, described in Section 4.2.1.

3.9.1.7 Analytical Methods for ASME Code Class 1 Components

The system or subsystem analysis used to establish or confirm loads specified for the design of components and supports was performed on an elastic basis. The analysis on the reactor vessel internals is based on the criteria discussed in Sections 4.2.1 and 4.2.2. Elastic stress analysis methods were also used in the design calculations to evaluate the effects of the loads on the components and supports.

Dynamic analysis, as described in Sections 3.9.1.3 and 3.7.6, is performed to verify that the stresses are within limits specified by the applicable code requirements. Allowable stresses for ASME Code Class 1 components are discussed in Sections 4.2 and 5.2.1.

The dynamic response to postulated pipe breaks of the RCS and surge line with the Replacement Steam Generators (RSGs) was determined by analysis. Since these analyses were performed for system operating parameters consistent with the uprate power level anticipated for Cycle 16, the results are applicable to the power uprate.

The dynamic response of the RCS to pipe breaks was determined, and response loads, motions, and spectra at interface locations were provided as input to specifications and to downstream analyses. Response loads and motions from the RCS analysis were provided as input to the RSG design specifications, NSSS component specifications, and balance of plant piping evaluations.

Hot leg response motions and spectra due to pipe breaks other than surge line breaks were provided as input to the surge line analysis, which is also discussed in this section. The response of the surge line to these excitations was also determined, and response loads at surge line pipe, nozzle, and support locations were provided as input to the surge line stress evaluation.

3.9.1.7.1 Dynamic Analysis of the Reactor Coolant System due to Pipe Break

Nonlinear response time history analyses were performed to calculate the RCS response to the fifteen pipe breaks listed in Table 3.6-1A. Two three-dimensional RCS models were developed for the pipe break analyses from the RCS seismic model, one for secondary side breaks and one for primary side breaks. Figure 3.7-30 shows a generalized picture of the RCS model used in the seismic and BLPB analyses, and Figure 3.9-1A shows the model of the RSG as converted to ANSYS for RCS analysis.

For both pipe break models, gapped and preloaded RCS supports were de-linearized. Directional spring supports, gaps, and preloads at full power were included for all pipe break analyses. The RVI snubbers between the core support barrel (CSB) and the inside of the RV lower head were modeled as gapped springs for all pipe break analyses.

For the secondary side pipe break model, the representation of the RVI is essentially the same as that for the RCS seismic model described in Section 3.7.3, because secondary side breaks do not cause blowdown, just vibratory input to the RV.

A more detailed model of the RVI was included in the primary side pipe break model, because these pipe breaks cause RV blowdown loads. This RVI model included hydro-mass and coupling terms, as well as additional nodes for RV blowdown input loadings. This model, which is shown in Figure 3.9-1B, is a simplified representation of the nonlinear RVI model used in the RVI detailed analysis (Section 3.9.1.4).

Input loadings applied to the RCS included thrust at the break locations, jet impingement loadings at and away from the break locations, RV blowdown loadings for the primary side BLPBs, and asymmetric pressurization loads on the RSG and RCPs for all pipe breaks except the main steam line break (MSLB), which does not cause SG subcompartment pressurization. Jet targets and jet impingement loadings are based on cone jets or fan jets, depending on the break type and break scenario. Jet types for each limiting BLPB are given in Table 3.6-1A. Following the elimination of main coolant loop breaks by application of LBB, none of the limiting BLPBs cause asymmetric pressurization to occur between the RV cavity and RV shell.

The ANSYS computer code was used to perform the dynamic transient time history BLPB analyses, using the modal superposition method and 3% modal damping.

3.9.1.7.1.1 Results – RCS Component and Support Loads

RCS component and support loads were maximized over the response time history for each of the 15 BLPB cases analyzed. Time history response accelerations and displacements were generated at the locations listed below. These results were used in the evaluations of tributary piping, RSG design, and evaluations of the RVI and RV head area components. Maximized RSG shell moments versus RSG shell elevation were also calculated for each break case for use in the detailed RSG design.

- RSG tributary nozzle interfaces
- RCS tributary nozzle interfaces
- RV upper head
- RV closure flange
- RV CSB snubber

3.9.1.7.2 Dynamic Analysis of the Surge Line due to Excitation from Other Pipe Breaks

Linear response time history analysis was used to calculate surge line response to non-surge line BLPBs. A three-dimensional model of the surge line and its supports was developed using ANSYS (Figure 3.9-1C). Time history motions at the RCS hot leg interface due to BLPBs, as discussed above, were applied to the surge line, and the surge line response was determined using the ANSYS computer code. Mass-stiffness damping of not more than 3% at significant modes of vibration was used in the time history analysis of the surge line.

3.9.1.7.2.1 Results of Surge Line Analysis

Responses of the surge line to RCS vibratory motion due to each of five non-surge line BLPBs listed in Table 3.6-1A were calculated. Surge line piping and support response loads were calculated and were maximized over time. These results were used in the surge line evaluation for the Faulted Condition.

3.9.2 ASME CODE CLASS 2 AND 3 COMPONENTS

3.9.2.1 Plant Conditions and Design Loading Combinations

3.9.2.1.1 Plant Conditions

ASME Code Class 2 and 3 components and system are identified in Section 3.2.2, System Quality Group Classification. ASME Code Class 2 and 3 components and systems are constructed for the following plant operating conditions.

A. All ASME Code Class 2 and 3 components and systems are designed and constructed for anticipated pressure and temperature conditions which may occur during normal plant operations and transients, including startup, power generation, cooldown, relief valve operation, load rejection, and shutdown.

B. Components required to function during and subsequent to the DBA are designed for the component pressure and temperature conditions which occur during and after this event. Such systems are identified in Chapter 15, Section 3.11, and Section 7.1.1.

C. All Seismic Category 1 components are also analyzed for a DBE and OBE as described in Section 3.7, Seismic Design.

3.9.2.1.2 Loading Combinations and Stress Limits

Design loading combinations and the corresponding allowable stress limits are given in Tables 3.9-2, 3.9-3 and 3.9-7.

3.9.2.2 Design Loading Combination

The design loading combinations and corresponding design stress limits for ASME Class 2 and 3 piping are provided in Table 3.9-2. The classification of the design loading combination into normal, upset, emergency and faulted conditions is also provided in Table 3.9-2. Design loading combinations and stress limits shown in Table 3.9-2 conform to the requirements of ASME Code, Section III, Winter, 1972 Addenda for the Design, Normal, Upset and Emergency Conditions and to ASME Code Case 1606 for the Faulted condition (or later appropriate ASME Section III code sections provided that they have been reconciled). Design loading conditions for ASME Code Class 2 and 3 vessels and pumps are shown in Table 3.9-7. There are no deformation criteria associated with the above design loading combinations. The design loading combinations listed in Table 3.9-2 do not apply to the plant operating conditions listed in Table 3.9-3, which relate only to design pressure. ASME Code Section III Class 2 and 3 valves used on Unit 2 conform to the requirements of ANSI B16.5 as specified by Subsections NC-3000 and ND-3000.

3.9.2.3 Design Stress Limits

The design stress limits for Class 2 and 3 components as given in Tables 3.9-2 and 3.9-3 are in accordance with the requirements of ASME Code Section III, 1971 (or later appropriate ASME Section III code sections provided that they have been reconciled). Design stress limits for ASME Code Class 2 and 3 vessels and pumps are shown in Table 3.9-7.

If, under pipe failure conditions, the calculated stresses in a portion of a piping system extended into the plastic range, the techniques described in BN-TOP-2 (Reference 8) were used.

3.9.2.4 Analytical and Empirical Methods for Design of Pumps and Valves

Suppliers of ASME Code Class 2 and 3 pumps and valves were required to show, by use of analytical methods, empirical methods and/or tests, that the components will function as designed under the conditions specified. As stated in Section NB-3524 of ASME Code, Section III, the piping, not the valves, is the limiting component.

The design requirements for Seismic Category 1 valves require several conditions be satisfied. The pressure requirements given in Table 3.9-3 ensure that the pressure containing boundary of the valve will not be violated as a result of a system pressure transient. The limits given are consistent with the pressure requirements of NB-3655 and NB-3656 for piping for the plant operating conditions given. Since valves have a greater cross section than the matching piping, their pressure boundary integrity is assured. Design requirements for seismic conditions ensure the top works, i.e. weakest portion of the valve yoke, will remain within the elastic region or be evaluated and qualified for the current loading conditions. Small deflections may result which will not inhibit valve operability during a seismic event.

In addition to the limits of Table 3.9-3, the primary pressure ratings of valves provided by CE are in accordance with the recommendations of Regulatory Guide 1.48.

CE design specifications require that the lowest natural frequency of a valve assembly be greater than 20 cps.

CE specifications require that the seller demonstrate by analysis or test that Class 2 valves be capable of withstanding a 3.0g load applied at the pipe ends in any direction.

A. Fisher Controls Company provided evidence that their valves would meet these requirements by analysis, with the exception of yoke strength, which was substantiated by actual yoke fracture tests. Control Components, Inc. provided an analysis to substantiate their design.

The following valve features were checked:

1. Yoke Legs
2. Yoke Lock Nuts
3. Combined Bonnet Tensile and Bending Stress
4. Bonnet Bolt Stress
5. Body Line Connection Welded Shear Stress
6. Natural Frequency of Actuator Frame and Yoke

Pressure loaded components such as the valve bonnet and body bolts were analyses by the equivalent pressure method in ANSI B31.7-1969 and ASME Section III. The combination of normal operating loads, dead weight, and seismic loads was considered.

The allowable stress for each component checked was considered to be 1.2 Sm or Sy, whichever is greater as provided for in the 1968 edition of Section III of the ASME Code.

B. Target Rock Corporation provided evidence that their valves would meet seismic requirements by analysis.

The following valve features were checked:

1. Yoke
2. Combined Bonnet Tensile and Bending Stress
3. Bonnet Bolt Stress
4. Natural Frequency of Actuator Frame and Yoke

Pressure loaded components such as the valve bonnet and body bolts were analyzed by the equivalent pressure method in ANSI B31.7-1969. and ASME Section III. The combination of normal operating loads dead weight, and seismic loads was considered.

The allowable stress for each component checked was considered to be Sm.

C. Wm. Powell Co. provided evidence that their valves would meet seismic requirements by analysis.

The following valve features were checked:

1. Yoke legs

2. Body Neck Maximum Operator thrust

3. Combined Bonnet Tensile and Bending Stress

4. Bonnet to Body Bolt Stress

5. Operator to bonnet bolt face stress

6. Natural Frequency of Valve

Pressure and operator thrust loaded components such as the body neck and bonnet to body bolts were analyzed by the equivalent pressure method in ANSI B31.7-1969 and ASME Section III. The combination of normal operating loads, dead weight, and seismic loads was considered.

The allowable stress for each component checked was considered to be Sm.

CE specifications require that the pressure boundary of all Class 3 valves will remain intact after a seismic acceleration of 3.0g applied at the pipe connections. Calculations or test results were not required to be provided to substantiate this requirements.

All operators for Class 1, 2 and 3 active valves have been tested in accordance with IEEE 382, "IEEE Trail-Use Guide for Type Test of Class 1 Electric Valve Operators for Nuclear Power Generating Stations."

Test criteria are based upon the seismic and accident conditions applicable to this plant design as called out in the design specification for the particular valve. Testing for operability of the mated valve/operator was performed on the following valve types:

A. Main steam isolation valves

B. All nuclear class ball valves

C. All nuclear class solenoid valves

A prototype valve was used in all cases and the testing criteria was taken from the design parameters for seismic and environmental conditions as defined in the design specification for the particular valve. Operability was checked during the environmental tests and the seismic tests. All active Class 1, 2 and 3 valve/operator combinations not tested under simulated conditions have an operator that has undergone the testing outlined above. The combinations used are of standard configurations which have a long history of use under power plant operation and therefore have a high reliability. The periodic functional testing and inspection of these valves together with their history will assure operability to the degree that can be expected from a prototype test program.

Table 3.2-3 lists the design codes for all ASME Code Class 1, 2 and 3 (or ASME Pump and Valve Code) pumps. The reactor coolant pumps are not "active" pumps since they are not required to function following any DBA.

The HPSI and LPSI pumps were ordered to the requirements of the draft ASME Code for Pumps and Valves for Nuclear Power, dated November, 1968, including the March, 1970 Addenda. The orders for both HPSI and LPSI pumps were placed on June 18, 1971. These pumps have been designed and manufactured to Code requirements in force at the time the purchase order was placed and they are presently installed at the Unit 2 site.

The draft ASME Code for Pumps and Valves does not establish pump design criteria but, rather, it places reliance on the cumulative past experience of the pump designer. Ingersoll Rand, the designer of the Unit 2 HPSI and LPSI pumps, has been established as a centrifugal pump designer and manufacturer for more than 50 years and none of the Unit 2 safety injection pumps' features are of a developmental nature.

Operability of the Unit 2 safety injection pumps has been assured both by design and by testing of the pump and motor combination. Loading conditions were evaluated and conservative loading requirements based upon the most adverse combination of loads were included in the pump specifications. The maximum allowable pump nozzle loads were established by the pump manufacturer. Ingersoll Rand was required to demonstrate by analysis or testing that the pumps would not suffer loss of function when seismic loads were imposed in addition to other applicable loads.

During the safety injection pump design process, limitations were placed on stress levels that may be attained in areas where deformation might affect performance. The stresses in the foundation bolting and bearing bracket bolting were examined to ensure that the pump and motor combination could remain functional during all loading conditions, including the DBE. These stresses were found to be extremely low which precludes any significant deformation in the pump and motor assembly.

Prototype test and analytical data were obtained from the safety injection pumps' motor supplier to verify that the motors were designed with conservative margins to drive the pumps under all required operating conditions. Routine NEMA tests were also performed on each motor to verify its electrical integrity per MGI-20.46. In addition, the pump and motor assembly were subjected to a thermal transient test. This test reproduced the maximum temperature change in the pumped fluid that is expected to occur during the plant faulted condition. Pump and motor performance throughout this transient test were satisfactory. The pump and motor assembly was also satisfactorily tested over the entire required performance range, including NPSH limit tests.

Site installation procedures and a preoperational testing program are relied upon to provide assurance of proper installation and onsite performance of the safety injection pumps. The quality assurance program ensures that the safety injection pumps have been designed, manufactured, installed and tested in accordance with applicable component specifications, codes, and regulatory requirements. Periodic testing and inservice inspection during their service life will provide continued assurance that the safety injection pumps will perform as required.

The overall operability assurance program for safety injection pumps described above provides adequate assurance that these pumps will function when called upon to do so. In addition, the component redundancy provided in the safety injection system design accommodates single

active random component failures without a loss of required system performance levels. All other ASME Code pumps were ordered to the requirements of the Code in effect at the time of purchase, which did not require prototype testing. The comments above concerning the HPSI and LPSI pumps are also applicable to the ASME Code Section III Class 2 and 3 pumps.

Industry testing programs conducted in response to Regulatory Guide 1.48 were considered in the design of active components to provide additional assurance of the ability to perform their intended functions.

Section 3.9.1.2 and the above discussion provide adequate assurance that ASME Code Section III Class 1, 2 and 3 valves will remain operable. Associated piping supports are designed in accordance with the ASME Code to remain elastic and deformation of the pipe or support should not directly affect the valves. Supports for active Class 2 and 3 were designed in accordance with the applicable codes listed in Section 3.8 for the location of the pump. No other specific criteria were applied.

3.9.2.5 Design and Installation Criteria, Pressure Relieving Devices

Safety valves are provided on the main steam headers in accordance with ASME Code, Section III for the protection of the steam generator shells and main steam lines against overpressure due to turbine trips or system upsets.

The safety valves are installed on main steam lines of increased wall thickness to reduce bending and compressive stresses. The safety valve discharges are also positioned to minimize the torsional moment of the main steam lines. The safety valves incorporate balanced dual discharges which transmit no moment to the relief valve headers. The dynamic effects of all safety relief valves discharging simultaneously are considered in pipe design.

The total capacity of the safety valves is sufficient to pass 100 percent of the steam flow generated in the steam generators. The nominal setpoint of at least one safety valve on each main steam header is less than or equal to the main steam piping pressure (1,085 psig). Additional valves are set to open at higher pressures; however, the highest setpoint does not permit pressure to exceed 110 percent of design pressure in accordance with the ASME Code, Section III.

Consideration is taken of the back pressure on the safety valve discharge created by the discharge piping. Deflection of the line during the period of jet thrust from the safety relief valves will be maintained within allowable limits based on stress, stability and function. This is accomplished by reinforcement of the header to transfer the loads to points convenient to receive reactive loads and any associated moments.

The forcing function used in the dynamic calculations was conservatively defined as a ramp function based on a valve actuation time of 50 milliseconds. A time history dynamic calculation of the local stress condition was performed in lieu of a dynamic load factor calculation. The stresses thus obtained were combined in accordance with Table 3.9-2.

3.9.2.6 Stress Levels for Category 1 Components

The stress levels and sketches of system configuration for high energy Category 1 system components are given in Section 3.6.4. The stress levels for low energy Category 1 system components at points of significant changes in flexibility are provided under the specified plant condition. Sketches of system configuration are included.

3.9.2.7 Field Run Piping Systems

All original ASME Code, Section III, Class 2 and 3 piping, including lines two inches and smaller, was routed by Bechtel's San Francisco engineering office.

3.9.3 COMPONENTS NOT COVERED BY ASME CODE

Safety-related mechanical components not covered by the ASME Code may be divided into two categories: Reactor Vessel Related and Other. The second category includes ventilation and air conditioning equipment and the emergency diesel generators.

3.9.3.1 Reactor Vessel Related Components Not Covered by ASME Code

Components not presently covered by the ASME Code include (1) reactor vessel internals, (2) fuel, (3) Control Element Drive Mechanisms (CEDMs) and (4) CEAs. Each of these components is designed and fabricated in accordance with specific procedures and criteria to ensure their operability as it relates to plant safety. The fundamental criterion to be met following a postulated faulted condition is to ensure safe and orderly shutdown of the plant and to maintain fuel cladding temperatures within acceptable limits.

3.9.3.1.1 Reactor Vessel Internals

The design loading conditions, stress and deformation limits selected for the reactor internals are discussed in Section 4.2.2. Adherence to these stress limits ensure that the deflections of the reactor internals are essentially elastic during normal and emergency conditions. Description of the analysis methods is presented in Section 3.6. During faulted conditions (see Section 4.2.2.3.3), the deformations of the reactor internals are limited such that the core is maintained in a coolable array and a free path is provided for CEA insertion.

3.9.3.1.2 Fuel

The fuel assembly structural design limits, and the bases for them, are defined in Section 4.2.1. The fuel assembly is designed to maintain its dimensional integrity when subjected to normal handling loads, dead weight, differential clad pressure, flow induced vibration and uplift forces, flow impingement, holddown forces, and shock and seismic loading, thermal stresses and temperature cycling.

3.9.3.1.3 Reactor Vessel Head Area Components

The response loads of the CEDM components and the ICI Flange Assembly and Support Post due to seismic and pipe break effects were determined by analysis for the reactor coolant system with the Replacement Steam Generator (RSG) configuration and power uprate conditions. These head components were evaluated by comparison to the original loads used in the stress analyses. It was necessary to demonstrate that the response loads are bounded by plant operation prior to and after implementation of the RSG installation and power uprate. The effect of power uprate on the CEDMs' normal operating drive impulse load was also evaluated as part of the CEDM evaluation.

The response loads for the Head Lift Rig (HLR) were determined by analysis for the CEDM Cooling shroud upgrade. The HLR components were evaluated by comparison to the original loads and by a new stress analysis.

3.9.3.1.3.1 CEDMs and CEAs Evaluation

The specific design stress and deformation limits for the CEDMs and CEAs are contained in Section 4.2.3. The CEAs are sufficiently flexible to conform to deflections or misalignments of the upper guide structure shrouds during emergency or faulted conditions. Tests on similar equipment have demonstrated CEA operability under conditions of adverse alignment of the upper guide structure and fuel assemblies.

The functional criteria established for the CEDMs ensure that the mechanical reactivity control system is capable for the required CEA insertions during normal operation and following those events classified as emergency or faulted conditions. The loading categories and stress limits for the CEDMs ensure that the mechanical reactivity control system is capable for the required CEA insertions during normal operation and following those events classified as emergency or faulted conditions. The loading categories and stress limits for the CEDMs are defined in Section 4.2.3.

The analyses performed in support of the criteria include the effects of reactor coolant temperature and pressure, dynamic loads induced by driving of the CEAs and by seismic excitation, and loads produced by postulated pipe breaks.

Linear response spectrum analyses were used for both seismic and pipe break excitation to calculate response loads in the CEDM nozzle and CEDM components. A combined axial and horizontal beam finite element model with all spatial degrees of freedom was generated with ANSYS (Reference 87) for these analyses. The numerical model included a sufficient number of nodes to accurately represent the dynamic characteristics of the nozzle components and provide a detailed load response distribution throughout the CEDM structure.

The seismic loads were applied to the CEDM with the longest nozzle length, and the pipe break loads were applied to the CEDM with the shortest nozzle length, because the longest length nozzle produces conservative results for seismic loads, while the shortest nozzle produces conservative results for pipe break loads. Combining the results from these two nozzle lengths produced results that bound the response loads for any one nozzle length. Thus, the results calculated are applicable and conservative for all CEDM locations.

The response distribution of the calculated loads were used as follows:

- Evaluate stresses in the CEDM components for normal operation plus pipe break loads.
- Perform the operability check for normal operating plus seismic loads.

The seismic OBE and DBE input spectra from the RCS seismic analyses described in Section 3.7.3 were generated for 2% and 4% damping respectively for the CEDM analysis. Both sets of spectra (for three orthogonal directions) were broadened by ±15%. The pipe break input spectra from the RCS pipe break analyses described in Section 3.9.1.7 was generated for 4% damping for the analysis of the CEDM response to pipe breaks.

The CEDM analyses were performed using ANSYS computer code. The CEDM modal responses were combined by ANSYS using the SRSS rule. The structural responses to each of three orthogonal components of motion (seismic or pipe break) were combined by ANSYS by the SRSS rule with the values of the co-directional responses caused by each of the three components of the considered motions.

The DBE and pipe break results were combined by the SRSS rule to yield the Faulted Condition results, which also included the normal operating loads.

CEDM operability was determined by comparing the critical CEDM deflections due to the DBE plus pipe break motions with those shown to be acceptable by previously documented static test results.

3.9.3.1.3.1.1 Results of CEDM Evaluation

The effect on the CEDM normal operating drive impulse load due to the RSGs and power uprate was evaluated and shown not to be affected by the difference in flow rate because the original loads conservatively envelop the changes in the hydraulic load.

The effect on the CEDM structure due to the RSGs and power uprate for Level A and B service conditions were addressed as follows:

- The RSG and power uprate do not affect CEDM and RV head thermal stresses. Therefore, Level A stresses were not affected.
- The major response load for Level B was the bending moment due to normal operation plus OBE at the head elevation. It was demonstrated that this bending moment is less than the allowable load calculated in the original analysis.
- The shear stresses due to normal operating plus OBE loads were also shown to be negligible and do not affect the total shear stress.

Therefore, the CEDM stresses for both the Level A and B service conditions are within the allowable limits.

CEDM stresses for the Level D service condition for all CEDM components were calculated from calculated response loads. All calculated stresses were shown to be within the allowable limits and no impacting between adjacent CEDMs was predicted when subjected to the combined effects of DBE and pipe break loads. The impact of DBE and pipe break loads on CEA insertability was determined by comparing the predicted horizontal CEDM displacements at the drive shaft upper elevation and at the upper pressure housing mid-point to test data. The tests determined the amount of CEDM deflection permissible for acceptable CEA insertion times. The calculated deflections were significantly less than the deflection established for acceptable CEA insertion time. The deflections of the CEDM were shown to be less than those for which the seismic qualification of the Reed Switch Position Transmitters (RSPTs) had been demonstrated by test.

3.9.3.1.3.2 Head Lift Rig Evaluation

An integrated Finite Element Model (FEM) of the HLR and CEDM Shroud upgraded structure was built using beam and shell elements to accurately represent eh dynamic characteristics and response. Figure 3.9-1D illustrates the FEM used in the HLR and CEDM Shroud upgraded structure analysis.

The HLR analyses were performed with the ANSYS computer code and the DBE and pipe break loads were combined by the SRSS rule to generate Faulted Condition results. The faulted loads also included the HLR dead weight load.

3.9.3.1.3.2.1 Results of HLR Evaluation

The HLR structure was analyzed for seismic and pipe break excitations based on the RSG configuration and HLR response loads were generated. The HLR response to loads due to dead weight, seismic (OBE and DBE) and pipe breaks have been evaluated upon the structural capacity of the new and existing components. The structural integrity of the HLR, CEDM Shroud assembly, three vertical ducts from shroud to manifold, and manifold has been evaluated and demonstrated that HLR stresses for all service level conditions are within respective allowable limits, thereby justifying the structural integrity of the HLR. Specific areas of the evaluation include the following:

- The torsion stress in the HLR vertical links, which was not considered in the original stress evaluation, was evaluated and determined to be acceptable.
- Stresses in the lead shield track assembly were calculated and the structural integrity of the lead shield track assembly was determined to be acceptable.
- Stresses in the tie rod assembly for the combined effects of DBE and pipe break loads were calculated and shown to be within allowables, thereby demonstrating its structural integrity.

3.9.3.1.3.3 ICI Flange Assembly and Support Post Evaluation

Linear response spectrum analyses were performed for both seismic and pipe break excitations to calculate response loads in the ICI flange assembly and support post. The seismic OBE and DBE input spectra from the RCS seismic analysis described in Section 3.7.3 were generated at the RV head for 2% and 4% damping, respectively, for the ICI analysis. Both sets of spectra (for three orthogonal directions) were broadened by $\pm$ 15%. The pipe break input spectra from the RCS pipe break analysis described in Section 3.9.1.7 were generated at the RV head for 4% damping for the ICI analysis.

A finite element model (FEM) of the closure head ICI nozzle, ICI nozzle flange adapter, ICI flange (including Grayloc clamp), ICI welded connectors and ICI support post was generated within the ANSYS environment with all necessary spatial degrees of freedom. Figure 3.9-1E shows the portion of the FEM representing the ICI nozzle, reducer, Grayloc and flange components and support post. A separate row of nodes and elements were used to define each of the six guide tubes. The details of this portion of the model are shown in Figure 3.9-1F. The FM was generated with a sufficient number of nodes to accurately represent the dynamic characteristics of the structure and provide detailed response loads.

Response spectrum analyses for specified loading spectra in both horizontal and vertical directions were performed using the modal superposition method in ANSYS for both the seismic and pipe break inputs. Response loads from the seismic and pipe break analyses were combined, and loads at all critical locations of the ICI flange assembly and the base of the support post were compared to response loads previously calculated. For locations where a comparison of loads was not possible, the stresses were calculated and compared to stress allowables.

3.9.3.1.3.3.1 Results of ICI Flange Assembly and Support Post Evaluation

Response loads of the ICI Flange Assembly and Support Post were calculated for OBE, DBE, and pipe break excitations based on the RSG configuration. Evaluation of these results showed the following:

Level A and B Service Conditions

- The significant response loads at the base of the ICI due to OBE are lower than those used in the previous analysis for this component, except for the axial loads which are higher. However, the axial loads comprise a very small portion of the total stress and are considered negligible.
- Similarly, the significant OBE response loads at the base of the Support Post and throughout the Weldable Connector structure are lower than previously calculated, except for the axial loads which are slightly higher. However, the axial loads are a very small fraction of the total stress and are considered secondary.

Since the OBE responses are lower, the stresses of all components of the ICI Nozzle Assembly, including the Support Post and Weldable Connectors, are lower than those in previous analyses, the stresses are acceptable and within the Level A and B allowables.

Level D Service Condition

- The significant response loads at the base of the ICI Nozzle due to DBE are lower than those used in the previous analyses for this component except for the axial loads, which are higher. Since the axial loads contribute insignificantly to the total stress, this increase is considered negligible.
- The significant DBE response loads at the base of the Support Post and throughout the Weldable Connector structure are lower than those used in the previous analysis except for the axial loads, which are slightly higher. Since the axial loads result in a small portion of the total stress, this increase is considered secondary.
- The pipe break response loads at the base of the ICI Nozzle are significantly lower than those used in the previous analysis for this component.
- The pipe break response loads at the base of the Support Post are also significantly lower than those used in the previous analysis for this structure.

Since the DBE and pipe break response loads are lower, the stresses in the ICI Nozzle and Support Post due to dead weight and the combined DBE and pipe break response loads are acceptable and within allowable limits for the Level D service condition.

3.9.3.2 Ventilation, Air Conditioning, and the Emergency Diesel Generators

The ventilation and air conditioning equipment and the emergency diesel generators are not covered by the ASME Code. The applicable codes are identified in Table 3.9-4. The manufacturer's supplying this equipment performed stress and dynamic calculations or performed tests to demonstrate that all design loading combinations will be sustained without impairment of structural integrity or functional capability. Seismic loading calculations are performed in accordance with the criteria presented in Section 3.7.

3.9.3.3 Pipe supports, Base Plates, and Anchors

All flexible pipe anchors and base plates using anchor bolts are analyzed to account for plate flexibility, bolt stiffness, shear tension interaction, minimum edge distance, and proper bolt spacing. Because a flexible base plate can significantly affect the applied forces to an anchor

bolt, a base plate is considered flexible if the unstiffened distance between the member welded to the plate and the edge of the base plate is greater than twice the plate thickness. Depending upon the complexity of the individual base plate configuration, the forces on the bolts are determined using one of the following methods: by hand, utilizing the AISC, ACI-318, or ACI-349 methodologies; the chart method for 2 inch or smaller piping, computer programs such as "Bolts", finite element programs such as "ANSYS", "ME-035", or "Base Plate II", and/or combinations thereof as may be applicable. The resulting force is compared against the bolt allowable; the design bases for which are documented in calculations and engineering reports and the results are summarized for use in a Structural Engineering Standard (SES-18). The bolt installation is controlled in the field by plant procedure and/or specification (ANO-C-2408).

Various types of anchors, including cast-in-place bolts and "J-bolts", grouted "Type 10" bolts, concrete expansion bolts (CEBs), wedge bolts, and undercut anchor bolts are used to attach components to the concrete structures. The initial testing of anchor bolts was either performed on site, at the Fast Flux Test Facility, or by the manufacturer and evaluated for use at the site. Different safety factors may be used depending upon the type of bolt and methodology used to establish the bolt allowables. Certain allowables are referenced in the IE Bulletins 79-02 and 79-14 responses to the NRC. The safety factor, i.e. ratio of bolt ultimate capacity to the design load, has been established as a mimimum of four (4) for wedge/CEB type bolts and five (5) for shell type anchors when a service type load is applied. The safety factor for these types of bolts may be reduced to three (3) when extreme environmental loads are included in accordance with Section B.7.2 of the proposed addition to Code Requirements for Nuclear Safety-Related Concrete Structures (ACI-349-76), August 1978. If the specific support has been verified, a safety factor of two (2) is considered to be satisfactory for these bolts if extreme loads are present. Other bolts, i.e. A36 Maxi Bolts undercut anchor bolts, have been extensively evaluated on site and have been demonstrated to be incapable of failing the concrete when designed and installed in accordance with site guidance and the results, including the safety factors, are documented by a series of engineering reports.

The safety factors for Concrete Expansion Bolts (CEBs) were not increased for loads that are cyclic in nature based upon the tests performed at the Fast Flux Test Facility (Drilled-In Expansion Bolts under Static and Alternating Loads, Report No. BR-5853-6-4 by Bechtel Power Corp., January 1975). The test results indicate:

A. The expansion anchors successfully withstood two million cycles of long-term fatigue loading at a maximum intensity of 0.20 of the static ultimate capacity. When the maximum load intensity was steadily increased beyond the aforementioned value and cycled 2,000 times at each load step, the observed value was about the same as the static ultimate capacity.

B. The dynamic load capacity of the expansion anchors, under simulated seismic loading, was about the same as their corresponding static ultimate capacities.

3.10 SEISMIC DESIGN OF CATEGORY 1 INSTRUMENTATION AND ELECTRICAL EQUIPMENT

3.10.1 SEISMIC DESIGN CRITERIA

See Table 3.2-2 for a listing of all Category 1 instrumentation and electrical equipment requiring seismic qualification.

3.10.1.1 Equipment Supplied by NSSS Vendor

Category 1 instrumentation and electrical equipment supplied by Combustion Engineering is designed such that it can meet the seismic qualification requirements established in IEEE 344-1971.

A Combustion Engineering Topical Report, CENPD-182, "Seismic Qualification of CE Instrumentation and Electric Equipment" was submitted in December, 1975. This topical report presents a summary of the CE seismic qualification program utilized to demonstrate the seismic design adequacy of the instrumentation and control equipment supplied by CE. Included in the report is a description of the qualification methods and a summary of the qualification effort for each piece of equipment. Appendix A to the report presents a listing of the CE supplied Unit 2 components to be seismically qualified. Appendix B presents the seismic qualification data sheets for the CE supplied equipment which has completed the seismic qualification program. Floor response spectra for Unit 2 are shown in Figures 3.7-11 through 3.7-18 for the OBE and DBE.

3.10.1.2 Equipment Supplied by Other Than NSSS Vendor

The Category 1 instrumentation and electrical equipment was designed to remain functional during and after DBE.

The Reactor Protective System (RPS) and Engineered Safety Features Actuation System (ESFAS) were designed to have the capability to initiate a protective action during the Design Basis Earthquake (DBE).

In addition, the emergency power system and Category 1 instrumentation and electrical equipment necessary for operation of Engineered Safety Features (ESF) were designed to withstand seismic disturbances of the intensity of the DBE and also to perform satisfactorily during and following the DBE.

Qualification and documentation procedures used for Seismic Category 1 equipment and/or systems meet the provisions of IEEE 344-1971 except as noted:

A. Category 1 Equipment is synonymous with Class 1 as defined in IEEE Standard 344, Paragraph 2.1.

B. Testing method described in Section 3.2.2.1 of IEEE 344-1971 was met. However, in addition an acceptable test condition was considered to be a uniaxial vibratory motion input at an angle to the horizontal plane of the vibration generator. This resulted in a biaxial test, where the component motions along the horizontal and vertical axes were in phase.

C. In lieu of IEEE 344-1971, the provisions of IEEE 344-1975 or IEEE 344-1987 are met.

3.10.2 SEISMIC ANALYSES, TESTING PROCEDURES, AND RESTRAINT MEASURES

3.10.2.1 Equipment Supplied by NSSS Vendor

Combustion Engineering Topical Report CENPD-182, provides a description of the seismic qualification program for CE supplied Class 1E instrumentation and electrical equipment.

In addition, the equipment design specifications for systems and components include the appropriate minimum "g" forces in the horizontal and vertical direction for which the equipment must qualify.

The equipment was designed to perform its intended function during and after the DBE, during normal and accident conditions.

The manufacturers are required to substantiate the adequacy of their design by analysis, testing, and/or operating experience, depending on the equipment under consideration and its intended safety function. The choice of the qualification method is made by Combustion Engineering, Inc.

The quality assurance program contains the procedures used in assuring the implementation of the requirements by equipment suppliers.

The plant protection system cabinet frame, reactor trip switchgear and the ESFAS panel were seismically qualified, by test, in accordance with IEEE 344-1971.

Testing of the PPS cabinet was done with the actual electronic subassemblies replaced with weights. The size, distribution and mounting of the weights was such that the dynamic characteristics of the cabinet remain unchanged. Accelerometers were strategically located throughout the cabinet to monitor the response motions, including those present at the subassemblies (simulated) mounting points. This test structurally qualified the cabinet and determined the immediate seismic environment of the subassemblies.

The reactor trip switchgear and the ESFAS panels were tested in their final completely assembled condition.

The results of the above three tests will be included in a Supplement to CENPD-182 which supercedes CENPD-61, and which is applicable to Unit 2.

The following is an item by item comparison of the above three tests, discussing the compliance of Combustion Engineering's instrumentation and electrical equipment seismic qualification program with the "Electrical and Mechanical Equipment Seismic Qualification Program".

Item I.1

In all cases, functional operability is confirmed by vibration testing. Structural integrity is confirmed by test or analysis.

Item I.2

The reference motions for seismic qualification are the in-structure response spectra of the containment and auxiliary building. These response spectra characterize the required input motions of equipment mounted directly to the building structure (floor or wall). For equipment

not mounted directly to the building structure, the seismic environment is not the in structure response spectra, but rather the motions of that mechanism which connects the equipment to the building structure. This will be determined by test or analysis.

Item I.3

Equipment operabilty is verified before, during, and after the seismic test.

Item I.4

The test input motions are characterized by response spectra. The Test Response Spectra (TRS) envelopes the Required Response Spectra (RRS) at all points of equipment resonance. The input amplitude (peak acceleration) is, at a minimum, equal to the zero period of the RRS.

Item I.5

As mentioned in Item I.4, the TRS envelopes the RRS at all points of equipment resonance. Since the in-structure RRS indicates single frequency predominance, a single frequency test input generates all the required modes of the equipment. However, should this not be the case for a specific piece of equipment, a controlled random input is used to create a broader TRS.

Item I.6

Biaxial testing was employed.

Item I.7

The tested equipment is fastened to the excitation system using the intended service mounting. Any test fixture, not intended for service, utilized to facilitate fastening must be rigid with respect to seismic frequencies.

Item I.8

There are at present no plans for the use of in-situ vibratory devices. Should this technique be employed, the results will include an analysis for justification.

Item I.9

Type testing is used wherever possible. Where variations exist within type, each variation is justified.

Item II.1 & II.2.a

See discussion of Item I.2.

Item II.2.b

Where analysis is employed, the calculated stresses are maintained within the required limits.

Item II.3

Enclosure and supports being tested are either the actual devices installed or the devices are simulated with weights in a manner which retains the original dynamic characteristics of the enclosure of support.

Item II.4

Equipment support tests are performed using the same criteria as equipment tests. Testing supports are simpler since there is no need to monitor electrical performance.

The PPS electronics drawers, the excore nuclear instrumentation monitoring system (including detectors), the process protective cabinet and its internal electronics, and the process instrumentation were seismically qualified as described in the PSAR and repeated here for clarity.

Earthquake loads for the design of these systems and equipment were determined consistent with the horizontal ground acceleration specified for the site for the Operating Basis Earthquake (OBE) and for the DBE.

From basic input ground motion data, a series of response curves at various building elevations were developed. This information was included in the purchase specifications for the emergency power system.

Based upon the data contained in these response spectra curves, applicable seismic accelerations were selected for inclusion in the purchase specifications for the RPS and the ESFAS.

Equipment suppliers were required to submit test data, operating experience, or calculations which substantiated that the components will not suffer loss of function before, during or after design loadings due to the DBE accelerations determined by the seismic analysis of the structure to ensure that there will be no loss of function in these systems during or following the DBE.

3.10.2.2 Equipment Supplied by Other Than NSSS Vendor

Category 1 instrumentation and electrical equipment and components were designed to ensure functional integrity of the specific operating requirements in accord with Section 3.7.2.1.3.

