DOCUMENT CATEGORIZATION

In accordance with the Holtec Quality Assurance Manual and associated Holtec Quality Procedures (HQP), this document is categorized as a:

- ☐ Calculation Package³ (Per HQP 3.2)
 ☒ Technical Report (Per HQP 3.2)(Such as a Licensing Report)
- ☐ Design Criterion Document (Per HQP 3.4)
 ☐ Design Specification (Per HQP 3.4)
- ☐ Other (Specify):

DOCUMENT FORMATTING

The formatting of the contents of this document is in accordance with the instructions of HQP 3.2 or 3.4 except as noted below:

DECLARATION OF PROPRIETARY STATUS

☐ Nonproprietary
 ☒ Holtec Proprietary
 ☐ Privileged Intellectual Property (PIP)

Documents labeled Privileged Intellectual Property contain extremely valuable intellectual/commercial property of Holtec International. They cannot be released to external organizations or entities without explicit approval of a company corporate officer. The recipient of Holtec's proprietary or Top Secret document bears full and undivided responsibility to safeguard it against loss or duplication.

Notes:

1. This document has been subjected to review, verification and approval process set forth in the Holtec Quality Assurance Procedures Manual. Password controlled signatures of Holtec personnel who participated in the preparation, review, and QA validation of this document are saved in the N-drive of the company's network. The Validation Identifier Record (VIR) number is a random number that is generated by the computer after the specific revision of this document has undergone the required review and approval process, and the appropriate Holtec personnel have recorded their password-controlled electronic concurrence to the document.
2. A revision to this document will be ordered by the Project Manager and carried out if any of its contents is materially affected during evolution of this project. The determination as to the need for revision will be made by the Project Manager with input from others, as deemed necessary by him.
3. Revisions to this document may be made by adding supplements to the document and replacing the "Table of Contents", this page and the "Revision Log".

FSAR SECTION REVISION STATUS, LIST OF AFFECTED SECTIONS AND REVISION SUMMARY		
FSAR Report No.: HI-2002444		FSAR Revision Number: 23
FSAR Title:	Final Safety Analysis Report on the HI-STORM 100 System	
<p>This FSAR is submitted to the USNRC in support of Holtec International's application to secure a CoC under 10CFR Part 72.</p> <p>FSAR review and verification are controlled at the chapter level and changes are annotated at the chapter level.</p> <p>A section in a chapter is identified by two numerals separated by a decimal. Each section begins on a fresh page. Unless indicated as a "complete revision" in the summary description of change below, if any change in the content is made, then the change is indicated by a "bar" in the right page margin and the revision number of the entire chapter including applicable figures (annotated in the footer) is changed.</p> <p>A summary description of change is provided below for each FSAR chapter. Minor editorial changes to this FSAR may not be summarized in the description of change.</p>

LIST OF CHANGES PURSUANT TO 10CFR72.48
PERIOD COVERED – July 1, 2021 through April 15, 2022

The changes authorized by the Holtec ECOs (with corresponding 10CFR72.48 evaluations, if applicable) listed in the following table are reflected in this Revision of the FSAR.

Affected Item	ECO Number	72.48 Evaluation or Screening Number
MPC-68/68F/68FF/68M Basket		
MPC-24/24E/24EF Basket		
MPC-32 Basket	1023-95	1565
MPC Enclosure Vessel		
HI-STORM Overpack	1024-165	1561
	1024-164	1532
	5014-310	1525
HI-STORM 100U VVM		
HI-TRAC 100, 100D, and 100-G Transfer Cask		
HI-TRAC 125 and 125D Transfer Cask		
HI-TRAC MS	1025-65	1545
General FSAR Changes	5014-339	1561
	5014-337R1	1558
	5014-336	1556
	5014-335	1554
	5014-333	1548
	5014-332	1545
	5014-327	1532
	5014-319	1488
	5014-295	1425
	5014-326R1	1536
	5014-343	N/A

GLOSSARY

ALARA is an acronym for As Low As Reasonably Achievable.

All Metamic Fuel Baskets or AMFBs refers to those baskets in which both the structural and neutron absorption functions are rendered by panels made from Metamic-HT. There is no separate neutron absorber or stainless steel in AMFBs.

