I. INTRODUCTION

This report describes the results and analysis of a comparison of data derived from the General Electric Company's PSTF Test Series 5806^[1] with results predicted by a one-dimensional analytical model^[2] developed to analyze the pool swell occurring early in the pressure suppression transient associated with a BWR loss-of-coolant accident (LOCA).

Although other geometries have been investigated, the pool swell model was developed primarily to analyze pool swell and allied transients resulting from air blowdown through horizontal vent (Mark III) geometries. Because test series 5806 involved a total of 12 air blowdowns in the one third scale PSTF operating with a horizontal vent geometry, these data provide an ideal test for the pool swell model.

The results of the comparison between the PSTF data and model prediction for pool surface displacement, slug thickness, and pool surface velocity, all as a function of time, are presented and analyzed in this report. For pool surface displacement, two comparisons between data and model prediction are made. Initially, the data are compared to the predicted values of surface displacement as a function of time while making no adjustments to the model input. Secondly, the critical parameter of the pool surface area assumed to be involved in the blowdown transient is adjusted until generally excellent agreement between theory and experiment has been achieved. Finally, development of a correlation to determine the appropriate adjustment factor to maximize the effectiveness of the model as a predictive tool is suggested for future inclusion in the one-dimensional pool swell model.

II. MODEL EVALUATION

The data from the 12 air blowdowns performed on the one third scale PSTF were used for model evaluation. The data for each run included:

- 1) Drywell temperatures vs time
- 2) Vent mass flow vs time
- 3) Air/water and water/air interface vs time
- 4) Surface velocity vs time
- 5) Slug length vs time

The first two data items included in the above information were used, along with PSTF geometrical parameters, as input for the one-dimensional pool swell model. Items 3, 4 and 5 above were compared to the corresponding prediction made by the model.

Table I represents a test matrix defining the major differences in the experimental test parameter for each of the twelve runs. Parameters other than venturi size and vent submergence were maintained at fairly constant values for each test. Since test runs 8 and 9 were repeats of runs 1 and 2, they were not included in the data chosen for model evaluation.

The procedure for the evaluation was to determine from the data the input required for each run, to obtain the calculated result, and to then compare the experimental and calculated results. Certain simplifying assumptions introduced into the model lead to time scale variation between the data and the model. A method must be chosen to normalize these time scales so that the time histories of the predicted results match the time histories of the experimental data analyzed. The assumptions, resulting difficulties, and solution will be discussed before the results are presented.

PROFANE INFORMATION

The experimental results display a time lag between initiation of blowdown, complete clearing of vents, and the beginning of the pool swell transient. Therefore, although the blowdown begins at time zero, the pool swell transient does not begin until a short period later. The one-dimensional pool swell model does not presently have the capability of following the blowdown from initiation through vent clearing, and thus the calculations are begun only after vent clearing is completed. The task when constructing model input, therefore, is to determine the experimental time corresponding to the completion of vent clearing and to use this time as time zero for the purposes of calculation.

The method used to determine the appropriate starting time was based upon an examination of the data involving vent mass flow as a function of time. For example, Figure 1 illustrates mass flow rate vs time for Test 5806/Run 1. It is noted that an apparently random and noisy signal exists for approximately 0.8 seconds before the mass flow rate becomes well defined and consistent. It is postulated that this initial signal originates from the vent clearing transient and, furthermore, that the cessation of these random signals is indicative of the completion of vent clearing. Therefore, the method used to approximate time zero for purposes of model calculations and data comparison was to select a point corresponding to the transition from "noise" to a well defined and consistent mass flow rate and to construct at this point a tangent to the curve of mass flow rate vs time. The intersection of this tangent with the abscissa is taken to be time zero. All data input determination as well as comparisons of predicted to theoretical results were initiated at this time. In Figure 1 a dotted line represents the tangent, and it is seen that time zero for this example corresponds to an experimental time of approximately 0.75 seconds. This method produces good and consistent results and has

Figure 1: Test 5906, Run 1, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100

been used exclusively throughout this evaluation.

Figures 2 through 31 illustrate the comparisons of theoretical results to data. Data points, rather than solid lines, are used to represent the theoretical predictions. Two sets of theoretical predictions for pool surface displacement are presented for each test run, except for Test 7. Initially, the theoretical calculations are based upon the assumption that upon vent clearing an air bubble, or "pancake", is established that covers the entire area of the test pool. This assumption results in the largest possible volume of water involved in the pool swell transient and thus leads to the smallest possible values for predicted pool surface displacement and pool surface velocities. Realistically, it is expected that the forming air bubble involves a pool volume corresponding only to some fraction of the total pool surface and therefore a smaller working volume of the pool would be involved in the transient. As expected, the initial assumption of full pool bubble expansion results in predictions that are generally smaller in magnitude than the corresponding experimental values; this is clearly seen for each run. Therefore, a second model calculation was made based upon a modified value of the input parameter determining the pool volume involved in the transient. The pool volume may be modified until the desired agreement with experimental results has been obtained. The graphs presented of pool surface velocity vs time are based upon this second calculation, while the predictions of slug thickness vs time do not depend on the area of the pool involved in the transient and are therefore generally valid.

Examination of the results shows that the one-dimensional pool swell model is capable of producing very good agreement with experimental results when the input parameter determining the working pool volume is suitably modified. It is noted that the largest discrepancy between data

and theory occurs near the beginning and end of each transient. It is postulated that this disagreement can be explained by examining these two extremes in some detail. Initially, there is some finite time interval involved in bubble formation and horizontal expansion. The pool swell model, however, assumes formation and expansion to occur instantaneously, and it is felt that this assumption explains the initial discrepancies. At the end of the transient, the experimental uncertainties introduced as a result of frothing and other phenomena associated with breakthrough make comparisons with theory more difficult. Likewise, for comparisons of slug thickness vs time, experimental difficulties due to frothing and turbulence make accurate bubble-pool and pool-air interface determinations difficult, and comparisons between experiment and theory become correspondingly more difficult and uncertain. Even with these difficulties, the results of the comparison of experiment to theory for slug thickness vs time indicate generally conservative predictions for slug thickness and the results are considered encouraging.

It should be noted that an attempt was made, when adjusting the pool surface area input parameter, to obtain close agreement between experiment and theory. More conservative theoretical predictions leading to greater magnitudes for pool surface displacement and pool surface velocity may be obtained by a correspondingly conservative pool area input.

Finally, in Appendix I, a sample output for Test 5806/Run 1 is presented.

III. CONCLUSIONS AND RECOMMENDATIONS

The results presented in this report indicate that the one-dimensional pool swell model is capable of accurate predictions of pool surface displacement, pool surface velocity, and slug thickness vs time when care

PROPER INFORMATION

is taken to normalize the time scale of theory and experiment, and when the input parameter determining the working volume of the pool is appropriately adjusted.

In order to facilitate accurate predictions of the appropriate pool volume input parameters, it should be possible to develop a correlation, based upon pool surface area, vent diameter, mass flow rate and other appropriate parameters, that would be capable of determining the desired input for any given PSTF or full scale system. Such a correlation would represent a worthwhile addition to the predictive capability of the one-dimensional pool swell model.