IEEE 344-1971, "IEEE Guide for Seismic Qualification for Class 1 Electric Equipment for Nuclear Power Generating Stations," was used as a guide for developing seismic qualification requirements in specifications.

IEEE 344-1975 and IEEE 344-1987 have also been used for the seismic qualification of various Category I instrumentation and electrical equipment.

The procedures described in Section 3.7.2.1.3 were used in the seismic analysis of equipment supports, such as battery racks, instrument racks, control consoles and cable tray supports. Suppliers of equipment were required to submit test data and/or calculations to substantiate that their components and systems would not suffer loss of function before, during, or after seismic loadings due to the DBE.

All cable tray and instrument tubing supports were designed by the response spectrum method. Analysis and seismic restraint measures for tray and tubing supports were based on combined limiting values for static load, span length, and computed seismic response.

The following bases were used in the seismic analysis of cable tray and instrument tubing supports:

A. All safety-related cable tray and instrument tubing supports were designed for loads determined by dynamic analysis (first mode) using the appropriate seismic response spectrum.

B. Conservative loading was assumed.

C. The support system was designed to exclude all natural frequencies in a band covering the peak or peaks of the response spectrum curve.

D. Maximum stress was limited to 90 percent of minimum yield for the DBE and code allowable stresses for one OBE.

3.10.2.2.1 4.16 kV Metal Clad Switchgear

The seismic qualification for switchgear assemblies 2A3 AND 2A4 is divided into three parts, as follows:

A. Structural adequacy

B. Performance of relays

C. Performance of circuit breaker operating mechanisms

This qualification was performed for the switchgear assemblies in the racked-up configuration only.

3.10.2.2.1.1 Structural Adequacy

A. Modal Analysis

Four variations of the manufacturer's basic vertical lift metal clad design are analyzed in the Modal Analysis Report. These include:

1. An M26H (350 MVA) 3,000 ampere breaker unit with typical relays, switches and meters. This unit was subjected to seismic tests in accordance with IEEE 344-1971, Section 3.2.3 at the General Electric Valley Forge Space Center in King of Prussia, Pennsylvania, in February, 1972.

2. Qualification of the replacement 1200 amperes, 250MVA to 350MVA upgrade breaker units was performed in accordance with Entergy Specification ANO-C-2506, “Specification for Seismic Qualification of Class 1E Equipment for Arkansas Nuclear One Units 1 & 2” at the Wyle Laboratories, Huntsville, Alabama. These units were subjected to seismic tests, documented in Calculation 88-E-0035-72, which justify that the anticipated frequencies subjected to the model meet or exceed the anticipated seismic response for the site.

3. Three M26 (250 MVA) 1,200 ampere breaker units furnished, as described below:

   a. Unit 2A310, typical feeder unit

   b. Unit 2A308, typical unit with superstructure relay cabinet.

   c. Unit 2A307, typical unit with PT rollout superstructure.

   These units represent the three design variations of breaker units used in the Class 1E, 4160-volt switchgear lineups 2A3 and 2A4.

4. The procedure for the modal analysis is as follows:

   a. Develop a mathematical model for the M26H unit.

   b. Justify the model selected by comparing the characteristic frequencies determine by modal analysis of the M26H unit with actual frequencies observed during the seismic testing of this unit.

   c. Perform analyses on the three M26 variations using the same modeling technique.

   d. Use the results of the analyses and the M26H unit test results to predict the seismic response of the M26 units.

B. Static Analysis

In the static analysis, the inertial forces calculated by modal analysis are superimposed on the normal design loads. The resultant stresses in structural members are calculated and compared to allowable stresses. This proves the structural adequacy of the design.

3.10.2.2.1.2 Relay Performance

The M26H test results and the modal analyses establish the maximum acceleration levels to which any of the critical relays mounted on the units will be subjected to for the specified seismic input. These acceleration values are then determined to be safe by comparing them with the results of separate seismic qualification tests conducted on the various types of relays.

The seismic tests on individual relays were done according to the following procedure:

All devices were mounted in their normal position. A search for resonance was made by sweeping from 5 to 33 Hz at a constant rate of 1 Hz per 15 seconds. If resonance was found in the sweep test, the devices were tested at that frequency. If not, then the devices were tested at 33 Hz for a period of two minutes or malfunction. A failure was defined as a 100 microsecond change of position of either normally open or normally closed contact. The tests included the deenergized and energized states of the relays.

3.10.2.2.1.3 Breaker Operating Mechanisms

The ability of the breaker to function correctly during and after a seismic disturbance was established by the following:

A. During the tests on the M26H unit, the breakers were tripped and closed successfully during the shaking at a much higher "g" level than specified for this plant.

B. A calculation by the manufacturer's Design Engineering subsection indicates that very high "g" levels are required, 44 g horizontally and 50 g vertically, before the mechanism would close or trip the breaker falsely.

C. Field experience (Sylmar, Ca, 1971 earthquake) demonstrated that the M26 units could successfully withstand a severe seismic disturbance.

3.10.2.2.1.4 Switchgear 2A5 Seismic Qualification

Seismic certification for the 2A5 switchgear assembly was furnished by BBC Brown Boveri, Inc. Moreover, functional integrity of the assembly was ascertained by tests before and after seismic simulation.

3.10.2.2.2 480-Volt AC Load Centers

The seismic qualification of the 480-volt load centers consists of seismic certification of the switchgear assembly and seismic certification of the load center transformer, independent of each other.

3.10.2.2.2.1 Switchgear Assembly

A 2-frame low voltage switchgear assembly was subjected to the following tests at the Environmental Test Laboratory under the auspices of Applied Services Corporation.

A. A frequency sweep establishing points of resonance by mounting the switchgear on a low frequency vibration machine and applying excitation was performed.

B. An attenuated sinusoidal accelerating force applied at selected frequencies with device monitoring to establish functional integrity. During tests at 4, 6, and 11 Hz the equipment was subjected to the following attenuated sine wave accelerating forces for the total time durations indicated:

CUMULATIVE TEST TIME (SEC)

	Acceleration (g)					
Frequency (Hz)	0.5	1.0	1.5	2.0	2.5	Total Time
4	24.25	11.50	5.50	1.75	-	43.00
6	32.49	20.31	10.83	5.00	1.31	69.94
11	9.36	4.54	2.17	0.81	-	16.88
Total Time	66.10	36.35	18.50	7.56	1.31	129.82

Whereas the above figures are cumulative times for the complete series of test, they are illustrative of the rate of decay of the attenuated sine wave inputs for each test frequency. For instance, at 4 Hz the attenuation is represented by 1.75-second duration at 2.0 g, 5.50 seconds at 1.5 g, 11.50 seconds at 1.0 g, and 24.25 seconds at 0.5 g.

All test input valves exceed the minimum required accelerations and the excitation response were above the required response spectra.

In each test, the method of securing the equipment approximated or equaled the actual mounting in the plant.

3.10.2.2.2.2 Load Center Transformer

The transformer was installed on a base and mounted on a flatbed trailer where it was anchored at the base. The method of restraint was rigid; chains were attached, but left slack, only being used as a safety precaution.

An Impactograph recording accelerometer was installed, monitoring input accelerations to the transformer. The transformer was transported over selected rough terrain at speeds between 0 and 50 mph.

The recording tape was examined after the test. The highest recorded impacts exceeded 10g in all three directions simultaneously. Moreover, functional integrity of the device was ascertained by tests before and after the road shocks.

3.10.2.2.3 480-Volt AC Motor Control Center

Seismic certification for the Class 1E 480-volt Motor Control Center (MCC) was furnished by ITE Imperial Corporation. This certification is based on simulated seismic testing performed on the Series 5600 MCC by MTS Systems Laboratory.

Two typical MCC stacks were mounted on a vibrating table, capable of applying a continuous amplitude, sinusoidal input waveform. The mounting of units on the shake table simulated the actual restraining conditions used in securing the MCC's to the floor in the plant.

3.10.2.2.3.1 Test Procedure

A. A low amplitude frequency search was performed to determine the natural frequency, regions of resonance, and the critical damping of the frame and structure.

B. A continuous, sinusoidal input wave form was applied at the required acceleration level for a period of 30 seconds.

C. A vibration test at the center band frequency set at the region of resonance, with a bandwidth of ± 3 Hz was conducted for a duration of 60 seconds.

D. A 5-cycle sine beat input was applied, each beat being delayed by two seconds from the preceding beat to minimize superposition of the equipment effects.

All test input forces exceeded the required minimum OBE, DBE, horizontal, and vertical forces. Output levels enveloped the required response spectra for the MCC plant locations. All components were monitored for malfunction during all phases of testing.

The specific requirements of IEEE 344-1971 have been satisfied by successful implementation of the test procedures described above.

3.10.2.2.4 Distribution Transformers and Panel Board

3.10.2.2.5 125-Volt Station Batteries

The seismic certification for the station batteries consists of qualifying the battery fuse and relay panel and qualifying the batteries and the racks.

3.10.2.2.5.1 Battery Fuse and Relay Panel

Analysis, establishing the structural adequacy, was used for certification. Stress and frequency computations provided allowable stresses and natural frequency figures to be used in verifying the capability of the panel to withstand OBE and DBE conditions.

Component testing on a shake table was performed. Random motion, biaxial input was applied to the devices to ascertain functional integrity. The method of mounting simulated actual panel anchoring while the test was being conducted. The requirements of IEEE 344-1971 are satisfied for this equipment.

3.10.2.2.5.2 Batteries and Racks

Calculations with analysis for stress, frequency, and stiffness were used for qualification for OBE and DBE conditions. Material test data, i.e. yield load, ultimate stress, and nominal stress were used, support the analysis. Stresses were calculated for the support frame, rails and wall bolts for OBE and DBE accelerations.

Prototype battery cells, identical to those used in Unit 2 were subjected to random biaxial seismic excitation. Additional random biaxial seismic excitation was performed on prototype battery cells, identical to those used in Unit 2 except for number of plates, cell length and weight. In the former test, battery performance was demonstrated before and after seismic excitation. In the latter test, battery performance was demonstrated before, during, and after seismic excitation. The above demonstrates the seismic qualification of battery cells.

3.10.2.2.6 125-Volt DC Control Centers

The seismic qualification of the Class 1E DC control centers, 2D01 and 2D02, consists of an analysis to establish the structural adequacy and component tests to provide the functional integrity of critical devices.

3.10.2.2.6.1 Structural Adequacy

Calculations were performed in three orthogonal directions using a conservative model, generally a lumped mass concept. However, where the structure was obviously uniformly loaded, a distributed mass concept was used.

The seismic document justified the modeling technique adopted which includes:

A. Frequency analyses of panels in the three orthogonal directions. The minimum natural frequency of the panels in any direction was found to be 37.0 Hz.

B. Stress analyses of structural members to prove the extent of conservative design of the members.

C. Anchorage calculations for the welding schedule.

D. Worst case amplification factors and acceleration values at the various component mounting locations. These values were used for the component seismic tests described in Section 3.10.2.2.6.2 below.

3.10.2.2.6.2 Component Tests

A. Air circuit breakers and auto transfer switches - These components were seismically qualified by simultaneous biaxial tests using random motion excitation. The test procedure used was the same as described in Section 3.10.2.2.8 for the station inverters. In this case, the test spectrum followed the required spectrum up to the frequency of panel resonance. Thereafter the test spectrum acceleration levels were increased in order to account for the amplification effects at the device mounting locations.

The devices were operated during the seismic tests to establish the capability of the devices to function reliably during a seismic disturbance. Also, the devices were monitored continuously during the tests to assure that no malfunction occurred.

B. Indicating instruments - The indicating instruments used were qualified by seismic tests. The procedure used is outlined below.

An exploratory sweep was made to determine resonant frequencies as follows:

	Acceleration (g)			
Frequency Range	Vertical	Horizontal	Long	Time
1-33-1 Hz	0.37	0.8	0.8	20 minutes
33-100-33 Hz	0.37	0.8	0.8	20 minutes
100-500 Hz, if no resonant frequencies exist 100 Hz &below	0.37	0.8	0.8	33 minutes

An operational endurance test was then conducted as follows:

1. At each resonant frequency found in the sweep test of 100 Hz and below, a 2-minute test was conducted at an acceleration of 1.5g in both the horizontal and longitudinal axes and 0.5g in the vertical axis.

2. A sweep was made over the frequency range of 1-33 Hz at the rate of 15 seconds per cycle and at accelerations of 3.0g in the horizontal and longitudinal axes and 1.5 g in the vertical axis.

   A malfunction test was then made at 33 Hz and at every resonant frequency below 33 Hz by increasing the acceleration value until a nondestructive malfunction was observed.

Since the acceleration values at the instrument mounting locations on the panel, determined by the analysis in Part 1 above were considerably lower than the levels at which the qualification tests were conducted, their performance was considered satisfactory.

C. Undervoltage (alarm) relay - These relays are GE type NGV. They were qualified by seismic tests as described in Section 3.10.2.2.1.2.

3.10.2.2.7 Battery Chargers

The seismic documentation for the battery chargers consists of:

A. Analysis for structural adequacy,

B. Seismic test documentation to establish the functional integrity of the components, and

C. Seismic Qualification(s) documented per applicable ANO/ENTEGY specification to the requirements of IEEE 344-1971, 1975, and/or 1985 standards.

Functional Integrity of Components

The functional capability of the electromechanical devices was established by seismic tests conducted on a battery charger of the same frame size and bracing as used in the charger furnished.

3.10.2.2.8 Station Inverters

The inverters that furnish the 120-volt vital AC power have been qualified by seismic simulation tests. Each inverter consists of two assemblies, the Uniterruptible Power Supply (UPS) assembly and the static switch assembly. Each of these units was tested separately in accordance with the procedures described below.

3.10.2.2.8.1 Test Procedure

The unit was placed on a multiaxis shake table.

The unit was attached to the test table to simulate the actual mounting conditions when finally installed in the plant.

Testing meets the applicable requirements of IEEE 344-1971, 1975, and 1985.

3.10.2.2.8.2 Functional Integrity

The unit was supplied with 135 VDC power. Additionally, 480 VAC, 1∅, 60 Hz power was applied to the input of the bypass transformer. The unit was then loaded to approximately 83 amps with a resistive load. Input and output voltages and output current were monitored throughout seismic testing.

The unit was inspected for structural damage and for any change in its functional characteristics before, during and after the simulated excitation.

The test report documents the satisfactory completion of the tests on the units.

3.10.2.2.9 Control Boards

The seismic qualification of the Class 1E control boards, which include consoles and vertical panels, consists of dynamic analysis to establish the control board structural adequacy and device tests to prove the functional integrity of the critical components.

3.10.2.2.9.1 Structural Adequacy

The dynamic analysis to verify the structural adequacy of the control boards follows the procedures presented in Section 3.7.2.1.3.

A stress analysis was performed and the control board structural stresses were checked against the applicable design criteria to verify structural adequacy.

3.10.2.2.9.2 Device Tests

Electrical relays, meters, switches, instruments, and other devices mounted on the consoles and vertical panels, which are required to remain functional during and after a DBE, to ensure functional adequacy of Class 1E systems, were subjected to simulated seismic tests and qualified by the device manufacturer in accordance with the requirements of IEEE 344-1971, 1975, or 1987.

3.10.2.2.10 Instrumentation and Racks

The seismic qualification of the Class 1E instrument racks consists of an analysis to establish the structural adequacy of the racks and device tests to prove the functional integrity of the critical devices.

3.10.2.2.10.1 Structural Adequacy

Instrument racks have been designed and built in accordance with the requirements stated in Section 3.10.1. Typical instrument rack installations are shown in Figure 3.10-7.

The method for qualification consists of a seismic analysis of a standard rack design. This rack was assumed to have the loads shown in Figure 3.10-8. All loads were conservatively chosen such that they would be greater than probable real loads. Neglecting dynamic loads, static loading was assumed. The combination of loads producing the most severe deflections were used. Static loads were combined with the allowable stress of the materials used to construct the rack. The analysis was carried further to show that by adding two additional horizontal supports as shown in Figure 3.10-7, the maximum rack length could be increased from four feet to five feet. The response spectra indicate that no amplification of the seismic input imposed on the rack by the floor would occur since the calculated natural frequency of the rack was found to be greater than 33 Hz.

A static analysis was performed on the design of the base plate anchorage used in the standard rack. The design was analyzed to determine the torsional rigidity and the bending rigidity of the base plate. Both the torsional and bending stresses were found to be within the allowable stress limits for the material used. These base plate loads were then applied to the anchor bolts and found to be within allowable limits of the bolt material.

3.10.2.2.10.2 Device Tests

Rack-mounted devices such as control switches, pressure and differential pressure transmitters and differential pressure indicating switches required for proper functioning of the safety-related systems have been seismically tested and qualified by the device suppliers in accordance with IEEE 344-1971, 1975, or 1987.

3.10.2.2.10.3 Instrument Mounting Details

Standard Seismic Class 1E instrument mounting details are shown in Figure 3.10-7.

3.10.2.2.11 Cable Tray and Instrument Tubing Supporting

The following bases were used in the seismic analysis of cable tray and instrument tubing supports:

A. All safety-related cable tray and instrument tubing supports were designed for loads determined by dynamic analysis (first mode) using the appropriate seismic response spectrum.

B. Conservative loading was assumed.

C. The support system was designed to exclude all natural frequencies in a band covering the peak or peaks of the response spectrum curve.

D. Maximum stress was limited to 90 percent of minimum yield for the DBE and code allowable stresses for the OBE.

Selected typical details showing the Category 1 cable tray supports and support connections are shown in Figures 3.10-1 and 3.10-6.

Instrument tubing support structures are designed and built in accordance with the requirements of Section 3.10.1. The instrument tubing support structures are shown in Figures 3.10-9 and 3.10-10.

The method for qualification consists of a seismic analysis of each configuration used. The installation is considered to be represented by a free body model subjected to loading in the horizontal plane in two mutually perpendicular directions, N-S and E-W, and in the vertical direction. Seismic loading occurs in all three directions simultaneously and is combined with a dead load in the vertical direction for this analysis. The analysis assumed bending in the horizontal plane and compression or tension in the vertical direction. Using the frequency and "g" level capacity based on 90 percent of yield capacity and using the appropriate damping (two percent for welded structure) and DBE floor response spectra, the "g" level loading for each direction was determined. The method used combines seismic loads for all three directions was determined. The method used combines seismic loads for all three directions plus the vertical dead load based on the square root of the sum of the squares. Conservative loading was assumed. Where the N-S and E-W coordinate axes of the model installation are at an angle with the N-S and E-W orthogonal coordinate axes of the building, then transformation equations were used to transform the loading directions to the same axes for the purpose of analysis.

The analysis showed that maximum stresses for each configuration analyzed did not exceed 90 percent of the minimum yield strengths for materials used.

3.10.2.2.12 Control Valve Assemblies

The valve operators are qualified in accordance with IEEE 344-1971. Test reports were submitted in accordance with IEEE Standards.

3.10.2.2.12.1 Test Outline

The operator was mounted on a shaker table and subjected to vibration testing along each of the three mutually perpendicular axis over the frequency range of 1 to 35 Hz with a maximum acceleration of 1.0 g's in order to determine natural frequencies. At each natural frequency three cycles of vibration at an excitation of 5.3 to 5.8g's were performed. A 1-minute rest period was allowed after each three cycles. If no natural frequencies were apparent, a 10-second dwell was performed at 2, 4, 6, 9, ..., N Hz utilizing maximum available control displacement up to a cutoff level of 3g's and at 5.3 to 5.8g's at 35 Hz.

No apparent natural frequencies were determined as a result of this testing. In all cases for all tests vibration was applied at 3g's for 10 seconds at all even numbered frequencies from 2 Hz to 34 Hz and at a level between 5.3 and 5.8g's at 35 Hz.

3.10.2.2.12.2 Calculations

In addition to the above testing static calculations for the valve operator combination are performed to a natural frequency greater than 33 Hz and acceptability of vibration of 3g's in three mutually perpendicular axes.

3.10.2.2.13 Emergency Diesel Generators

A seismic analysis was done on the engine generating unit skid assembly, including skid mounted and off-skid accessories, to demonstrate ability to perform its required function when subjected to a seismic disturbance. The analysis included evaluation of stresses to meet the requirements of Section 3.7. The following criteria were used for stress analysis:

A. Operating Basis Earthquake Conditions

   The load combinations include gravity loads, operating loads, applicable operating temperatures and pressures, combined with the simultaneously applied horizontal and vertical OBE inertial forces. The horizontal and vertical inertial forces are obtained from the appropriate method specified in Section 3.7.

   Stresses in the structural portions do not exceed the allowable working stress limits accepted as good practice as set forth in the appropriate design standards that is, the AISC Manual of Steel Construction, the ASME Boiler and Pressure Vessel Code or other industrial codes. If the applicable code permits stress increases for load combinations which include earthquake loads, such stress increase do not apply. The resulting deflections will not prevent normal operation of the equipment.

B. Design Basis Earthquake Conditions

   The load combinations include gravity loads, applicable temperatures and pressures combined with the simultaneously applied horizontal and vertical inertial forces and are obtained from the appropriate method specified in Section 3.7.

Note: The vertical DBE acceleration values are 2.0 times the vertical OBE acceleration values.

Allowable stresses in the structural portions of equipment may be increased to a maximum value of 0.90 F_y for bending or tension, and 0.50 F_y for shear. The resulting deflections will not prevent operation of the equipment nor will the calculated deflections exceed 0.8 times those which could cause loss of function of equipment.

3.10.2.2.13.1 Diesel Engine Generating Unit

The equipment investigated is a Fairbanks Morse 12 cylinder Model 38TD8-1/8 opposed piston diesel engine connected to a Fairbanks Morse 3250 kW generator. The complete unit is mounted on a heavy skid. The generator is of the two bearing design with the connection between the engine crankshaft and generator shaft made with a flexible rubber type coupling. Due to the rigid box type construction of the accessory equipment section of the skid, it was possible to analyze the engine generating unit with its portion of the skid independent of the accessory equipment section. Based on prior experience in Navy shock testing of this engine, the following assumptions were made for the seismic analysis: A) engine block assumed rigid, and B) internal rotating elements such as pistons, connecting rods and crankshafts were not investigated due to their inherent design nature, e.g., all rotating elements were initially designed to withstand normal firing and inertia loads which are far in excess of any seismic loading.

The seismic analysis was concentrated on areas of either known damage during Navy shock testing or new items not shock tested, and was prepared to test the adequacy of the following:

A. All main equipment holddown bolts;

B. Turbocharger bracket mounting on engine block; and,

C. The last two engine bearing and generator bearings.

The dynamic analysis to determine seismic loads was performed in accordance with Section 3.7.2.1.3. The engine generating unit and skid was modeled separately for horizontal (at 90 percent to engine crankshaft center line) and vertical excitation. Using the lumped masses and spring constant concept, natural frequencies were calculated. Applying a 2-percent damping factor and the applicable acceleration response spectrum, modal forces were determined. The resultant forces for all mode orders, for each of the horizontal and vertical excitation modes, were calculated by adding the absolute maximum mode value plus the square root of the sum of the squares of the others, e.g.,

$$\text{Maximum Resultant} = (\max) + \sqrt{\sum \text{others}^2}$$

The simultaneous effect of horizontal and vertical excitation forces combined with weight and accelerating torque determine the net forces in the equipment hold down bolts, the turbocharger mounting block, and the engine and generator bearings. The following conclusion has been arrived at:

A. Holddown Bolts

The maximum principal stresses are low and are within the stresses allowed in Section 3.7.

B. Mounting Bolts and Bracket of the Engine Mounted Turbo-Charger

The maximum principal stresses for the DBE case are low and are within the allowable stresses of Section 3.7.

C. Engine and Generating Bearings

The vector sum of the horizontal and vertical seismic forces on the generator and on the last two engine bearings combined with operating forces are low. The engine and bearing, which has the highest seismic load, has a total combined seismic and normal peak operating load less than normal operating load on some intermediate bearings. Therefore, a momentary shock will not harm the bearings.

The engine generating unit and skid assembly was also modeled for fore and after horizontal excitation (parallel to engine shaft). The seismic forces for this mode, combined simultaneously with vertical excitation and operating loads were calculated to determine the stresses at the engine thrust bearing support arm and the generator spherical bearing. The engine maximum stresses are low and are within the allowable stresses. The engine thrust bearing support arm will not fail during a seismic disturbance.

SKF No. 22240 spherical bearings are used in the generator. Assuming a seismic disturbance lasting five minutes, the estimated decrease in life expectancy due to maximum seismic and operating loads is 0.05 percent in life per seismic shock which is acceptable.

3.10.2.2.13.2 <u>Analysis of Components</u>

The following components of the emergency diesel generator units have been analyzed for structural integrity. Seismic loads, based on 2-percent damping, including simultaneous horizontal and vertical excitation were combined with gravity loads to determine the effects on the supports. In each case the maximum resultant of different mode orders was calculated using the formula:

$$\text{Maximum Resultant} = (\max) + \sqrt{\sum \text{others}^2}$$

A. Lubricating Oil Filter

The filter is a tall cylinder with its center of gravity near the central height and it is assumed to be rigid with system flexibility at the four mounting feet. The total foot stiffness was calculated to determine the natural frequency.

The results indicate that the lube oil filter will adequately withstand the seismic disturbance.

B. Lubricating Oil Strainer and Starting Air Receiver

The lubricating oil strainer and the starting air receivers are considered tall cylinders with center of gravity near the central height. The same approach and analysis as was used for the lubricating oil filter was applied and the conclusion is that this equipment can adequately withstand the seismic disturbance.

C. Fuel Oil Day Tank

The day tank is a horizontal cylinder of welded steel fabrication. It is supported by an attached saddle at each end which is bolted to the floor. Predominant flexibility is at the saddles so the tank is assumed to act as a rigid body with the center of gravity at the geometric center of the tank. For horizontal excitation two cases were evaluated: one is with excitation parallel to tank axis and the other normal to tank axis. In each case, the horizontal forces on the tank are the same. The effects of horizontal vertical excitation using 2-percent damping and gravity loads due to a full load tank were evaluated for stud stresses, stresses at the tank end and stress in the tank. The maximum calculated stresses are all less than the respective allowable stresses. In this case, there are no critical deflection locations, so no deflections were calculated. Wave effects for both transverse and longitudinal waves due to a partially filled tank were also investigated but it was concluded that the filled tank contributes the worst loading condition.

D. Jacket Water Expansion Tank

The expansion tank is a horizontal cylinder with elliptical ends wall mounted with two saddle shaped supports. Flexibility is assumed in the support saddle and in the tank wall at the saddle connection. The spring constants for each horizontal and vertical excitation were calculated for natural frequencies. Using a 2-percent damping factor seismic forces were established. The simultaneous effects of horizontal and vertical excitation combined with gravity loads determined the net forces. Consequently, the stresses on the parts examined. None of the calculated stresses exceeded the allowed valves. Again, deflections were not considered since their effects were not critical. The conclusion is that the tank will adequately withstand the seismic disturbance.

E. Overspeed Governor and Shutdown System

In the event of excessive speed the governor shuts off the fuel injection pumps. The influence of seismic forces have been investigated to determine the safety factor against shutting down of the engine. There are four ways by which linear acceleration of the engine block can put energy into the overspeed system.

1. Due to lateral or vertical accelerations, the overspeed rotating weight assembly can respond at what it would think was an overspeed.

2. The latch and lever system could unhook from vertical acceleration.

3. The manual emergency shutdown linkage could actuate from sufficient lateral acceleration.

4. Plunger inertia causing unhooking of latch.

The lowest linear acceleration determined from the above cases, and the acceleration based on the possibility of an arithmetic summation, were determined to arrive at a safety factor greater than 1.0. Therefore, seismic forces will not result in a failure of the governor system.

F. Skid Piping

For the systems, the largest run of pipe with the longest unsupported section was evaluated. This is the pipe which is expected to have the lowest natural frequency and the highest seismic stresses. Motions from vertical and horizontal excitation were assumed to be uncoupled.

A mass elastic model of the piping was prepared for both horizontal and vertical excitation. Flexible joints were assumed to act as hinges while other joints and points of attachments were assumed to be rigid. This resulted in a system consisting of spans and lumped masses. As anticipated, the resulting stresses are low and a seismic disturbance will not cause any malfunction. Piping stresses at some locations reached as low as 100 to 300 psi and at one support reached 2,300 psi. There are not thought to be any critical deflections which must be considered.

G. Heat Exchanger Stack Assembly

The heat exchangers and the engine inlet air filters make up the heat exchanger stack assembly. The assembly has been analyzed as an independent system assuming no forces on the stack from any external piping. For the analysis, equipment has been modeled separately for vertical and horizontal excitation. For horizontal excitation, two cases were considered: one is parallel to the engine crankshaft, and the other is in the lateral direction. System frequencies were determined and modal forces calculated on the basis of a 2-percent damping factor. Each case of horizontal excitation was simultaneously considered with the vertical excitation and combined gravity and applicable operating forces. The following parts have been examined for stresses: stack bracing, holddown and clamp bolts, welds on attachment plates, brace tubings, spacer blocks, and engine inlet air filter bolts.

The results indicate no overstressing of these parts in either the DBE or OBE design case. The actual deflections at all mass points were considered small and there are no critical points on the heat exchanger stack assembly where momentary deflections due to seismic disturbance would prevent operation of the equipment.

H. Air Compressor Skid Assembly

The air compressor skid is built from a 12-inch channel provided with mounting feet at two places along each side of the channel. The compressor and motor are bolted to the skid.

As in the above cases, a horizontal transverse and a horizontal fore and after excitation were each simultaneously combined with vertical excitation and combined with gravity forces. For horizontal transverse excitation, torisonal flexibility of the channel, except for the part under the compressor and motor, was considered. The forces in the holddown bolts and mounting feet are low and the maximum calculated principal stress is far less than the material allowable stress.

I. Local Electric Control Cabinet

The control cabinet is separate from the engine skid. It is made of sheet metal and angle weldment and contains the static exciter and the various meters, switches, and controls for operating the emergency generating set. In the analysis the mass-elastic

model is defined, mode shapes and frequencies are calculated, and modal forces are calculated first for horizontal excitation, then for vertical excitation. Finally, resultant forces and stresses are calculated at critical locations, per specification, a 2-percent damping factor was applied.

The following were evaluated:

1. stresses in bolts and studs

2. stresses in reactor feet

3. stresses in current transformer feet

4. stresses in neutral grounding tansformer feet

5. acceleration of relays

Results of the analysis indicate that the maximum principal stresses are low and are far less than the allowed stresses for the materials under consideration.

Device Qualification

Diesel generator instrumentation, control, metering, and relay devices required to remain functional during and after a DBE to ensure functional adequacy of Class 1E systems, have been seismically tested and qualified by the device suppliers in accordance with IEEE 344-1971, 1975, or 1987.

3.10.2.3 Amplification of Floor Inputs by Supports

The equipment was analyzed and/or tested as an assembly that simulated the intended service mounting, which accounted for possible amplification of the seismic input by the equipment support.

Seismic documentation for instrumentation and electrical equipment submitted by the vendor, was then reviewed by Bechtel to ensure that the support system had been considered.

Where it was necessary to test individual devices, e.g., relays or instruments, separate from the panel on which they were mounted, the devices were qualified for acceleration levels higher than those they would experience at their mounting locations on the panel.

3.11 ENVIRONMENTAL DESIGN OF MECHANICAL AND ELECTRICAL EQUIPMENT

The current Environmental Qualification (EQ) Program is based on 10 CFR 50.49, "Environmental qualification of electric equipment important to safety for nuclear power plants," and IEB 79-01B, Enclosure 4, "Guidelines for Evaluating Environmental Qualification of Class 1E Electrical Equipment in Operating Reactors" (commonly known as the DOR Guidelines). This program, which encompasses electrical equipment important to safety located in a harsh environment, is described in section 3.11.5. The remainder of this section and sections 3.11.1 through 3.11.4 contain the information required to be in section 3.11 of the SAR by the guidelines to which the SAR was written. This covers environmental conditions and design bases for the electrical and mechanical portions of the Reactor Protective System (RPS) and Engineered Safety Features (ESF) to assure acceptable performance in all environments.

The electrical and mechanical equipment of the Reactor Protective System (RPS) and Engineered Safety Features (ESF) system is designed to assure acceptable performance in all environments (normal and accident). The RPS (including the Core Protection Calculator system and the reactor trip switchgear) and the Engineered Safety Features Actuation System (including the auxiliary relay cabinets) were originally qualified for use using IEEE 323-1971 as a guide, even though IEEE 323-1971 was not a requirement for Unit 2 at the time of issuance of the construction permit.

The design criteria for the RPS and the ESF system are based on equipment location. As far as practical, equipment for these systems is located outside the containment or other areas where high activity levels or adverse environmental conditions could exist.

The RPS and ESF are capable of performing their intended functions under the following environmental service conditions:

A. All RPS and ESF components are capable of meeting their rated performance specifications under the environmental service conditions expected as a result of normal operating requirements and expected extremes in operating requirements.

B. All RPS and ESF equipment required to accomplish protective actions in response to a design basis event are capable of completing their function under the environmental service conditions related to the design basis event. The environmental service conditions related to a design basis event are specified to include normal operating conditions before the event, conditions produced by the event, and conditions existing subsequent to the event for such time as is required for the protective actions to be carried to completion.

C. The RPS and ESF equipment is capable of meeting the specified performance requirements for the most degraded conditions resulting from the long-term environment to which the equipment is normally exposed.

The required qualification envelope for equipment inside containment is defined in Section 3.11.5. Those requirements are the same for all of the equipment although some equipment may not have to operate during all phases of the accident, e.g., hydrogen recombiners and containment isolation valves. The required integrated lifetime radiation dose, including a LOCA, for all of the equipment is 3.3×10^7 rads unless otherwise documented. Because of the conservatism of the calculations which determined the above requirements, additional margin was not always a requirement. The equipment was qualified for the accident radiation level by test.

The valves listed in Table 3.11-3 are EQ motor operated valves within containment which would be submerged following a postulated LOCA. Two of these are part of the Emergency Core Cooling System (ECCS). All of these valves are designed for the environment to which they will be exposed when required to function. Valves 2CV-5647-1 and 2CV-5648-2, the sump isolation valves, are locked open and thus are not required to function in the post-accident environment. The other valves will have completed their isolation function before they are submerged and will not be required to function again.

Ferrous surfaces of equipment exposed to the containment atmosphere had the following protective coating systems installed during construction:

A. Liner plate dome, walls, structural steel and miscellaneous steel were coated with an inorganic zinc primer. The liner plate is finish painted with a modified phenolic or epoxy to a height of five feet above all grating platforms, to a depth of three feet, six inches below all grating platforms, to a height of five feet above concrete floors, and surrounding penetrations. All remaining liner plate walls from the spring line down, including the brackets for the polar crane rail are finish painted with a modified phenolic or epoxy.

B. Mechanical and electrical equipment coatings are as follows:

   1. Polar Crane: Epoxy primer and epoxy finish

   2. H&V Equipment: Modified phenolic or epoxy primer and finish

   3. CEDM Cooling Unit Fans: Baked on epoxy primer and baked on epoxy enamel

   4. Safety Injection Tanks: Inorganic zinc primer

C. Carbon steel pipes, valves, and hangers are primed with an inorganic zinc primer.

Repairs of damaged coatings may use reformulated replacement coatings that contain materials different than the previous coatings, may not require a primer, and may not be the same type (e.g., inorganic). Coatings and repairs are governed by Specification ANO-A-2437.

Although not currently used in the EQ program, originally the plant environmental service conditions were classified in the following environmental design categories:

I-A Short-term containment environment following a LOCA or MSLB accident;
I-B Long-term containment environment following a LOCA or MSLB accident;
I-C Containment environment following all other accidents;
I-D Control room environment following all other accidents; and
I-E Auxiliary building environment following LOCA.

The environmental conditions specified in procuring components in each category are given in Table 3.11-1. The radiation environment specified for Categories I-A and I-B is based on a LOCA fission product release source consisting of 25 percent of the core halogen inventory, 100 percent of core noble gas inventory and one percent of core solid fission product inventory.

Instrumentation located inside the containment which must function while subject to severe environment caused by either a LOCA or an MSLB was designated as Category I-A or I-B. These safety system instruments are intended to limit the effects of the accident by initiating or monitoring Engineered Safety Features (ESF) and include pressurizer pressure and level and steam generator pressure and level. Containment pressure, also required to initiate and monitor engineered safety features, was categorized as I-B.

Additional instrumentation located inside the containment is not required to initiate or monitor engineered safety features after the LOCA or MSLB accident and was categorized as I-C. Category I-C included such instrumentation as out-of-core neutron detectors, reactor coolant temperature detectors, reactor coolant pump speed sensors, and Control Element Assembly (CEA) position indicators (reed switch assemblies). Since these Category I-C instruments do not provide information required subsequent to the design accident, they do not have the survival requirements that were imposed on Category I-A or I-B instruments.

Equipment in Category I-D is designed to withstand continuous temperatures of 104 °F, which is considered a mild environment.

Following a LOCA, service water may be recycled through the emergency cooling pond. In this event, the maximum expected pond temperature is less than 116 °F, and equipment originally classified as Category 1E may experience the temperatures shown in Table 3.11-1.

3.11.1 EQUIPMENT IDENTIFICATION

The current EQ program (see Section 3.11.5) identifies equipment required to be environmentally qualified in accordance with 10CFR50.49 and IEB 79-01B.

RPS and ESFAS components were originally classified according to the environmental design categories described above dependent upon their location and functional requirements. The components listed in each category were procured to operate in the temperature, pressure, humidity, and radiation environment for the time shown in Table 3.11-1. Components in Categories I-A and I-B are designed to withstand the environmental conditions shown in the table in addition to long-term operation in Category I-C environment.