Alloy X Fuel Baskets refers to those baskets that are fabricated from alloy X, which provides the structural support to house fuel assemblies. Separate neutron absorber panels are affixed to this basket in an irremovable configuration. An **Alloy X MPC** is one that contains an Alloy X Fuel Basket (MPC-24, MPC-32, and MPC-68 feature Alloy X Fuel Baskets). The MPC with fuel basket is also referred to as a canister.

Ancillary or Ancillary Equipment is the generic name of a device used to carry out Short -term Operations.

Boral is a generic term to denote an aluminum-boron carbide cermet manufactured in accordance with U.S. Patent No. 4027377. The individual material supplier may use another trade name to refer to the same product.

Boral™ means Boral manufactured by AAR Advanced Structures.

BWR is an acronym for boiling water reactor.

C.G. is an acronym for center of gravity.

Commercial Spent Fuel or CSF refers to nuclear fuel used to produce energy in a commercial nuclear power plant.

Confinement Boundary means the outline formed by the all-welded cylindrical enclosure of the Multi-Purpose Canister (MPC) shell, MPC baseplate, MPC lid, MPC port cover plates, and the MPC closure ring which provides redundant sealing.

Confinement System means the Multi-Purpose Canister (MPC) which encloses and confines the spent nuclear fuel during storage.

Controlled Area means that area immediately surrounding an ISFSI for which the owner/user exercises authority over its use and within which operations are performed.

Cooling Time (or post-irradiation cooling time) for a spent fuel assembly is the time between reactor shutdown and the time the spent fuel assembly is loaded into the MPC.

Critical Characteristic means a feature of a component or assembly that is necessary for the proper safety function of the component or assembly. Critical characteristics of a material are those

attributes that have been identified, in the associated material specification, as necessary to render the material's intended function.

DAS is the abbreviation for the Decontamination and Assembly Station. It means the location where the Transfer Cask is decontaminated and the MPC is processed (i.e., where all operations culminating in lid and closure ring welding are completed).

DBE means Design Basis Earthquake.

DCSS is an acronym for Dry Cask Storage System.

Damaged Fuel Assembly is a fuel assembly with known or suspected cladding defects, as determined by review of records, greater than pinhole leaks or hairline cracks, empty fuel rod locations that are not replaced with dummy fuel rods, missing structural components such as grid spacers, whose structural integrity has been impaired such that geometric rearrangement of fuel or gross failure of the cladding is expected based on engineering evaluations, or those that cannot be handled by normal means. Fuel assemblies that cannot be handled by normal means due to fuel cladding damage are considered fuel debris.

Damaged Fuel Container (or Canister) or DFC means a specially designed enclosure for damaged fuel or fuel debris which permits flow of gaseous and liquid media to escape while minimizing dispersal of gross particulates.

Damaged Fuel Isolator or DFIs are specially designed barriers installed at the top and bottom of the storage cell space which permit flow of gaseous and liquid media while preventing the potential migration of fissile material from fuel assemblies with cladding damage. DFIs are only used with DAMAGED FUEL ASSEMBLIES which can be handled by normal means and whose structural integrity is such that geometric rearrangement of fuel is not expected. Damaged fuel stored in DFIs may contain missing or partial fuel rods and/or fuel rods with known or suspected cladding defects greater than hairline cracks or pinhole leaks.

Design Basis Load (DBL) is a loading which bounds one or more events that are applicable to the storage system during its service life.

Design Heat Load is the computed heat rejection capacity of the HI-STORM system with a certified MPC loaded with CSF stored in uniform storage with the ambient at the normal temperature and the peak cladding temperature (PCT) at 400°C. The Design Heat Load is less than the thermal capacity of the system by a suitable margin that reflects the conservatism in the system thermal analysis.

Design Life is the minimum duration for which the component is engineered to perform its intended function set forth in this FSAR, if operated and maintained in accordance with this FSAR.

Design Report is a document prepared, reviewed and QA validated in accordance with the provisions of 10CFR72 Subpart G. The Design Report shall demonstrate compliance with the

requirements set forth in the Design Specification. A Design Report is mandatory for systems, structures, and components designated as Important to Safety. The FSAR serves as the Design Report for the HI-STORM 100 System.