The following equipment was included in each category:

Category I-A

Pressurizer pressure sensors
Steam generator pressure sensors
Valves and valve controllers for the Safety Injection System (SIS), CIS, and CSS
Electrical cables and penetration assemblies for the above

Category I-B

Containment sump level sensors
Containment spray headers
Containment cooling units
Containment recirculation fans
Hydrogen recombiners
Associated valves and piping for the above
Electrical cable & penetration assemblies for the above
Pressurizer pressure sensors
Pressurizer level sensors
Steam generator pressure sensors
Steam generator level sensors
Containment pressure sensors
Containment radiation sensors

Category I-C

Reactor coolant temperature sensors
Reactor coolant pump speed sensors
Out of core neutron detectors
CEA position indicators (reed switch assemblies)

Category I-D

RPS cabinets
ESFAS measurement and actuation cabinets
RPS trip switchgear

Category I-E

High pressure safety injection pumps and motors
Low pressure safety injection pumps and motors
Containment spray pumps and motors
Shutdown cooling heat exchangers
All automatically activated and remotely actuated valves, controllers, and instrumentation associated with the above
Hydrogen analyzers
Associated valves and piping for the above
Cooling unit fans and motors for the purpose of cooling rooms where motors driving safety equipment are located, to include:
- Shutdown cooling heat exchanger room unit coolers
- High pressure safety injection pump room unit coolers
- Charging pump room unit coolers
- ESF switchgear room unit coolers
- Auxiliary building electric equipment room unit cooler
- Auxiliary building emergency diesel generator room exhaust fan
- Penetration rooms ventilation system
- Control room emergency air conditioner units
- Control room emergency supply air unit

Auxiliary electrical equipment for ESF:
- 4.16 kV switchgear (Bus 2A3, 2A4 and 2A5)
- 4160-480-volt load center transformers (2X25 and 2X26)
- 480-volt load centers (Bus 2B5 and 2B6)
- 480-volt motor control centers (2B51, 2B52, 2B53, 2B54, 2B61 2B62, 2B63, 2B64)

120-Volt vital AC distribution panels (2RS1, 2RS2, 2RS3, and 2RS4)
DC Equipment for ESF:
- Battery bank #1 (2D11)
- Battery bank #2 (2D12)
- Inverter channels 1-4 (2Y11, 2Y22, 2Y13, 2Y24, 2Y1113, and 2Y2224)
- DC motor control center 2D01 and 2D02
- DC power and distribution panels

Cables and raceways associated with the ESF system
Containment isolation valves and valve controllers
Emergency diesel generators to include:
- Starting air tanks
- Jacket CW heat exchanger
- Lube oil coolers
- Air after coolers
- Associated valves and instrumentation

Refueling water tank level sensors
Containment atmosphere monitors (gaseous only)
Emergency Feedwater System Pump MOVs:
- Turbine drive steam admission valves
- 2P7B suction valve from SW header
- 2P7B suction valve from condensate

3.11.2 QUALIFICATION TESTS AND ANALYSES

As specified by the current EQ program (see Section 3.11.5), electrical equipment is qualified by test and/or analysis in accordance with 10CFR50.49 and IEB 79-01B.

Seismic qualification of original plant Class 1 equipment was completed using IEEE 344-1971 as a guide. Seismic qualification of non-original plant Class 1 equipment was completed using the guidance of IEEE 344-1971, 1975, or 1987.

Isolation valve motor operators located within the containment were designed to operate during and/or after an accident in accordance with IEEE 382-1972 and supplementary requirements of Regulatory Guide 1.73, "Qualification Test of Electric Valve Operators Installed Inside the Containment of Nuclear Power Plants." The qualification documentation was in accordance with IEEE 323-1971 (although it is now required to be in conformance with 10 CFR 50.49).

All seismic, normal and accident environmental conditions are specified in the valve design specifications.

The containment cooling units, recirculation fan units and reactor cavity booster fan motors are of the same type and construction as a prototype that has successfully completed the test outlined by IEEE 334-1971 "Guide for Type Tests of Continuous Duty Class 1 Motors Installed Inside the Containment of Nuclear Power Generating Stations."

3.11.2.1 <u>Category I-A and I-B Equipment (Original Classification)</u>

The equipment was qualified for the specified environmental conditions by a combination of type testing and analysis. Type tests are performed wherein the components are subjected to the specified temperature, pressure and humidity conditions. The components were operational during these tests. No zero or span adjustments were allowed during the tests. The acceptance criteria for instrument sensors were:

A. During the test the calibration must not change more than plus or minus five percent.

B. The post test calibration must be within plus or minus one percent of the pretest values.

The containment fan cooler motors were qualified in accordance with IEEE 334-1971, "IEEE Trial-Use Guide for Type Tests of Continuous-Duty Class 1 Motors Installed Inside the Containment of Nuclear Power Generating Stations."

3.11.2.2 <u>Category I-C, I-D and I-E Equipment (Original Classification)</u>

This equipment was rated for continuous operation under the specified conditions. Since the extremes of the temperature, pressure and humidity conditions are within the design ratings of standard commercial components, qualification was accomplished by requiring vendor certification of the required capability and supporting documentation of test results or operating experience on similar equipment.

The requirement for meeting the specified performance requirements from the most degraded conditions resulting from long-term environmental effects was met by limiting the amount of degradation allowed. The periodic test and calibration program described in the Technical

Specifications verifies the capability of the equipment to meet the original performance requirements. Periodic testing allows detection of any gradual equipment deterioration and effectively re-qualifies the equipment for the short-term operational period between tests.

3.11.3 QUALIFICATION TEST RESULTS

3.11.3.1 Categories I-A and I-B

Equipment in Categories I-A and I-B is qualified in accordance with the requirements of 10 CFR 50.49 to the conditions specified in Table 3.11-2 as documented by ANO Environmental Qualification - Environmental Conditions, Engineering Standard NES-13. For a historical reference to the original qualification information refer to the ANO-2 Final Safety Analysis Report (FSAR).

3.11.3.2 Category I-C, I-D and I-E

The equipment in this category (except for the electrical trip switchgear) is standard instrument packages for which the vendors specifically certified the individual equipment's capability to meet the operating environments as delineated in the purchase specification. These conclusions were based on a combination of type testing and proven operating capability in similar environments in industrial and previous nuclear power plant applications.

3.11.4 LOSS OF VENTILATION

The control room is normally air conditioned by four 100 percent capacity air conditioning units receiving chilled water from four 100 percent capacity chillers (two for Unit 1 and two for Unit 2). One air conditioning unit from each unit is normally running, with the others in standby status, available for manual actuation in the event of failure of the operating units. In the unlikely event that all four of the normal chilling systems and the emergency air conditions systems fail, the maximum temperature in the control room will be 115 °F Dry Bulb (DB) using forced circulation with outside air. In the event of a failure of all fans and subsequent isolation of the control room from the outside air, either of the emergency air conditioning units located in ANO-2 will cool the control room and instrumentation adequately to permit safe shutdown of both units. The emergency air conditioning units were originally sized such that, if all off-site power was lost and either of the emergency air conditioning units starts, the maximum temperature of the control room would be approximately 84 °F DB. The worse case outside environment assumed for this analysis is 103 °F DB, 83 °F Wet Bulb (WB) and 43 percent relative humidity maximum and is based on records of ambient conditions at the site.

All components of the RPS and ESFAS which are located in the control room are designed to operate in ambient conditions of 104 °F and 90 percent relative humidity. The heat loads within the RPS and ESFAS cabinets are low and the cabinets do not require specific air conditioning ducting. Forced air cooling of each PPS bay is provided by redundant 260 cfm fans.

Individual components and modules of the RPS have been specified to require factory testing at design temperatures and humidity conditions. Similar RPS cabinets, including all portions of the system located in the control room, have been tested as a system at temperatures in excess of the 104 °F design limit. Additional information on environmental testing performed on the PPS has been provided in CE Test Report 00000-ICE-3712.

3.11.5 CURRENT ENVIRONMENTAL QUALIFICATION PROGRAM

The current environmental qualification program is based on 10 CFR 50.49, "Environmental qualification of electric equipment important to safety for nuclear power plants," and IEB 79-01B, Enclosure 4, "Guidelines for Evaluating Environmental Qualification of Class 1E Electrical Equipment in Operating Reactors" (commonly known as the DOR Guidelines).

Promulgated in 1983, 10 CFR 50.49 is applicable to electrical equipment important to safety located in a harsh environment, which includes safety-related equipment, non-safety-related equipment whose failure could adversely affect a safety-related component, and certain post-accident monitoring equipment. Excluded from its scope are requirements for seismic and dynamic qualification, protection against other natural phenomena and external events, and qualification of equipment located in mild environments. A mild environment is defined in 10 CFR 50.49 as an environment that would at no time be significantly more severe than the environment that would occur during normal plant operation, including anticipated operational occurrences.

10 CFR 50.49 requires that licensees perform the following:

1. Establish a program for qualifying electrical equipment important to safety;

2. Prepare and maintain a list of equipment important to safety,

3. Establish and maintain a qualification file which includes details about each item of electrical equipment required to be qualified;

4. Qualify the equipment based on factors such as temperature, pressure, humidity, radiation, etc;

5. Qualify equipment by one of the following methods:
   testing of an identical component under required conditions,
   testing a similar equipment item with supporting analysis,
   use of experience with supporting analysis, or
   analysis in combination with partial type test data that supports the analytical assumptions and conclusions;

6. Maintain the qualification file in an auditable form during the entire period of storage for future use and installation within the plant; and,

7. Qualify replacement equipment to 10 CFR 50.49 requirements unless there are sound, documented reasons to the contrary.

Licensees were exempted from requalifying equipment to 10 CFR 50.49 requirements if the equipment was previously qualified to prior regulations (such as IEB 79-01B).

ANO established an Environmental Qualification (EQ) Program based primarily on the requirements of the DOR Guidelines. The ANO EQ Program compliance to 10 CFR 50.49 is based in part on the exemption granted for equipment previously qualified to IEB 79-01B. The EQ Program is described in engineering standards and is administratively controlled by plant procedures.

The current list of equipment required to be EQ (the EQ Master List, or EQML) is maintained by the controlling plant database (such as equipment database/component database). Though the specific qualification requirements of 10 CFR 50.49 did not apply to all equipment at ANO (i.e., some items are 79-01B equipment), ANO was required to demonstrate that the scope requirements had been addressed. ANO achieved this through the programmatic development of its EQML.

The environmental conditions at ANO have been determined specifically for the EQ Program. These conditions include normal temperature, pressure, humidity, and radiation, as well as accident (LOCA/HELB) temperature, pressure, humidity, radiation, chemical spray, and submergence. These environmental conditions are incorporated into a single document for ease of use. SAR Section 6.2 and figures in Chapter 6 provide the containment DBA temperature and pressure profiles used in the qualification process to qualify the equipment. Procedural controls identify potential EQ Program impact when plant environmental conditions are revised. The plant environmental conditions are included within the EQ Program evaluation and documentation process. At ANO, a harsh environment exists if the accident temperature exceeds 140 °F or the total normal plus accident radiation dose exceeds 5.0E+4 rads (total integrated dose).

For equipment important to safety located inside containment, the two accident conditions considered were the MSLB and LOCA. These pipe breaks envelop all other potential HELBs for equipment inside containment. With respect to the MSLB, IE Bulletin 79-01B (Section 4.2 of the DOR Guidelines) states that equipment qualified for a LOCA environment is considered qualified for a MSLB environment in plants with automatic spray systems not subject to disabling single component failures. Therefore, the LOCA temperature profiles are used in lieu of the MSLB (inside containment) temperature conditions. This provision is considered applicable to equipment evaluated against 79-01B and for equipment purchased to 10 CFR 50.49.

Outside containment, a harsh environment may be created by HELBs or recirculating fluids from inside containment. Electrical equipment important to safety located in these environments is also environmentally qualified.

The EQ Program has an established process to evaluate and document the qualification of EQ equipment. This process is described and administratively controlled by engineering standards and procedures. The evaluation process identifies and evaluates information including component identification, qualification rules, service conditions, qualified parameters, interfaces, installation details, and comparison of required versus qualified environmental conditions. This process addresses various attributes of qualification including similarity, synergistic effects, margins, sequential tests, use of analysis, test anomalies, and qualification methods. It also includes evaluating, identifying, and documenting requirements necessary to maintain the qualification of EQ equipment. Requirements necessary to maintain qualification are integrated into plant activities to ensure compliance with the EQ Program. Documentation associated with or produced from the evaluation process is maintained within the records management system as an auditable record of qualification.

STRUCTURES, SYSTEMS AND COMPONENT CLASSIFICATION

Category 1	Category 2
A. Plant features required to assure (1) the integrity of the reactor coolant pressure boundary, (2) the capability to shut down the reactor and maintain it in a safe shutdown condition, or (3) the capability to prevent or mitigate the consequences of accidents which could result in potential off-site doses comparable to the guideline doses of 10 CFR Part 100.	A. Plant features not required to assure (1) the integrity of the reactor coolant pressure boundary, (2) the capability to shut down the reactor and maintain it in a safe shutdown condition, or (3) the capability to prevent or mitigate the consequences of accidents which could result in exposures comparable to the guideline exposures of 10 CFR Part 100.
B. Plant features required to meet AEC GDC-1 of Appendix A to 10 CFR Part 50 and Appendix B of 10 CFR Part 50.	B. Plant features not required to meet AEC GDC-1 of Appendix A to 10 CFR Part 50 and Appendix B to 10 CFR Part 50.
C. Plant features required to meet AEC GDC-2 of Appendix A to 10 CFR Part 50 and proposed Appendix A to 10 CFR Part 100. Plant features designed to withstand effects of the Design Basis Earthquake.	C. Plant features not required to meet AEC GDC-2 of Appendix A to 10 CFR Part 50 and proposed Appendix A to10 CFR Part 100. Plant features not designed to withstand the effects of the Design Basis Earthquake.

Category 1			Category 2
Quality Group A	Quality Group B	Quality Group C	Quality Group D
Category 1 components of the reactor coolant pressure boundary whose failure during normal operations would prevent orderly shutdown and cooldown assuming makeup is provided by normal makeup systems.	Components of the reactor coolant pressure boundary not included in Quality Group A or components of fluid systems directly required for emergency core cooling, post accident containment heat removal, reactor shutdown, or containment integrity.	Fluid system components not part of the reactor coolant pressure boundary nor included in Quality Group B. These include cooling water or emergency feedwater systems indirectly required for emergency core cooling, post accident containment heat removal, reactor shutdown, or radioactive gas holdup systems.	Category 2 fluid system components which are not essential for safe shut down of the nuclear systems and equipment. Failure of such equipment could cause loss of power generation but would not endanger public safety. This group includes systems which contain radioactive material but whose failure could not release quantities of radioactive material sufficient to endanger public safety.

Table 3.2-2 (continued)

GENERAL NOTES:

1. Seismic 1 classification necessitates Q-listing and the Q-list is defined to include all Category 1 structures, systems, and equipment.

2. For further definition of Seismic Category 1 boundaries, see the specific system P&ID. To locate the P&ID, see Table 1.7-2.

3. All Seismic Category 1 electrical equipment (Electrical Category 1E) that would otherwise be included in this table is listed in Table 8.3-2.

4. All containment penetration piping and containment isolation valves are Seismic Category 1 and Q-listed.

5. All Seismic Category 1 piping is supported by Seismic 1 supports. In addition, at Seismic Category 1/Seismic Category 2 interfaces, the Seismic Category 2 pipe is supported with Seismic Category 1 supports up to the first pipe anchor.

6. Seismic classification of control and instrumentation devices is appropriate to that of the associated piping or equipment.

7. A more detailed listing of "Q" listed components is contained in the component level Q list (See Table 3.2-6.)

Table 3.2-3

EQUIPMENT CODE GROUP CLASSIFICATION

Components	Code Group	Code: Before 7/1/71	Code: After 7/1/71
Reactor Coolant System			
Reactor Vessel	A	ASME III, Class A	
Steam Generator	A	ASME III, Class A	ASME III, Class 1
Pressurizer	A	ASME III, Class A	
Reactor Coolant Pump	A	ASME III, Class A	
Reactor Coolant Piping	A	ASME III, Class A	
Quench Tank	C	ASME VIII, Div. 1	
Pressurizer Safety Valves	A	ASME P&VC, Class I	
Chemical & Volume Control System			
Regenerative Heat Exchanger	B/B		ASME III, Class 2 ASME III, Class 2
Letdown Heat Exchanger	B/C		ASME III, Class 2 ASME III, Class 3
Purification Ion Exchanger	B	ASME III, Class C	
Deborating Ion Exchanger	B	ASME III, Class C	
Volume Control Tank	B	ASME III, Class C	
Charging Pumps	B	ASME P&VC, Class II	
Boric Acid Makeup Tank	B	ASME III, Class C	
Boric Acid Makeup Pumps	B		ASME III, Class 2
Purification Filter	B		ASME III, Class 2
Chemical Addition Tank	D		ASME VIII, Div. 1 (Guide Only)

0-15 psig Storage Tanks	N/A	API-620 with Supplementatry NDE Req. per ASME III, Class C rules	API-620 with Supplementatry NDE Req. per ASME VIII, Div. 1	API-620	Before 7/1/71 See Note (a)
	N/A	ASME III, Class 2	ASME III, Class 3, or ASME VIII, Div. 1	API-620	After 7/1/71 See Note (b)
Atmospheric Storage Tanks	N/A	API-650 or AWWAD100 with Supplementary NDE Req. per ASME III, Class C	API-650 or AWWAD100 with Supplementary NDE Req. per ASME III, Div. 1	API-650 or AWWAD100	Before 7/1/71 See Note (a)
	N/A	ASME III, Class 2	ASME III, Class 3 or ASME VIII, Div. 1	API-650 or AWWAD100	After 7/1/71 See Note (b)

Table 3.2-4 (continued)

Component(f)	Group A	Group B	Group C	Group D	Comments
Piping	ANSI B31.7, Class I	ANSI B31.7, Class II	ANSI B31.7, Class III	ANSI B31.1.0	Before 7/1/71 See Note (a)
	ASME III, Class 1	ASME III, Class 2	ASME III, Class 3	ANSI B31.1.0	After 7/1/71 See Note (b)
Pumps & Valves	ASME P & VC, Class I	ASME P & VC, Class II	ASME P & VC, Class III	Valves – ANSI B31.1.0 Pumps - ASME VIII, Div. 1 See Note (c)	Before 7/1/71
Pumps & Valves	ASME P & VC, Class I	ASME P & VC, Class II	ASME P & VC, Class III	Valves – ANSI B31.1.0 Pumps - ASME VIII, Div. 1 See Note (c)	After 7/1/71

Table 3.2-4 (continued)

General Notes:

(a) ASME III means ASME Boiler and Pressure Vessel Code, Section III, 1968, Nuclear Vessels plus addenda and Code interpretations to date of purchase award or later appropriate ASME Section III Code sections provided that they have been reconciled.

ASME VIII, Division 1 means ASME Boiler and Pressure Vessel Code, Section VIII, Pressure Vessel Division 1, 1968 Edition, plus addenda and Code interpretations to date of purchase award.

ANSI B31.7 means ANSI B31.7 - 1969, Nuclear Power Piping plus addenda and Code interpretations to date of purchase award or later appropriate ASME Section III Code sections provided that they have been reconciled.

ASME P & VC means the November 1968 Draft ASME Code for Pumps and Valves, plus addenda and Code interpretations to date of purchase award.

ANSI B31.1.0 means ANSI B31.1.0 - 1967 Power Piping Code plus addenda and Code interpretations to date of purchase award.

(b) For purchase awards on or after July 1, 1971, reference to ASME III, ANSI B31.7 and Draft ASME P & VC should be to ASME Boiler and Pressure Vessel Code, Section III 1971, Nuclear Power Plant Components plus addenda and Code interpretations to date of purchase award or later appropriate ASME Section III Code sections provided that they have been reconciled. Reference to ASME VIII Division 1 should be to ASME Boiler and Pressure Vessel Code, Section VIII, 1971, Pressure Vessels plus addenda and Code interpretations.

(c) Section VIII, Division 1, of the Boiler and Pressure Vessel code shall be used as a guide in calculating the thickness for pressure rated parts and sizing the cover bolting of pumps operating above 150 psig and 212°F. Below 150 psig and 212°F, use manufacturer's standard for service intended.

(d) Refer to Chapter 5, "Reactor Coolant System", for reactor pressure vessel requirements.

(e) The Containment Vessel is ASME III, Class B.

(f) "Component" refers only to process equipment, Instrument sensing lines up to and including the first process shutoff valve (root valve) are fabricated and installed to the same quality standards as the associated process component. Downstream of the root valve, instrument lines are fabricated and installed in accordance with ASME Section III, Class 3. This exceeds the Unit 2 PSAR commitment to design instrument lines to ANSI B31.1.0 (see Unit 2 PSAR section A.2.1).

(g) The steam generators are constructed to the requirements of the ASME Code, Section III, 1989 Edition, no Addenda.

Table 3.2-5

COMPONENTS BUILT TO CODES OTHER THAN THOSE SPECIFIED IN REGULATORY GUIDE 1.26

Reactor Coolant System

Quench Tank - Quality Group C; ASME VIII, Division 1.

Specifications required full RT of Category A, B, C butt welds over 3/16-inch thickness, MT or PT under 3/16-inch, MT or PT root and final pass of all nozzle welds, submittal of welding and cleaning procedures and code calculations for CE review, and a Manufacturing and Quality Control Plan in accordance with CE Specification WQC-11.1 (See Chapter 17 of the Unit 2 FSAR).

Chemical and Volume Control System

Purification Ion Exchangers* & Deborating Ion Exchanger*, - Quality Group B; ASME III, Class C. Specification required full RT of shell and nozzle butt welds, PT root and final pass of nozzle welds, submittal of welding, cleaning, hydro, PT, RT procedures and code calculations for CE review, and a Manufacturing and Quality Control Plan in accordance with CE Specification WQC-11.1.

Volume Control Tank* and Boric Acid Makeup Tanks*, - Quality Group B; ASME III, Class C. Specification requirements were same as for Quench Tank.

Charging Pumps - Quality Group B; ASME Pump and Valve Code, Class II. Specification required performance tests in accordance with PTC 7.1 of the ASME Power Test Code followed by disassembly and visual inspection, and a Manufacturing and Quality Control Plan in accordance with CE Specification WQC-11.1.

Chemical Addition Tank and Boric Acid Batching Tank - Quality Group D; ASME VIII, Division 1 used as a guide. Specification required weld design and PT in accordance with ASME VIII, welder qualification and materials in accordance with ASME IX, submittal of welding, cleaning and PT procedures for CE review, and a Manufacturing and Quality Control Plan.

Reactor Makeup Water Pumps - Quality Group D; Hydraulic Institute Standards. Specification required final acceptance inspection by Bechtel.

* While these components are normally used during plant shutdown, they are not absolutely required for plant shutdown and could be considered quality group D. Associated piping and valves are designed to ASME III, Class 2 requirements.

Table 3.2-5 (continued)

Safety Injection System

Shutdown Cooling Heat Exchangers - Quality Group B and ASME III, Class 3 (reactor coolant side); Quality Group C and ASME VIII, Division 1 (Service Water Side). Specification required PT of tube-to-tubesheet welds, post weld heat treatment in accordance with ASME III and VIII, full RT of Category A,B,C welds, MT or PT root and final pass of nozzle welds, PT of clad surfaces, UT of clad bonding, bubble test of tube-to-tubesheet welds, submittal of welding and cleaning procedures and code calculations for CE review, weld procedure qualification in accordance with ASME III, and a Manufacturing and Quality Control Plan in accordance with CE Specification WQC-11.1.

Boron Management System

Reactor Drain Tank - Quality Group C; ASME VIII, Division 1.

Specification requirements were same as for Quench Tank.

Degasifier Effluent Pumps - Quality Group D; Hydraulic Institute Standards and ASME VIII, Division 1 for pressure-containing parts. Specification required PT of root and final pass and full RT of Category A, B, and C welds, hydrostatic test in accordance with ASME VIII, and submittal of weld procedures, welder qualifications, cleaning and NDE procedures for Bechtel approval.

Holdup Tanks - Quality Group C; API-620 and ASME VIII, Division 1. Specification required PT of all welds, submittal of welding, PT, and cleaning procedures for CE review, and a Manufacturing and Quality Control Plan.

Holdup Tank Drain Pumps, Holdup Recirc. Pump, Boric Acid Condensate Pumps - Quality Group D; Hydraulic Institute Standards. Specification required CE shop inspection.

Waste Management System

Waste Tanks, Waste Condensate tanks, Resin Addition Tank - Quality Group D; ASME VIII, Division 1 used as a guide. Specification requirements were same as for Chemical Addition Tank.

Waste Condensate Pumps, Waste Pumps - Quality Group D; Hydraulic Institute Standards. Specification requirements were same as for Holdup Tank Drain Pumps.

Auxiliary Building Sump Pumps - Quality Group D; Hydraulic Institute Standards. Specification required submittal of weld procedures for Bechtel Approval.

Gas Surge Tank, Gas Decay Tanks - Quality Group C; ASME VIII, Division 1. Specification requirements were same as for Quench Tank.

Solid Radioactive Waste System

Bottoms Transfer Pump-Quality Group D; Hydraulic Institute Standards.

Table 3.2-5 (continued)

Fuel Pool System

Fuel Pool Heat Exchangers - Quality Group C; ASME VIII, Division 1 (fuel pool side), Quality Group D; ASME VIII, Division 1 (Service Water side). Specification required material mill test reports, submittal of inspection and test procedures for CE review, a Manufacturing and Quality Control Plan, and NDT as required for the Shutdown Cooling Heat Exchanger.

Fuel Pool Ion Exchanger - Quality Group C; ASME VIII, Division 1. Specification requirements were same as for the Chemical and Volume Control System Ion Exchangers.

Component Cooling Water System

Component Cooling Water Pumps - Quality Group D; Hydraulic Institute standards. Specification required submittal of weld procedures for Bechtel approval.

Emergency Diesel Generator System

Emergency Fuel Oil Tanks - Quality Group C; ASME VIII, Division 1. Specification required welding in accordance with Bechtel standards and submittal of welding and RT procedures for Bechtel approval.

Emergency Diesel Generators - Quality Group C; ASME VIII, Division 1. Specification required a fully-documented Quality Assurance Program including a description of the vendor's organization, activities, procedures, training, etc., to control quality; submittal of welding procedures for Bechtel approval was also required.

Table 3.2-6

QUALITY ASSURANCE

SUMMARY LEVEL Q-List

GENERAL

The purpose of this "Summary Level" Q-List (SLQL) list is to generally identify those items required to be within the scope of the ANO Quality Assurance Program. Items listed require special consideration during design, manufacture, construction, operation and maintenance as described by Quality Assurance Program Manual (QAPM).

The SLQL is divided into five major sections:

1. CIVIL STRUCTURAL
2. NUCLEAR MECHANICAL
3. CONVENTIONAL MECHANICAL
4. AUXILIARY ELECTRICAL
5. ARCHITECTURAL

NOTES:

1. The designation "Penetration piping" defines the piping connecting to the containment penetration up to the first external and internal isolation valves on either side of the penetration.

2. When structures, systems or equipment as a whole are on this list, portions not associated with a loss of safety function are not meant to be included. The CLQL identifies the specific components that are Q (safety related).

3. Civil-Structural items required to be within the scope of the Nuclear Quality Assurance Program are limited to the following:

   Containment
   Auxiliary building housing the engineered safety features, emergency diesel generators, control room and radioactive materials.
   Emergency diesel fuel tank vaults.
   Intake structure housing service water pumps.
   Supports for Seismic Category 1 system components.
   Emergency Pond and pipelines.
   Spent Fuel Pool (Excluding Liner Plate)

4. Safety-related materials and equipment were purchased to one of the corresponding specifications listed (if a specification is referenced). Not all items purchased to these specifications are used in safety-related functions, i.e., classified as “Q”.

This SLQL is provided as general reference information only. It preserves the summary level information provided in previous amendments of the SAR "Q-List" with the exception of "Q-numbers", which are no longer used, and "Line or Equip. numbers." A detailed "Component Level Q-List" (CLQL) has been implemented which provides classification of "Q" devices at the component level.

Table 3.2-6 (continued)

A classification of "Q" whether for the CLQL or SLQL is generally intended to be synonymous with the term "Safety-Related" in accordance with criteria of 10 CFR 100, Appendix A. Consequently, the CLQL and SLQL are intended to encompass those structures, systems and components required to assure:

- The integrity of the reactor coolant pressure boundary,
- The capability to shutdown the reactor and maintain it in a safe shutdown condition, or
- The capability to prevent or mitigate the consequences of accidents which could result in potential off site doses comparable to the guideline exposures of 10 CFR 100.

Some non-Safety Related components are included on the list because they are required to be designed to withstand the Design Basis Earthquake.

	Piping Thermal Wells with RTD	277	100.92	1.75	Edge of Solid Disk 2-3/4" Diameter And 1/2" Thick
VII.	Main Coolant				
	Thermal Well with RTD	1095	93.85	8	Edge of Solid Disk 2-3/4" Diameter And 1/2" Thick

Notes:

(1) Missile material is assumed to be entirely steel.

(2) Missile impact orientation is assumed to be the orientation which presents the minimum projected area.

(3) The selection of potential missiles is based on the application of a single-failure criteria to the normal retention features of plant equipment for which there is a source of energy capable creating a missile in the event of the postulated removal of the normal retention features. Where redundancy is provided by the normal retention features such that sufficient retention capability remains to prevent creation of a missile in the event of a postulated failure of a single retention feature, no potential missile is postulated.

(4) Replacement pressurizer heater is not considered as a potential missile because the likelihood of a complete circumferential weld (between the heater and heater sleeve) failure leading to the ejection of a heater is not credible. The following is the justification for the same:

- The weld is designed as a structural weld that meets the ASME Code Case N-405-1 requirements for connecting appurtenances to nozzles of ASME Section III, Division 1, Class 1 vessel.
- The weld is examined by liquid penetrant (PT) method for multiple passes.
- The weld is inspected per NB-5350 of the ASME Code, Section III, with indications limited to 1/64 inch rather than 3/16 inch recommended by the Code.
- The weld is located at the outer extension of the heater sleeve away from the heating element and has a limited exposure to the reactor coolant, and there are no significant additional externally applied thermal or mechanical loadings.

Table 3.5-5A

SELECTED PRESSURIZED COMPONENT MISSILE CHARACTERISTICS FROM OTHER THAN NSSS
(Inside Containment)

	Item	Kinetic Entergy	Impact Velocity (ft/sec)	Weight (lb)	Impact Section
I.	Main Steam				
	A. Thermal Well with Element	542.5	66.08	8	Edge of solid disk 2-3/4” diameter and 1/2" thick
	B. Pressure Test Connection (Two Valves with 3/4" pipe nipple)	542.5	53.96	12	Annular Ring ID = 1.0” OD = 1.6”
	C. Hydrostatic Vents (Two 3/4" Gate Valves with pipe nipple)	542.5	53.96	12	Annular Ring ID = 1.0” OD = 1.6”
	D. Hydrostatic Drains (Two 1” Gate Valves with pipe nipple)	542.5	51.84	13	Annular Ring ID = 1.25” OD = 1.8”
II.	Feedwater				
	A. Thermal Well with Element	780	79.24	8	Edge of solid disk 2-3/4” diameter and 1/2" thick
	B. Pressure Test Connection (One 3/4" Root Valve with 3/4" pipe nipple)	780	95.57	5.5	Annular Ring ID = 1.0” OD = 1.7”
	C. Drains (Two 1” Gate Valves with pipe and nipple)	780	56.03	16	Annular Ring ID = 1.25” OD = 1.9”

Table 3.5-5A (continued)

	Item	Kinetic Entergy	Impact Velocity (ft/sec)	Weight (lb)	Impact Section
III.	Sample System				
	Pressure Test Connections (One 3/4" Root Valve with pipe nipple)	550	80.23	5.5	Annular Ring ID = 1" OD = 1.6"
IV.	Miscellaneous				
	Valve Bonnet Bolt (Bolt used for example was 3/4" diameter and 7-1/2" long)	77	72.89	1.0	Solid Circle 3/4" in diameter

NOTES:

(1) Missile material is assumed to be entirely steel.

(2) Missile impact orientation is assumed to be the orientation which presents the minimum projected area.

(3) The selection of potential missiles is based on the application of a single-failure criteria to normal retention features of plant equipment for which there is a source of energy capable of creating a missile in the event of the postulated removal of the normal retention features. Where redundancy is provided by the normal retention features such that sufficient retention capability remains to prevent creation of a missile in the event of a postulated failure of a single retention feature, no potential missile is postulated.

Table 3.5-5B

SELECTED PRESSURIZED COMPONENT MISSILE CHARACTERISTICS
(Auxiliary Building)

Item and Line No.	Fig. Ref.	Weight (lb)	Impact Velocity (ft/sec)	Kinetic Entergy (ft-lb)	Impact Diameter (in.)

	C. Hydrostatic Vent – 2DBB-3-4” (Two 3/4"" Gate Valves with pipe and nipple)	3.5-17	33.2	11.1	63.6	1.375
V.	SG Blowdown					
	A. Pressure Test Connection – 2DBD-10-4” (Two 3/4" Root Valves with pipe and nipple)	3.5-10	19.1	14.0	58.5	1.375
	B. Hydrostatic Vent – 2DBB-8-4” (Two 3/4"" Gate Valves with pipe and nipple)	3.5-10	33.2	10.8	60.4	1.375

NOTES:

(1) Missile material is assumed to be entirely steel.

(2) Missile impact orientation is assumed to be the orientation which presents the minimum projected area.

(3) The selection of potential missiles is based on the application of a single-failure criteria to the normal retention features of plant equipment for which there is a source of energy capable of creating a missile in the event of the postulated removal of the normal retention features. Where redundancy is provided by the normal retention features such that sufficient retention capability remains to prevent creation of a missile in the event of a postulated failure of a single retention feature, no potential missile is postulated.

Table 3.5-6

TORNADO MISSILE CHARACTERISTICS

Item	Weight (Lbs)	Impact Area (Sq/Ft)	Maximum Velocity (Ft/Sec)	Kinetic Energy (Ft/Lbs)
1. A wood plank, 4-inches by 12-inches in cross section, weighing 108 lbs., traveling end on at a speed of 300 mph, striking the structure at any elevation.	108	0.333	440	3.25×10^5
2. A steel pipe, Schedule 40, 3-inches in diameter by 10-feet long, weighing 75.8 lbs., traveling end on at 100 mph, striking the structure at any elevation.	75.8	0.063	147	2.54×10^4
3. An automobile of 4000 lbs. weight, striking the structure at 50 mph on a contact area of 20 sq. ft., any portion of the impact being not more than 25 ft. above grade.	4000	20.0	73.5	3.36×10^5

Table 3.5-8

SAFETY-RELATED COMPONENTS LOCATED OUTDOORS

Component	Location	Seismic Design Category	Protection from Tornado Generated Missiles	Remarks
Intake Structure Exhaust Fans and Air Intake	Fig. 3.5-7	I	Yes	
Emergency Diesel Generator Rooms Air Intake & Exhaust Fans	Figs. 3.5-5 and 3.5-6	I	Yes	See Section 9.4.2.4 for detail
Penetration Room Ventilation System Exhaust	Fig. 3.5-6	I	No, destruction of exhaust pipes will not jeopardize operation of system since they are downstream of the filters and absorber.	See Section 6.5 for detail
Refueling Water Tank	Fig. 3.5-4	I	No – not required for safe shutdown after a tornado	See Sections 6.2 and 6.3 for detail
Main steam lines	Fig. 3.5-6	I	No – a postulated missile cannot destroy integrity of lines	See Table Q310.16-1 for capability to withstand missiles
Emergency Diesel Generator Combustion Air Intake & Exhaust	Fig. 3.5-6 and 3.5-6	I	Intake – Yes Exhaust – No	See Table Q310.16-1 for exhaust capability to withstand missiles

Table 3.5-8 (continued)

Component	Location	Seismic Design Category	Protection from Tornado Generated Missiles	Remarks
Service Water Piping Between ECP and Intake Structure / Auxiliary Building	N.A.	I	Yes – 3’ Earth	See Table Q310.16-2 for capability to withstand missiles
ECP Sluice Gate	N.A.	I	Horizontal – Yes Vertical – Yes	
Emergency Diesel Generator Fuel Storage Tanks	Fig. 3.5-1	I	Yes	

Notes:

1. Control Room, Auxiliary Building, and Fuel Handling Area ventilation air inlets and discharges are not safety-related.

2. Protection is for missiles listed in Table 3.5-6 and includes both horizontal and vertical missiles unless otherwise stated.

TABLE 3.6-1

HIGH ENERGY PIPING SYSTEMS

Service	Pipe Size	Operating Conditions upon which the high energy classification is based*
Reactor Coolant System Major Piping	30"/42#	2235 psig/582 °F(T_{avg})
Pressurizer Surge Line	12"	2235 psig/653 °F
Pressurizer Spray Lines	3"/4"	2235 psig/553 °F
Shutdown Cooling Line (2CCA-25 only)	14"	2235 psig/611 °F
Safety Injection Lines (2CCA-21, 2CCA-22, 2CCA-23, 2CCA-24 only)	12"/8"/6"/3"	610 psig/120 °F
Safety Injection Lines (2DCB-1, 2DCB-3, 2CCB-12)	4”/3”/2”	635 PSIG/40 °F
Reactor Coolant Letdown Line	2”	2235 psig/550 °F
Reactor Coolant Charging Line to Regenerative Heat Exchanger	3"/2"	2250 psig/120 °F
Reactor Coolant Charging Line from Regenerative Heat Exchanger	2"	2250 psig/479 °F
Main Steam Lines	38"	985 psig/545 °F
Main Feedwater Lines	24"	1085 psig/455 °F
Main Steam Supply to Atmospheric Dump Valves	10"	985 psig/545 °F
Main Steam Supply to Emergency Feedwater Pump Turbine Driver	4"	985 psig/545 °F
Steam Generator Blowdown Lines	4"	985 psig/545 °F
Emergency Feedwater	4"	1085 psig/85 °F
Steam Supply to Concentrators**	3"	885 psig/529 °F
Steam Supply to Concentrators**	8"	215 psig/400 °F
Steam Supply to Concentrators**	6"/10"	100 psig/400 °F

* The values listed are original design conditions and may not reflect current operating conditions. The latest pressure-temperature analyses shall be utilized for determination of pressure-temperature design inputs.

** Currently not in use.

Table 3.7-1

**SYNTHETIC TIME HISTORY RESPONSE SPECTRA-
FREQUENCY RANGES AND INCREMENTS**

Frequency Range (cps)	Frequency Increment (cps)
(1) 0.2 to 7.5	0.05
(2) 7.5 to 10	0.1
(3) 10 to 15	.5
(4) 15 to 25	1.0

Table 3.7-2

PERCENTAGE OF CRITICAL DAMPING FACTORS

Type of Structure	Operating Basis* Earthquake (E) .1g Ground Acceleration	Design Basis** Earthquake (E') .2g Ground Acceleration
Vital Piping	0.50	1.00
Welded Steel Frame Structures	2.00	5.00
Bolted and Riveted Steel	3.00	5.00
Reinforced Concrete Structures and Equipment Supports	3.00	5.00
Prestressed Concrete Structures	2.00	5.00

* The Operating Basis Earthquake condition corresponds to ordinary working stress level in design.

** The Design Basis Earthquake condition corresponds to stress level at or just below yield point in design.

*** In lieu of these values, the damping values of ASME Code Case N-411 may be used provided the analysis is performed as identified in Section 3.7.1.3.1.

Table 3.7-3

SUMMARY OF NATURAL FREQUENCIES

Category 1 Structure		Mode #1 cps.	Mode #2 cps.	Mode #3 cps.
Containment	N-S&E-W	3.8	14.5	28.8
Internal Structures	N-S	12.5	34.6	-
	E-W	12.2	35.4	-
Auxiliary Building	N-S	11.6	32.7	-
	E-W	11.4	31.5	-
Intake Structure	N-S*	19.5	59.1	-
	E-W*	9.7	27.2	-

* Because of the Intake Structure orientation, directions corresponding to N-S and E-W are actually NW-SE and NE-SW respectively.

		3	Accepted	
2P – 68	Incomplete Fusion	1	Accepted	

* All repairs consisted of excavating the unacceptable portion of the weld and rewelding.