Design Specification is a document prepared in accordance with the quality assurance requirements of 10CFR72 Subpart G to provide a complete set of design criteria and functional requirements for a system, structure, or component, designated as Important to Safety, intended to be used in the operation, implementation, or decommissioning of the HI-STORM 100 System. The FSAR serves as the Design Specification for the HI-STORM 100 System.

Drop Postulate Exempt (or DPE) refers to lifting and handling equipment with enhanced safety margin criteria which render them exempt from a postulated drop consequence analysis. DPE is synonymous with the term “Single Failure Proof” used in NUERG-0612 and Regulatory Guide 1.13.

Enclosure Vessel (or MPC Enclosure Vessel) means the pressure vessel defined by the cylindrical shell, baseplate, port cover plates, lid, closure ring, and associated welds that provides confinement for the contents within the MPC. The Enclosure Vessel (EV) and the fuel basket together constitute the multi-purpose canister.

Equivalent (or Equal) Material is a material with critical characteristics (see definition above) that meet or exceed those specified for the designated material.

Fracture Toughness is a property which is a measure of the ability of a material to limit crack propagation under a suddenly applied load.

FSAR is an acronym for Final Safety Analysis Report (10CFR72).

Fuel Basket means a honeycombed structural weldment with square openings which can accept a fuel assembly of the type for which it is designed.

Fuel Building is the generic term used to denote the building in which the fuel loading and where part of “short-term Operations” will occur. The Fuel Building is a Part 50 controlled structure.

Fuel Debris is ruptured fuel rods, severed rods, loose fuel pellets, containers or structures that are supporting these loose fuel assembly parts, or fuel assemblies with known or suspected defects which cannot be handled by normal means due to fuel cladding damage.

Fuel Spacer or Shim is a metallic part interposed in the space between the fuel and the MPC cavity at either the top or the bottom (or both) ends of the fuel to minimize the axial displacement of the SNF within the MPC due to longitudinal inertia forces.

High Burnup Fuel, or HBF is a commercial spent fuel assembly with an average burnup greater than 45,000 MWD/MTU.

HI-TRAC is an acronym for **Holtec International Transfer Cask**.

HI-TRAC transfer cask or HI-TRAC means the transfer cask used to house the MPC during MPC fuel loading, unloading, drying, sealing, and on-site transfer operations to a HI-STORM storage overpack or HI-STAR storage/transportation overpack. The HI-TRAC shields and protects the loaded MPC. The term HI-TRAC is used as a generic term to refer to all HI-TRAC transfer cask designs, unless the discussion requires distinguishing among the designs..

HI-STORM overpack or storage overpack means the cask that receives and contains the sealed multi-purpose canisters containing spent nuclear fuel for long term storage. It provides the gamma and neutron shielding, ventilation passages, missile protection, and protection against natural phenomena and accidents for the MPC. The term “overpack” as used in this FSAR refers to the HI-STORM 100S, HI-STORM 100S Version B, and HI-STORM 100S Version E.

HI-STORM 100 System consists of any loaded MPC model placed within any design variant of the HI-STORM overpack.

HoltiteTM is the trade name for polymeric neutron shielding materials developed by Holtec beginning in early 90s and used in a variety of casks supplied by the Company. Holtite-A and Holtite B are qualified versions of Holtite.

Important to Safety (ITS) means a function or condition required to store spent nuclear fuel safely; to prevent damage to spent nuclear fuel during handling and storage, and to provide reasonable assurance that spent nuclear fuel can be received, handled, packaged, stored, and retrieved without undue risk to the health and safety of the public.

Independent Spent Fuel Storage Installation (ISFSI) means a facility designed, constructed, and licensed for the interim storage of spent nuclear fuel and other radioactive materials associated with spent fuel storage in accordance with 10CFR72.

Inspection is an activity controlled by the QC department and used to ensure that the manufactured part or assembly satisfies the specific *critical characteristics* of a *safety significant* SSC set down in its design specification. An inspection is characterized by a procedure-controlled or drawing-controlled examination on the actual SSC (not a specimen). Inspection includes non-destructive examination (NDE) of *safety significant* welds specified in the FSAR, such as liquid penetrant examination, radiography, ultrasonic examination, and confirmation of as-built dimensions designated as a critical characteristic therein.