Table 3.8-3

COMPUTER PROGRAMS USED IN THE DESIGN OF CATEGORY 1 STRUCTURES

PART I - PROGRAM INDEX

STRUCTURE	PROGRAMS USED
Containment	CE 316, CE 611 A & B, CE 639-2, CE 641, CE 650, CE 784, CE 901, CE 917 ASHSD
Internal Structures	CE 309, CE 316, CE 611 A & B, CE 641, CE 650, CE 78
Auxiliary Building	CE 309, CE 611 A & B, CE 641, CE 650, CE 779, CE 784, CE 917
Other Category I Structures	
Intake Structure	CE 611 A & B, CE 641, CE 650, CE 784

PART II - PROGRAM INFORMATION

PROGRAM TITLE	PROGRAM DESCRIPTION	PROGRAM USE	PROGRAM VERIFICATION
CE 309 "STRESS"	This program performs a linear analysis of two or three dimensional, elastic, statically loaded, framed structures, whose members and joints may be pinned or rigidly connected. "Stress" can use either a stiffness or displacement method of analysis and can determine joint displacements, reactions, member end forces, and member distortions for each specified loading condition.	This program was used in the design and analysis of the secondary shield walls, structural steel, and pipe restraints in the Containment. The program was also used in the design and analysis of concrete and structural steel in the Auxiliary Building.	See Note 1

Table 3.8-3 (continued)

PROGRAM TITLE	PROGRAM DESCRIPTION	PROGRAM USE	PROGRAM VERIFICATION
CE 316 "FINEL"	A description of the features and capabilities of the Bechtel Computer Program "Finel" is given in Section 5.1.1.5.2 of the Arkansas Nuclear One Unit 1 FSAR, Docket No. 50-313.	"Finel" was used in the axisymmetric analysis of the Containment, Equipment Hatch and the Primary Shield.	See Notes 3 & 4
CE 611 A & B "TIME HISTORY RESPONSE ANALYSIS"	This program performs a response time history analysis using modal superposition techniques. The response can be calculated in terms of displacement, velocity, and acceleration time histories. In addition, time histories, inertia forces, moments, and shears can be computed for cantilevered structures. Maximum response values and times of occurrence can be found. The response spectra at selected points can be determined and plotted.	This program was used in the seismic analysis and design of the Containment, Internal Structures, Auxiliary Building and Intake Structure.	See Note 1
CE 639-2 "FORCES AND PRESSURES ACTING ON DOME DUE TO PRESTRESSING OR TENDONS"	This program performs an analysis of forces and pressures acting on a dome subjected to prestressed tendons. The shape of the dome can be either sphere-torus, sphere-cone, hemisphere, cone, or ellipsoid, and the tendons may be in one, two, or three directions. The program is capable of analyzing the prestressing losses due to friction and seating of the anchorages. In addition, the program can consider the prestressing sequences.	This program was used in the design and analysis of the Containment.	See Note 1

Table 3.8-3 (continued)

PROGRAM TITLE	PROGRAM DESCRIPTION	PROGRAM USE	PROGRAM VERIFICATION
CE 641 "EARTHQUAKE SPECTRUM RESPONSE ANALYSIS OF STRUCTURES"	This program computes the response of a structure subjected to an earthquake using spectrum response techniques. The input data defines the structure in terms of natural frequencies, mode shapes, lumped masses, and elevations. The earthquake is defined in terms of acceleration values associated with the structure's natural frequencies. The response of the structure is determined at specified locations in terms of inertial forces, shears, moments, accelerations and displacements.	This program was used in the seismic analysis and design of the Containment, Internal Structures, Auxiliary Building and Intake Structure.	See Note 1
CE 650 "BEAM PROPERTIES"	This program computes the cross sectional properties of beams and beam segments. The properties computed are cross sectional area, shear area, moment of inertia, centroidal axes and segment weights.	This program was used in the seismic analysis and design of the Containment, Internal Structures, Auxiliary Building, and Intake Structure.	See Note 1
CE 779 "STRUCTURAL ANALYSES PROGRAM"	This program performs linear elastic analysis of three dimensional structural systems using finite element techniques. The program is capable of analyzing a variety of structural elements, including three dimensional truss, three dimensional beam, plane stress, plane strain, two dimensional axisymmetric solid, three dimensional solid, plate, and shell. Combinations of the above elements may be used.	This program was used in the design and analysis of the spent fuel pool in the Auxiliary Building.	See Notes 3 & 4

Table 3.8-3 (continued)

PROGRAM TITLE	PROGRAM DESCRIPTION	PROGRAM USE	PROGRAM VERIFICATION
CE 784 "PLANE FRAME RESPONSE"	This program generates natural frequencies and mode shapes for modeled structures. Input data consists of lumped masses, elevations, and cross sectional properties of elements of the structural model.	This program was used in the seismic analysis and design of the Containment, Internal Structures, Auxiliary Building, and Intake Structure.	See Note 1
CE 901 "STRUDL"	This program performs analysis of a wide range of structural types, both two and three dimensional structures consisting of truss, frame and continuous finite elements. Any combination of these compounds may be used with a variety of analysis and design procedures.	This program was used in the analysis of secondary shield walls.	See Note 6
CE 917 "MODAL DYNAMIC ANALYSIS"	This program computes the reduced stiffness matrix from the basic geometry input for plane frame or plane truss models, accepts a diagonal or full mass matrix, and computes mode shapes, frequencies, participation factors, and modal damping values.	This program was used in the seismic analysis and design of Class I cable tray supports in all Category I structures.	See Note 3
ASHSD "ANALYSIS OF AXISYMMETRIC SHELL AND SOLID SUBJECT TO NON- AXISYMMETRIC STATIC LOADING, DYNAMIC LOADING OR BASE ACCELERATION"	This program analyzes complex axisymmetric structures of arbitrary shape which may be idealized as shell or solid finite elements for dead load, non-axisymmetric static loading as well as for dynamic characteristics and response to any non-axisymmetric dynamic loading or to any given base acceleration history. The shell is discretized as a series of conical frustrums and the solid is idealized as an assemblage of quadrilateral or triangular finite elements.	This program was used to analyze the Equipment Hatch Area of the Containment.	See Note 5

Table 3.8-3 (continued)

NOTES:

1. The descriptions and results of verification tests results on this program are on file at the Bechtel International Corporation, Data Processing Division.

2. Verification tests on this program are currently in process. Results of these tests will be placed on file at the Bechtel International Corporation, Data Processing Division.

3. The descriptions and results of verification tests on this program were submitted in Amendment 6 of the Grand Gulf Nuclear Station, PSAR, AEC Docket No. 50416-23.

4. The description and results of verification tests on this program were submitted in Amendment 3 of the Alvin W. Vogtle Nuclear Plant, PSAR, AEC Docket No. 50424-18.

5. The theoretical background and results of verification tests on this program can be obtained in the following publication: "Dynamic Stress Analysis of Axisymmetric Structures Under Arbitrary Loading", Report No. EERC 69-10, September, 1969, by Sukumar Ghosh and Edward Wilson. A copy of this publication is on file with the National Technical Information Service, National Bureau of Standards, U.S. Department of Commerce, Springfield, Virginia.

6. ICES STRUDL CE 901 is a recognized computer program in the public domain and has had sufficient history of use to justify its applicability and validity without further demonstration.

7. The computer codes listed in this table reflect original construction design and analysis. Other computer codes may have been used for design and analysis activities since the original construction of ANO-2. See the current calculations for details of specific codes used.

Table 3.8-6

CALCULATED RESULTS - INTERNAL STRUCTURES

A. Definitions

M = Required design moment capacity

M_u = Actual design moment capacity

P = Required axial design load capacity (tension positive)

P_u = Actual axial design load capacity (tension positive)

NOTE: 1. Capacities for walls and slabs are given per foot width

2. For definition of load combination variables see Section 3.8.3.3.2

B. Materials Design Strengths

a) Concrete design strengths:

Primary and secondary shield walls, refueling canal floor slab, steam generator pedestal and columns: f'_c = 5500 psi

Miscellaneous slabs and walls: f'_c = 3000 psi

b) Steel reinforcement design strength:

All reinforcement for Internal Structures

f_y = 60,000 psi

SPECIFIED SEISMIC CONSTANTS FOR CLASS 2 AND 3 EQUIPMENT

Equipment	Design Acceleration Horizontal/Vertical	Manufacturer Analysis
Pumps		
Charging	1.5/1.0	Vendor calculations based on specified seismic constants
Other CVCS	1.5/1.0	
Engineered Safety Features	1.0/.66	
Fuel Pool	1.5/1.0	
Waste Management	1.5/1.0	
Waste Gas Compressors	1.5/1.0	
Tanks		
All code tanks	1.0/.66	Vendor calculations based on specified seismic constants
Ion Exchangers	1.0/.66	C-E calculations based on specified seismic constants with vendor concurrence
Filters	1.0/.7	Vendor calculations based on specified seismic constants
Heat Exchangers		
Letdown	1.0/.7	Vendor calculations based on specified seismic constants
Regenerative	1.0/.7	
Shutdown	1.0/.7	
Fuel Pool	1.0/.7	
Valves		
Safety and Relief	3.0/3.0	Vendor calculations based on specified seismic constants
Check and Manual	3.0/3.0	
Motor Operated	3.0/3.0	
Pneumatic Control	3.0/3.0	
Diaphragm	3.0/3.0	

Table 3.9-2

DESIGN LOADING COMBINATIONS AND STRESS LIMITS FOR ASME SECTION III CODE CLASS 2 AND 3 PIPING

LOADS

PD - Design Pressure
PO - Operating Pressure
DW - Piping Dead Weight
OBE - Operating Basis Earthquake (inertia portion)
DBE - Design Basis Earthquake (inertia portion)
RVC - Relief Valve-Closed System (transient)
RVO - Relief Valve-Open System (sustained)
FV - Fast Valve Closure
DU - Other Transient Dynamic Events Defined as an Upset Plant Condition
S_E - Thermal Expansion Stress (2)
E_q - Earthquake (anchor point displacement) (2)
DE - Dynamic Events Defined as an Emergency Condition
DF - Dynamic Events associated with a Faulted Condition (3)

PLANT OPERATING CONDITION	DESIGN STRESS LIMITS (1)	DESIGN LOADINGS COMBINATIONS
DESIGN	1.0 S_h	PD
NORMAL	1.0 S_h	PO + DW
UPSET	1.2 S_h	PO + DW + OBE PO + DW + RVC PO + DW + FV PO + DW + OBE + RVO PO + DW + DU
EMERGENCY	1.8 S_h	PO + DW + DE
FAULTED	2.40 S_h	PO + DW + DBE + RVO PO + DW + DBE + DF
THERMAL (2)	S_A	$S_E + E_q$

1. Where S_h (the basic material allowable stress at the operating temperature), S_A (the allowable expansion stress), and S_E are defined in ASME Code, Section III. Either a vectorial combination or absolute sum of stresses will be used.

2. Thermal expansion stress, S_E, is based on Normal and Upset operating conditions per ASME Code, Section III. If stress due to earthquake anchor point displacement is added to OBE stress in Upset load combination it does not need to be added to the thermal expansion stress, S_E.

3. Due to application of leak before break (LBB) technology to ANO-2 RCS, the postulated breaks in the reactor coolant loop are replaced with branch line pipe breaks (BLPBs). The Faulted load case DF for the BLPBs (LOCA) is combined with the DBE by square root sum of the square (SRSS) method.

Table 3.9-3

**DESIGN STRESS LIMITS FOR ASME SECTION III
CODE CLASS 2 AND 3 VALVES**

PRESSURE REQUIREMENTS

PLANT OPERATING CONDITIONS	DESIGN UNIT
NORMAL	P_d
UPSET	P_d
EMERGENCY	1.5 P_d
FAULTED	2.0 P_d

DYNAMIC QUALIFICATION

1. PROCUREMENT REQUIREMENTS FOR VALVES WITH EXTENDED TOP WORKS

   a. FREQUENCY OF TOP WORKS

   The design specifications require the valve manufacturer to analyze the valve and demonstrate that the frequency of the top works is in the rigid range of the applicable spectrum response curve.

   b. APPLIED ACCELERATION

   The design specifications require that valves identified in the Valve Requisition as Seismic Category 1 shall be capable of operation during and after loadings due to seismic forces. Specifically, valves having operators or similar features of extended proportions shall be able to withstand an inertial load of 3.0g in any direction in addition to normal operating loads. The extended parts of the valves shall have a frequency of vibration greater than 33 cps. Fulfillment of this requirement shall be demonstrated either by tests or calculations. In either event, copies of the test data or calculations shall be submitted for approval by the Buyer prior to acceptance of the valves.

The primary bending stress criteria in the weakest section of the valve is as a minimum per the Code of Record for Unit 2:

2. DESIGN REQUIREMENTS FOR INSTALLED VALVES WITH EXTENDED TOP WORKS

   a. FREQUENCY OF TOP WORKS

   The design requirements for installed valves are that the lowest natural frequency of the top works should be in the rigid range of the applicable spectrum response curve or greater than 33 cps. If the lowest natural frequency of the top works is not in the rigid range, then an appropriate safety factor should be applied to the seismic acceleration for the direction that the frequency is low in the valve seismic qualification calculation. The valve may also be physically changed to raise the lowest natural frequency above 33 cps.

Table 3.9-3 (continued)

b. APPLIED ACCELERATION

Seismic Category 1 valves shall be capable of performing their safety function during and after loading due to seismic forces. Specifically, valves having operators or similar features of extended proportions shall be able to withstand the loading associated with actual seismic accelerations in each direction as calculated in the piping stress calculations in addition to normal or accident operating loads as required by the valve design basis.

c. DESIGN STRESS LIMITS

The design stress limits for pressure retaining components shall be, as a minimum, in accordance with the code of record for Unit 2. The design stress limits for non pressure retaining components shall be designated by the analyst as to ensure that the component stays within the elastic region or be analyzed and qualified using accepted engineering practices.

d. DESIGN VERIFICATION

The piping system analysis, including the valves, is reviewed to assure calculated valve accelerations do not exceed those specified for valve manufacturer analysis or do not exceed those accelerations for which the valve is qualified by analysis or testing.

3. COMPACT VALVES (NO EXTENDED TOP WORKS)

As stated in NB-3524, "....the piping, not the valves, will be limiting."

Therefore, the stresses given in Table 3.9-2 for piping govern the valve stresses.

<u>ACTIVE vs INACTIVE</u>

As stated in 3.9.2, the manufacturer of active valves is required, by analyses or tests, to assure the operability of the valve under imposed loadings.

P_d = DESIGN PRESSURE - the pressure corresponding to the design temperature on the appropriate valve rating table.

P_d = PRIMARY BENDING STRESS

S = DESIGN STRESS

Table 3.9-4

Design	Design	S	-
Faulted[(5)]	Normal and DBE	.90 yield	AISC allowables with no increase permitted for seismic

where

S = Code allowable stress
S_m = Code allowable stress intensity
S_{yield} = Yield strength of material
P_m = Primary membrane stress
P_B = Primary bending stress
P_L = Local membrane stress

NOTES:

1. These pumps meet applicable requirements of the draft ASME Code for Pumps & Valves for Nuclear Power. Design limits were those which the manufacturer demonstrated to be satisfactory for the specific design condition.

2. The same stress limits were considered for normal, upset, emergency and faulted operating conditions. Therefore, since the faulted condition is limiting it was the only condition analyzed.

3. The manufacturer of active pumps was required to demonstrate, by analyses or tests, the operability of the pump under imposed loading.

4. Refer to Table 3.2-3 for listing of equipment with applicable quality group classification and design codes.

5. Faulted conditions apply to those components listed in Seismic Category 1 in Table 3.2-2.

Table 3.11-1

POST LOCA ENVIRONMENTAL CONDITIONS SPECIFIED FOR PROCUREMENT OF EQUIPMENT (HISTORICAL)

NOTES

1. USE DETAIL #1 FOR INDIVIDUALLY MOUNTED INSTRUMENTS EXCEPT THOSE REQUIRING SEISMICALLY ACCEPTABLE MOUNTING. USE ONLY DETAIL #4 FOR MOUNTING INSTR. COVERED BY SEISMIC REQU REMENTS
2. USE SAME BASE PLATE FOR DETAILS #1, 3 & 15
3. DO NOT WELD SERVICE CLAMPS OR STANCHIONS TO PROCESS LINES
4. ALL LOCALLY MOUNTED INSTR'S. TO BE 4'-6" ABOVE GRADE IF POSS BLE
5.
6. ● - SEAL OPEN ENDS OF ALL PIPE
7. DO NOT DESIGN RACKS FOR MOUNTING ELECTRICAL JUNCTION BOXES ON RACK. ELECTRICAL JUNCTION BOXES ARE TO BE MOUNTED ON WALL BEHIND RACK AND CONNECTIONS TO NSTRUMENTS ON RACK MADE WITH FLEXIBLE CONDUIT. TERM NATION OF RIGID CONDUIT AT THE RACK WILL REQUIRE SEPARATE SEISMIC ANALYSIS FOR EACH RACK
8. WELD UNISTRUT P-1000 TO LOWER 2" P PE (DETAIL #15) FOR A RSETS (DET. #12) WHEN REQUIRED. ADD UNISTRUT IN SAME MANNER TO ANY 2" CROSS MEMBER TO MOUNT GAGES OR SWITCHES (DET. # 13)
9. STANDARD NSTRUMENT RACK SHOWN N DETAIL 15 WITH MAX AMOUNT OF INSTRUMENTS MOUNTED ON FOUR HORIZONTAL ROWS IS ADEQUATE FOR SEISMIC CATEGORY 1
10. STANDARD NSTRUMENT RACK LENGTH CAN BE NCREASED TO 5'-0" MAX BY ADDING TWO HORIZONTAL SUPPORTING MEMBERS AS SHOWN N DETAIL 15

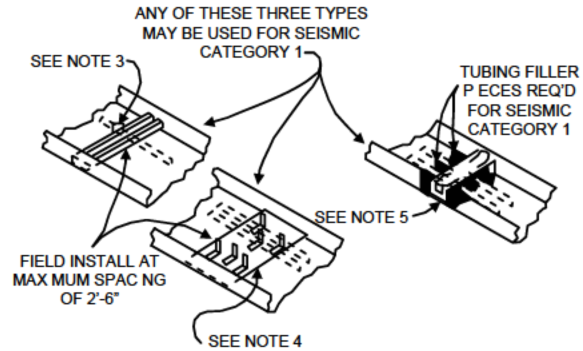
TYPICAL TRAY JO N NG METHODS



BURNDY TRAY AVAILABLE WITH CLIPS FACTORY NSTALLED ON 2'-6" CENTERS – BURNDY PRT4-6-144
PRT4-12-144

TUB NG HOLD-DOWN DETAILS

1. All joints welded, except straight runs use tray vendors standard connectors. Use portion of bottom for overlap as shown. Paint weld areas. All trays are galvanized steel.
2. Approved Vendors and Trays:

Width	Catalog No.	Capacity
	P&W Industries	
*12"	2817-0012-12	19 tubes
* 6"	2817-0012-06	10 tubes
1½"	2501-0016-15	3 tubes
2½"	2501-0016-25	4 tubes
3-3/8"	2501-0016-33	6 tubes
	Globe (Div. of U.S. Gypsum Co.)	
*12"	SB-SS00-1200-3	19 tubes
* 6"	SB-SS00-0600-3	10 tubes
	Unistrut Corp.	
1-5/8"	P-3000	2 tubes
	Husky-Burndy Co.	
* 6"	SS J6-144	10 tubes
*12"	SS J12-144	19 tubes

3. For Unistrut P-4000 on tray, use Unistrut clip # P-7604
4. Burndy Clip Part # PRT-3, 6, 12-144
5. P&W Clip Part # D S-9004
6. Maximum distance between tube supports in tray – 2'-6" (Seismic Category 1)
7. Refer to Figure 3.7-10 for details on tray supports for Seismic Category 1
8. Do not layer tubing on trays. All seismic analysis based on one layer of 3/8" O D. tubing tray

*Require flanged covers for Seismic Category 1

4 REACTOR

4.1 SUMMARY DESCRIPTION

Arkansas Nuclear One - Unit 2 incorporates a Pressurized Water Reactor (PWR) with two reactor coolant loops. A vertical cross section of the reactor is shown in Figure 4.1-1. The reactor core is composed of 177 fuel assemblies and 81 Control Element Assemblies (CEAs). The fuel assemblies are arranged to approximate a right circular cylinder with an equivalent diameter of 123 inches and an active length of 150.0 inches for fuel Batches A through H and 149.610 inches for fuel Batches J through N. The active fuel length for Batch P (Cycle 12 reload batch) and subsequent reload batches is 150 inches. Each fuel rod shall contain a maximum total weight of 2114 grams of uranium. The fuel assembly, which provides for 236 fuel rod positions, consists of five guide tubes welded or bulged to spacer grids and is closed at the top and bottom by end fittings. The welded construction was used for fuel Batches A through Y. A bulged construction was introduced in Batch Z with the implementation of Next Generation Fuel (NGF). The guide tubes each displace four fuel rod positions and provide channels which guide the CEAs over their entire length of travel. In selected fuel assemblies, the central guide tube houses incore instrumentation.

The analyses in Section 4.4 were developed using the W-3 Correlation which yielded a minimum DNBR of 1.30, and the COSMO and INTHERMIC computer codes applicable to Cycle 1 operation. Subsequent cycles through Cycle 20 utilized the CE-1 Correlation, the TORC, and CETOP-D computer codes and a DNBR safety limit of 1.25. Beginning in Cycle 21, both the ABB-NV and WSSV-T Correlations were utilized with the TORC and CETOP-D computer codes along with a DNBR safety limit of 1.23 for NGF assemblies. The DNBR safety limits are described in Section 4.4.2.3.2. TORC and CETOP-D are described in Section 4.4.3.4.2.

The fuel is low enrichment UO_2 in the form of ceramic pellets and is encapsulated in prepressurized Zircaloy, ZIRLO™, or Optimized ZIRLO™ tubes which form a hermetic enclosure.

The reactor coolant enters the inlet nozzles of the reactor vessel, flows downward between the reactor vessel wall and the core barrel, passes through the flow skirt where the flow distribution is equalized, and then into the lower plenum. The coolant then flows upward through the core removing heat from the fuel rods. The heated coolant enters the outlet plenum where it flows around the outside of the CEA shrouds to the reactor vessel outlet nozzles. The CEA shrouds protect the CEAs from the effects of coolant crossflow in the outlet plenum.

Figures 4.1-2 and 4.1-2A contain views of the reactor core cross section and show certain dimensional relations between fuel assemblies, fuel rods and CEA guide tubes.

The reactor internals support and orient the fuel assemblies, CEAs, and incore instrumentation, and guide the reactor coolant through the reactor vessel. They also absorb the static and dynamic loads and transmit the loads to the reactor vessel flange. They will safely perform their functions during normal operating, upset and emergency conditions. The internals are designed to safely withstand the forces due to deadweight, handling, pressure differentials, flow impingement, temperature differentials, vibration and seismic acceleration. All reactor components are considered Seismic Class 1 for seismic design. The reactor internals design limits deflection where required by function. The stress values of all structural members under normal operating and expected transient conditions are not greater than those established by the ASME Code, Section III. The effect of neutron irradiation on the materials concerned is included in the design evaluation. The effect of accident loadings on the internals is included in the design analysis.

Reactivity control is provided by two independent systems: the Control Element Drive System (CEDS) and the Chemical and Volume Control System (CVCS). The CEDS controls short-term reactivity changes and is used for rapid shutdown. The CVCS is used to compensate for long-term reactivity changes and can make the reactor subcritical without the benefit of the CEDS. The design of the core and the Reactor Protective System (RPS) prevents fuel damage limits from being exceeded for any single malfunction in either of the reactor control systems.

Each CEA consists of five neutron absorber rods assembled in a square array, with one rod in the center. The rods are connected to a spider structure which couples to the Control Element Drive Mechanism (CEDM) shafting. There are a total of 81 CEAs. Originally, 8 of the 81 CEAs were part length CEAs (PLCEAs). The PLCEAs were replaced at the end of Cycle 11 with full length CEAs. The original purpose of the PLCEAs was to provide control of axial power distribution, particularly in the event of axial xenon oscillation.

The CEAs are positioned by magnetic jack type CEDMs mounted on the reactor vessel head. The 81 CEAs are divided into control and shutdown groups.

The maximum reactivity worth of the CEAs and the associated reactivity addition rate are limited by system design to prevent sudden large reactivity increases. The design restraints are such that reactivity increases will not result in violation of the fuel damage limits, rupture of the reactor coolant pressure boundary, or disruption of the core or other internals sufficient to impair the effectiveness of emergency cooling.

Boric acid dissolved in the coolant is used as a neutron absorber to provide long-term reactivity control. In order to reduce the boric acid concentration required at beginning of cycle operating conditions, and thus reduce the algebraic magnitude of the moderator temperature coefficient, burnable poison rods (also called shims) or integral burnable absorber rods are provided in certain fuel assemblies. The burnable poison is boron carbide dispersed in alumina pellets; the pellets are clad in Zircaloy to form rods which are similar to the fuel rods and were placed in Batch P (Cycle 12) and all prior reload assemblies. Gadolinia was used as the integral burnable absorber with Batch R (Cycle 13; see Section 4.2.1.2.1.1), Erbia was introduced with Batch U (Cycle 16; see Section 4.2.1.2.1.2), and IFBA (ZrB2) was introduced with Batch X (Cycle 18; see Section 4.2.1.2.1.3).

A multi-batch fuel management scheme is employed which may use zoned fuel assemblies and poison rods. ANO-2 can operate with an individual rod average fuel burnup (burnup averaged over the length of a fuel rod) not to exceed 60,000 MWD/MTU. Sufficient margin is provided to ensure that peak burnups are within acceptable limits.

The nuclear design of the core ensures that the combined response of all reactivity coefficients in the power operating range to an increase in reactor thermal power yields a net decrease in reactivity.

CEAs are moved in groups to satisfy the requirements of shutdown and power level changes. The control system is designed to produce power distributions that are within the acceptable limits on overall nuclear heat flux factor (F_q) and Departure from Nucleate Boiling Ratio (DNBR). The RPS and administrative controls ensure that these limits are not exceeded.

Axial xenon oscillations, should they occur, will be manually controlled by either utilizing the CEAs or RCS temperature. Axial power information to be used in controlling the xenon oscillation is provided by the nuclear detectors.

The core makes use of a low-leakage fuel management scheme, which places previously burned assemblies on the core periphery and fresh assemblies throughout the interior of the core. This type of fuel management is economically attractive because it reduces uranium requirements for a specific total energy output. It also reduces the total neutron fluence that the reactor vessel is exposed to during the cycle.

Prior to Cycle 10, the core also contained two Plutonium 238-Beryllium neutron sources for initial and subsequent startups. The sources were supported from the fuel assembly upper end fitting and were contained within CEA guide tubes.

A tabulation of the analysis techniques, load conditions and computer codes utilized in the analysis of various reactor internals components is presented in Table 4.1-1. The core mechanical design is discussed in Section 4.2; the nuclear design of the core is discussed in Section 4.3; the thermal and hydraulic design is discussed in Section 4.4. Summary lists of significant core parameters are presented in Tables 4.2-1, 4.3-1, and 4.4-2.

Certain material in this chapter is a nonproprietary version of material submitted in CEN-20(A)-P, Arkansas Nuclear One - Unit 2, Docket 50-368, Final Safety Analysis Report, Combustion Engineering, Inc., Proprietary Information. Specific information classified as proprietary was deleted from this nonproprietary version. The reason for the proprietary classification of the material is that the information consists of test data or other similar data concerning a process, method or component, the application of which results in a substantial competitive advantage to Combustion Engineering, Inc. (now Westinghouse).

4.2 MECHANICAL DESIGN

This section summarizes the mechanical design characteristics of the reactor and discusses the design parameters which are of significance to the performance of the reactor. A summary of mechanical design parameters is presented in Table 4.2-1. The data are intended to be descriptive of the design. Limiting values of these and other parameters will be discussed in the appropriate sections.

4.2.1 FUEL

4.2.1.1 Design Bases

4.2.1.1.1 Structural Design Bases

4.2.1.1.1.1 Fuel Assembly

The fuel assemblies are required to meet design criteria for the following loading combinations.

A. Normal Operating and Upset Conditions

The fuel rods and fuel assemblies are required to satisfy the design criteria under the following loading combinations:

1. Normal operating conditions of temperature, pressure and steady state and transient power generation up to design burnup and linear heat rate.

2. Flow impingement loads.

3. Weights, reactions and superimposed loads (hydraulic uplift, mechanical holddown).

4. Vibration loads.

5. Seismic loads (OBE).

6. Handling loads (not combined with other loads above).

Under normal and upset conditions, the following criteria for structural integrity apply to components other than fuel rods:

1. $P_m \leq S_m$

   $P_m + P_B \leq F_s\ S_m$

2. Deflections are limited so that no permanent deformation occurs, the Control Element Assemblies (CEAs) can function and adequate core cooling is preserved.

3. Cumulative fatigue damage fraction to any component shall not exceed 1.0.

Typical normal and upset conditions that are considered are as follows:

1. Heatup and Cooldowns
2. Power Changes
3. Startup Testing
4. Normal Variations in Operating Temperature and Pressure
5. Reactor Trip
6. Seismic Event (OBE)
7. CEA Withdrawal
8. Loss of Coolant Flow
9. Idle Loop Startup
10. Loss of External Load
11. Loss of Feedwater Flow
12. Excess Feedwater Flow
13. Excess Load

B. Emergency Conditions

The fuel is required to satisfy the emergency conditions design criteria under the conditions of temperature, pressure and flow which occur as results of the emergency conditions. The seismic event up to a DBE combined with normal operating loads is considered an emergency condition.

The following criteria apply:

1. $P_m \leq 1.5\ S_m$

   $P_m + P_B \leq 1.5\ F_s\ S_m$

2. Deflections are limited to a value allowing the CEAs to scram, but not necessarily within the prescribed time.

3. Adequate core cooling is provided although some local yielding may occur. A small number of fuel rods may be damaged.

C. Faulted Conditions

The fuel assembly is designed to meet the stress and deflection limits specified below during postulated (faulted) incidents. Some permanent deformation of the fuel assemblies may occur under these conditions. Typical faulted conditions that are considered are as follows:

1. Complete loss of secondary pressure (steam line break)
2. Control element assembly ejection
3. Reactor coolant pump shaft seizure
4. Fuel handling accident
5. Reactor coolant branch line pipe break (BLPB)

The primary stresses of the fuel assembly end fittings (excluding holddown springs) are limited by the following:

$$P_m \leq S_m^1$$

$$P_m + P_B \leq F_s\, S_m^1$$

where:

S_m^1 = smaller value of 2.4 S_m or 0.7 S_u

For components other than the end fittings, the fuel assembly deformation shall be limited to a value not exceeding the loss of function deformation limit which would preclude satisfactory insertion of the CEAs.

NOMENCLATURE

The symbols used in defining the allowable stress levels are as follows:

P_m = Calculated general primary-membrane stress*

P_B = Calculated primary bending stress*

S_m = Design stress intensity value as defined by Section III, ASME Boiler and Pressure Vessel Code **

S_u = Minimum unirradiated ultimate tensile strength

F_s = Shape factor corresponding to the particular cross section being analyzed***

F_s = 1.5 for a rectangular section

S_m^1 = Design stress intensity value for faulted conditions

* P_m and P_B are defined by Article NB-3000, Section III, ASME Boiler and Pressure Vessel Code, 1971.

** With the exception of zirconium base alloys, the design stress intensity values, S_m, of materials not specified by the Code are determined in the same manner as the Code, classifying the materials into two groups according to their unirradiated minimum yield strength at temperature. The design stress intensity of zirconium base alloys will not exceed two-thirds of the unirradiated minimum yield strength at temperature. Where material properties are significantly affected by radiation, the effect will be accounted for in the design.

*** The shape factor F_s is defined as the ratio of the "plastic" moment (all fibers just at the yield stress) to the initial yield amount (extreme fiber at the yield stress and all other fibers stressed in proportion to their distance from the neutral axis). The capability of cross sections loaded in bending to sustain moments considerably in excess of that required to yield the outermost fibers is discussed in Reference 12. The allowable stresses for fuel assembly end fittings under faulted conditions are:

$P_m \leq S_m^1$ and $P_B \leq F_s S_m^1$, for which S_m^1 is defined as the lesser of 2.4 S_m and 0.7 S_u

The definition of S_m^1 as the lesser value of 2.4 S_m and 0.7 S_u is contained in the ASME Boiler Pressure Vessel Code (1974) Section III, Appendix F-1323.1. (Note that these criteria apply only to the 304 stainless steel end fittings).

4.2.1.1.1.2 <u>Fuel Cladding</u>

The fuel cladding design will prevent fuel element damage under steady state and transient operating conditions. The fuel rod design accounts for external pressure, differential expansion of fuel and clad, fuel swelling, clad creep, fission and other gas releases, initial internal helium pressure, thermal stress, pressure and temperature cycling and flow-induced vibrations. The structural criteria are based on the following for the normal and upset loading combinations identified in Section 4.2.1.1.1.1.

A. The maximum tensile stress in the Optimized ZIRLO™, ZIRLO™, or Zircaloy clad will not exceed two-thirds of the minimum unirradiated yield strength of the material at the applicable temperature.

B. Net unrecoverable circumferential strain will not exceed one percent as predicted by computations considering clad creep and fuel-clad interaction effects. In addition, the incremental total strain induced during a transient is also limited to one percent, as described in Reference 176 for Zircaloy-4 cladding, Reference 183 for ZIRLO™ cladding, and Reference 195 for the NGF design with Optimized ZIRLO™ cladding.

   Data from O'Donnell (Reference 121) and Weber (Reference 155) were used to determine the present one percent strain limit. O'Donnell developed an analytical failure curve for Zircaloy cladding based upon the maximum strain of the material at its point of plastic instability. O'Donnell compared his analytical curve to circumferential strain data obtained on irradiated coextruded Zr-U metal fuel rods tested by Weber. The correlation was good, thus substantiating O'Donnell's instability theory.

Since O'Donnell performed his analysis, additional data have been derived at Bettis (References 70, 74, and 106) and AECL (Reference 119 and 120). These new data are shown in Figure 4.2-1 along with O'Donnell's curve and Weber's data. This curve was then adjusted because of differences in anisotropy, stress states and strain rates; and the Combustion Engineering design limit was set at one percent.

The conservatism of the clad strain calculations is provided by the selection of adverse initial conditions, e.g. clad and pellet diameters, and material behavior assumptions, e.g. minimum assumed inpile densification, and by the assumed operating history (daily power cycling). The acceptability of the one percent unrecoverable circumferential strain limit is demonstrated by data from irradiated Zircaloy-clad fuel rods which show no cladding failures (due to strain) at or below this level, as illustrated in Figure 4.2-1.

The ductility of ZIRLO^{TM} should be at least equivalent to Zircaloy-4 (Reference 183, Section 5.3.5). Section B.7 of Reference 194 documents that the ductility of Optimized ZIRLO^{TM} and ZIRLO^{TM} are indistinguishable from each other at temperatures above room temperature, so the ductility of Optimized ZIRLO^{TM} is also at least equivalent to that of Zircaloy-4. Ductility is a function of irradiation and hydride formation in the cladding. Since the corrosion rates of Optimized ZIRLO^{TM} and ZIRLO^{TM} are significantly less than Zircaloy-4, fewer hydrides will be formed at high burnups. Therefore, the 1% strain capability limit criterion will continue to be applied and satisfied in Westinghouse fuel mechanical design analysis.

C. The clad will be initially pressurized with helium (without evacuating air present prior to pressurization) to an amount sufficient to prevent gross clad deformation under the combined effects of external pressure and long-term creep.

The clad collapse calculation method (Reference 12) itself does not include arbitrary safety factors. However, the calculation inputs are deliberately selected to produce a conservative result. For example, the clad dimensional data are chosen to be a worst case combination based either upon drawing tolerances or 95 percent confidence limits on as-built dimensions; the internal pressure history is based on minimum fill pressure with no assistance from released fission gas; and the flux and temperature histories are based on conservative assumptions.

A modification of the above method is described in Reference 171. This modification is applied to the normal CEPAN results to account for the support provided to the cladding by the pellets at the edges of an axial gap. The adjustment varies as a function of the length of the gap or unsupported cladding. As the gap considered becomes longer the modified results approach the result originally calculated by CEPAN.

No large axial gaps have ever been observed in Westinghouse Combustion Engineering's modern design fuel which has prepressurized fuel rods and stable, "nondensifying" fuel pellets. The gaps would be evidenced by large local ovalities of the fuel rod cladding, by a distinct region of atypical crud deposition around the cladding circumference, or by atypical signals during gamma scanning. None of these indications have been observed for major axial gaps during the extensive post-irradiation examination programs conducted on both 14 x 14 and 16 x 16 fuel designs.

Post irradiation examination of fuel rods has shown that axial gaps in the fuel column are typically a small fraction of the length of a pellet. These gaps are measured in the cold condition. It can be shown that at reactor operation conditions, thermal expansion of the fuel column would close most of the gaps or significantly reduce their length.

The longest axial gap in the cold condition ever observed in any modern Westinghouse C-E fuel rod was measured at 0.90 inches. During operation this gap is calculated to reduce to $\leq$ 0.2 inches due to thermal expansion of the fuel column. This reduced gap was supported by corrosion patterns observed during visual examination.

The modified method with these conservative assumptions has shown that predicted collapse times far exceed the longest residence time expected. It has therefore been concluded that unless significant design changes or manufacturing methods are introduced, modern Westinghouse C-E fuel and poison rods for both 16 x 16 and 14 x 14 designs are not susceptible to cladding collapse. On this basis, Westinghouse C-E will no longer address cladding collapse specifically for new cores or reload batches unless design or manufacturing changes are introduced which would significantly alter predicted collapse time results.

In the event such changes do occur, the modified method described above will be used to confirm that cladding collapse will not occur during the design lifetime of the fuel.

With the addition of ZrB_2 pellets to the design for Batch X and subsequent batches, the collapse methodology now may also use testing to verify that the holddown spring will prevent clad collapse in the plenum region (Reference 185, Section 4.2.2.4).

D. Cumulative strain cycling usage, defined as the sum of the ratios of the number of cycles in a given effective strain range ($\Delta\varepsilon$) to the permitted number (N) at that range, as taken from Figure 4.2-2, will not exceed 0.8

The cyclic strain limit design curve shown on Figure 4.2-2, is based upon the "Method of Universal Slopes" developed by S.S. Manson (Reference 102) and has been adjusted to provide a strain cycle margin for the effects of uncertainty and irradiation. The resulting curve has been compared with known data on the cyclic loading of Zircaloy and ZIRLO™ and has been shown to be conservative (Reference 183, Section 5.3.6). Specifically, it encompasses all the data of Reference 122. With respect to Optimized ZIRLO™, Appendix B.10 of Reference 194 documents that there is no distinguishable difference in the fatigue characteristics of ZIRLO™ and Optimized ZIRLO™.