Intact Fuel Assembly is defined as a fuel assembly without known or suspected cladding defects greater than pinhole leaks and hairline cracks, and which can be handled by normal means. Fuel assemblies without fuel rods in fuel rod locations shall not be classified as Intact Fuel Assemblies unless dummy fuel rods are used to displace an amount of water greater than or equal to that displaced by the fuel rod(s).

License Life means the duration for which the system is authorized by virtue of its certification by the U.S. NRC.

Lifting Device means a component of a lifting and handling system that is not classified as a *special lifting device*. ANSI N14.6 is not applicable to a lifting *device*. These include non-active structural components (components that bear the primary load but are not a constituent of a moving part, e.g., gear train, hydraulic cylinder) of the system. Examples of lifting devices used with Holtec's systems include: A Low Profile Transporter, a VCT overhead beam or the main girder of a gantry crane.

Licensing Basis Heat Load (LBHL) of a canister/cask is the aggregate of the permissible heat load for all fuel storage locations that constitute the fuel basket.

Location Specific Heat Load is the permissible heat load associated with a storage location; also known as the Specific heat load for that location.

Long-term Storage means the time beginning after on-site handling is complete and the loaded overpack is at rest in its designated storage location on the ISFSI pad.

Lowest Service Temperature (LST) is the minimum metal temperature of a part for the specified service condition.

Maximum Reactivity means the highest possible k-effective including bias, uncertainties, and calculational statistics evaluated for the worst-case combination of fuel basket manufacturing tolerances.

METAMIC® is a trade name for an aluminum/boron carbide composite neutron absorber material qualified for use in the MPCs and in wet storage applications.

METAMIC-HT is a trade name for the metal matrix composite made by imbedding nano-particles of aluminum oxide and fine boron carbide powder on the grain boundaries of aluminum resulting in improved structural strength properties at elevated temperatures.

METAMIC HT Fuel Basket (also called *All Metamic Fuel Basket*) means those fuel baskets that employ Metamic-HT to render both structural and criticality control functions. MPC-32M and MPC-68M feature Metamic-HT Fuel Baskets. A **Metamic-HT MPC** is one that has a Metamic-HT Fuel Basket. The MPC with fuel basket is also referred to as a canister.

METCON™ is a trade name for the HI-STORM overpack structure. The trademark is derived from the **metal-concrete** composition of the HI-STORM overpack.

MGDS is an acronym for Mined Geological Disposal System.

Minimum Enrichment is the minimum assembly average enrichment. Natural uranium and low enrichment blankets are not considered in determining minimum enrichment.

Moderate Burnup Fuel, or MBF is a commercial spent fuel assembly with an average burnup less than or equal to 45,000 MWD/MTU.

Multi-Purpose Canister (MPC) means the sealed canister consisting of a honeycombed fuel basket for spent nuclear fuel storage, contained in a cylindrical canister shell (the MPC Enclosure Vessel). There are different MPCs with different fuel basket geometries for storing PWR or BWR fuel, but all MPCs have identical exterior diameters. The MPC is the confinement boundary for storage conditions.

MPC Transfer means transfer of the MPC between the overpack and the transfer cask which begins when the MPC is lifted off the HI-TRAC bottom lid and ends when the MPC is supported from beneath by the overpack (or the reverse).

NDT is an acronym for Nil Ductility Transition Temperature, which is defined as the temperature at which the fracture stress in a material with a small flaw is equal to the yield stress in the same material if it had no flaws.

Neutron Absorber Material is a generic term to indicate any neutron absorber material qualified for use in the HI-STORM 100 System.

Neutron Shielding means a material used to thermalize and capture neutrons emanating from the radioactive spent nuclear fuel.

Non-Fuel Hardware is defined as Burnable Poison Rod Assemblies (BPRAs), Thimble Plug Devices (TPDs), Control Rod Assemblies (CRAs), Axial Power Shaping Rods (APSRs), Wet Annular Burnable Absorbers (WABAs), Rod Cluster Control Assemblies (RCCAs), Control Element Assemblies (CEAs), Neutron Source Assemblies (NSAs), water displacement guide tube plugs, orifice rod assemblies, instrument tube tie-rods (ITTRs), vibration suppressor inserts, and components of these devices such as individual rods.

Part 50 Operations is the segment of Short-Term Operations that occurs within the confines of the building regulated by 10CFR 50.

Part 71 Operations is the segment of Short-Term Operations that occurs between the Part 50 structural boundary and the off-site transporter.

Part 72 Operations is the segment of Short-Term operations that occurs between the Part 50 structural boundary and the ISFSI pad.

Planar-Average Initial Enrichment is the average of the distributed fuel rod initial enrichments within a given axial plane of the assembly lattice.

Plain Concrete is concrete that is unreinforced.

Post-Core Decay Time (PCDT) is synonymous with cooling time.

PWR is an acronym for pressurized water reactor.

Reactivity is used synonymously with effective neutron multiplication factor or k-effective.

Regionalized Fuel Storage is a term used to describe an optional fuel loading strategy wherein the storage locations are ascribed to distinct regions each with its own maximum allowable specific heat generation rate.

SAR is an acronym for Safety Analysis Report.

Service Life means the duration for which the component is reasonably expected to perform its intended function, if operated and maintained in accordance with the provisions of this FSAR. Service Life may be much longer than the Design Life because of the conservatism inherent in the codes, standards, and procedures used to design, fabricate, operate, and maintain the component.

Short-term Operations means those normal operational evolutions necessary to support fuel loading or fuel unloading operations. These include, but are not limited to MPC cavity drying, helium backfill, MPC transfer, and onsite handling of a loaded HI-TRAC transfer cask or HI-STORM Overpack.

Single Failure Proof in order for a lifting device or special lifting device to be considered single failure proof, the design must follow the guidance in NUREG-0612, which requires that a single failure proof device have twice the normal safety margin. This designation can be achieved by either providing redundant devices (load paths) or providing twice the design factor required by the applicable code.

SNF is an acronym for spent nuclear fuel.

Special Lifting Device refers to a components to which ANSI N14.6 applies. As stated in ANSI N14.6 (both 1978 and 1993 versions), “This standard shall apply to *special lifting devices* that transmit the load from lifting attachments, which are structural parts of a container to the hook(s) of an overhead hoisting system.”

Examples of special lifting devices used with Holtec’s systems include MPC lift cleats, lift brackets, and lift yokes.

SSC is an acronym for Structures, Systems and Components.

Stainless Steel Fuel Baskets or SSFBs refer to fuel baskets that employ stainless steel for structural function, and neutron absorption capability is provided by a discrete panel of Metamic or an equivalent neutron absorber. MPC-68 contains an SSFB.(See also “Alloy X Fuel Basket “)

STP is Standard Temperature and Pressure conditions.

Testing in this FSAR means an activity carried out to quantify the margin of safety of a safety

significant part or SSC. The Hydrostatic test, Charpy impact test, Helium leak test and Drop weight test are examples of “Tests” invoked in this FSAR. The protocols for performing the tests are generally available in national standards but can be superseded by NRC’s review and approval of a specialized process developed by the certificate holder for a specific application.

Thermal Capacity of the HI-STORM system is defined as the amount of heat the storage system, containing an MPC loaded with CSF stored in *uniform storage*, will actually reject with the ambient environment at the normal temperature and the peak fuel cladding temperature (PCT) at 400°C.

Thermosiphon is the term used to describe the buoyancy-driven natural convection circulation of helium within the MPC fuel basket.

Traveler means the set of sequential instructions used in a controlled manufacturing program to ensure that all tests and examinations required upon completion of each significant manufacturing activity are performed and documented for archival reference.

Undamaged Fuel Assembly is: a) a fuel assembly without known or suspected cladding defects greater than pinhole leaks or hairline cracks and which can be handled by normal means; or b) a BWR fuel assembly with an intact channel, a maximum planar average initial of 3.3 wt% U-235, without known or suspected grossly breached spent fuel rods, and which can be handled by normal means. An undamaged fuel assembly may be a repaired/reconstituted fuel assembly.

Uniform Fuel Loading is a fuel loading strategy where any authorized fuel assembly may be stored in any fuel storage location, subject to other restrictions in the CoC, such as those applicable to non-fuel hardware, and damaged fuel containers.