As discussed in Section 4.2.1.3.7, the fatigue calculation method includes the effect of clad creep to reduce the pellet to clad diametral gap during that portion of operation when the pellet and clad are not in contact. The same model is used for predicting clad fatigue as is used for predicting clad strain. Therefore, the effects of creep and fatigue loadings are considered together in determining the End of Cycle (EOC) cumulative fatigue damage factor and the EOC clad strain. Moreover, the current fatigue damage calculation method includes a factor of 2.0 which is applied to the calculated strain before determining the allowable number of cycles associated with that strain. Therefore, the allowable fatigue usage factor of 0.8 ensures a considerable degree of conservatism (See Figure 4.2-2).

For determining the ability of the fuel rod to satisfy the above criteria, the analyses take into account the most limiting set of temperatures, fluxes and transient rates which would occur in the core for the operating condition being evaluated. It should be noted that the use of most limiting conditions does not necessarily imply the use of "hot spot" values. For example, owing to the effect of local transient rates on the severity of Pellet Clad Interaction (PCI) effects, the "most limiting" situation for PCI during a transient may not coincide with the peak power location in the reactor.

The analytical method presently used to calculate the effects of interaction between the fuel pellets and fuel rod cladding is based on experimentally derived properties and behavioral models. A digital computer model is employed in which the behavior of the fuel pellet and cladding under time varying operating conditions is represented by the response of a set of equations to the effects of a periodic power transient. The cumulative effect of a series of power transients, e.g. daily variation in power level repeated for the design life of the fuel rod, is determined by allowing the transient to be repeated until a preset burnup level has been attained. The net clad circumferential strain and cumulative fatigue damage fraction, based on the circumferential strain range sustained during the series of transients, are calculated at the end of each transient and printed at preselected intervals and after the desired burnup level has been attained.

The transient is divided into 24 intervals called "hours" but having, in fact, not necessarily equal time durations. The transient is input as a set of 24 values of local linear heat rate. The only restrictions on the shape of the transient are that the curve of power level versus time may have not more than one relative maximum during the transient cycle and that power levels selected for time intervals 1 and 24 should be equal.

The sequence of operations followed by the model during a single transient cycle is presented below:

A. Determine temperature distributions in fuel pellet and cladding based on instantaneous power level.

B. Determine fuel rod internal pressure based on accumulated burnup and instantaneous power level.

C. Determine pellet and clad diameters corresponding to the new power level and internal pressure.

D. Determine changes in clad diameters and pellet diameter which will occur during the time step as the result of cladding creep and pellet swelling.

E. Based on the information generated in Steps C and D, above, determine the pellet and clad diameters corresponding to the end of the time interval.

This series of steps is repeated for each time interval during which the power level equals or exceeds that which existed during the preceding time interval.

If the time interval being calculated is the first interval in which the power level has decreased, the following additional calculations are made:

F. Determine the strain range for the cladding based on the difference in dimensions between the beginning of the transient cycle and the maximum power level point during the transient cycle.

G. Determine the incremental fatigue damage fraction which occurs as a result of the strain range calculated in Step F. This incremental damage fraction is added to the cumulative fatigue damage fraction.

H. Determine the amount of clad plastic strain which has occurred due to differential thermal expansion between pellet and clad which occurred during the power increasing portion of the transient cycle.

I. Adjust the cladding reference dimension to account for the amount of plastic strain calculated in Step H.

Steps F through I are only performed at the end of the last time interval in the power increasing portion of the transient cycle. For all remaining time intervals in the cycle, Steps A through E are repeated.

The 24 time intervals in the transient cycle are recalculated until the desired burnup level is reached.

The calculational steps discussed above take into account the following effects:

A. Variation of clad temperature (O.D., I.D. and mid-wall) with power level.

B. Clad diametral thermal expansion based on mid-wall temperature.

C. Clad elastic deformation due to differential pressure.

D. Pellet temperature distribution and resulting thermal expansion.

E. Clad elastic and plastic deformation due to differential thermal expansion between the fuel pellet and the clad.

F. Variation of internal pressure with power level and burnup (based on linear interpolations of pressures calculated using other analytical models).

G. Variation of fast flux level with power level.

H. Clad plastic deformation due to creep strain, including the effects of power dependent temperature, fast flux and differential pressure.

I. Irreversible pellet swelling due to irradiation, including the dependence of the swelling rate on power level and whether the clad and pellet are in contact.

J. Fuel pellet in-reactor densification, and the resultant changes in pellet dimensions.

K. The accumulation of fission products in the dish and porosity volume of the pellet, and the higher apparent pellet swelling rate which is observed when no open volume remains within the pellet for fission product accommodation.

The net cladding circumferential strain and the cumulative fatigue damage fraction are calculated during each transient cycle. The values calculated for the last transient cycle, i.e., for the design burnup, are compared to the allowable design limit values of circumferential strain and cumulative fatigue damage factor.

As a sample of calculation results, the case of a nominal Arkansas Nuclear One - Unit 2 fuel rod was analytically subjected to daily power variation from 15 percent to 100 percent to 15 percent peak linear heat rate (12.5 kW/ft) until the peak local burnup value reached 55,000 MWD/MTU. The daily power cycle consisted of three hours at 15 percent, a 6-hour ramp to 100 percent, six hours at 100 percent, a 6-hour ramp to 15 percent, and three hours at 15 percent. For this case, the predicted EOC clad circumferential strain (referenced to Beginning of Cycle (BOC) dimensions) is .05 percent, and the calculated cumulative fatigue damage fraction is 0.41.

The portion of the cladding strain criterion related to total strain is limited to the incremental strain induced during a transient. The criterion is evaluated by subtracting the existing cladding total strain at the beginning of the transient by the maximum cladding total strain at any time during the transient and comparing that incremental total strain to the one percent criterion.

New NRC models for fuel cladding strain and assembly flow blockage were developed since the evaluation of these factors for the Arkansas Nuclear One - Unit 2 ECCS analysis. Because the NRC models are more conservative in part than those used for the Arkansas Nuclear One – Unit 2 ECCS analysis, the fuel vendor conducted the following additional analysis for plants with Combustion Engineering fuel: "Sensitivity Evaluation of the C-E ECCS Evaluation Model to Cladding Rupture Strain and Fuel Assembly Flow Blockage Models." This analysis confirms that all Combustion Engineering operating plants continue to meet the ECCS acceptance criteria of Appendix K and 10 CFR 50.46. The applicability of the analysis to Unit 2 is provided in Sections 5 and 6 of the Combustion Engineering report.

The average discharge burnup for equilibrium cycle fuel is approximately 45,000 MWD/MTU. The peak rod average burnup will be 60,000 MWD/MTU. This burnup is consistent with the structural criteria described above, and the fuel design as described in Section 4.2.1.2.1. Fuel burnup experience, as described in Section 4.2.1.3.9, demonstrates this to be an acceptable limit.

4.2.1.1.2 Deflections

The design of the fuel assembly and core arrangement will limit the deflection of the assemblies to a value not exceeding the loss of function deflection or deformation limit which would preclude satisfactory insertion of the CEAs or result in refueling difficulties. Tests corresponding to the earlier 14 x 14 design have been conducted which demonstrate that functioning of the CEA is not adversely affected when the guide tubes are bowed one inch. Tests have also shown that the fuel assembly could be deflected one inch at its center without exceeding the yield strength of its structural members. However, some residual deflection will remain due to the interaction of the fuel rods with the spacer grids, but this deflection is small and would not result in refueling difficulties. Based on these tests, the loss-of-function deformation limit was in excess of one inch. The loss-of-function deformation limit for the 16 x 16 fuel assembly design is expected to exceed that value determined by the 14 x 14 tests.

The maximum possible fuel assembly deflection allowed by the core arrangement would occur in a fuel assembly located on the periphery of the core and would result from an extremely unlikely condition where all fuel assemblies are bowed in the same direction at the same time across the maximum width of the core and no clearance exists between assemblies. The maximum deflection under these conditions will be less than one inch.

There is no specific limit for lateral fuel rod deflection for structural integrity determination except that which is brought about through application of cladding stress criteria. The absence of a specific limit on rod deflection is justified because it is the fuel assembly structure, and not the individual fuel rod, that is the limiting factor for fuel assembly lateral deflection.

4.2.1.1.3 Capacity for Fission Gas Inventory

The greater portion of the gaseous fission products remain either within the lattice or the microporosity of the UO_2 fuel pellets and does not contribute to the fuel rod internal pressure. However, a fraction of the fission gas is released from the pellets by diffusion and pore migration and thereafter contributes to the internal pressure.

The determination of the effect of fission gas generated in and released from the pellet column is discussed in Section 4.2.1.1.4. The rod pressure increase which results from the release of a given quantity of gas from the fuel pellets depends upon the amount of open void volume available within the fuel rod and the temperatures associated with the various void volumes. The annular pellet design has been introduced in Cycle 18 (Batch X) for typical use in the poison rod top and bottom cutback/blanket zones (see Figure 4.2-3C) to increase the rod void volume available and, thus, to enhance the fission gas capacity within the rod (to prevent an excessive gas pressure buildup). In some cycles, annular pellets may also be used in fuel-only rods. In the fuel and poison rod design, the following sources of void volume are considered in computing internal pressure:

A. Fuel rod upper end plenum;

B. Fuel clad annulus;

C. Fuel pellet end dishes;

D. Fuel pellet open porosity; and,

E. Hollow center of annular pellets.

The volume available from those sources is not constant during the life of the fuel. The model used for computing the available volume as a function of burnup and power level accounts for the effects of fuel and clad thermal expansion, fuel pellet densification, clad creep, and irradiation induced swelling of the fuel pellets.

4.2.1.1.4 Maximum Internal Gas Pressure

Fuel rod internal pressure increases with increasing burnup, and towards the EOL, the total internal pressure can approach values comparable to the external coolant pressure due to the combined effects of the initial helium fill gas, the released fission gas, and helium gas released from the IFBA coating in the ZrB_2-UO_2 rods. The normal external pressure is equal to the design operating pressure given in Table 4.4-1 plus a small increment equal to the elevation plus flow losses between the reactor core and the pressurizer. The maximum predicted fuel rod internal pressure will be consistent with the following criteria.

A. The primary stress in the cladding resulting from differential pressure will not exceed the unirradiated clad yield strength during a plant depressurization transient which does not involve a break in the primary system.

B. The internal pressure will not cause the clad to creep outward from the fuel pellet surface while operating at the design peak linear heat rate for normal operation. In determining compliance with this criterion, internal pressure is calculated for the peak power rod in the reactor, including accounting for the maximum computed fission and helium gas releases. In addition, the pellet swelling rate (to which the calculated clad creep rate is compared) is based on the observed swelling rate of "restrained" pellets, i.e., pellets in contact with clad, rather than on the greater observed swelling behavior of pellets which are free to expand.

If the maximum fuel rod internal pressure is anticipated to rise above the external coolant pressure, an additional evaluation is performed for application of the No-Clad Lift-Off methodology (Reference 173).

4.2.1.1.5 Material Selection

The fuel material is uranium dioxide in the form of sintered, high density, cylindrical pellets. This material is chemically inert with respect to Optimized ZIRLO™, ZIRLO™, or Zircaloy-4 cladding at reactor operating temperatures and pressures and is also highly resistant to attack by reactor coolant in the event cladding defects should occur. Extensive experimental work and operating experience have shown that the design parameters chosen conservatively account for changes in thermal performance during operation and that coolant activity buildup resulting from cladding rupture is limited by the ability of uranium dioxide to retain solid and gaseous fission products.

The BOC moderator coefficient is reduced by either poison pellets of Al_2O_3-B_4C, Gd_2O_3-UO_2, Er_2O_3-UO_2, or ZrB_2 coated pellets contained within burnable poison rods. Al_2O_3-B_4C has been previously evaluated under irradiated conditions and its behavior (irradiation induced swelling and helium release) is well within acceptable limits. In addition, Al_2O_3-B_4C is chemically compatible with Zircaloy-4 and can encompass all boron loadings required for a given fuel cycle by adjusting the Al_2O_3-B_4C ratio. The material properties that influence the thermal performance of Gd_2O_3-UO_2 relative to UO_2 are discussed in Section 4.2.1.2.1.1. The material properties that influence the thermal performance of Er_2O_3-UO_2 relative to UO_2 are discussed in Section 4.2.1.2.1.2. The material properties that influence the thermal performance of ZrB_2-UO_2 relative to UO_2 are discussed in Section 4.2.1.2.1.3.

Prior to Batch Z, the fuel assembly grid cage structure consisted of 11 Zircaloy-4 spacer grids, one Inconel-625 spacer grid (at the lower end), five Zircaloy-4 CEA guide tubes, and two stainless steel end fittings. With the introduction of the NGF design in Batch Z, the fuel assembly grid cage structure consists of 14 spacer grids (an Inconel-718 top grid, seven vaned Optimized ZIRLO™ mid grids, three unvaned Optimized ZIRLO™ mid grids, two vaned Optimized ZIRLO™ Intermediate Flow Mixing grids (IFMs), and one Inconel-625 bottom grid), five Stress-Relief Annealed (SRA) ZIRLO™ guide tubes, and two stainless steel end fittings. For Batch P and subsequent reload fuel, the lower Inconel-625 spacer grid has been replaced with the GUARDIAN™ lower spacer grid.

Zirconium alloys, selected for fuel rod cladding, guide tubes and spacer grids, have a low neutron absorption cross section, high corrosion resistance to reactor water environment, and there is little reaction between the cladding and fuel or fission products. As described in Section 4.2.1.3, Zircaloy-4 has demonstrated its ability as a cladding, CEA guide tube and spacer grid material.

Beginning with Batch X Fuel, ZIRLO™ fuel cladding has been used to replace the Zircaloy-4 cladding. ZIRLO™ is a Westinghouse proven zirconium-based alloy that improves fuel assembly corrosion resistance and dimensional stability under irradiation. The topical report (Reference 183) summarizes the ZIRLO™ material properties as they pertain to fuel rod cladding and provides an evaluation of these properties and the correlations for use in design and licensing analysis activities. Reference 197 updates the cladding corrosion model. In addition, since the ZIRLO™ cladding will be implemented in Zircaloy-4 cages with no changes to structural materials, Reference 183 provides a review of Westinghouse experience with ZIRLO™ cladding and Zircaloy-4 structural components to justify full batch implementation in the Westinghouse CENP fuel design.

The chemical composition of the fuel rod cladding fabricated with ZIRLO™ alloy beginning with Batch X fuel assemblies is similar to the Batch W Zircaloy-4 fuel rod cladding except for a slight reduction in the content of tin (Sn), iron (Fe), and the elimination of chromium (Cr). The ZIRLO™ alloy also contains a nominal amount of niobium (Nb). These composition changes, although small, are responsible for the improved corrosion resistance of ZIRLO™ compared to Zircaloy-4. The Batch X ZIRLO™ fuel rod is the same length as the Zircaloy-4 clad fuel rods used in the previous regions. The ZIRLO™ clad fuel rods grow less than their Zircaloy-4 equivalents.

Beginning with Cycle 20 (Batch Z), the NGF design has been in use with the Optimized ZIRLO™ fuel cladding to replace the ZIRLO™ cladding. The topical report, Reference 194, summarizes the material properties as they pertain to fuel rod cladding, design and licensing activities. Reference 197 updates the cladding corrosion model. The difference between Optimized ZIRLO™ fuel cladding and ZIRLO™ cladding is that Optimized ZIRLO™ has a slight reduction in tin content for improved corrosion resistance (0.6% minimum for Optimized ZIRLO™ versus 0.8% minimum for ZIRLO™). The NGF Optimized ZIRLO™ rods are smaller in diameter than those of the preceding designs (outside diameter of 0.374” versus 0.382”) to partially offset the pressure drop increase associated with the NGF spacer grids. To minimize the loss in void volume due to the diameter reduction, the overall length of the rod is increased by 0.7” which, in combination with a minor upper end cap change, lengthens the end plenum by 0.875”.

The bottom spacer grid is Inconel-625 and is welded to the lower end fitting. In this region of high crossflow, Inconel-625 was selected rather than Zircaloy-4 to provide additional strength and conservatism. Inconel-625 is a very strong material with good ductility, corrosion resistance and stability under irradiation at temperatures below 1,000 °F.

The previous Inconel Spacer Grid Assembly is replaced with a redesigned Inconel spacer grid assembly called the GUARDIAN™ Grid for Batch P and subsequent reload fuel. The design features employed in the GUARDIAN™ Grid improve the spacer grid assembly's ability to entrap debris. To assure that the trapped debris does not breach the cladding, the fuel and poison rods were designed to have long, solid Zircaloy-4 end caps in this region of the core. These end caps will absorb any wear induced by the trapped debris without the rod failing. All rods are secured in place by a detent groove-spring tab feature that prevents a rod from being uplifted. Reconstitution, however, is permitted by overcoming the retaining force provided by the detent groove-spring tab geometry.

The basic GUARDIAN™ Grid design is preserved with the introduction of the NGF design in Batch Z. Although changes to the grid are made for compatibility with pull-loading of the smaller diameter fuel rods, the GUARDIAN™ Grid maintains the benefits of the strong Inconel material with its debris-trapping features (changes described in detail in Section 4.2.1.2.3).

The NGF design also incorporates an Inconel grid at the top of the assembly to achieve the same benefits as at the bottom; improved strength with good ductility, corrosion resistance, and stability. The grid, discussed in detail in Section 4.2.1.2.3, is an Inconel-718 design with age-hardened straps that are brazed together. The material and basic design have been used in Westinghouse reactors for many years with excellent performance results.

The remaining grids in the NGF design are fabricated using Optimized ZIRLO™ strips. These grids include seven vaned mid grids, three unvaned mid grids, and two vaned IFM grids, and are discussed in detail in Section 4.2.1.2.3. The use of Optimized ZIRLO™ improves the corrosion resistance dimensional stability of the grids, thereby reducing grid growth and improving fretting resistance.

The guide tubes in the NGF design are fabricated from SRA ZIRLO™ instead of SRA Zircaloy-4. As with the NGF mid and IFM spacer grids, this improves the corrosion resistance dimensional stability of the guide tubes. The use of SRA material with the same material strength requirements as the prior guide tubes ensures the NGF guide tubes maintain the same structural capability as the prior guide tubes.

The fuel assembly lower end fitting is of Grade CF-8 or, since 1993, Grade CF-3 cast stainless steel and the upper end fitting assembly consists of two cast Type 304 stainless steel plates and five Type 304 stainless steel machined alignment posts. At these locations, neutron economy is not of great importance, but high strength and high corrosion resistance are required. Type 304 stainless steel has been utilized in almost all pressurized water environments. Grade CF-8 or CF-3 castings (the cast counterpart of wrought Type 304), will exhibit equivalent properties.

4.2.1.1.6 Radiation Damage to Fuel Cladding

Optimized ZIRLO™, ZIRLO™, and Zircaloy-4 fuel cladding have been utilized in Pressurized Water Reactors (PWRs) at temperatures and burnup anticipated in current designs with no failures attributable to radiation damage. Mechanical property tests on ZIRLO™ and Zircaloy-4 cladding exposed up to neutron irradiation of 9.06×10^{21} n/cm^2 (estimated) have revealed that the cladding retains a significant amount of ductility from about 1 to over 4 percent total strain. Results are shown in Table 4.2-2 for Zircaloy-4 and in Reference 184 for ZIRLO™. Due to the minimal material compositional differences between Optimized ZIRLO™ and ZIRLO™ and the indistinguishable difference in ductility derived from burst testing, the ZIRLO™ results of Reference 184 are also concluded to be applicable to Optimized ZIRLO™.

4.2.1.1.7 Mechanical Properties of Cladding

Table 4.2-3 is a list of unirradiated mechanical properties of Zircaloy-4, ZIRLO™, and Optimized ZIRLO™ fuel rod cladding at room temperature and at 675 °F.

4.2.1.1.8 Effect of Swelling

Fuel swelling due to irradiation (accumulation of solid and gaseous fission products) and thermal expansion results in an increase in the fuel pellet diameter. The design makes provision for accommodating both forms of pellet growth. The fuel-clad diametral gap is more than sufficient to accommodate the thermal expansion of the fuel. To accommodate irradiation-induced swelling, it is conservatively assumed that the fuel-clad gap is used up by the thermal expansion and that only the fuel porosity and the dishes on each end of the pellets are available. Thermal and irradiation induced creep of the restrained fuel results in redistribution of fuel so that the swelling due to irradiation is accommodated by the free volume (8.4 percent of the fuel volume).

For such restrained pellets, and at a total fission-products-induced swelling rate of 0.7 percent $\Delta V/V$ per 10^{20} fiss/cm^3, 0.54 percent would be accommodated by the fuel porosity and dishes through fuel creep, and 0.16 percent would increase the fuel diameter. Assuming peak burnup, this would correspond to using up a void volume equal to ~ 7.4 percent of the fuel volume and increasing the fuel rod diameter by a maximum of < 0.0025 inch (< 0.7 percent clad strain). When these numbers were compared to the minimum available volume and the maximum allowable strain, it was concluded that sufficient accommodation volume has been provided even under the most adverse burnup and tolerance conditions.

Demonstration of the margin which exists is seen in the Large Seed Blanket Reactor (LSBR) irradiation. Two rods which operated in the B-4 loop of the MTR offer an interesting simulation for current PWR design (References 47, 70 and 74). Both rods were comprised of 95 percent theoretical density pellets with dished ends and clad in Zircaloy. The first of these, No. 79-21, was operated successfully to a burnup of 12.41 x 10^{20} fiss/cm^3 (> 48,000 MWD/MTU). The second fuel pin, No. 79-25, operated successfully to 15.26 x 10^{20} fiss/cm^3 (>60,000 MWD/MTU). The linear heat rating ranged from 7.1 to 16.0 kW/ft. The wall thickness for the latter pin was 0.028 of an inch as compared with 0.016 of an inch for the former. All other parameters were essentially identical. The two rods were assembled by shrinking the cladding onto the fuel. The maximum diametral increase measured at the ridge heights for rod 79-21 was 0.005 of an inch, while it was less than 0.002 of an inch for rod 79-25. From post-irradiation examination, it was concluded that approximately 84 percent of the total fuel swelling was accommodated by the porosity and dishes, while 16 percent caused diametral expansion of the clad and ridging at pellet interfaces. These results indicate that a comparable irradiation of the fuel elements for the Combustion Engineering design (cold diametral gap 0.007 of an inch, wall thickness of 0.025 of an inch, density 95 percent TD) would allow adequate margin for swelling accommodation.

The successful combined VBWR-Dresden irradiation of Zircaloy-clad oxide pellets provides additional confidence with respect to the design conditions for the fuel rods for this core (References 44 and 111). Ninety-eight rods which had been irradiated in VBWR to an average burnup of about 10,700 MWD/MTU were assembled in fuel bundles and irradiated in Dresden to a peak burnup greater than 48,000 MWD/MTU. The reported maximum heat rating for these rods is 17.3 kW/ft which occurred in VBWR. Post-irradiation examination (Reference 109) revealed that diametral increases in the fuel rods ranged from 0.001 to 0.003 of an inch maximum.

The maximum diametral change corresponds to 1.42 percent $\Delta V/V$ (or .12 percent $\Delta V/V$ per 10^{20} fiss/cm^3) for these .424-inch diameter rods. The relevant fuel parameters are listed below for the above test and the Combustion Engineering design.

	Fuel Density % TD	Cold Diametral Gap (In.)	Peak Burnup (Mwd/MTU)
VBWR-Dresden	95	0.004 to 0.008	> 48,000
LSBR-MTR	95	0.001	50,000; 61,000
C-E Design	95	0.007	55,000
ZIRLO^{TM} Design	95	0.0062	60,000
Optimized ZIRLO^{TM}	95	0.0065	60,000

A comparison of the design parameters above, in Reference 183 for ZIRLO^{TM}, and in Reference 194 for Optimized ZIRLO^{TM}, relative to the test results, provides a demonstration of the clad strains resulting from the swelling of fuel.

4.2.1.1.9 Variation of Melting Point and Fuel Conductivity With Burnup

The variation of melting point and fuel conductivity with burnup is discussed in Section 4.4.3.4.3.

4.2.1.1.10 Combined Effects of Fast Flux and Cladding Temperature

The combined effects of fast flux and cladding temperature are considered in three ways as discussed below:

A. Cladding Creep Rate

The in-pile creep performance of Zircaloy-4, ZIRLO^{TM}, and Optimized ZIRLO^{TM} is dependent upon both the local material temperature and the local fast neutron flux. The functional forms of the dependencies are presented in Reference 10 for gap conductance calculations, and in Reference 12 for Zircaloy-4 cladding collapse time predictions. The functional forms of the dependencies are presented in Reference 183 for ZIRLO^{TM}, while Reference 194 documents the applicability of the ZIRLO^{TM} functional forms to Optimized ZIRLO^{TM}.

B. Cladding Mechanical Properties

The yield strength, ultimate strength and ductility of Zircaloy-4, ZIRLO^{TM}, and Optimized ZIRLO^{TM} are dependent upon temperature and accumulated fast neutron fluence. The temperature and fluence dependence is discussed in Section 4.2.1.2.4.1. It is Westinghouse's practice to use unirradiated or irradiated properties depending upon which is more restrictive for the phenomenon being evaluated.

C. Irradiation Induced Dimensional Changes

Zircaloy-4, ZIRLO^{TM}, and Optimized ZIRLO^{TM} have been shown to sustain dimensional changes (in the unstressed condition) as a function of the accumulated fast fluence. These changes are considered in the appropriate clearances between the various core components. The irradiation induced growth correlation method is discussed in Section 4.2.1.3.8.

4.2.1.1.11 New Fuel Handling and Shipping Design Loads

Three specific design bases have been established for shipping and handling loads. These are as follows:

A. The fuel assembly, when supported in the fuel shipping container, will be capable of sustaining the effects of 5 g axial, lateral or vertical acceleration without sustaining stress levels in excess of those allowed for normal operation.

   Impact recorders are included with each shipment which indicate if loadings in excess of 5 g's were sustained by the fuel assembly. A record of shipping loads in excess of 5 g's indicates an unusual shipping occurrence, in which case the fuel assembly is inspected for damage prior to releasing it for use.

   The axial shipping load path is through either end fitting to the guide tubes. A 5 g axial load produces a compressive stress level in the guide tubes less than the two-thirds yield stress limit that is allowed for normal operation. The fuel assembly is prevented from buckling by the clamshell. For lateral or vertical shipping loads, the grid spring tabs have an initial preload which exceeds five times the fuel rod weight. Therefore, the spring tabs see no additional deflection as a result of 5 g lateral or vertical acceleration of the shipping container. In addition, the side load on the grid faces produced by a 5 g lateral or vertical acceleration is less than the measured impact strength of the grids.

B. The fuel assembly will be capable of sustaining a 5,000-pound axial load applied at the upper end fitting by the refueling grapple (and resisted by an equal load at the lower end fitting) without sustaining stress levels in excess of those allowed for normal operation.

C. The fuel assembly will be capable of withstanding a 0.125 inch deflection in any direction whenever the fuel assembly is raised or lowered from a horizontal position without sustaining a permanent deformation beyond the fuel assembly inspection envelope.

   Fuel handling procedures require the fuel assembly deflection be limited to a maximum of 0.125 inch in any direction whenever the fuel assembly is raised from or lowered to a horizontal position. This limits the stress and strain imposed upon the fuel assembly to values well below the limits set for normal operating conditions.

New fuel assemblies arrive at ANO in shipping containers. Each shipping container holds one new fuel assembly and weighs approximately 5100 pounds when loaded. The shipping containers are normally transferred from the ANO train bay to a laydown area in the vicinity of the spent fuel pool by the L3 fuel handling crane. This transfer is conducted in accordance with the procedure for the control of heavy loads. The control of heavy loads procedure implements the requirements of NUREG-0612 and ensures safe load paths and proper heavy load handling practices are observed during the transfer of new fuel. Individual new fuel assemblies weigh less than 2000 pounds and do not meet the definition of a heavy load. New fuel assemblies are removed from the shipping container using the 2L35 crane and are then transferred to the new fuel storage racks or the spent fuel pool storage racks.

The capability of the fuel assembly to withstand the above loading conditions is verified by the structural testing described in Section 1.5.

4.2.1.2 Fuel Design Description

4.2.1.2.1 Fuel Rod

The fuel rods consist of slightly enriched UO_2 cylindrical ceramic pellets, a round wire Type 302 stainless steel compression spring, and an alumina spacer disc located at each end of the fuel column, all encapsulated within a Zircaloy-4 tube seal welded with Zircaloy-4 end caps for fuel Batches K, M, and N. The upper alumina disc was removed in the Batch P and subsequent reload fuel. The lower alumina disc was removed in the Batch U and subsequent reload fuel (Figure 4.2-3). ZIRLO™ cladding was also used beginning with Batch X. Annular fuel pellets are also used in the cutback/blanket zones in the fuel rods for Batch Y, consistent with the use of such pellets in the poison rods (see Section 4.2.1.2.1.3 and Figure 4.2-3C). The fuel rods are internally pressurized with helium during assembly. A small number of fuel rods of unique design may be included for purposes of testing.

Although the basic configuration of the NGF fuel rod is the same as that prior to Batch Z, there are significant differences in the detailed design of the rods. The nominal active length remains 150", but the fuel rod stack does not include any cutback/blanket pellets. The use of Optimized ZIRLO™ for the NGF rods has been discussed in Section 4.2.1.1.5, as well as the NGF fuel rod having a smaller outside diameter than prior designs (0.374" versus 0.382") to compensate for some of the pressure drop increase associated with the NGF spacer grids. The 0.374" diameter rod is the same as the standard Westinghouse 17 x 17 design, which precipitated the use of the 17 x 17 cladding dimensions and pellet geometry for the NGF design. Therefore, the cladding outside/inside diameters are 0.374" and 0.329", while the fuel pellet has a diameter of 0.3225", a length of 0.387", and a spherical dish at each end instead of a truncated dish. Also as identified in Section 4.2.1.1.5, the overall length of the fuel rod is increased by 0.7" to minimize the loss of void volume associated with the diameter reduction of the rod. To further offset the effect of the diameter reduction, the initial fill gas pressure of the fuel rods has been reduced to approximately 275 psig. The bottom end cap has been modified to include a recess in the bottom end that is necessary for pull-loading the rods into the fuel assemblies. The length of the upper end cap has been reduced and the "acorn" removed to allow as large an increase as possible to the plenum to facilitate the accommodation of fission gas release.

4.2.1.2.1.1 Fuel Rod with Gadolinia (Gd_2O_3) Addition

Some fuel rods in the fuel assembly may contain pellets which incorporate gadolinia (Gd_2O_3) as a burnable absorber into the central portion of the pellet column (Figure 4.2-3a). These fuel rods are analyzed by the same methods and subject to the same design criteria as fuel rods containing only urania pellets.

The gadolinia-urania pellets are fabricated by mechanically blending gadolinia powder with urania powder to produce a homogenous mixture, followed by pressing and sintering.

The addition of gadolinia fuel pellets may influence the thermal properties of fuel. Of particular importance are the properties that are used in the fuel performance analyses. These properties are: 1) solidus temperature, 2) specific heat, 3) density, 4) thermal expansion, and 5) thermal conductivity. The effect of gadolinia addition on these properties of gadolinia is discussed in Reference 172.

The performance criterion employed in Reference 172 for the gadolinia-urania (Gd_2O_3-UO_2) fuel rod is to assure that these rods are always less limiting in terms of fuel temperature (stored energy), internal rod pressures, and margin-to-melting than the UO_2 rods in a given core.

4.2.1.2.1.2 Fuel Rod with Erbia (Er_2O_3) Addition

Some fuel rods in the Batch U and subsequent fuel assemblies may contain pellets which incorporate erbia (Er_2O_3) as a burnable absorber into the central portion of the pellet column (Figure 4.2-3b). These fuel rods are analyzed by the same methods and subject to the same design criteria as fuel rods containing only urania pellets.

The urania erbia pellets are fabricated by mechanically blending erbia powder with urania powder to produce a homogeneous mixture, followed by pressing and sintering.

The addition of erbia to urania fuel pellets may influence the thermal properties of the fuel. Of particular importance are the properties that are used in fuel performance analyses. These properties are: 1) solidus temperature, 2) specific heat, 3) density, 4) thermal expansion and 5) thermal conductivity. The effect of erbia addition on these properties of urania is discussed in Reference 182.

4.2.1.2.1.3 Fuel Rod with IFBA (ZrB_2) Addition

Beginning with Batch X, the fuel rods include a thin ZrB_2 coating on standard UO_2 pellets as an Integral Fuel Burnable Absorber (IFBA) and include annular pellets in the poison cutback region as new features of the ANO-2 fuel rod design (Figure 4.2-3C). The poison cutback region is the nominal 8 inches of fuel pellets located at each end of the fuel rod pellet stack and may vary with cycles. The fuel pellets in the poison cutback region are annular pellets. The annular pellets have the same pellet outside diameter (.3250 inch) and pellet edge chamfer as the current enriched solid fuel pellets, but have no dish on the pellet ends. The annular pellets are also longer than the solid fuel pellets (.500 inch versus .390 inch prior to Batch Z). The diameter of the annulus is 0.1625 inches which results in about 25% annular volume to accommodate gas release in the IFBA rods. The annular pellets are used to increase the void volume for gas accommodation within the fuel rod, thereby providing margin to meet the rod internal pressure criterion. The annular pellets utilize chamfered pellets, which are slightly different in length from the enriched solid pellets to help prevent accidental mixing during manufacturing.

The NGF IFBA rod design introduced in Batch Z is the same as the NGF fuel rod design discussed in Section 4.2.1.2.1 except for the initial fill gas pressure and the stack configuration. To accommodate the helium release associated with irradiation of the IFBA coating, the initial fill gas pressure of the IFBA rods is approximately 150 psig (consistent with to the prior IFBA rod designs). The stack configuration for Batch EE consists of a 138” central region of IFBA coated enriched pellets and 6” top and bottom cutbacks comprised of enriched annular pellets. The coated pellets are the same configuration as in the fuel rod, while the annular pellets are longer (0.5” versus 0.387” beginning with Batch Z), have a central hole (0.155” diameter), and do not have dishes on the ends.

The IFBA coated fuel pellets are identical to the enriched UO_2 pellets except for the addition of a thin ZrB_2 layer on the pellet cylindrical surface. The ZrB_2 is uniformly coated as a very thin layer (less than half a mil) onto the outer surface of the UO_2 pellets prior to loading into the fuel rod cladding tubes. This is done rather than being mixed with the UO_2 as done with other IFBA

materials (e.g., erbia or gadolinia). As the B-10 absorber burns out, the fuel rod is left with no residual absorber worth as is the case with other IFBA materials. However, the burnout of the absorber results in production of helium gas, some of which is released into the fuel rod void volume. Coated pellets occupy the central portion of the fuel stack. The number and pattern of IFBA rods within an assembly vary depending on specific application. The ends of the enriched coated pellets are dished to allow for greater axial expansion at the pellet centerline and to increase the void volume for fission gas release. Also, to compensate for the additional helium released from the ZrB_2 coating, the initial fill gas pressure, designed to reduce pressure differences across the cladding, is reduced as compared to non-IFBA rods.

The topical report (Reference 185) describes Westinghouse's 15-year fabrication and operational experience with ZrB_2 IFBA and the implementation and effect of using the coating on the CE fuel assembly design and safety analyses. The neutronics effect, the helium production effect on internal gas pressure, and the mechanical effect of the coating thickness are all taken into account in the design and safety evaluations for CE designed PWRs as described in the reference.

4.2.1.2.2 Burnable Neutron Absorber Rods

Fixed burnable neutron absorber (poison) rods are included in selected fuel assemblies. They replace fuel rods at selected locations. The poison rod cladding and end caps are identical to those in fuel rods. They contain a shorter column of burnable poison pellets instead of fuel pellets. The poison material is alumina with uniformly dispersed boron carbide particles. The balance of the column consists of spacers made of Zircaloy tubing fluted on its end and a stainless steel plenum spring (Figure 4.2-6). A small number of poison rods of unique design may be included for purposes of testing and/or demonstration. The use of test rods has been previously reviewed and accepted by the NRC as described in CEN-50-A(P), Revision 1, which is incorporated by reference.

The design of the poison rods incorporates a number of features aimed at reducing the potential for pellet clad interaction and poison rod failures due to hydriding of the cladding. These include rod pressurization, increased pellet clad diametral gap, reduced plenum spring preload, use of chamfered and tumbled pellets, and spacers made from Zircaloy tubing. In addition, the pellet moisture specification limit was lowered and the manufacturing process eliminates moisture ingress from other components.

The design of the poison rod assembly was changed in Cycle 8 to incorporate a debris-fretting-resistance feature at the lower end of the rod. Similar to the fuel rod assembly (discussed in Section 4.2.1.2.3), a long lower end cap provides this feature. Listed below are the differences between the Cycles 7 and 8 poison rod assemblies:

a) The overall length of the lower end cap has increased from 0.641 inch to 3.701 inches.

b) The overall length of the lower spacer tube was decreased from 10.281 inches to 7.250 inches.

c) The overall length of the upper plenum was increased from 11.008 inches to 11.310 inches.

These changes in the design will enable the use of a debris-fretting-resistance feature at the lower end of the rod while not limiting the mechanical-design-life of the poison rod assembly.

Unlike Batch N which used burnable poison pellets having a length of one inch, the Cycle 12 Batch P poison rod assemblies used pellets with a length of 0.5". An evaluation shows that replacing one inch pellets with 0.5" pellets will neither positively nor negatively affect the form, fit, or function of the column of pellets.

4.2.1.2.3 Fuel Assembly

The fuel assembly (Figure 4.2-4) consists of 236 fuel rods, five control element guide tubes, 12 fuel rod spacer grids, upper and lower end fittings, and a holddown device. The outer guide tubes, spacer grids and end fittings, form the structural frame of the assembly.

The fuel spacer grids maintain the fuel rod pitch over the full length of the fuel rods providing positive lateral restraint to the fuel rod but only frictional axial restraint to fuel rod motion. The grids are fabricated from preformed Zircaloy or Inconel strips (the bottom spacer grid material is Inconel) interlocked in an egg crate fashion and welded together. Each fuel rod is supported by two leaf springs and two arches which are directly opposite these leaf springs. The leaf springs press the rod against the arches to restrict relative motion between the grids and the fuel rods. The spring and arch positions are reversed from grid to grid to provide additional restriction to relative motion. The perimeter strips also contain springs and arches in addition to special features to prevent hangup of grids during a refueling operation.

In Cycle 11 the HID-1L, laser welded Zircaloy spacer grid assembly, replaced the HID-1, TIG welded Zircaloy spacer grid assembly. The quality of the HID-1L spacer grid assembly is improved because the weld process produces a greater consistency in dimensional control.

A discussion of the HID-1L spacer grid assembly follows:

1. The Cycle 11 fuel bundle HID-1L spacer grids are 0.006 inches larger in width than the Cycle 10 fuel bundle HID-1 spacer grids (8.140 inches vs. 8.134 inches). This initial increase in width is acceptable since this strip is stamped in the transverse direction. Irradiation produces contraction for transversely stamped strips whereas irradiation produces expansion for longitudinally stamped strips (Cycle 10 Fuel). The 0.006 inch increase in width was chosen to preserve the mid-life fuel bundle envelope. The increase in the outside envelope of the spacer grid assembly was accomplished by increasing the perimeter strip spring tab and arch height while making no change in the rod pitch.

2. The four perimeter strips of the HID-1L spacer grid assembly are lap joint welded at the center of each face of the spacer grid assembly, unlike the perimeter strips of the HID-1 spacer grid assembly which are butt joint welded at the corners. This change in the design produces more uniform dimensions since the four corners are preformed.

3. Laser welding produces a smaller and more uniform weld nugget than TIG welding. Strength testing has shown that the laser welded grids will meet all of the design criteria for LOCA and seismic loads.

The GUARDIAN™ Grid was introduced in the Batch P reload fuel assemblies in Cycle 12 and has been retained in subsequent reload fuel assembly designs. The specific changes to the fuel bundle design are as follows:

1. The top grid surface of the GUARDIAN^{TM} Grid design with respect to the top of the lower end fitting is 2.025" lower than the standard Inconel spacer grid assembly design. The height of the lower end fitting is 3.112" for both Batch N and P fuel.

2. To provide a snug fit up between the GUARDIAN^{TM} Grid and the lower end fitting, the four sides adjacent to the top surface of the lower end fitting were machined to provide a recess midway along each of the four sides. The recess allows the overlap in the four welded joints that connect the GUARDIAN^{TM} Grid perimeter strips to fit properly with the lower end fitting under worse case tolerance conditions. Because this change is not within the normal flowpath of the coolant this modification will not affect the form, fit, or function of the lower end fitting assemblies.

3. The number of welds attaching the GUARDIAN^{TM} Grid to the lower end fitting was increased from five to seven welds per side. This change was necessary to secure the corners of the perimeter strips. The GUARDIAN^{TM} Grid assembly added four cutouts in the perimeter strip corners to allow the bottom edge of the perimeter strip to be tapered inward. The purpose of a taper on the perimeter strips is to assure contact between the grid and lower end fitting. A snug fit-up precludes possible burn through of the strip during welding. The additional two welds located at the corners of the grid assembly and lower end fitting interface assure the perimeter strip will not be bent at these locations during bundle handling. The new weld requirements do not cause any of the design limits in the design criteria to be exceeded.

4. Because the top of the GUARDIAN^{TM} Grid is 2.025" lower than the standard Inconel Spacer Grid Assembly, the length of the standard long 16 x 16 lower end cap for both the fuel and poison rods decreased by 1.140". The length of the Batch N end cap is 3.370" and the length of the Batch P end cap is 2.230". This change in end cap length will keep the clad out of the GUARDIAN^{TM} Grid.

5. To compensate for the decrease in the lower end cap length of 1.140", the length of the fuel rod plenum region was increased by 1.000", the active fuel length was increased to 150.000" and the 0.25" upper alumina spacer disc was removed.

6. The plenum length for the fuel rods was increased from 7.888" for Batch N to 8.888" for Batch P. Because of the change in plenum length, the plenum spring for the fuel rods was redesigned. The new Batch P plenum spring is longer and has a larger material volume than the Batch N design (0.111 in^3 vs. 0.096 in^3). These changes allow the fuel rods to meet all of their design criteria.

7. The upper alumina spacer disc was removed from the fuel rods to maximize internal rod void volume. As a result of removing the Al_2O_3 spacer disc, the spring to clad and spring to pellet interfaces were evaluated. These evaluations concluded that removing the upper spacer disc will neither have a positive nor a negative impact on fuel rod performance.

8. Using the newly designed long lower end cap causes the active fuel region to be lowered by 1.140". This change in the location of the active fuel region relative to the Batch N design will not impact any of the results for the various accident analyses nor will it negatively impact the reactor vessel and its internals.

9. The configuration of the lower end cap's tip has been modified to improve the ease of loading the fuel and poison rods into the grid cage assembly. The region where the serial number was engraved in the previous design has been eliminated to provide the end cap with a continuous taper. A continuous taper improves the rod's passage through the spacer grid assembly. The serial number is located within the groove of the lower end cap. These design changes to the end cap design do not impact any of the fuel rod or fuel bundle assembly design criteria.

10. The plenum length for the poison rod design was increased from 11.310" for Batch N to 11.450" for Batch P. Because of the change in plenum length, the plenum spring for the poison rods was redesigned. The new plenum spring is longer and has approximately the same material volume as the Batch N design (0.044 in^3 vs. 0.042 in^3). These changes allow the poison rods to meet all of their design criteria.

11. To compensate for the decrease in the lower end cap length of 1.140", the length of the poison rod plenum region was increased by 0.140" and the length of the poison column was increased from 135.000" for Batch N to 136.000" for Batch P or 1.000".

Subsequent to implementation of the Guardian grid, the following changes were made (beginning with Batch U assemblies) due to transition of fuel manufacturing to a different facility:

1. To be compatible with the new Tungsten Inert Gas (TIG) welding process, the lower end cap length was changed to 2.125”. Additionally, the inclusion of a lower alumina spacer disc was a result of the previous Magnetic Force (MF) welding process. The lower alumina disk has therefore been eliminated.

2. As a result of eliminating the lower alumina disc and changing end cap lengths to support the TIG weld process, the plenum length has increased to 9.138”. The basic geometry of the plenum spring was changed in response to the increased plenum length.

3. The result of eliminating the lower alumina spacer disc and the shortening of the lower end cap is a reduction in the active core region bottom elevation. The active fuel elevation is lowered an additional 0.355” relative to the change made for implementation of the Guardian grid.

The 11 Zircaloy-4 spacer grids are fastened to the Zircaloy-4 guide tubes by welding, and each grid is welded to each guide tube at eight locations, four on the upper face of the grid and four on the lower face of the grid, where the spacer strips contact the guide tube surface. The lowest spacer grid (Inconel) is not welded to the guide tubes due to material differences. It is supported by an Inconel-625 skirt which is welded to the spacer grid and to the perimeter of the lower end fitting.

The upper end fitting is an assembly consisting of two cast stainless steel plates, five machined posts, and five helical Inconel X-750 springs, and serves as an attachment for the guide tubes, the fuel assembly lifting fixture, and the alignment device which locates the upper portion of the fuel assembly. The lower cast plate locates the top ends of the guide tubes and is designed to retain the fuel rods in the event of certain postulated accident conditions.

All fuel assemblies are fitted with stainless steel inserts. These inserts are added to the upper ends of the guide tubes and flared in place to protect against wear from CEA rod vibration. Required fittings inspections performed following Cycle 1 operation indicate that this modification has significantly reduced wear from CEA rod vibration.

The upper cast plate of the assembly which resembles a spider, together with the helical compression springs, comprise the holddown device. The spider is moveable and acts on the underside of the fuel alignment plate. The spider is loaded by the compression springs; one spring is located around each of the posts. Since the springs are located at the upper end of the assembly, the spring load combines with the fuel assembly weight to counteract upward hydraulic forces. The springs are sized and the spring preload selected such that a net downward force will be maintained for all normal and unanticipated transient flow and temperature conditions. The design criteria limit the maximum stress under the most adverse tolerance conditions to below yield strength of the spring material. The maximum stress occurs during cold conditions and decreases as the reactor heats up. The reduction in stress is due to a decrease in spring deflection resulting from differential thermal expansion between the Zircaloy fuel bundles and the stainless steel internals.

During normal operation, a spring will never be compressed to its solid height. However, if the fuel assembly were loaded in an abnormal manner such that a spring were compressed to its solid height, the spring would continue to serve its function when the loading condition returned to normal.

The lower end fitting is a single piece stainless steel casting consisting of a plate with circular flow holes and four support legs which also serve as alignment posts. Precision drilled holes in the support legs mate with four core support plate alignment pins, thereby properly locating the lower end of the fuel assembly. In Cycle 8, the lower end fittings were changed. Listed below are those changes:

1) The design of the lower end fittings has been changed to incorporate the following features:

   a) Two (2) stanchions or panels that face the outer perimeter of the flow plate are placed on each of the four lower end fitting posts. This feature will improve the ease of installing the fuel bundle assemblies in-core.

   b) The location of the bottom surface of the ribbing that connects the four lower end fitting posts has been changed from being flush to being 0.125" above the bottom seating surface of the posts. Because the lower end fitting was redesigned, this feature was incorporated into the design to improve the fabricability of the lower end fitting.

   c) Additionally, the height of the ribbing has been increased from 0.613" to 1.000". The change in this feature, in addition to the change discussed above, increases the strength of the lower end fitting under many of the load conditions that a fuel bundle assembly is subjected to.

2) The locking discs that are used in the lower end fitting-to-guide tube connection as an anti-rotation device have been redesigned. The basis for the redesign is to enable one locking disc to be used in all of the various C-E designed fuel bundle assemblies without affecting any of the design interface requirements between the fuel bundle assembly and the four fuel alignment pins located on the core support plate and without affecting the structural integrity of the guide tube connection.

The four outer guide tubes have a widened region at the upper end which contains an internal thread. Connection with the upper end fitting is made by passing the externally threaded end of the guide posts through holes in the flow plate and into the guide tubes. When assembled, the flow plate is tightly secured between flanges on the guide tubes and on the guide posts. The connection with the upper end fitting is locked with a mechanical crimp. Each outer guide tube has, at its lower end, a welded Zircaloy-4 fitting. This fitting has an externally threaded portion which is secured by a Type 304 steel bolt which passes through a hole in the fuel assembly lower end fitting. This joint is secured with a stainless steel locking disc tack welded to the lower end fitting in two places.

The central guide tube inserts into a socket in the upper end fitting and is thus restrained laterally by the relatively small clearance at this location and has an end fitting at the lower end with an internally threaded portion. The central guide tube is secured by a Type 304 stainless steel bolt which passes through a hole in the fuel assembly lower end fitting. This joint is secured with a stainless steel locking disc tack welded to the lower end fitting in two places. The upper end fitting socket is created by the center guide tube post which is threaded into the lower cast flow plate and tack welded in two places.

The guide tubes are fabricated from Zircaloy-4 in the fully-annealed condition for Batches A thru D, except for 10 Batch A fuel assemblies. The guide tubes in those 10 Batch A assemblies, as well as all guide tubes in Batches E thru Y, are fabricated from Zircaloy-4 in the stress-relief annealed (SRA) condition. The guide tubes in Batch Z and beyond are fabricated from SRA ZIRLO™.

The mechanical design of the Cycle 10 and successive cycles reload fuel is essentially the same as the debris-resistant batches of fuel that were used in Cycle 9. The main differences between the Cycle 10 and successive cycles and the Cycle 9 fuel bundle assembly designs are in the designs of the skirt located at the bottom end of the upper end fitting's outer posts and in the flange located at the upper end of the outer guide tube assembly. The outer post, which is screwed into the guide tube flange to fasten the upper end fitting assembly to the grid cage, has its skirt expanded within the flange. The expansion of the skirt into the holes of the flange provides the anti-rotation or locking feature that precludes the post from unfastening. For Cycle 10, the minimum wall thickness of the post's skirt was increased from 0.0115 inch to 0.014 inch and its length was increased by 0.050 inch. The centers of the holes located through the wall of the guide tube flange were placed 0.025 inch lower than the holes in the previous batches and the two 1/4 inch diameter holes were replaced with four 0.188 inch diameter holes. These changes to the designs of the post skirt and guide tube flange, in addition to the changes made to the tooling that is used to expand the post skirt within the guide tube flange, allow the skirt to be expanded without distorting adjacent sections of the post. Distortion in the nonskirt regions of a post could potentially make removal of the post difficult. In addition, these changes will minimize the potential for the skirt material to rupture during the expansion process.

The NGF design implemented in Batch Z was designed to be mechanically compatible with the standard design of recent batches for reactor operation with mixed fuel cores. The NGF design incorporates many of the same features and geometry as the standard fuel assembly. Both designs have the same overall length at beginning of life. The basic structure consists of 5 large guide thimble tubes connected to spacer grids at intermediate locations and to nozzles at the ends. In both designs the guide thimbles have the same diameters and spacing, the structural spacer grids are at essentially the same elevations, the top and bottom nozzles are very similar, and the guide thimbles are connected to the top and bottom nozzles using the same type of connections. Both designs have 236 fuel rods with the same pitch, and the two designs have a very similar Guardian™ (bottom Inconel debris-filtering/retention) grid. In addition, structural testing has demonstrated that the response to external loads is similar and meets the design criteria for both designs.

Although similar in overall design, the details of the NGF design features a full complement of innovative components to improve fuel reliability, fuel cycle economics, fuel duty, manufacturability, burnup capability, and thermal performance. The major differences between the two designs are the following:

- Two changes in the fabrication of the NGF assembly include the use of bulged joints to build the grid cage versus welded joints and the use of a pull rod loading process versus the current push loading process. These process changes were selected for NGF to improve fabrication of the design while preserving the rigidity of the fuel assembly structure.

- The guide thimbles are made of SRA Zircaloy-4 in the standard design and SRA ZIRLO™ in the NGF design. This change was made because of ZIRLO™'s improved corrosion resistance and dimensional stability under irradiation.

- The NGF guide tube flange is connected to the guide tube by bulging instead of by welding as in the standard design. The bulged flange to guide tube connection retains adequate strength and is necessary with a bulged grid cage design to compensate for the shrinkage of the guide tubes during the forming of the grid-to-guide tube bulges.

- An anti-rotation feature has been incorporated in NGF to prevent the transmittal of torque to the grids during the installation or removal of the upper end fitting outer posts. The guide tube flange design includes four “lugs” or “keys” that engage four slots machined in the upper end fitting flow plate, thereby preventing rotation of the guide tube flange while the outer posts are being installed.

- The welded top grid in the standard design (prior to NGF design) is made of Zircaloy-4, and has cantilever springs. The NGF top grid is made of Inconel-718, has vertical springs, horizontal dimples, and an anti-snag perimeter strap design to minimize adverse assembly interactions during core loading and unloading. Stainless steel sleeves are brazed into the grid at guide tube locations and are bulged with the guide tubes during cage fabrication to secure the grid to the guide tubes. Other than the size and number of guide tube openings, the design is equivalent to that which has an extensive history of successful operation in Westinghouse NSSS nuclear power plants.

- Mid Spacer Grids

    - The standard design Mid grids (HID-1L) are made using wavy strap Zircaloy-4, while the NGF Mid grids use straight strap Optimized ZIRLO™. The material change was made because of Optimized ZIRLO™'s improved corrosion resistance and dimensional stability under irradiation. The change to straight straps was made to improve fabrication and to facilitate the incorporation of the "I-spring" design and mixing vanes.

    - The standard HID-1L grids have cantilever springs, while the NGF grids have vertical springs with support arches at either end, hence the name "I-springs", which are designed to reduce grid-to-rod gap formation and to provide a longer contact length to increase grid-to-rod fretting margin.

    - The NGF Mid grids in the upper portion of the fuel assembly have side supported mixing vanes to improve thermal performance and allow reconstitution from the top of the fuel assembly.

    - As with the top grid, the Mid grids have sleeves (in this case, Optimized ZIRLO™ sleeves) welded into the guide tube openings and bulged with the guide tubes both above and below the grid.

- Intermediate Flow Mixing (IFM) Grids

    - The NGF design incorporates two IFM grids to improve thermal performance in two critical grid spans near the top of the active core.

    - The IFMs are short, non-structural grids that are made from straight strap Optimized ZIRLO™ with side-supported mixing vanes and opposing dimples with small grid-to-rod gap in lieu of an active (preloaded spring-dimple) support system.

    - The IFM grids have sleeves that are similar to the Mid grid sleeves, except the protrusion of the sleeve above the IFM grids is less than above the Mid grids because the IFM sleeves are only bulged with the guide tubes below the grid.

- To accommodate the transition from rod push loading to rod pull loading for NGF, changes were made to the Guardian grid design, the lower end fitting, the connection between the two, and the initial axial positioning of the fuel rods:
    - In lieu of direct welding to the lower end fitting, the NGF Guardian grid is retained by inserts that are welded to the four outer guide tube openings and then clamped between the bottom of the guide tube and the lower end fitting.

    - Since the bottom edge of the NGF Guardian grid outer strap is not welded to the lower end fitting, the outer strap was modified to be the same as the upper edge of the outer strap and the NGF lower end fitting has chamfers on both the top and bottom edges of the lower end fitting plate.

    - The head of the NGF bolt has a skirted region that is crimped into recesses in the lower end fitting to secure the bolt, rather than using a separate locking disc that is welded to the lower end fitting to secure the bolt.

- To facilitate the installation of the lower end fitting after the rods have been pulled into the grid cage, a small gap remains between the bottoms of the NGF fuel rods and the bottom nozzle. This differs from the standard fuel where the rods are seated directly on the upper surface of the lower end fitting.

- As a result of the various design changes associated with the transition from push-loading to pull-loading, the nominal, beginning-of-life location of the start of the active length has been raised to 5.402 inches above the core support plate for NGF (Batch Z and beyond), instead of the 5.237 inches for the recent standard fuel batches prior to Batch Z.

- The NGF bolt design includes a small diameter hole through the center of the bolt to allow water to drain out of the guide tubes after washing the fuel assemblies during fabrication, or prior to the installation of the fuel assemblies in dry casks for spent fuel storage.

- The NGF fuel rod design includes several changes relative to the previous standard fuel rod design, the most significant of which are the reduced diameter/thickness of the cladding, a modified pellet geometry, the use of Optimized ZIRLO^{TM} cladding, and an increase in the overall rod length. These changes, as well as the other design changes associated with the NGF fuel rods, are detailed in Section 4.2.1.2.1 (fuel rod) and Section 4.2.1.2.1.3 (IFBA rod).

The fuel assembly design enables reconstitution, i.e., removal and replacement of fuel and poison rods, of an irradiated fuel assembly. The fuel and poison rod lower end caps are conically shaped to insure proper insertion within the fuel assembly grid cage structure; the upper end caps are designed to enable grappling of the fuel and poison rod for purposes of removal and handling. Threaded joints which mechanically attach the upper end fitting to the control element guide tubes are properly torqued and locked during service, but may be removed to provide access to the fuel and poison rods. Testing has been completed which provides verification of the structural integrity of the upper end fitting to control element guide tube joints. The results of this testing program are presented in References 20 and 21. Although the title of the reports identified the design tested as System 80, the Arkansas Nuclear One - Unit 2 guide tube connection and secondary lock are the same as those tested. In addition, inspection and operational checks have been conducted to determine the behavior of the end fitting to CEA guide tube connection after thermal cycling, crudding, and long-term soaking.

In the Arkansas Nuclear One - Unit 2 fuel assembly design, axial loads (other than hydrostatic) are applied to the fuel rod due to differential thermal expansion and differential irradiation induced growth between fuel rods and guide tubes. All loads are transmitted through the grids, due to the axial clearance in the design which precludes hard contact between the fuel rods and the end fittings, taking into account the combined effects of thermal expansion and fuel rod axial growth. These components are designed to provide the necessary restraint without sustaining excessive stresses. The resultant loading is considered along with other loads encountered in normal operation.

It is a design criterion that the axial restraint offered by the grids and the grid spacing be such that the axial forces on a fuel rod are not sufficient to cause the rod to buckle. The long-term effects of clad creep (reduction in clad O.D.) and partial relaxation of the grid material result in decreased axial restraining force between grids and fuel rods, thereby improving the margin between actual and applied loadings as the fuel is operated.

As it is currently understood, the observed instances of fuel rod bowing have occurred because the axial restraint of the spacer grids on the fuel rods has been such that relative motion between the fuel rods and the grids, e.g. differential thermal expansion, cannot occur except at axial forces high enough to cause slight bowing of the fuel rods. Fuel assemblies for Arkansas Nuclear One - Unit 2, however, are designed such that the combination of fuel rod rigidity, grid spacing and grid preload will not cause significant fuel rod deformation under axial loads. Moreover, Combustion Engineering's visual inspection of irradiated fuel assemblies from the Maine Yankee (14 x 14), Palisades (15 x 15), and Omaha (14 x 14) reactors has not shown any significant bowing of the fuel rods. In view of these factors, Combustion Engineering does not believe that fuel rod bowing presents a significant problem to the fuel design.

Regarding the effect on thermal margin of fuel rod bowing, Combustion Engineering has obtained experimental information showing that significant rod bowing can occur without significant effect on Departure from Nucleate Boiling (DNB). The information consists of DNB data for two electrically heated 16 x 16 type rod bundles which were virtually identical except that one had a number of heater rods bowed in the vicinity of the DNB location. Comparison of the DNB data obtained with those bundles showed no noticeable effect of the bowed rods.

The bundles used in the tests mentioned above were 21 rod bundles representative of the Combustion Engineering 16 x 16 fuel assembly. The bundles had a heated length of seven feet with uniform axial and non-uniform lateral power distributions. Combustion Engineering standard spacer grids were used. The axial grid spacing was 14.3 inches, and the last grid in the heated length was 14.3 inches from the end of the heated length. Data were obtained first with the bundle having the bowed rods, after which the bowed rods were replaced with straight rods and more data were taken. The bowed rods became bowed in the span just upstream of the end of the heated length due to overheating in an earlier test with special spacer grids. For the test described here with Combustion Engineering standard grids, the bowed rods were reinstalled in the original positions and orientations.

Figure 4.2-20 indicates the rods which were bowed and the direction of bow. That figure also gives, based on detailed measurements at several axial elevations, the magnitude and location of minimum rod-to-rod gaps found to be less than 0.100 of an inch. (nominal rod-to-rod gap is 0.124 of an inch). It can be seen that the rod-to-rod gaps were reduced by as much as 40 percent and that the bowing is most severe just upstream of the DNB elevation (the end of the heated length).

Figures 4.2-21 and 4.2-22 show DNB data obtained from the two tests described above. It can be seen that there is no noticeable effect of the bowed rods on DNB.

However, because rod bowing is fuel burnup dependent, Departure from Nucleate Boiling Ratio (DNBR) penalty factors are applied to the maximum radial power peak for each batch of fuel. These DNBR penalty factors are determined in accordance with Technical Specification 4.2.4.4. In Cycles 2, 3, and 4, a 2% rod bow penalty based on Reference 165 was included in the MDNBR for bundle burnups up to 30,000 MWD/MTU. For Cycles 5 through 15, a 0.5% rod bow penalty based on Reference 169 was used. Starting with Cycle 16, a 0.6% rod bow penalty based on Reference 169 was used for bundle burnups up to 33,000 MWD/MTU. Bundles having burnups in excess of 33,000 MWD/MTU are not limiting with respect to DNB margin. Since the rod bow allowance is specifically included in the DNBR limit, there is no need for additional penalties on the rod radial peak in the Technical Specifications; therefore, Technical Specification 4.2.4.4 was deleted.

Differential lateral thermal expansion between the stainless steel upper end fitting and the topmost Zircaloy or Inconel spacer grid several inches below it does not cause any stress in the fuel rods because the fuel rods are supported by the spacer grid and receive no lateral support from the upper end fitting. The same situation exists at the lower end fitting.

In the Arkansas Nuclear One - Unit 2 fuel assembly design, the tubular control elements travel through the core in guide tubes. These guide tubes have the effect of ensuring that swelling of the adjacent fuel rods cannot result in obstruction of the control element pathway. This is so because: (1) there is sufficient clearance between the fuel rods and the guide tube surface to allow an adjacent fuel rod to reach rupture strain without contacting the guide tube surface, and (2) the guide tube, having considerably greater diameter and wall thickness (and also, being at a lower temperature) than the fuel rod, is considerably stiffer than the rods and would, therefore, remain straight, rather than be deflected by contact with the surface of a rapidly swelling adjacent fuel rod. Therefore, the swelling of fuel rods during a Loss of Coolant Accident (LOCA) would not result in obstruction of the control element channels such as could hinder CEA movement. This conclusion is equally valid for a case in which the postulated obstruction mechanism is lateral deflection (bowing) of the fuel rod resulting from excessive axial force applied through the grids due to differential thermal expansion between the fuel rods and the guide tubes. Dimension changes in the fuel assembly components occurring as a result of creep during operation are small compared to the clearances involved between the components, and therefore, will not have a significant effect on this particular aspect of LOCA response.

A series of tests were conducted to verify the adequacy of the Arkansas Nuclear One - Unit 2 fuel assembly holddown design. The load deflection characteristics of the holddown device were measured. In addition, tensile testing was conducted to verify the ability of the holddown device to accommodate handling loads. A holddown spring was also subjected to an extensive number of full deflections to verify an acceptable fatigue lifetime for the spring material. The results of these tests indicate that the holddown device will exhibit satisfactory performance characteristics in-reactor. Additional testing of the holddown characteristics was a part of the full scale hot loop testing program described below.

To qualify the complete fuel assembly, full scale hot loop testing has been conducted. The tests are designed to evaluate fretting and wear of components, fuel assembly uplift forces, holddown performance and compatibility of the fuel assembly with interfacing reactor internals, CEAs and Control Element Drive Mechanisms (CEDMs) under conditions of reactor water chemistry, flow velocity, temperature and pressure. The test assembly is identical to the 16x16 guide tube Arkansas Nuclear One - Unit 2 fuel design. The results of this hot flow test program are presented in Reference 1.

Mechanical testing of the fuel assembly and its components has been performed to support analytical means of defining the assembly's structural characteristics. The test program consisted of static and dynamic tests of spacer grids and static and vibratory tests of a full size fuel assembly. The results of tests to determine the axial and lateral deflection characteristics of the 16 x 16 fuel assembly grid cage and the results of mechanical tests on the threaded connection of CEA guide tubes to end fittings are presented in References 3, 20, and 21, respectively. The results of combined axial and lateral deflection tests and pluck tests on the 16 x 16 fuel assembly and the results of 16x16 spacer grid impact testing are presented in References 4 and 9. The results of the forced vibration tests and pluck impact tests are presented in References 2 and 5.

Extensive testing, both flow testing and mechanical testing, was performed to demonstrate the acceptability of the NGF design introduced in Batch Z. The flow testing program for the NGF design is described in Section 4.2.1.3.6.2 and concludes that the hydraulic performance of the NGF design is acceptable and should be superior to that of the prior designs. The mechanical tests were performed for two reasons: a) to determine fuel assembly mechanical properties that were then modeled in analyses that calculated fuel assembly spacer grid impact loads and component stresses for comparison to the stress limits given in Section 4.2.1.1.1.1; and b) to determine the load carrying capabilities of spacer grids and fuel assembly joints for direct comparison to predicted loads. Reference 195, Section D, identifies the mechanical tests that were performed and states the results of the tests. Application of the mechanical test results through the fuel assembly modeling and through their direct comparison to requirements demonstrates that the NGF design satisfies the design criteria of Section 4.2.1.1.1.

4.2.1.2.4 Fuel Component Properties and Tolerances

The following is a list of chemical, metallurgical, dimensional, thermal and mechanical characteristics of the fuel pellet, cladding and fuel assembly hardware. The material properties that influence the thermal performance of gadolinia-urania (Gd_2O_3-UO_2) fuel are discussed in Section 4.2.1.2.1.1. The material properties that influence the thermal performance of erbia-urania (Er_2O_3-UO_2) fuel are discussed in Section 4.2.1.2.1.2. The material properties that influence the thermal performance of zirconium diboride (ZrB_2 IFBA) fuel are discussed in Section 4.2.1.2.1.3.

4.2.1.2.4.1 Fuel Rod Cladding

4.2.1.2.4.1.1 Zr-4 Fuel Rod Cladding

Chemical Properties

Chemical analyses are performed for the following alloying elements: Tin, iron, chromium, oxygen and zirconium. Limits are placed on impurity content.

Metallurgical Properties:

Hydride Orientation

A restriction is placed on the hydride orientation factor for any third of the tube cross section (inside, middle or outside). The hydride orientation factor equals the ratio of the radial hydride platelets to the total number of hydride platelets.

Dimensional Requirements:

Tube straightness is limited to 0.010 inch/foot, and inside diameter and wall thickness are tightly controlled.

Ovality is measured as the difference between maximum and minimum inside diameters and is acceptable if within the diameter tolerances.

Eccentricity is measured as the difference between maximum and minimum wall thickness at any one cross section and is acceptable if within the wall tolerances.

Mechanical Properties:

A. Modulus of Elasticity (Reference 135)

Young's Modulus x 10^{-6} = [*]

(*See CESSAR Proprietary Appendix, Section 4.2.4.1)

where:
T = °F

B. Poisson's Ratio (Reference 117)

u = [*]

(*See CESSAR Proprietary Appendix, Section 4.2.4.1)

where:
T = °F

C. Thermal Coefficient of Expansion (Reference 19)

diametral direction α = [*]

where:
T_{av}= average temperature, °F

(*See CESSAR Proprietary Appendix, Section 4.2.4.1)

D. Yield Strength (References 15, 19, 89, 90, 96, 114, 135, 156 and 158)

- Yield strength in the non-irradiated condition is shown in Figure 4.2-6a as a function of temperature.

- Yield strength in the irradiated condition at 650 °F is:

ys = [*] where: ϕt = fluence x 10^{-21}

(*See CESSAR Proprietary Appendix, Section 4.2.4.1)

The cladding stress limits identified in Section 4.2.1.1.1.2 are based on values taken from the minimum yield strength curve at the appropriate temperatures. The limits are applied over the entire fuel lifetime, during conditions of reactor heatup and cooldown, steady state operation, and normal power cycling. Under these conditions, cladding temperatures and fast fluences can range from 70 °F to 750 °F, and from 0 to 1 x 10^{22} nvt, respectively.

E. Ultimate Strength (References 15, 19, 89, 90, 96, 114, 135, 156 and 158)

- Ultimate tensile strength in the non-irradiated condition is shown in Figure 4.2-6b as a function of temperature.

- Ultimate tensile strength in the irradiated condition is at 650 °F.

UTS = [*]

where:
ϕt = fluence x 10^{-21}

(*See CESSAR Proprietary Appendix, Section 4.2.4.1)

F. Uniform Tensile Strain (References 15, 19, 89, 90, 96, 114, 135, 156 and 158)

- Uniform tensile strain in the non-irradiated condition is shown in Figure 4.2-6c as a function of temperature.

- Uniform tensile strain in the irradiated condition approaches one percent at 6 x 10^{20} nvt and remains relatively constant.

G. Thermal Conductivity

(See Section 4.2.1.2.4.5)

H. Specific Heat

(See Section 4.2.1.2.4.5)

I. Hydrostatic Burst Test

Hydrostatic burst tests are conducted to verify that minimum burst pressure and circumferential elongation exceed prescribed minimum values.

4.2.1.2.4.1.2 ZIRLO™ Fuel Rod Cladding

Chemical Properties

Chemical analyses are performed for the following alloying elements: Tin, iron, niobium, oxygen and zirconium. Limits are placed on impurity content.

Metallurgical Properties:

Hydride Orientation

A restriction is placed on the hydride orientation factor for any third of the tube cross section (inside, middle or outside). The hydride orientation factor equals the ratio of the radial hydride platelets to the total number of hydride platelets.

<u>Dimensional Requirements</u>:

Tube straightness is limited to 0.010 inch/foot, and inside diameter and wall thickness are tightly controlled.

Ovality is measured as the difference between maximum and minimum inside diameters and is acceptable if within the diameter tolerances.

Wall thickness variation (WTV) shall not exceed 0.002 inch for each tube.

<u>Mechanical Properties:</u>

A. Modulus of Elasticity (Reference 183)

Young's Modulus x 10^{-6} = [*]

(*See “Implementation of ZIRLO™ Cladding,” Section 4.3.5.1)

where
T = °F

B. Poisson's Ratio (Reference 183)

u = [*]

(*See “Implementation of ZIRLO™ Cladding,” Section 4.3.5.2)

where:
T = °F

C. Thermal Coefficient of Expansion (Reference 183)

Circumferential and axial direction α = [*]

where:
T_{av} = average temperature, °F

(*See “Implementation of ZIRLO™ Cladding,” Section 4.3.4.)

D. Yield Strength

- The best-estimate unirradiated yield strength is given in Reference 183, Section 5.3.7.1, as a function of temperature.

- Yield strength in the irradiated condition is given in Reference 186, Reference 2-17.2, as a function of temperature.

For saturation damage irradiated cladding, these yield strength equations are considered valid for nvt > 2 x 10^{21} (> 1 MeV), clad mid-wall irradiation temperature below ~ 700 °F, and no significant annealing of irradiation damage in situ.

E. Ultimate Strength

- The best-estimate unirradiated ultimate strength is given in Reference 183, Section 5.3.7.2, as a function of temperature.

- Ultimate strength in the irradiated condition is given in Reference 186, Section 2.18.2, as a function of temperature.

For saturation damage irradiated cladding, these ultimate strength equations are considered valid for nvt > 2 x 10^{21} (> 1 MeV), clad mid-wall irradiation temperature below ~ 700 °F, and no significant annealing of irradiation damage in situ.

F. Uniform Tensile Strain

- Ductility is a function of irradiation and hydride formation in the cladding wall. The ductility of ZIRLO™ should be at least equivalent to Zr-4 because the waterside corrosion is significantly lower for ZIRLO™ and will result in less hydrogen uptake and less hydride formation. Total strain capability of ZIRLO™ is projected to be in excess of 1% at burnups of 60 MWd/kgU.

G. Thermal Conductivity

- The correlation for measured thermal conductivity of ZIRLO™ cladding material is given in Reference 183, Section 4.3.3, as a function of temperature.

H. Specific Heat

- The specific heat of ZIRLO™ is given by the values listed in Reference 183, Section 4.3.3, as a function of temperature. The values include the heat of transformation associated with the alpha-to-beta phase change that is slightly different from that of Zr-4 because of the difference in the temperature range over which the phase change occurs for the two alloys.

I. Contractile Strain Ration (CSR)

The ratio of circumferential strain to radial strain shall be determined by Specification (Reference 187) and shall be acceptable if within 1.20 to 2.25.

4.2.1.2.4.1.3 Optimized ZIRLO™ Fuel Rod Cladding

Reference 195 compares the properties of Optimized ZIRLO™ cladding and ZIRLO™ cladding and documents the equivalency of the material properties, with the following exceptions:

Chemical Properties: The specified range of the tin content in the Optimized ZIRLO™ cladding is allowed to be 0.2% lower than in ZIRLO™ cladding.

Mechanical Properties: The unirradiated yield strength and ultimate strength of the Optimized ZIRLO™ cladding are slightly lower than the corresponding ZIRLO™ cladding due to the lower tin content. These mechanical properties are shown in Table 4.2-3 for both cladding materials.

4.2.1.2.4.2 Control Element Assembly Guide Tubes

Chemical Properties:

Chemical analyses are performed for the alloying elements. For Zircaloy-4 guide tubes, the analyses check for tin, iron, chromium, oxygen, and zirconium. For ZIRLO^{TM} guide tubes, the analyses check for tin, iron, niobium, oxygen, and zirconium.

Limits are placed on impurity content.

Mechanical Properties:

The guide tubes are fabricated from Zircaloy-4 in the fully-annealed condition for Batches A thru D, except for 10 Batch A fuel assemblies. The guide tubes in those 10 Batch A assemblies, as well as all guide tubes in Batches E thru Y, are fabricated from Zircaloy-4 in the stress-relief annealed (SRA) condition. The guide tubes in Batch Z and beyond are fabricated from SRA ZIRLO^{TM}.

Dimensional Requirements:

Dimension Permissible Tolerance (inches)

O.D. ± .003

I.D. ± .005 (thru Batch Y)

I.D. ± .002 (Batch Z and beyond)

4.2.1.2.4.3 Zircaloy-4 Bar Stock

Chemical Properties:

Chemical analyses are performed for the following alloying elements: Tin, lead, chromium, oxygen and zirconium. Limits are placed on impurity content.

Metallurgical Properties:

Grain Size

The maximum average grain size is restricted.

4.2.1.2.4.4 Zirconium-based Strip Stock

Chemical Properties:

Chemical analyses are performed for the alloying elements. For Zircaloy-4 strip stock, the analyses check for tin, iron, chromium, oxygen, and zirconium. For Optimized ZIRLO^{TM} strip stock, the analyses check for tin, iron, niobium, oxygen, and zirconium. Limits are placed on impurity content.

Metallurgical Properties:

Grain Size

The maximum average grain size is restricted.

4.2.1.2.4.5 Zircaloy-4 Thermal Properties

Heat Content of Zircaloy-4 (Figure 4.2-7)

Thermal Conductivity of Zircaloy-4 (Figure 4.2-8).

4.2.1.2.4.6 Stainless Steel Castings

All stainless steel castings are fabricated in accordance with ASTM A744-84 (Grade CF-8 before 1993 and Grade CF-3 thereafter) with additional requirements.

4.2.1.2.4.7 Stainless Steel Tubing

Stainless steel tubing is fabricated in accordance with ASTM A269 (with additional requirements) for wear sleeves and the Guardian grid inserts, and in accordance with either ASTM A213 or A249 (both with additional requirements) for the top Inconel grid sleeve.

4.2.1.2.4.8 Stainless Steel Compression Springs

All stainless steel springs are fabricated in accordance with AMS 5688 thru Batch Y. For Batch Z and beyond, the stainless steel springs are fabricated in accordance with ASTM 313.

4.2.1.2.4.9 Inconel X-750 Compression Springs

All Inconel springs are fabricated in accordance with AMS 5699 with additional requirements.

4.2.1.2.4.10 UO_2 Fuel Pellets

Chemical Properties:

A. Chemical analyses are performed for the following constituents:

Total Uranium	Chlorine and Fluorine	Nickel	Magnesium
Carbon	Iron	Chromium	
Nitrogen	Thorium	Silicon	
Fluorine	Aluminum	Calcium	

B. Limits are placed on the oxygen-to-uranium ratio.

C. The sum of the cross sections of the following impurities will not exceed a specified equivalent thermal-neutron capture cross section of natural boron.

1. Boron
2. Silver
3. Cadmium

4. Gadolinium
5. Europium
6. Samarium
7. Dysprosium
8. Erbium

D. The total adsorbed and absorbed gas content of finished ground pellets shall not exceed a specified limit as determined by hot extraction techniques on whole pellets.

E. The total moisture content of finished ground pellets is restricted.

F. The nominal enrichment of the fuel pellets will be specified and shall be held within ± .05 percent U-235.

Microstructure:

The pellet fabrication process will maximize the pore content of pellets in a specified range. Acceptable porosity distribution will be determined by comparison of approved visual standards with photomicrographs from each pellet lot.

The average grain size shall exceed a specified minimum diameter.

Density:

Until 1989, the density range of the sintered pellet after grinding was 93.5 - 96.0 percent of theoretical density, based on a UO_2 theoretical density of 10.96 g/cm^3, at the 95/95 confidence level. Thereafter, the density range was increased to 94.0 – 96.5 percent of theoretical density.

Thermal Properties:

A. Thermal Expansion

The thermal expansion of the UO_2 fuel pellets is described by the following temperature dependent equations (References 59 and 62):

% Linear Expansion (from 25 °C) = $(-1.723 \times 10^{-2}) + (6.797 \times 10^{-2}T) + (2.896 \times 10^{-7}T^2)$ up to 2,200 °C.