Verification in this FSAR means confirmation of compliance of a characteristic that is not specified by the Code invoked in this FSAR or called out as requiring inspection therein or determined by Certificate Holder’s licensing organization to not be of significant safety consequence. A Verification can be performed by a person trained under the Certificate holder’s quality organization program to establish compliance with a provision of minor safety import in the FSAR. Verification covers the whole gamut of activities that don’t lie within the purview of Inspection or testing.

ZPA is an acronym for zero period acceleration.

ZR means any zirconium-based fuel cladding material authorized for use in a commercial nuclear power plant reactor. Any reference to Zircaloy fuel cladding in this FSAR applies to any zirconium-based fuel cladding material.

CHAPTER 1[†]: GENERAL DESCRIPTION

1.0 GENERAL INFORMATION

This Final Safety Analysis Report (FSAR) for Holtec International's HI-STORM 100 System is a compilation of information and analyses to support a United States Nuclear Regulatory Commission (NRC) licensing review as a spent nuclear fuel (SNF) dry storage cask under requirements specified in 10CFR72 [1.0.1]. This FSAR describes the basis for NRC approval and issuance of a Certificate of Compliance (C of C) for storage under provisions of 10CFR72, Subpart L, for the HI-STORM 100 System to safely store spent nuclear fuel (SNF) at an Independent Spent Fuel Storage Installation (ISFSI). This report has been prepared in the format and content suggested in NRC Regulatory Guide 3.61 [1.0.2] and NUREG-1536 Standard Review Plan for Dry Cask Storage Systems [1.0.3] to facilitate the NRC review process.

The purpose of this chapter is to provide a general description of the design features and storage capabilities of the HI-STORM 100 System, drawings of the structures, systems, and components important to safety, and the qualifications of the certificate holder. This report is also suitable for incorporation into a site-specific Safety Analysis Report, which may be submitted by an applicant for a site-specific 10 CFR 72 license to store SNF at an ISFSI or a facility similar in objective and scope. The glossary contains a listing of the terminology and notation used in this FSAR.

To aid NRC review, additional tables and references have been added to facilitate the location of information requested by NUREG-1536. Table 1.0.1 provides a matrix of the topics in NUREG-1536 and Regulatory Guide 3.61, the corresponding 10CFR72 requirements, and a reference to the applicable FSAR section that addresses each topic.

The HI-STORM 100 FSAR is in full compliance with the intent of all regulatory requirements listed in Section III of each chapter of NUREG-1536. However, an exhaustive review of the provisions in NUREG-1536, particularly Section IV (Acceptance Criteria) and Section V (Review Procedures) has identified certain deviations from a verbatim compliance to all guidance. A list of all such items, along with a discussion of their intent and Holtec International's approach for compliance with the underlying intent is presented in Table 1.0.2 herein. Table 1.0.2 also contains the justification for the alternative method for compliance adopted in this FSAR. The justification may be in the form of a supporting analysis, established industry practice, or other NRC guidance documents. Each chapter in this FSAR provides a clear statement with respect to the extent of compliance to the NUREG-1536 provisions. Chapter 1 is in full compliance with NUREG-1536; no exceptions are taken.

[†] This chapter has been prepared in the format and section organization set forth in Regulatory Guide 3.61. However, the material content of this chapter also fulfills the requirements of NUREG-1536. Pagination and numbering of sections, figures, and tables are consistent with the convention set down in Chapter 1, Section 1.0, herein. Finally, all terms-of-art used in this chapter are consistent with the terminology of the glossary and component nomenclature of the drawings (Section 1.5).

The generic design basis and the corresponding safety analysis of the HI-STORM 100 System contained in this FSAR are intended to bound the SNF characteristics, design, conditions, and interfaces that exist in the vast majority of domestic power reactor sites and potential away-from-reactor storage sites in the contiguous United States. This FSAR also provides the basis for component fabrication and acceptance, and the requirements for safe operation and maintenance of the components, consistent with the design basis and safety analysis documented herein. In accordance with 10CFR72, Subpart K, site-specific implementation of the generically certified HI-STORM 100 System requires that the licensee perform a site-specific evaluation, as defined in 10CFR72.212. The HI-STORM 100 System FSAR identifies a limited number of conditions that are necessarily site-specific and are to be addressed in the licensee's 10CFR72.212 evaluation. These include:

- Siting of the ISFSI and design of the storage pad (including the embedment for anchored cask users) and security system. Site-specific demonstration of compliance with regulatory dose limits. Implementation of a site-specific ALARA program.
- An evaluation of site-specific hazards and design conditions that may exist at the ISFSI site or the transfer route between the plant's cask receiving bay and the ISFSI. These include, but are not limited to, explosion and fire hazards, flooding conditions, land slides, and lightning protection.
- Determination that the physical and nucleonic characteristics and the condition of the SNF assemblies to be dry stored meet the fuel acceptance requirements of the Certificate of Compliance.
- An evaluation of interface and design conditions that exist within the plant's fuel building in which canister fuel loading, canister closure, and canister transfer operations are to be conducted in accordance with the applicable 10CFR50 requirements and technical specifications for the plant.
- Detailed site-specific operating, maintenance, and inspection procedures prepared in accordance with the generic procedures and requirements provided in Chapters 8 and 9, and the technical specifications provided in the Certificate of Compliance.
- Performance of pre-operational testing.
- Implementation of a safeguards and accountability program in accordance with 10CFR73. Preparation of a physical security plan in accordance with 10CFR73.55.
- Review of the reactor emergency plan, quality assurance (QA) program, training program, and radiation protection program.

The generic safety analyses contained in the HI-STORM 100 FSAR may be used as input and for guidance by the licensee in performing a 10CFR72.212 evaluation.

Within this report, all figures, tables and references cited are identified by the double decimal system m.n.i, where m is the chapter number, n is the section number, and i is the sequential number. Thus, for example, Figure 1.2.3 is the third figure in Section 1.2 of Chapter 1.

Revisions to this document are made on a section level basis. Complete sections have been replaced if any material in the section changed. The specific changes are noted with revision bars in the right margin. Figures are revised individually. Drawings are controlled separately within the Holtec QA program and have individual revision numbers. Bills-of-Material (BOMs) are considered separate drawings and are not necessarily at the same revision level as the drawing(s) to which they apply. If a drawing or BOM was revised in support of the current FSAR revision, that drawing/BOM is included in Section 1.5 at its latest revision level. Drawings and BOMs appearing in this FSAR may be revised between formal updates to the FSAR. Therefore, the revisions of drawings/BOMs in Section 1.5 may not be current.

Through revision 3 of this FSAR, discussions and specific analyses were presented that described and evaluated MPC designs called the MPC-24EF, MPC-32F, and MPC-68FF. These designs contained features required to classify them as secondary containments, permitting transportation of fuel debris under the auspices of 10 CFR 71, and were the only MPC designs allowed to be loaded with fuel debris. Recent changes to 10 CFR 71 have eliminated the need for secondary containment of fuel debris, so the non-F type MPCs (i.e., MPC-24E, MPC-32 and MPC-68) can now accept fuel debris. Any contents that used to require loading into an MPC-24EF, MPC-32F or MPC-68FF may therefore now be loaded in an MPC-24E, MPC-32 or MPC-68, respectively.

Supplements identified by a Roman numeral “I” (i.e. Chapter 1 and Supplement 1.I) have been inserted in the FSAR as placeholders for future use.

1.0.1 Design Compatibility of Licensed HI-STORM 100 System Components

Each of the licensed HI-STORM 100 System components (i.e., the MPC, overpack, and transfer cask), if fabricated in accordance with any of the approved CoC Amendments, may be used with one another provided an assessment is performed by the CoC holder that demonstrates design compatibility.

The following certified HI-TRAC transfer casks have been determined to have design compatibility and may be used with the MPCs and overpacks fabricated in accordance with the CoC #1014 amendments as listed in the table below:

HI-TRAC Design Compatibility			
HI-TRAC Model	Program Number	Serial Number	Applicable CoC Amendments ^{Note 1}
125	1025	001	0,1,2,3,4,5,6,7,8,9,10,11,12,13,14,15
125	1025	002	0,1,2,3,4,5,6,7,8,9,10,11,12,13,14,15

100D	1026	005	2,3,4,5,6,7,8,9,10,11,12,13,14,15
100D	1026	006	2,3,4,5,6,7,8,9,10,11,12,13,14,15
100D Version IP1	1026	008	4
100D	1026	009	6,7,8,9,10,11,12,13,14,15
100G	1026	001	13,14,15

Note 1: The changes approved in Revision 1 to CoC Amendments 8 and 9 do not have any impact on the HI-TRAC designs and compatibility. Therefore, any HI-TRAC identified as compatible with Amendments 8 or 9 is by extension compatible with Amendment 8 Rev. 1 or Amendment 9 Rev. 1 respectively. Amendment 8 Rev 1 is incorporated into HI-STORM 100 FSAR Rev. 11.1.