% Linear Expansion (from 25 °C) = $0.204 + (3 \times 10^{-4}T) + (2 \times 10^{-7}T^2) + (10^{-10}T^3)$ above 2,200 °C.

where
T = degrees centigrade

B. Thermal Emissivity

A value of 0.85 is used for the thermal emissivity of UO_2 pellets over the temperature range 800 °K to 2600 °K (References 56, 83 and 92).

Mechanical Properties:

A. Young's Modulus of Elasticity

The Young's modulus of elasticity for UO_2 is used in the analytical model for prediction of the effects of pellet clad interaction. It is described by the following porosity and temperature dependent equation: (Reference 157)

$$E = [3.34 \times 10^7 (1\text{-}3.02 P + 3.57 P^2)] [1.003\text{-}1.405 \times 10^{-4} (T\text{-}298)]$$

where
E = modulus of elasticity, lb/in^2
T = degrees Kelvin
P = volume fraction porosity

B. Poisson's Ratio for UO_2 Pellets

Fuel Density (%TD)	Poisson Ratio
93	0.2970
94	0.3025
95	0.3073
96	0.3110
97	0.3130
98	0.3145
99	0.3155
100	0.3160

C. Yield Stress (not applicable)

D. Ultimate Stress (not applicable)

E. Uniform Ultimate Strain (not applicable)

4.2.1.2.4.11 $A1_2O_3$-B_4C Burnable Poison Pellets

The Al_2O_3-B_4C burnable poison pellets used in Combustion Engineering designed reactors consist of a continuous matrix of Al_2O_3 with a relatively small volume fraction of fine B_4C particles dispersed in the Al_2O_3 matrix. Typical compositions of B_4C are 0.7 to 4.0 w/o (1 to 6.0 w/o) in the pellets, which have a bulk density of about 90 percent of theoretical. Therefore, many thermal properties of the 2-phase Al_2O_3-B_4C mixture such as swelling, helium release, melting point, and corrosion are dependent on the presence of B_4C. The operating centerline temperature of burnable poison is less than 1100 °F, with maximum surface temperatures close to 750 °F.

A. Swelling

The swelling of Al_2O_3-B_4C is dependent on B^{10} burnup and neutron fluence. Early investigations found that generally the irradiation-induced swelling of Al_2O_3-B_4C increases with B^{10} burnup (see Reference 54). Pellets of Al_2O_3 - 3 w/o B_4C swelled from one to two percent in diameter (see References 43 and 54). Other data shows that the swelling of the Al_2O_3 matrix increased linearly with neutron fluence to about two percent ΔD after an exposure of 6 x 10^{21} nvt. Recent measurements performed on material irradiated in a Combustion Engineering PWR (with two w/o B_4C or less) revealed that diametral swelling ranged from [*]. These pellets were irradiated to 100 percent B^{10} burnup at a fluence of 2 x 10^{21} nvt (E > .8 Mev).

The above data lead to a design value for the EOL swelling of Al_2O_3-B_4C with up to two w/o B_4C of [*] while the EOL swelling of material with > 2 w/o B_4C is [*].

At EOL, Al_2O_3-B_4C will have exposures up to 9.8 x 10^{21} nvt (E > .8 Mev), with complete burnup of the B^{10} isotopes.

*Proprietary Information

B. Thermal Expansion

The mean thermal expansion coefficients of Al_2O_3 (see Reference 68) and B_4C (see Reference 129) from zero to 1,850 °F are 4.9 and 2.5 x 10^{-6} in/in-°F, respectively. The thermal expansion of the Al_2O_3-B_4C 2-phase mixture can be considered to be essentially the same as the value for the continuous Al_2O_3 matrix, as the dispersed B_4C phase has a lower expansion coefficient and occupies only five w/o of the available volume. The low temperature (80 to 250 °F) thermal expansion coefficient of Al_2O_3 irradiated at 480, 900, and 1300 °F does not change as a result of irradiation (see Reference 147). The expansion of a similar material, beryllium oxide, up to 1,900 °F has also been reported to be relatively unchanged by irradiation (see Reference 132). It is therefore appropriate to use the values of thermal expansion measured for Al_2O_3 (see Reference 68) for the burnable poison pellets:

Temp. Range, °F (from 70 °F to)	Linear Expansion, %
400	.12
600	.23
800	.30
1000	.40

C. Melting Point

The melting points of Al_2O_3 (3,710 °F) (see Reference 128) and B_4C (4,440 °F) (see Reference 132) are higher than the melting point of the Zircaloy-4 cladding. No reactions have been reported between the components, which would lower the melting point of the pellets to any significant extent. As the B_4C burns up, the lithium atoms born may form compounds with carbon and boron, although no ternary compounds with B_4C are expected (see Reference 136). The formation of these compounds should not influence the melting point of the Al_2O_3-B_4C pellets although the small

quantity of (~.5 w/o) lithium compounds formed during irradiation, may melt below the 3,710 °F value reported for Al_2O_3. The maximum temperature of operation will be below 1,100 °F, however, and irradiation testing has shown no adverse effects due to the ingress of lithium.

D. Thermal Conductivity

The thermal conductivity of Al_2O_3-B_4C was calculated from the measured values for Al_2O_3 and B_4C using the Maxwell-Eucken relationship (see Reference 95) for a continuous matrix phase (Al_2O_3) with a spherical dispersed phase (B_4C) particles. Because of the high Al_2O_3 content of these mixtures and the similarity in thermal conductivity, the resultant values for Al_2O_3-B_4C were essentially the same as the values for Al_2O_3. The measured, unirradiated values of thermal conductivity at 750 °F are 0.06 cal/sec-cm-°K for B_4C and .05 cal/sec-cm-°K for Al_2O_3.

The thermal conductivity of Al_2O_3 after irradiation decreases rapidly as a function of burnup to values of about one-third the unirradiated values (see Reference 147). The irradiated values of Al_2O_3-B_4C calculated from the above relationships, are given below as a function of temperature (see References 147 and 152).

Thermal Conductivity

Temp. °F	cal/sec-cm-°K
400	.015
600	.013
800	.010
1000	.008

E. Specific Heat

The specific heat of the Al_2O_3-B_4C mixture can be taken to be essentially the same as pure Al_2O_3 since the concentration of B_4C is low (6.0 w/o maximum). In addition, the effect of irradiation on specific heat is expected to be small based on experimental evidence from similar materials, which do not sustain transmutations as a function of neutron exposures.

The values for Al_2O_3 measured on unirradiated (see References 117 and 152) samples are given below:

Temp. °F	cal/gm-°F
250	.12
450	.13
800	.14
000 and above	.15

F. Helium Release

Experimental measurements reveal that less that 5 percent of the helium formed during irradiation will be released (see Reference 54). These measurements were performed on Al_2O_3-B_4C pellets irradiated at temperatures to 500 °F and subsequently

annealed at 1,000 °F for five days. The helium release in a burnable poison rod, which operated for one cycle in a Combustion Engineering PWR, as calculated from internal pressure measurements to be [*] Combustion Engineering bases the design on a release of [*] of the helium generated. The design of the burnable poison rod is not limited by helium pressure, despite the conservative use of [*] release. The internal pressure produced under operating conditions will be [*] system pressure at EOL. This will not cause clad creep and not limit design life.

*Proprietary Information

G. Al_2O_3-B_4C Coolant Reactions

Prior to sustaining significant burnup, the corrosion resistance of Al_2O_3-B_4C pellets is sufficient to retard any appreciable reaction with the coolant in the event of a cladding leak.

Available evidence shows that in the event of a cladding leak in a burnable poison rod, the Al_2O_3-B_4C pellets will react with the coolant. Those pellets which sustained significant burnup, react fairly fast as they disintegrated after 24 hours at 600 °F in pressurized water (see Reference 54). The disintegration of the pellets is a result of the reaction between irradiated B_4C and water or steam to form B_2O_3 (see Reference 80). There is some evidence that the lithium formed, as B^{10} is burned up along with microcracking, causes the relatively high corrosion rate. The corrosion products formed are soluble in water (B_2O_3, Li_2O), and therefore cause no detrimental effect on the operation of the plant.

4.2.1.2.5 Fuel Assembly Identification

Exterior means of identification coupled with manufacturing and loading procedures insure proper orientation and placement of each fuel assembly. Additional checks and quality assurance records enable determination of the specifications associated with every component.

Loading and movement of the fuel assemblies is conducted in accordance with strictly monitored administrative procedures, and, at the completion of fuel loading, an independent check as to the location and orientation of each fuel assembly in the core is required.

Markings provided on the fuel assembly upper end fitting enable verification of fuel enrichment and orientation of the fuel assembly.

During the manufacturing process, the lower end cap of each rod is marked to provide a means of identifying the pellet enrichment, pellet lot and fuel stack weight. For some Batch U fuel assemblies, lower end cap markings were not made and individual laser etched bar codes on the top of the fuel rod will be the sole means of identifying the rods. In addition, a quality control program specification requires that measures be established for the identification and control of materials, components, and partially fabricated subassemblies. These means provide a method of relating an item or assembly from initial receipt through fabrication, installation, repair or modification, to an applicable drawing, specification, or other pertinent technical document.

4.2.1.3 Design Evaluation

4.2.1.3.1 Materials Adequacy Throughout Lifetime

Based on evidence currently available, design bases for Optimized ZIRLO™, ZIRLO™, and Zircaloy-4 fuel cladding have been conservatively established and indicate that cladding and UO_2 fuel performance will be satisfactory.

Evidence of materials adequacy through a period of time far in excess of that contemplated for this design is provided by the combined Vallecitos Boiling Water Reactor (VBWR) - Dresden irradiation of assembly SA-1 (Zircaloy-clad uranium dioxide pellets). This assembly operated about 3.5 years in VBWR (Reference 44) and subsequently in excess of five years in Dresden (Reference 112). The nearly nine years of operation resulted in no time related material failures.

Experience at KWO reactor (Kraftwork Obrigheim) involved nonpressurized fuel rods operating over three full cycles to burnups over 34,000 MWD/MTU average without evidence of life limit failures. Combustion Engineering fuel has operated well, as indicated by primary system iodine values on the order of 10^{-2} and 10^{-4} microcuries per cc for Palisades (at peak burnup of 6000 MWD/MTU) and Maine Yankee, respectively. These extremely low iodine values substantiate the argument that conservatism in fuel design coupled with attention to manufacturing detail and quality control leads to low incidence of fuel rod defects.

ZIRLO™ cladding has been in widespread domestic use in at least 38 Westinghouse nuclear plants where it has seen service at burnups of 50,000 MWD/MTU and greater (Reference 183). Optimized ZIRLO™ cladding has been used in a number of LTAs programs (Section D of Reference 195) and, due to the material composition similarities of Optimized ZIRLO™ and ZIRLO™, the performance of the Optimized ZIRLO™ cladding is predicted to be at least as good as that of ZIRLO™ cladding.

4.2.1.3.2 Results of Vibration Analyses

Three sources of periodic excitation are recognized in evaluating the ANO-2 fuel assembly susceptibility to vibration damage. These sources are as follows:

A. Reactor Coolant Pump Blade Passing Frequency: Precritical vibration monitoring on previous Combustion Engineering reactors indicates that peak pressure pulses are expected at the pump blade passing frequency (75 Hz), and a lesser but still pronounced peak at twice this frequency.

B. Core Support Plate Motion: Experience with earlier Combustion Engineering reactors indicates that random lateral motion of the core support plate is expected to occur with an amplitude of 0.001 to 0.002 inch and a frequency range of between 2 and 10 Hz.

C. Flow-induced vibration resulting from coolant flow through the fuel assembly.

These sources of periodic motion are not expected to have an adverse effect on the performance of the Arkansas Nuclear One - Unit 2 fuel assembly. This conclusion is based on the fact that the fuel assembly itself has a predicted lateral natural frequency of 1.55 Hz, and the fuel rod, supported between grids, has a calculated frequency of 109 Hz. Both of these frequencies lie well away from the predicted excitation frequencies.

The NGF fuel assembly design introduced in Batch Z was designed to have a lateral stiffness comparable to the prior designs that have operated successfully in the Arkansas plant. In addition, bounding NGF configurations were tested to confirm the hydraulic stability of the fuel assembly design and to demonstrate the acceptability of the fretting performance of the fuel assembly design. To address fuel assembly vibration concerns, full scale single bundle tests of the NGF and standard designs were run, as well as a full scale dual bundle test with a NGF fuel assembly and a standard fuel assembly. The single bundle tests demonstrated the hydraulic stability of both designs over the expected range of flow rates. The dual bundle test was an endurance test that provided additional confirmation of the hydraulic stability of the designs and showed a significant improvement in the fretting performance of the NGF design compared to the standard design. Therefore, the similarity of the fuel assembly stiffness between the NGF and prior designs, coupled with the results of the flow testing, indicates that the NGF design should be less susceptible to any vibration effects than the prior designs.

The Unit 2 design includes three specific means for eliminating the consequences of CEA vibration. These are the extension of upper guide structure flow channels, the sleeving of all guide tubes in the fuel assemblies and typically, the programmed insertion of CEAs.

Measurements taken following Cycle 1 operation confirmed the effectiveness of this design change in limiting CEA guide tube wear. These measurements are summarized in the report, CEN-164(A)-P, "A Summary of Fuel Status at ANO-2 End of Cycle 1 Including Preliminary Findings," dated May 18, 1981.

Several vibration analyses have been performed on the similar 14x14 fuel assembly containing fuel rods of slightly larger diameter than those of the 16x16 design. These analyses were conducted to determine the effects of flow-induced vibrations on the fuel assembly under normal operating conditions. Natural frequency and amplitude of vibration of a rod were determined and used as input for autoclave testing. The rods were excited at the computed natural frequency to determine the extent of wear resulting from fuel rod-spacer grid interactions. The test showed that wear between the components is acceptable.

The effect of the vibration of the core support barrel on the entire fuel assembly was also examined. The frequency of core barrel excitation was determined and used as an input in dynamic flow tests discussed in Section 4.2.1.3.6. The tests have shown that under normal operating flow conditions and simulated core barrel vibration, there would be no long-term damage to the fuel bundles.

Vibrations within the Reactor Coolant System (RCS) and reactor core are monitored by the Vibration and Loose Parts (V&LP) Monitoring System. This system has vibration and acoustic channels, and consists of piezoelectric sensors, preamplifiers, a signal processor unit, and other peripheral equipment.

The sensors detect vibration from flow-induced or rotating equipment sources, loose parts in the coolant systems, and other signals. The signals from these channels are compared with preset levels to generate alarms when abnormal conditions are detected. Various diagnostic equipment is available to further identify the source of the problem.

To provide optimum effectiveness of the V&LP, the transducers for the reactor primary system are placed on the lower vessel, upper vessel, and steam generators.

One accelerometer is located on the lower part of the reactor vessel. An accelerometer is located in the upper vessel region to quantitatively monitor the control rod extensions and vessel internals for vibration. Location of this sensor is on the control rod drive extension tube protection shroud. On the steam generators, accelerometers are located on the channel head.

The loose parts, and core internals channels monitor the major reactor primary system components in which an anomaly could occur. The selection provides a qualitative difference indication of vibration throughout the primary loop. The nuclear channels provide reactivity-related indication of vessel internals motion. The core internals signals are obtained from the ex-core power range ion chamber buffer amplifiers.

4.2.1.3.3 Fuel Assembly Stress Analyses

A fuel assembly stress analysis was conducted to evaluate the fuel assembly stress, circumferential strain and fatigue usage factor resulting from normal and anticipated operational occurrences. The design criteria used in the evaluation, and their bases, are specified in Sections 4.2.1.1.1 and 4.2.1.1.2.

The cladding temperatures used in the analyses are listed in Table 4.2-3a, and are the maximum values calculated during normal operation and anticipated operational occurrences. The temperatures are representative of typical peak power locations.

For fuel assembly components other than fuel rods, the maximum stresses for normal conditions are summarized below:

A. Guide Tubes - the most limiting stress sustained during normal operation is approximately 6,000 psi. The corresponding allowable stress is 10,500 psi.

B. End Fitting Springs - the maximum stress sustained during normal operation is approximately 98,000 psi (shear). The corresponding allowable shear stress is 110,000 psi. This minimum margin condition is a conservative estimate of cold EOL shutdown conditions.

C. Spacer Grids - The acceptability of the spacer grid design is verified by test and through prior operating experience with similar grids. No confirmatory stress analysis is performed for this component.

For the components listed above, the only anticipated operational occurrences which impose significant additional loads are seismic excitations and the postulated branch line pipe breaks. The response of the fuel assembly to combined seismic and branch line pipe break loadings has been analyzed and shown to be within the acceptance criteria. The methods of analysis and results for the Arkansas Nuclear One - Unit 2 fuel assembly design are presented in Reference 36.

Due to the introduction of the NGF design in Batch Z, a fuel assembly stress analysis was performed to address the design and material differences from prior batches. The evaluation used the same design criteria as prior batches, as specified in Sections 4.2.1.1.1 and 4.2.1.1.2. Due to the similarity in the structural design and mechanical properties of the components in the NGF assemblies and the prior assemblies, the results of the evaluation were comparable to those of prior analyses and demonstrated that all applicable criteria continue to be satisfied.

4.2.1.3.4 Potential for Waterlogging Rupture

The potential for waterlogging rupture is considered remote. Basically, the necessary factors, or combination of factors, include the presence of a small opening in the cladding, time to permit filling of the fuel rod with water, and finally, a rapid power transient. The size of the opening necessary to cause a problem falls within a fairly narrow band. Below a certain defect size, it takes a long time to fill a fuel rod with water. Above a certain defect size, the rod can fill rapidly, but during a power increase it also expels water or steam readily without a large pressure buildup. Holes or defects which could result in an opening in cladding are scrupulously checked for during the fuel rod manufacturing process by both ultrasonic and helium leak testing. Clad defects which could develop during reactor operation due to hydriding are also controlled by limiting those factors, e.g., moisture content of fuel pellets, which contribute to hydriding.

The most likely time for a waterlogging rupture incident would occur after an abnormally long shutdown period. After this time, however, the startup rate is controlled so that even if a fuel rod were filled with coolant, it would "bake out", thus minimizing the possibility of additional cladding rupture. The combination of control and inspection during the manufacturing process and the limits on the rate of power change restrict the potential for waterlogging rupture to a very small number of fuel rods.

4.2.1.3.5 Potential for Chemical Reaction

4.2.1.3.5.1 Corrosion

Corrosion tests of Ziracoly-4 fuel rod tubing which were conducted in excess of 4,000 hours exposure include 600 °F and 650 °F autoclave tests and 600 °F loop tests with borated lithium hydroxide additives to the water chemistry. The test results agree with long-term corrosion tests in lithium hydroxide reported by Bettis (WAPD-MRP-108, Pressurized Water Reactor Project Period January 24, 1964 to April 23, 1964). No deleterious effects have occurred. Experience at both Shippingport and Saxton Core I have shown under PWR conditions (hydrogen overpressure and water additives) in reactor behavior with low heat flux was similar to autoclave behavior.

Experience at Saxton Reactor in Cores II and III, however, have shown that with severe nucleate boiling, some accelerated corrosion was encountered. Similar accelerated corrosion with high crud deposits was also reported at KWO, but was terminated by using hydrogen overpressure and water chemical additives. The potential for chemical reaction will be closely monitored by Westinghouse.

Batch X and Y fuel rods were fabricated with ZIRLO™ cladding to improve the corrosion resistance of the fuel. Section 4.5 of Reference 183 presents corrosion data at high burnup for both Zircaloy-4 cladding and ZIRLO™ cladding and concludes that the ZIRLO™ cladding offers a significant improvement in the corrosion resistance of the cladding. The NGF fuel rods were fabricated with Optimized ZIRLO™ cladding that has a slightly reduced tin content compared to ZIRLO™ specifically to improve its corrosion resistance. Autoclave steam testing demonstrated almost a 20% corrosion resistance improvement of Optimized ZIRLO™ compared to ZIRLO™. Reference 197 presents additional cladding corrosion data and provides updated cladding corrosion models for both ZIRLO® and Optimized ZIRLO™ cladding.

4.2.1.3.5.2 External Hydriding

During operation of the reactor with exposure to high temperature, high pressure water, Zirconium-based cladding will react to form a protective oxide film in accordance with the following equation.

$$Zr + 2H_2O \rightarrow ZrO_2 + 2H_2$$

Approximately 20 percent of the hydrogen is absorbed by the Zircaloy. Based on data described in WAPD-MRP-107, the cladding would be expected to contain up to 250 ppm of hydrogen following three years of exposure.

A series of 600 °F burst tests was performed on Zircaloy-4 tubes containing 200 to 250 and 400 ppm of hydrogen precipitated as hydride platelets in various orientations from radial to circumferential. Little difference in burst test ductility was evident. Therefore, hydrogen normally absorbed in Zircaloy-4 tubing will not prove deleterious to the cladding integrity.

The impact of hydrides and hydride reorientation in ZIRLO™ cladding is discussed in Section 4.4.2.5 of Reference 183, where it is concluded that the performance of the ZIRLO™ cladding will be similar to that of the Zircaloy-4 cladding since the hydride reorientation is primarily a function of the tensile stresses and temperatures in the cladding. Due to the similarity of the material composition of Optimized ZIRLO™ and ZIRLO™, the same conclusion applies for Optimized ZIRLO™ cladding. Reference 197 provides updated data and models for ZIRLO® and Optimized ZIRLO™ cladding.

4.2.1.3.5.3 Internal Hydriding

A number of reported fuel rod failures have resulted from excessive moisture available in the fuel. Under operation, this moisture would flash to steam and oxidize the cladding.

The hydrogen, which was not absorbed during normal oxidation, would then be absorbed into the cladding through a scratch in the oxide film. This localized hydrogen absorption by the cladding would shortly result in a localized fuel rod failure. Work performed at the Institute for Atomenergi, Halden, Norway, of which Westinghouse is a member, demonstrated that a threshold value of water moisture is required for hydride sunbursts to occur. Through a series of in-pile experiments, the level of this threshold value was established. Westinghouse's allowable moisture limit in the fuel complies with this requirement, ensuring that hydride sunbursts will not occur.

4.2.1.3.6 Fretting Corrosion

The phenomenon of fretting corrosion particularly in ZIRLO™ or Zircaloy clad fuel rods supported by Zircaloy spacer grids has been extensively investigated. Since irradiation-induced stress relaxation causes a reduction in grid spring load, spacer grids must be designed for EOC conditions as well as BOC conditions to prevent fretting caused by flow-induced tube vibrations. To ensure this, Westinghouse has performed extensive out-of-pile fretting tests, concentrating on the more severe EOC conditions. Two testing approaches have been used, i.e., autoclave vibration tests and dynamic flow tests.

4.2.1.3.6.1 Autoclave Vibration Tests

The autoclave tests were performed by vibrating a fuel rod sample supported by two rigidly held spacer grid sections. Test conditions matched reactor coolant chemistry, temperature and pressure. Variable parameters provided data to evaluate the effects of:

A. Time;

B. Frequency of tube vibration;

C. Spacer grid spring load (preset); and,

D. Axial tube movement (simulating reactor load following characteristics).

Data from such tests have indicated wear starts with a brief break-in period and then proceeds at a negligible rate. Changes in frequency, spring preset (including zero preset) and amplitude within representative limits do not significantly alter fretting characteristics. At no time under any conditions was fretting significant.

4.2.1.3.6.2 Dynamic Flow Tests

Dynamic flow tests have been performed on 4x4 rod arrays (16 fuel rods) and on full size fuel assemblies. The 4x4 rod array testing was conducted under the following conditions:

A. Flow velocities ranged from 14 ft/sec to 25 ft/sec.

B. Coolant temperature was 590 °F.

C. Coolant pressure was 2,150 psia.

In addition, the 4 x 4 rod arrays were subjected to cross flow and a mechanically induced forced vibration of the lower end of the rod array at a frequency of 15 Hz and an amplitude of 5 mils (representing vibratory forces imparted by the reactor internals). The 4 x 4 rod array testing also included rod arrays with preset spacer grid springs ranging from approximately 10 mils interference to gaps of up to 5 mils, simulating both tightly held and loose rods. The 4 x 4 rod arrays were tested for intervals from 1,000 hours up to 3,182 hours for a total accumulated test time of 18,000 hours.

The fuel rods in the 4 x 4 assemblies were either of a 0.413-inch diameter on a 0.550-inch pitch or of a 0.440-inch diameter on a 0.580-inch pitch which are representative of a 15 x 15 and 14 x 14 fuel array, respectively. All fuel rods were visually inspected at each spacer grid interface. The depth of wear marks was accurately determined using an optical micrometer. The maximum depth of wear noted for the conditions above was less than 1/2 mil. In a special test where a fuel rod was completely unsupported at its lower end for a distance of 15 inches, a depth of wear of 3 mils was noted after 2,000 hours of flow at 25 ft/sec. This test was not representative of any design condition, but was performed to demonstrate the need for supporting the lower end of the fuel rod. Based on test results of 4 x 4 assemblies which follow the same trend as found in the autoclave vibration test, the maximum expected clad wear at EOL will be less than 3 mils.

Separate full scale flow tests at or exceeding reactor flow conditions were run with an array of four full size prototypical 15 x 15 fuel assemblies, four full size 14 x 14 fuel assemblies of which two were prototypical and two contained stainless steel fuel rods, and several tests of individual full size 14 x 14 fuel assemblies. The test conditions were as follows:

A. Flow velocities ranged from 16 ft/sec for 15 x 15 fuel assemblies up to 23.7 ft/sec for some of the 14 x 14 fuel assemblies. In all cases, the flow test velocities exceeded the maximum calculated velocity at operating conditions for fuel assemblies in each particular reactor.

B. A large number of fuel rods (in some cases all rods within a fuel assembly) were tested with zero preset spacer grid spring loads to conservatively represent EOL spacer grid conditions. A number of fuel rods were also loosely supported at various spacer grid locations, and, in some cases, over the entire length of the rod.

C. Test time accumulated exceeds 13,500 hours, with the longest single test 4,000 hours in length.

The results of these tests are similar to those of the 4 x 4 fuel assemblies with a few exceptions. On the 14 x 14 fuel assemblies subjected to 4,000 hours of continuous testing at 23.7 ft/sec and 1,000 hours at 19.1 ft/sec., the maximum depth of wear on one assembly was 1.7 mils, while on the other assembly, one wear mark was found to be 2.2 mils deep and a few others ranged from 1.6 to 1.8 mils. The only incidence of significant wear on a full size fuel assembly occurred in special test of the off-design condition where the lower end of the fuel assembly was essentially unrestrained laterally. In this test, the depth of wear of one fuel rod was 10.9 mils after only 1,188 hours of testing at 23.7 ft/sec. Again, this test, as in the case of the cantilevered fuel rod test in a 4 x 4 fuel assembly, showed the need for laterally restraining the lower end of the fuel assembly.

Extrapolation of the test data for design test conditions again indicates that the maximum depth of fuel clad wear at EOL will be less than 3 mils, representing only 12 percent of the cladding wall thickness. Since the 0.440- and 0.413-inch diameter fuel rods did no show any difference in wear characteristics, 0.382-inch diameter fuel rods for 16 x 16 fuel assemblies are also expected to exhibit the same low wear rate.

A hot flow test program has been conducted for the Arkansas Nuclear One - Unit 2 16 x 16 fuel assembly design. A brief description of this test program is presented in Sections 1.5.1 and 4.2.1.2.3. The results of the hot flow testing are presented in Reference 1.

An extensive flow test program was conducted to support the implementation of the NGF design in Batch Z. Bounding NGF configurations were tested to confirm the hydraulic stability of the fuel assembly design and to demonstrate the acceptability of the fretting performance of the fuel assembly design. These tests (discussed in Reference 195, Section 2.3.1.2, Section D, and Enclosure 3 of Section D) included full scale single bundle tests of the NGF and standard designs, a full scale dual bundle test with a NGF fuel assembly and a standard fuel assembly, and a full cross-section/short length bundle test of the NGF design. The single bundle tests were run to evaluate the hydraulic stability of the fuel assemblies. The tests demonstrated the hydraulic stability of both designs over the expected range of flow rates. The dual bundle test was an endurance test to evaluate fretting performance of the two designs. This test provided additional confirmation of the hydraulic stability of the designs and showed a significant improvement in the fretting performance of the NGF design compared to the standard design.

The short length bundle test was run to confirm the absence of flow-induced strip vibration within the spacer grids, which it did. The successful results of the flow test program demonstrate that the hydraulic performance of the NGF design is acceptable and should be superior to that of the prior designs.

A fatigue analysis of Westinghouse's grid spring has shown that the cyclic stress caused by tube vibration is 30 times lower than the cyclic stress endurance limit based on Goodman diagram calculations. This conservatism is shown in results of all the autoclave fretting tests which act as fatigue tests, where a typical 60-day test induces 2.3 x 10^8 cycles in the spring.

To further evaluate the fatigue limits in the hydrided condition, a spacer grid section was hydrided, tested at 650 °F for 10^8 cycles, and then tested at room temperature for another 10^8 cycles with no fatigue damage.

The specific criteria for allowable fuel rod stress and strain including cyclic loading are discussed in Sections 4.2.1.1.1 and 4.2.1.1.2. These criteria are applied to analytical predictions, not directly to stress-strain data generated by flow testing.

Fuel assembly stiffness decreases with time due to grid tab relaxation and fretting and is not significantly affected by creep or fatigue. Earlier experiments have shown that about two-thirds of the fuel assembly stiffness is attributed to the fuel assembly frame (no fuel rods). The other one-third of the fuel assembly stiffness is from the fuel rods and fuel rod to spacer grid interaction. Relaxation and wear at the spacer grid locations would result in a reduction in the degree of fuel rod fixity with respect to the assembly, thereby reducing the one-third contribution. However, this contribution would never fall below the case where the fuel rods act completely independently of the fuel assembly structure. In this case, the rods would contribute about one-eighth of the overall stiffness of the assembly. With the exception of two tests, the flow tests described above were performed with fuel assemblies of reduced stiffness to simulate an EOL condition. This was done by presetting the spacer grid spring tabs so as to achieve either zero interference or, in some cases, a clearance between the spring tabs and the fuel rods. There are no stiffness limitations imposed on the spacer grid assembly or on the grid spring.

4.2.1.3.7 <u>Cycling and Fatigue</u>

A fatigue analysis will be performed to determine the cumulative fatigue damage of fuel rods exposed to lifetime power cycling conditions. The fatigue cycle will be determined by considering combinations of normally anticipated events that would produce conservative estimates of strain in the clad. Some of the major conservative assumptions will be as follows:

A. Hot spot fuel radii will be used in the calculations.

B. The most adverse tolerance conditions on the fuel and cladding dimensions will be chosen to produce maximum interactions and hence maximum clad strains.

C. Primary creep rate data for the clad will be used in the calculation of both tensile and compressive strains.

The chosen fatigue cycle represents daily operation at both full and reduced power. Clad strains will be calculated from the primary creep rate of the clad and used to calculate the effective strain ranges. The cumulative fatigue damage fraction will be determined by summing the ratios of the number of cycles at a given effective strain range to the permitted number at that range as taken from the fatigue curve presented in Figure 4.2-2.

4.2.1.3.8 <u>Dimensional Stability</u>

4.2.1.3.8.1 <u>Dimensional Stability of Zircaloy</u>

Zircaloy components are designed to allow for dimensional changes resulting from irradiation-induced growth. Combustion Engineering has performed extensive analyses of in-pile growth data to formulate a comprehensive model of in-pile growth.

The Zircaloy growth phenomenon has been examined both in the case of fuel cladding and for the case of non-fueled Zircaloy components. Combustion Engineering's Zircaloy irradiation growth model is based on post-irradiation measurements on experimental and production fuel (including Combustion Engineering's Palisades and Maine Yankee reactors, Obrigheim (KWO) and on non-fueled Zircaloy cladding data (References 32, 39, 65, 71, 82, 97, 100, 101, 103 and 113).

The data shown in Figures 4.2-8a and 4.2-8b for cold worked, stress relief annealed and for annealed materials respectively obey the following empirical relationship:

ε = (*) (*See Proprietary Reference 25 for growth strain equation)

where

ε = growth strain (in/in)

øt = fast neutron fluence (E > 0.8 Mev)

The upper and lower 95-95 confidence limits are also shown on the figures. Note that the annealed data fall generally between the best estimate and lower 95-95 confidence limit (applicable to annealed guide tubes and spacer grids).

For design calculations of the maximum and minimum irradiation-induced growth of fuel rods, guide tubes and grids, including relative growth, the specific correlations are shown in the following figures from Reference 40.

Fuel Rods:	Figure 3-1
Standard Guide Tubes:	Figure 3-3
High Strength Guide Tubes:	Figure 3-2
Spacer Grids:	Figure 3-3

It will be noted that these figures show both "best fit" and upper and lower 95 percent tolerance limit correlations. It is Combustion Engineering's practice to base design calculations on correlations which are either conservatively above or conservatively below the best fit correlations, depending on which has the more severe effect on the aspect being evaluated.

4.2.1.3.8.2 Dimensional Stability of ZIRLO™

Fuel rod axial growth is one of the parameters included in the mechanical design methodology to assess irradiation-induced dimensional changes of the fuel. It is well established that fuel rods exhibit axial elongation when irradiated in a neutron flux.

Although fuel rod growth with ZIRLO™ cladding has been observed to be less than that of Zircaloy-4 fuel rod growth. The ZIRLO™ fuel rod growth correlation conservatively ignores this reduced growth for shoulder gap evaluations. The functional form of the fuel rod growth model is given by:

ε = (*) (*See Reference 183, Section 5.3.2, for growth strain equation and constants)

where:

ε = growth strain (in/in)

øt = fast neutron fluence (E > 1.0 Mev)

Guide tube axial growth is another parameter included in the mechanical design methodology to assess irradiation-induced dimensional changes of the fuel. As with fuel rods, it is well established that guide tubes exhibit axial elongation when irradiated in a neutron flux.

The method for predicting axial growth of the SRA ZIRLO™ guide tubes is specified in Section 2.3.1.1 of Reference 195. This technique involves applying an adjustment factor to predictions made for SRA Zircaloy-4 guide tubes using the SIGREEP code (Reference 176), thereby making the growth predictions dependent on the guide tube stresses during operation.

4.2.1.3.8.3 Dimensional Stability of Optimized ZIRLO™

Section 2.5.8 of Reference 195 identifies the fuel rod growth correlation to be used in irradiation-induced dimensional change evaluations of NGF rods with Optimized ZIRLO™ cladding as the Westinghouse model from Reference 194. The functional form of that growth model is specified in Reference 183 as:

ε = (*) (*See Reference 183, Section 4.3.2, for growth strain equation and constants)

where:

ε = growth strain (in/in)

φt = fast neutron fluence (E> 1.0 MeV)

4.2.1.3.9 Fuel Burnup Experience

Design bases for the ZIRLO™ and Zircaloy-4 cladding have been established which are conservative with respect to the reported data. Evidence currently available indicates that Optimized ZIRLO™, ZIRLO™, and Zircaloy and UO_2 fuel performance is satisfactory to exposures in excess of 60,000 MWD/MTU.

The effect on fuel mechanical performance when ZIRLO™ cladding is substituted for Zircaloy-4 cladding in fuel rods has been thoroughly evaluated in Reference 183, Section 5.4. Evaluation of the change examined the mechanical performances in areas of creep collapse, stress, strain, fatigue damage, shoulder gap margin, rod bow, cladding wear/fretting, assembly bow, spacer

grid growth and spring tab relaxation effects, hold down margin, spent fuel handling accident, and seismic and LOCA loads and have shown that the use of ZIRLO™ would result in fuel assembly designs that are fully capable of meeting their current design criteria. Similarly, an evaluation of the effect on fuel mechanical performance when Optimized ZIRLO™ cladding is substituted for ZIRLO™ cladding (Reference 194), along with the effect of the design changes associated with the NGF design (Reference 195), has shown that the NGF design with Optimized ZIRLO™ cladding are fully capable of meeting their design criteria.

A. High Linear Heat Rating Irradiation Experience

The determination of the effect of linear heat rating and fuel cladding gap on the performance of Zircaloy-clad UO_2 fuel rods was the object of two experimental capsule irradiation programs conducted in the Westinghouse Test Reactor (WTR) (Reference 24). In the first program, 18 rods containing 94 percent theoretical density UO_2 pellets were irradiated at 11, 16, 18 and 24 kW/ft with cold diametral gaps of 0.006 inch, 0.012 inch and 0.025 inch. The wall thickness to diameter ratio (t/OD) of the Zircaloy cladding was 0.064 which is comparable to the 0.066 value in this design. Although these irradiations were of short duration (about 40 hours), significant results applicable to this design were obtained. No significant dimensional changes were found in any of the fuel rods. Only one rod, which operated at a linear heat rate of 24 kW/ft with an initial diametral gap of 0.025 inch, experienced center melting. Rods which operated at 24 kW/ft with cold gaps of 0.006 inch and 0.012 inch did not exhibit center melting. On these bases, the initial gap of 0.007 inch and the maximum linear heat ratings for this design provide adequate margin against center melting, even when 112 percent overpower conditions are considered. These results also indicate that an initial diametral gap of 0.007 inch is adequate to accommodate radial thermal expansion without inducing cladding dimensional changes even at a linear heat rate of 24 kW/ft. This margin with respect to thermal expansion will be diminished with increasing burnup at a rate of 0.16 percent $\Delta V/V$ per 10^{20} fissions/cm^3. However, the linear heat rating will decrease with burnup and thus limit the sum of the strains to values below the allowable.

Further substantiation of the capability of operation at maximum linear heat ratings in excess of those in this design is obtained from later irradiation tests in WTR (Reference 24). Thirty-eight-inch long and 6-inch long fuel rods were irradiated at linear heat ratings of 19 kW/ft and 22.2 kW/ft to burnups of 3,450 and 6,250 MWD/MTU. The cold diametral gaps in these Zircaloy clad rods containing 94 percent dense UO_2 were 0.002 inch, 0.006 inch and 0.012 inch. The cladding t/OD was 0.064. No measurable diameter changes were noted for the 0.006 inch or 0.012 inch fuel clad gap rods. Only small changes were observed for the rods with a 0.002-inch diametral gap.

B. Shippingport Irradiation Experience

Zircaloy clad fuel rods have operated successfully (three defects have been observed which were a result of fabrication defects) in the Shippingport blanket with burnups of about 37,000 MWD/MTU and maximum linear heat ratings of about 13 kW/ft (Reference 24, 29, 144). Although higher linear heat ratings will be experienced, swelling (primarily burnup dependent) and thermal expansion (linear heat rating dependent) provide the primary forces for fuel cladding strain at the damage limit. Thus, the Shippingport irradiations have demonstrated that Zircaloy clad rods with a

cladding t/OD less than that for this plant (0.066) can successfully contain the swelling associated with 37,000 MWD/MTU burnup while at the same time containing the radial thermal expansion associated with peak heat ratings. Irradiation test programs in support of Shippingport in in-reactor loops demonstrated successful operation at burnups of 40,000 MWD/MTU and linear heat ratings of about 11 kW/ft with cladding t/OD ratios as low as 0.053 (Reference 42).

C. Saxton Irradiation Experience

Zircaloy-4 clad fuel rods containing UO_2-PuO_2 pellets of 94 percent theoretical density have been successfully irradiated in Saxton to peak burnups of 31,800 MWD/MTU at 16 kW/ft linear heat rate under USAEC Contract AT (30-1)-3385 (Reference 116). The t/OD of the cladding was 0.059 which is less than that of this design. The amount of PuO_2, 6.6 percent, is considered as insignificant with respect to providing any difference in performance when compared with that for UO_2. Subsequent tests on two of the above rods (18,000 MWD/MTU at 10.5 kW/ft) successfully demonstrated the capability of these rods to undergo power transients from 16.8 kW/ft to 18.7 kW/ft.

D. Vallecitos Boiling Water Reactor (VBWR) - Dresden Experience

The combined VBWR - Dresden irradiation of Zircaloy clad oxide pellets provides additional confidence with respect to the design conditions for the fuel rods for this core (References 44, 110, 111). Ninety-eight rods which had been irradiated in VBWR to an average burnup of about 10,700 MWD/MTU were assembled in fuel bundles and irradiated in Dresden to a peak burnup greater than 48,000 MWD/MTU. The reported maximum heat ratings for these rods is 17.3 kW/ft which occurred in VBWR. The t/OD cladding ratio of 0.052, and the external pressure of about 1,000 psi are conditions which are all in the direction of less conservatism with respect to fuel rod integrity when compared with the design values of 0.066 cladding t/OD ratio and an external pressure of 2,250 psi. Ten of these VBWR - Dresden rods representing maximum combinations of burnup, linear heat rating and pellet density have been examined in detail and found to be in satisfactory condition. The remaining 88 rods were returned to Dresden and successfully irradiated to the termination of the program.

E. Large Seed Blanket Reactor (LSBR) Rods Experience

Two rods operated in the B-4 loop at the Materials Testing Reactor (MTR) provide a very interesting simulation for current PWR designs (References 47, 70 and 74). Both rods were comprised of 95 percent theoretical density pellets with dished ends, clad in Zircaloy. The first of these, No. 79-21, was operated successfully to a burnup of 12.41 x 10^{20} f/cc (~ 48,000 MWD/MTU) through several power cycles which included linear heat rates from 5.6 to 13.6 kW/ft. The second fuel pin, No. 79-25, operated successfully to 15.26 x 10^{20} f/cc (~ 60,000 MWD/MTU). The basic difference in this rod was the 0.028-inch wall thickness, as compared to 0.016-inch (t/OD = 0.058) in the first rod. All other parameters were essentially identical.

The linear heat rating ranged from 7.1 to 16.0 kW/ft. After the seventh interim examination, the rod operated at a peak linear power of 12.9 kW/ft at a time when the peak burnup was 49,500 MWD/MTU. These high burnups were achieved with fuel elements which were assembled by shrinking the cladding onto the fuel and indicate that a comparable irradiation of the fuel elements for this reactor (cold diametral gap of 0.007-inch) would allow a considerable increase in swelling life at a given clad strain.

F. Central Melting in Big Rock Point Experience

As part of a Joint U.S. - Euratom Research and Development Program, Zircaloy-clad UO_2 pellet rods (95 percent theoretical density) were irradiated under conditions designed to induce central melting in the Consumers Power Co. Big Rock Point Reactor (Reference 48). The test includes 0.7-inch diameter fuel rods (cladding t/OD = 0.057; fuel clad gap of about 0.012 inch) at maximum linear heat ratings of about 27 kW/ft and 22 kW/ft with peak burnups up to 30,000 MWD/MTU. Results of these irradiations provide a basis for incorporating linear heat ratings well in excess of those calculated for this reactor, and show that the presence of localized regions of fuel melting is not catastrophic to the fuel rod.

G. KWU Irradiations - KWU Reactor, Obrigheim, Germany

In the area of nuclear fuel performance, the experience at Obrigheim has shown successful operation through three operating cycles. Fuel batches of 95 percent T.D., both pressurized and nonpressurized, have been irradiated. Substantial testing has been performed in the reactor on the load following ability of both pressurized and nonpressurized fuel rods. Selected rods were subjected to power changes from 50 to 100 percent at rates of 20 percent per minute for more than 900 cycles. Peak power densities in the rods were 15 kW/ft with maximum burnups in excess of 30,000 MWD/MTU. No failures have been observed to date. This experiment demonstrates the load-following capability of a design similar to Combustion Engineering's in an operating PWR.

H. High Burnup Combustion Engineering Operational Experience

Reference 176 presents fuel performance data obtained during poolside examinations and hot cell examinations of high burnup fuel utilizing Zircaloy-4 cladding in Combustion Engineering cores. The data demonstrates the acceptability of the fuel's performance to rod average exposures in excess of 60,000 MWD/MTU.

I. Westinghouse Experience Database:

ZIRLO™ cladding material is in widespread use domestically in at least 38 nuclear power plants (Reference 183, Section 3.3). ZIRLO™ has been shown to have improved corrosion resistance compared to Zircaloy-4. Also, no oxide spalling has been observed in current ZIRLO™ fuel rods for normal operation. With over 1 million ZIRLO™ fuel rods in assemblies with Optimized Fuel Assembly type spacer grids, no incidences of leakers due to grid-to-rod fretting has been observed.

Optimized ZIRLO™ cladding has a slightly lower allowed tin level than ZIRLO™ (lower by 0.2%) with the remainder of the material composition requirements being the same. The reduced tin level is to further enhance the corrosion resistance of the cladding. Reference 194 documents that ZIRLO™ material properties currently utilized in various models and methodologies are applicable to analyses for Optimized ZIRLO™ and shows the differences are negligible with no impact on any design or safety analyses. Reference 197 presents additional cladding corrosion data and provides updated cladding corrosion models for both ZIRLO® and Optimized ZIRLO™ cladding. Therefore, in addition to the operational experience of Optimized ZIRLO™, the ZIRLO™ operational experience discussed above is applicable to Optimized ZIRLO™.

4.2.1.3.10 Long-Term Irradiation Testing

Combustion Engineering Fuel Development Programs:

Since mid-1972, Combustion Engineering has performed an extensive irradiation test program on fuel densification. When fuel densification became apparent, Combustion Engineering immediately initiated an irradiation test program to determine the causes of densification and to define the specifications and processes required to limit densification of fuel. The first irradiation test program in the sequence confirmed that the phenomenon is real and defined the parameters important in the effect. An immediate response was a change in the Combustion Engineering fuel pellet specification and a modification of the fuel fabrication process to provide densification resistant UO_2 fuel. The irradiation tests were continued to confirm that the changes to the Combustion Engineering fuel pellet specification and fabrication process would result in densification resistant fuel. Results were reported in Reference 17. The summaries of the data and conclusions from Reference 17 were incorporated in Reference 10 which has received NRC approval.

Combustion Engineering is also a participating member of the Halden Reactor Project in Halden, Norway. The Halden project has underway a spectrum of fuel development programs from which Combustion Engineering can further verify present fuel design models and continually evaluate advance fuel design concepts.

Combustion Engineering/Kraftwerk Union Fuel Development Programs:

The primary objectives of the cooperative fuel development program were:

A. To assess the causes of fuel densification and provide process changes which will preclude densification. Then subsequently to verify through irradiation testing that the process changes have been effective;

B. To obtain long-term data to further verify fuel performance models;

C. To evaluate advanced fuel design concepts in reactor.

Combustion Engineering and Kraftwerk Union participated in densification test programs in both U.S. and European test reactors. In addition, Combustion Engineering and Kraftwerk Union participated in the densification test program under the primary sponsorship of the Edison Electric Institute.

Kraftwerk Union Fuel Development Programs:

The design of the Combustion Engineering fuel rods is very similar to the KWU fuel utilized in the Obrigheim Reactor. The Obrigheim core has operated with peak power densities up to 15 kW/ft with maximum burnups in excess of 35,000 MWD/MTU without observed life limiting failures. Several fuel rods, both pressurized and unpressurized, from the Obrigheim Reactor have undergone detailed hot cell examination under the direction of KWU. The results of all nondestructive fuel examinations performed during shutdowns and the complete results of the hot cell program were available to Combustion Engineering under a technical agreement with KWU.

In addition to the programs to routinely examine high burnup standard fuel, KWU also had comprehensive fuel development programs underway which utilize special test assemblies in the Obrigheim Reactor. Under this program, fuel rod design parameters were varied over significant ranges to experimentally establish the basis for further design optimization. Included in special assemblies were segmented rods or "rodlets" which were connected to form a complete fuel rod.

These rodlets were pre-irradiated in the Obrigheim Reactor and then subsequently separated and irradiated in a test reactor. The test reactor irradiations evaluated fuel rod performance under transient conditions.

In summary, Westinghouse has in process or in the planning stages fuel development programs that will provide additional assurance of fuel design adequacy.

4.2.1.3.11 <u>CEA Guide Tube Evaluation</u>

The CEA guide tubes have been evaluated for structural adequacy using the criteria given in Section 4.2.1.1.1 in the following areas.

A. Steady axial load due to the combined effects of axial hydraulic forces and upper end fitting holddown forces - For normal operating conditions, the resultant guide tube stress levels are less than 50 percent of the 2/3 yield stress criterion.

B. Short-term axial load due to the impact of the spring loaded CEA spider against the top of the fuel assembly at the end of a CEA scram - For scrams occurring during normal power operation, solid impact is not predicted to occur due to the kinetic energy of the CEA being dissipated in the hydraulic buffer and by the CEA springs.

C. Short-term differential pressure load occurring in the hydraulic buffer regions of the outer guide tubes at the end of each scram stroke - The buffer region slows the CEA during the last few inches of the scram stroke. The resultant differential pressure across the guide tube in this region is predicted to be 300 psi, and this gives rise to circumferential stresses of 3,300 psi, which is less than one-quarter of the yield stress, for a very short-term. The scram is assumed to be repeated daily. However, the resultant stress is too small to have a significant effect on fatigue usage.

For conditions other than normal operation, the additional mechanical loads imposed on the fuel assembly by an Operating Basis Earthquake (OBE), Design Basis Earthquake (DBE) and branch line pipe break (BLPB) and their resultant effect on the control rod guide tubes are discussed in the following paragraphs:

A. OBE: During the postulated OBE, the fuel assembly is subjected to lateral and axial accelerations which, in turn, cause the fuel assembly to deflect from its normal shape. The magnitude of the lateral deflections is evaluated for acceptability. The fuel assembly is designed to be capable of withstanding the axial loads without buckling and without sustaining excessive stresses.

B. DBE: The axial and lateral loads and deformation sustained by the fuel assembly during a postulated DBE have the same origin as those discussed above for the OBE, but they arise from initial ground accelerations twice those assumed for OBE.

C. BLPB: In the event of a BLPB, there will occur rapid changes in pressure and flow within the reactor vessel. Associated with the transient are relatively large axial and lateral loads on the fuel assemblies. The response of a fuel assembly to the mechanical loads produced by a BLPB is considered acceptable if the fuel rods are maintained in a coolable array, i.e., acceptably low grid crushing.

The methods and results of the combined DBE/BLPB analysis for the Arkansas Nuclear One - Unit 2 16 x 16 fuel assembly design are presented in Reference 36. Implementation of leak-before-break, which resulted in lower LOCA loads, was based on SAR Section 3.12, Reference 79.

CEA guide tube evaluations were performed for the Batch Z NGF design. Due to the similarity in the structural design of the NGF assemblies of Batch Z and beyond versus the prior assemblies, the results were comparable to prior analyses and all applicable criteria continue to be satisfied.

4.2.1.3.12 Fuel Rod Plenum Design

The fuel rod upper end plenum is required to serve the following functions:

A. Provide space for axial thermal expansion and burnup swelling of the pellet column.

B. Contain the pellet column holddown spring.

C. Act as a plenum region to ensure an acceptable range of fuel rod internal pressures.

Of these functions, item "C" is expected to be the most limiting constraint on plenum length selection, since the range of temperatures in the fuel rod, together with the effects of swelling, thermal expansion, and fission gas release, and including the helium release in the ZrB_2 IFBA fuel rods, can produce a wide range of internal pressure during the life of the fuel. The fuel rod plenum pressure will be consistent with the pressurization and clad collapse criteria specified in Sections 4.2.1.1.4 and 4.2.1.1.2, respectively.

The procedure used to size the fuel rod plenum is outlined below:

A. A parametric study of the effects of plenum length on maximum and minimum rod internal pressure is performed. Because the criteria pertaining to maximum and minimum rod internal pressure differ, the study is divided into two sections:

   1. Maximum internal pressure calculation - Maximum rod pressure is limited by the stress criteria. Maximum EOL pressure is determined for each plenum length by including the fission gas released, selecting conservative values for components dimensions and properties, and accounting for burnup effects on component dimensions. The primary cladding stress produced by each maximum pressure is then compared to the stress limits to find the margin available with each plenum length.

   2. Minimum internal pressure/collapse calculation - Minimum rod pressure is limited by the criterion that no rod will be subject to collapse during the design lifetime. The minimum pressure history for each plenum length is determined by neglecting fission gas release, selecting the worst combination of component dimensions

and properties, and accounting for dimension changes during irradiation. Each minimum pressure history is input to the Combustion Engineering cladding collapse model (Reference 12) to establish the acceptability of the associated plenum length. With the introduction of IFBA rods in Batch X, credit may be taken for the radial support provided to the cladding in the end plenum region by the plenum spring.

B. For each plenum length, there is a resultant range of acceptable initial fill pressures. The optimum plenum length is generally considered to be the shortest which satisfies all criteria related to maximum and minimum rod internal pressure including a range sufficient to accommodate a reasonable manufacturing tolerance on initial fill pressure.

Additional information on those factors which have a bearing on determination of the plenum length are discussed below:

A. Creep and dimensional stability of the fuel rod assembly influence the fission gas release model and internal pressure calculations, and are accounted for in the procedure of sizing the fuel rod plenum length. Creep in the cladding is accounted for in a change in clad inside diameter, which in turn influences the fuel/clad gap. The gap change varies the gap conductance in the FATES computer code (Reference 10) with resulting change in annulus temperature, internal pressure, and fission gas release. In addition, the change in clad inside diameter causes a change in the internal volume, with its resulting effect on temperature and pressure. Dimensional stability considerations affect the internal volume of the fuel rod, causing changes in internal pressure and temperature. Fuel pellet densification reduces the stack height and pellet diameter. Irradiation-induced radial and axial swelling of the fuel pellets decreases the internal volume within the fuel rod. In-pile growth of the fuel rod cladding contributes to the internal volume. Axial and radial elastic deformation calculations for the cladding are based on the differential pressure the cladding is exposed to, resulting in internal volume changes. Thermal relocation, as well as differential thermal expansion of the fuel rod materials, also affect the internal volume of the fuel rods.

B. The maximum expected fission gas release in the peak power rod is calculated using the FATES computer code. Rod power history input to the code is consistent with the design limit peak linear heat rate and therefore the gas release used to size the plenum represents an upper limit. Because of time-varying gap conductance, fuel depletion, and expected fuel management, the release rate varies as a function of burnup.

4.2.1.3.13 <u>Fuel Rod Pressurization</u>

Fuel rods are initially pressurized with helium (without evacuating air present prior to pressurization) for two reasons:

A. To preclude clad collapse during the design life of the fuel. The internal pressurization, by reducing stresses from differential pressure, extends the time required to produce creep collapse beyond the required service life of the fuel.

B. To improve thermal conductivity of the pellet to clad gap within the fuel rod. Helium has a higher coefficient of conductivity than the gaseous fission products.

In unpressurized fuel, the initially good helium conductivity is eventually degraded through the addition of the fission product gases released from the pellets. The initial helium pressurization results in a higher helium to fission products ratio over the design life of the fuel with a corresponding increase in the gap conductivity and heat transfer.

The initial helium fill pressure is set at [*], resulting in EOL maximum pressure less than the critical pressure for no clad lift off. The power history used in the determination of the [*] initial fill pressure represents conservative power levels during normal operations. The procedure for calculating the internal pressure of the fuel rods, as well as the initial fill pressure is described in Section 4.2.1.3.12.

Introduction of the ZrB_2 IFBA design has influence fuel rod pressurization as discussed in the topical report, Reference 185. During irradiation, the B-10 isotope absorbs a neutron and fissions into helium and lithium. Much of the helium may be released from the thin coating into the fuel rod void by the time complete burnout is attained. This added helium contributes to the rod internal pressure at end of life. Consequently, the fuel rod is pre-pressurized at a lower helium fill pressure to avoid an unacceptable maximum end of life pressure. The released helium compensates for the reduction in helium fill gas and mitigates the impact of less helium fill gas on the thermal heat transfer from the fuel pellets to the cladding and into the coolant. Thus, the IFBA coating and corresponding helium release has no significant impact on the heat transfer characteristic of the fuel rod after B-10 burnout is complete.

*Proprietary Information

4.2.1.4 Testing and Inspection Plan

Fuel bundle assembly quality assurance is attained by adherence to the ANS Quality Assurance Program Requirements for Nuclear Power Plants, ANSI N45.2-1971. Vendor product certifications, process surveillance, inspections, tests and material check analyses are performed to ensure conformity of all fuel assembly components to the design requirements from material procurement through receiving inspection at the plant site. The following are basic quality assurance measures which are performed in addition to dimensional inspections and material verifications.

4.2.1.4.1 Fuel Pellets

During the conversion of UF_6 to ceramic grade uranium dioxide powder, the UO_2 powder is divided into lots blended to form uniform isotopic, chemical and physical characteristics. Two containers are selected from the total number of containers in each lot for certification sampling. Samples are removed from each of the two selected containers and subdivided to verify specification limits (see Section 4.2.1.2.4.10).

Pellets are divided into lots during fabrication with all pellets within the lot being processed under the same conditions. Representative samples are obtained from each lot for product acceptance tests. Total absorbed and adsorbed gas content and moisture content of finished ground pellets is restricted (Section 4.2.1.2.4.10). The pellets' diameters are 100 percent inspected. Pellets for Batch U and subsequent batches are inspected with a sampling plan that has a 95/99 (95% confidence that at least 99% of the pellets meet diameter) requirement. All other pellet dimensions meet a 90/90 confidence level. Density requirements of the sintered pellet (Section 4.2.1.2.4.10) must meet a 95/95 confidence level. A minimum of 10 pellets from

each pellet lot is subjected to a duplicate sintering cycle, limiting the resultant average measured increase in density. Longitudinal sections of two sample pellets from each pellet lot are prepared for metallographic examination to ensure conformance to microstructure requirements (See Section 4.2.1.2.4.10). Surface finish of ground pellets is restricted to 63 micro-inches or less arithmetic average when measured in accordance with ASA Specification B46.1-1962; and shall meet a 90/90 confidence limit, with a minimum of one determination per pellet lot. Pellet surfaces are inspected for chips, cracks, and fissures in accordance with approved standards.

Beginning with Batch X, a ZrB_2 IFBA fuel design is introduced. ZrB_2 is applied as a very thin uniform coating on the outer surface of the UO_2 pellet stack prior to loading into the fuel rod cladding tube. The ZrB_2 IFBA coating is applied over the center of the UO_2 pellet stack length and does not extend to either end of the fuel rod. Pellets at the ends of the pellet stack are of an annular design. Helium is released from the thin IFBA coating during burnup which contributes to the rod internal pressure at end of life. The annular pellets provide additional void volume to help control the rod pressure.

4.2.1.4.2 Fuel Cladding

Lots are formed from tubing produced from the same ingot, annealed in the same final vacuum annealing charge, and fabricated using the same procedures. Samples randomly selected from each lot of finished tubing are chemically analyzed to ensure conformance to specified chemical requirements, and to verify mechanical properties, hydride orientation and other tests. Each finished tube is ultrasonically tested over its entire length for defects; visually inspected for cleanliness and the absence of acid stains, surface defects, and deformation; and inspected for dimension and drawing requirements. The following summarizes the test requirements.

Test (Reference Section 4.2.1.2.4.1)

A. Chemical Analysis - Ingot analysis is required for top, middle and bottom of each ingot.

B. Tensile Test at Room Temperature (ASTM E8)

C. Corrosion Resistance Test (ASTM G2)

D. Hydride Orientation (ASTM B811)

E. Surface Roughness

F. Visual Examination

G. Ultrasonic Test

H. Dimensions

I. Contractile Strain Ratio test for ZIRLO™ replaces burst test

4.2.1.4.3 Fuel Rod

The moisture content of fuel pellets prior to loading is limited. Loading and handling of pellets is carefully controlled to minimize chipping of pellets.

Immediately prior to loading, pellets must be capable of passing approved visual standards. Each fuel pellet stack is weighed to within 0.1 percent accuracy. The loading process is such that cleanliness and dryness of all internal fuel rod components are maintained until after the final end cap weld is completed. Loaded fuel rods are evacuated and back filled with helium to a prescribed level as determined for the fuel batch. Fuel rods for Batch U and subsequent batches are no longer evacuated prior to being backfilled with helium. Impurity content of the fill gas shall not exceed 0.1 percent, including moisture. End cap welds are visually inspected and helium leak tested. Quality of the end cap welds is ensured by evaluating sections cut from weld samples. A quality control plan ensures a minimum weld bond of 85 percent of the measured tube wall thickness and absence of any continuous defect greater than 10 percent of the wall thickness. All finished fuel rods are scanned to ensure a continuous pellet stack, and visually inspected to ensure a proper surface finish (scratches greater than 0.001 inch in depth, cracks, slivers, and other similar defects are not acceptable). The fuel rods must be capable of passing a corrosion test (ASTM G2-67) with no preferential oxidation at the weld in water at 650 °F, 2,200 psi for 3 1/2 days. Each fuel rod is marked to provide a means of identification.

The following procedure is used during fabrication to assure that there are no axial gaps in fuel rods:

A. Plug Gauge

   Following loading of the fuel pellets into the fuel rod, a plug gauge is used to verify the stack length is within the required tolerance.

B. Rod Scanner

   Finished fuel rods are run through a gamma scanner prior to being loaded into bundles. The gamma scanner is qualified to detect gaps in the pellet stack and to provide an accurate measurement of the plenum length. The fuel rod is assumed to be within tolerances if no gaps are detected and the plenum length is correct.

4.2.1.4.4 Spacer Grids, Guide Tubes

The chemical composition and sampling for testing for all Zircaloy-4 strip conforms to the chemical analysis required by Grade RA-2 under Table I of ASTM B352. Similar sampling is done for all Optimized ZIRLO™ strip. Each lot consists of material of the same size, shape, condition and finish, from the same ingot, and annealed in the same vacuum charge.

The chemical composition and sampling for testing of Inconel-625 strips is specified by ASTM B443.

Welds joining intersections (both Zircaloy grids and Optimized ZIRLO™ grids) and welds joining the Zircaloy grids to the CEA guide tubes are inspected to approved standards. The quality of the grid materials and welds shall be such that they are capable of passing a corrosion test, also in accordance with an approved standard.

Guide tube material is in accordance with ASTM B353 (with additional requirements) and is visually inspected for surface defects and acid stains and ultrasonically inspected for internal defects.

4.2.1.4.5 Upper and Lower End Fittings

The flow plate, holddown plate and lower end fitting castings are in accordance with ASTM A744 and are examined after machining for casting defects. All castings must be capable of meeting reference radiographic standards of ASTM E192 to specified severity levels.

Holddown spring material is specified by AMS 5699; and any evidence of cracks is cause for rejection.

Upper end fitting posts are in accordance with ASTM A269 or A276 and are ultrasonically inspected to ensure absence of internal defects.

4.2.1.4.6 Fuel Assembly

The welded joints used in the Arkansas Nuclear One - Unit 2 fuel assembly design are listed below in a series of paragraphs which describe the type and function of each weld, and including a brief description of the testing (both destructive and nondestructive) performed to ensure the structural integrity of the joints. The welds are listed from top to bottom in the fuel assembly.

The fuel rod upper end cap to fuel rod cladding tube weld will be a butt weld between the Zircaloy-4 cladding tube and the Zircaloy-4 end cap machined from bar stock. The weld process will be Magnetic Force Welding (MFW). Batch U and subsequent batches will utilize a Tungsten Inert Gas (TIG) weld, accomplished using a friction fit of the cladding on a reduced diameter pedestal section of the end cap. Beginning with Batch X, the ZIRLO™ cladding tube and the Zircaloy-4 end caps are TIG welded. Similarly, beginning with Batch Z, the Optimized ZIRLO™ cladding tube and the Zircaloy-4 end caps are TIG welded. Quality assurance on the end cap weld will be as follows:

A. Destructive examination of a sufficient number of weld samples to establish that the allowable percent of unbonded wall thickness and the maximum allowable continuous unbonded region are satisfied.

B. Visual examination of all end cap welds to establish freedom from cracks, seams, inclusions, and foreign particles after final machining of the weld region.

C. Helium leak checking of all end cap welds to establish that no leak rate greater then 10^{-8} cc/sec. is present.

D. Corrosion testing of a sufficient number of samples to establish that weld zones do not exhibit excessive corrosion compared to a visual standard.

The CEA guide tube joints (between the tube and the threaded upper and lower ends) will be butt welds between the two Zircaloy subcomponents. The welds are required to be full penetration welds and must not cause violation of dimensional or corrosion resistance standards.

The upper end fitting center guide post to lower cast flow plate joint has a threaded connection which is prevented from unthreading by tack welding the center guide post to the bottom of the lower cast plate using the Gas Tungsten Arc (GTA) process. Each weld is inspected for compliance with a visual standard.

The spacer grid welds at the intersection of perpendicular Zircaloy-4 grid strips are made by the GTA process. Each intersection is welded top and bottom, and each weld is visually inspected by comparison with a visual standard.

For the spacer welds at intersections between inner strips and perimeter strip (both components Zircaloy-4), each inner strip is welded to the perimeter strip using the GTA processor, starting in Cycle 11, the laser welding process. Each weld is inspected by comparison to a visual standard.

For the spacer grid to CEA guide tube weld (both components Zircaloy-4), each grid is welded to each guide tube with eight small welds, evenly divided between the upper and lower faces of the grid. Each weld is required to be free of cracks and burn-through and each weld is inspected by comparison to a visual standard. Also, sufficient testing of sample welds is required to establish acceptable corrosion resistance of the weld region. Each guide tube is inspected after welding to show that welding has not affected clearance for CEA motion.

The lower spacer grid welds at spacer strip intersections and between spacer and perimeter strips (all components Inconel-625) have the same general configuration as for the Zircaloy and are all inspected for compliance with appropriate visual standards.

The lower spacer grid (Inconel) to Inconel skirt weld is made using the GTA process. Each weld is inspected to ensure compliance with a visual standard. With the introduction of the Guardian grid in Batch P, this weld has been eliminated since the Guardian perimeter strips are welded directly to the lower end fitting.

The Inconel skirt (or perimeter strip) to lower end fitting (Grade CF-8 stainless steel) weld is made using the GTA process and each weld is inspected to ensure compliance with a visual standard.

The lower end fitting is fastened to the Zircaloy guide tubes using 304 stainless steel bolts. The bolts are prevented from unthreading by stainless steel locking rings which are welded to the lower end fitting. Each ring is tack welded to the end fitting using the GTA process, and each weld is inspected for compliance with a visual standard.

The implementation of the NGF design in Batch Z replaces the Zircaloy grid strips with Optimized ZIRLO^{TM} grid strips while maintaining the same inner-to-inner and outer-to-inner laser welded joints within the grid assembly. The NGF implementation also eliminates two weld types within the fuel assembly and introduces two different weld types. As described in Section 4.2.1.2.3, the welds between the flange and the guide tubes and the welds between the Zircaloy-4 spacer grids and the guide tubes are eliminated in the NGF design and replaced by mechanical bulges. The two new weld types involve the welding of ZIRLO^{TM} sleeves to the Optimized ZIRLO^{TM} grids (both mids and IFMs) and the welding of stainless steel inserts to the Inconel Guardian grid. For both weld types, each weld is visually inspected to verify that it is free of cracks. To verify the acceptability of any weld penetration on the inside of the sleeve/insert, each sleeve/insert is inspected with a plug gage of the appropriate diameter. In addition, each sleeve-to-grid weld is inspected for compliance with the weld length requirement on the design drawing, and each insert-to-grid weld is inspected for capture by comparison to a standard.

There is no formal ranking of these welds with respect to categorization of the weld joints by "importance for safety". The inspection requirements and acceptance standards are established on the basis of providing adequate assurance that the connections will perform their required functions.

All guide tubes are internally gauged ensuring free passage within the tubes including the reduced diameter buffer region. An alpha smear test is performed on the exterior surface of the fuel rods, and guide tube to end fitting joints are inspected in accordance with a visual standard. The spacer grid to fuel rod relationship is carefully examined at each grid location.

A comprehensive quality control plan is established to ensure that dimensional requirements of the drawings are met. In those cases where a large number of measurements are required and 100 percent inspection is impractical, these plans shall ensure with 95 percent confidence that 95 percent of these dimensions are within tolerance. Sensitivity and accuracy of all measuring devices are within ± 10 percent of the dimensioned tolerance.

Material traceability is established in accordance with ANSI N45.2-1971 which states:

> "Measures shall be established and documented for the identification and control of materials, parts, and components, including partially fabricated subassemblies. These measures shall provide for assuring that only correct and accepted items are used and installed, and relating an item or production 'batch, lot, component, part' at any stage from initial receipt through fabrication, installation, repair or modification, to an applicable drawing, specification, or other pertinent technical document. Physical identification shall be used to the maximum extent possible. Where physical identification is either impractical or insufficient, physical separation, procedural control or other appropriate means shall be employed. Identification may be either on the item or on records traceable to the item, as appropriate."
>
> "Where identification marking is employed, the marking shall be clear, unambiguous and indelible, and it shall be applied in such a manner as not to affect the function of the item. Markings shall be transferred to each part of an item when subdivided, and shall not be obliterated or hidden by surface treatment or coatings, unless other means of identification are substituted."
>
> "When codes, standards or specifications require traceability of materials, parts or components to specific inspection or test records, the program will be designed to provide such traceability."

Each completed fuel assembly is inspected for cleanliness, wrapped to preserve its cleanliness, and loaded within shipping containers.

Protection of the fuel bundle in transit is ensured through proper design of the shipping container. Clamping and support surfaces are provided by the clamshell design. Design of the container will prevent shock loads to the fuel assembly form exceeding 5 g's in any direction when the shipping container assembly is subjected to handling and shipping peak loads typical of the carriers used in accomplishing delivery. Impact recorders are contained within each shipment to determine if shock loads sustained by the fuel assembly in the axial, vertical and lateral directions have exceeded 5 g's. Should the recorders indicate that accelerations have exceeded 5 g's in transit, the fuel assembly will be visually inspected for evidence of damage and repaired, if necessary.

Visual inspection of the conveyance vehicle, shipping container and fuel assembly are performed at the reactor site. Approved procedures are provided for unloading the fuel assemblies. Following unloading, exterior portions of the fuel assembly components are inspected for shipping damage and cleanliness.

4.2.2 REACTOR INTERNALS

4.2.2.1 Design Bases

The reactor internals are designed to support and position the reactor core fuel assemblies and CEAs, provide holddown for the fuel assemblies, absorb the dynamic loads and transmit these and other loads to the reactor vessel flange, provide flow paths for the reactor coolant and guide in-core instrumentation.

The reactor internals are held in place against the upward hydraulic lift of reactor coolant flow by the reactor internals holddown rings. The Arkansas Nuclear One - Unit 2 holddown ring utilizes a low spring rate design concept which is less sensitive to small changes in deflection than the earlier interference fit design resulting in less holddown load fluctuation. Table 4.2-4a lists the net down load on reactor vessel internals for representative Combustion Engineering installations with this holddown ring design. In all cases, the net down load is sufficient to provide adequate holddown margin.

Earlier holddown ring designs such as the Calvert Cliffs Unit 1 design utilized during the first cycle of operation produced a net down load of approximately one-half the values shown in the table. The newer and heavier design was necessitated by the measurement of much larger than expected irradiation induced Zircaloy growth rate during the first Palisades fuel inspection, and provides additional holddown margin.

4.2.2.1.1 Reactor Internals Structures

The reactor internals are designed to meet the loading conditions listed in Section 4.2.2.3 and the design limits specified in Section 4.2.2.4. The details of the dynamic analysis, input forcing functions and response loadings are described in Section 3.9. The materials used in fabrication of the reactor internal structures are primarily Type 304 stainless steel. The flow skirt is fabricated from Inconel. Welded connections are used where feasible; however, in locations where mechanical connections are required, structural fasteners are used which are designed to remain captured in the event of a single failure. Structural fastener material is typically a high strength austenitic stainless steel; however, in less critical applications, Type 316 stainless steel is employed. Hardfacing, of Stellite material, is used at wear points. The effect of irradiation on the properties of the material is considered in the design of the reactor internal structures.

Reactor internal components are designed to ensure that the stress levels and deflections are within the ASME Code limits. Stress limits for the reactor vessel core support structures are presented in Table 4.2-4. In the design of critical reactor vessel internal components which are subject to fatigue, the stress analysis will be performed utilizing the design fatigue curve of Figure I-9-2 of Section III of the ASME Boiler and Pressure Vessel Code and a cumulative usage factor of less than one as the limiting criteria.

Reactor internal components are subject to pre-critical and periodic surveillance in accordance with the reactor internals inspection and monitoring plan. This plan includes pre-critical and periodic vibration monitoring programs, and surface and visual examinations.

The Pre-critical Vibration Monitoring Program (PVMP) for Unit 2 was established in accordance with the requirements of Regulatory Guide 1.20, Revision 0, as it relates to reactor internals similar to the prototype design, which includes Paragraphs D.2(a) through D.2(e).

With regard to requirements of and definitions within Regulatory Guide 1.20, Revision 0, Unit 2 is considered to be a non-prototype plant for vibration monitoring of the reactor internals. The Unit 2 plant is designated as non-prototypical in Combustion Engineering's report CEN-8(A), "Comparison of Arkansas Nuclear One - Unit 2, Maine Yankee and Fort Calhoun Reactor Internals Design Parameters and Flow Induced Structural Response." The Maine Yankee and Fort Calhoun plants are designated as prototypical plants in this report, and consequently both plants have fully instrumented PVMPs. As a non-prototypical plant, Unit 2 has a non-instrumented PVMP. The CEN-8(A) report, and Supplement 1 to this report, contain the following findings:

A. The structural response of the Arkansas Nuclear One - Unit 2 reactor internals is well within design allowable criteria for all normal steady state and transient flow modes of reactor coolant pump operation;

B. The Unit 2 reactor internals' maximum predicted stress, using a conservative estimate of the inlet pressure, is an order of magnitude below the allowable stresses for the structures;

C. For the two prototype reactors, measured inlet pressures were used to re-compute the maximum predicted stresses, resulting in "best estimate" predicted stresses which were approximately one-third of the former conservative predictions; and,

D. The measured responses of the two prototype reactor internals confirmed that actual stresses resulting from normal operating flow induced vibrations were seen lower, and were so low as to be negligible (See Figure 6.4 in CEN-8(A), Supplement 1).

The Arkansas Nuclear One - Unit 2 PVMP consists of photographically documented visual inspections and nondestructive weld tests which are repeated periodically. In addition, an installed neutron noise monitoring system is in continuous operation.

Prior to initial hot flow testing with reactor internals installed, a photographically documented visual examination of all major points of contact for load transmission (such as the core barrel flange and snubbers) was conducted. In addition, a baseline liquid penetrant examination of the core barrel flange to cylinder girth weld in the vicinity of the proposed pre-critical instruments was conducted. The results of these examinations have been recorded. The reactor vessel internals have been subjected during the preoperational and functional testing program to all significant flow modes of normal reactor operation for a sufficient period of time to determine whether the reactor vessel internals exhibit any unexpected vibration problems.

After completion of the preoperational and functional tests, the reactor vessel internals were subjected to the same type of photographically documented visual examination to detect any evidence of unanticipated or excessive vibrations. In addition, the liquid penetrant examinations of the flange to cylinder girth weld were repeated. A summary of the inspections is maintained on file at the plant. This program is considered sufficient to address any concerns related to short-term vibration effects on the reactor internals.

In addition, AP&L has purchased a neutron noise monitoring system which can utilize signals available from the ex-core nuclear instrumentation to permit continuous surveillance of reactor internals motion over extended observation periods. As indicated in CEN-8(A), Supplement 1, neutron noise analysis techniques have been able to consistently characterize both the extent and character of the steady state response of the core support barrel for four different CE plants. Thus, equipment is available which provides a means of long-term monitoring of reactor internals to insure adequate structural performance. This capability goes beyond the requirements of Regulatory Guide 1.20, Revision 0, and provides a significant additional level of assurance that unforeseen vibrational problems of the reactor internals (which typically are not detectable in PVMPs but can develop over extended periods of operation) will be detected, if they occur.

AP&L conducted a visual inspection of all accessible areas of the core support barrel and vessel internals during the first refuel outage of ANO Unit 2. This inspection was conducted in accordance with the 1974 Edition of the ASME Section XI Boiler and Pressure Vessel Code. Additional visual inspections were performed at the end of the first and second 10 year inspection interval in accordance with the latest site approved ASME Section XI Code during that interval. The results of the examinations performed during the first refueling outage and at the end of the first 10 year interval, including documentation required by paragraph D.4 of Regulatory Guide 1.20, Revision 0, will also be maintained on file at the plant. The combination of neutron noise monitoring of reactor internals along with the first refueling inspection and the first 10 year inspection are considered sufficient to address any concerns related to long term vibration effects on the reactor internals.

4.2.2.1.2 In-Core Instrumentation Support and Guidance

The pressure boundary portions of the in-core instrumentation support system are designed to Section III of the ASME Boiler and Pressure Vessel Code. The supports for the pressure tubing are designed to withstand design loadings plus earthquake forces. All components and materials are consistent with a 10-year surveillance cycle and a 5-year mean-time between instrument replacements. The guide tubes are designed to provide smooth and snag-free paths for easy insertion and removal of the instrument assemblies.

The complete system is designed to accommodate the mechanical tolerances and thermal movement of the pressure vessel and reactor internals.

In addition to guiding the instruments, the pressure vessel head nozzles and the instrumentation plate structure guide tubes protect the instruments from crossflow.

4.2.2.2 Description and Drawings

4.2.2.2.1 Reactor Internals Structures

The components of the reactor internals are divided into two major parts consisting of the core support structure and the upper guide structure (including the CEA shrouds). The flow skirt, although functioning as an integral part of the coolant flow path, is separate from the internal and is affixed to the bottom head of the pressure vessel. These components are shown in Figure 4.1-1.

4.2.2.2.1.1 **Core Support Structure**

The major structural member of the reactor internals is the core support structure. The core support structure consists of the core support barrel and the lower support structure. The material for the assembly is Type 304 stainless steel.

The core support structure is supported at its upper end by the upper flange of the core support barrel, which rests on a ledge in the reactor vessel. Alignment is accomplished by means of four equally spaced keys in the flange which fit into the keyways in the vessel ledge and closure head.