1.0.2 Summary of Changes to the HI-STORM 100 CoC

The HI-STORM 100 System, USNRC Docket No. 72-1014, has undergone several changes throughout the CoC Amendment revision process. A summary of the changes made in each amendment revision can be found in Table 1.0.3. Strictly editorial changes that do not alter the content of the CoC have been excluded below. Full details of all changes may be found in each respective CoC Amendment and Safety Evaluation Report (SER).

Notes:

- (1) The stated requirement is the responsibility of the licensee (i.e., utility) as part of the ISFSI pad and is therefore not addressed in this application.
- (2) It is assumed that approval of the FSAR by the NRC is the basis for the Commission's acceptance of the tests defined in Chapter 9.
- (3) Not applicable to HI-STORM 100 System. The functional adequacy of all important to safety components is demonstrated by analyses.
- (4) The stated requirement is the responsibility of licensee (i.e., utility) as part of the ISFSI and is therefore not addressed in this application.
- (5) The stated requirement is not applicable to the HI-STORM 100 System. No monitoring is required for accident conditions.
- “—” There is no corresponding NUREG-1536 criteria, no applicable 10CFR72 or 10CFR20 regulatory requirement, or the item is not addressed in the FSAR.
- “NA” There is no Regulatory Guide 3.61 section that corresponds to the NUREG-1536, 10CFR72, or 10CFR20 requirement being addressed.

NUREG-1536 Guidance	Alternate Method to Meet NUREG-1536 Intent	Justification
<p>2.V.2.(b)(1) "The NRC accepts as the maximum and minimum "normal" temperatures the highest and lowest ambient temperatures recorded in each year, averaged over the years of record."</p>	<p><u>Exception:</u> Section 2.2.1.4 for environmental temperatures utilizes an upper bounding value of 80°F on the annual average ambient temperatures for the United States.</p>	<p>The 80°F temperature set forth in Table 2.2.2 is greater than the annual average ambient temperature at any location in the continental United States. Inasmuch as the primary effect of the environmental temperature is on the computed fuel cladding temperature to establish long-term fuel cladding integrity, the annual average ambient temperature for each ISFSI site should be below 80°F. The large thermal inertia of the HI-STORM 100 System ensures that the daily fluctuations in temperatures do not affect the temperatures of the system. Additionally, the 80°F ambient temperature is combined with insolation in accordance with 10CFR71.71 averaged over 24 hours.</p>
<p>2.V.2.(b)(3)(f) "10CFR Part 72 identifies several other natural phenomena events (including seiche, tsunami, and hurricane) that should be addressed for spent fuel storage."</p>	<p><u>Clarification:</u> A site-specific safety analysis of the effects of seiche, tsunami, and hurricane on the HI-STORM 100 System must be performed prior to use if these events are applicable to the site.</p>	<p>In accordance with NUREG-1536, 2.V.(b)(3)(f), if seiche, tsunami, and hurricane are not addressed in the SAR and they prove to be applicable to the site, a safety analysis is required prior to approval for use of the DCSS under either a site specific, or general license.</p>

NUREG-1536 Guidance	Alternate Method to Meet NUREG-1536 Intent	Justification
<p>3.V.1.d.i.(2)(a), page 3-11, "Drops with the axis generally vertical should be analyzed for both the conditions of a flush impact and an initial impact at a corner of the cask..."</p>	<p><u>Clarification:</u> As stated in NUREG-1536, 3.V.(d), page 3-11, "Generally, applicants establish the design basis in terms of the maximum height to which the cask is lifted outside the spent fuel building, or the maximum deceleration that the cask could experience in a drop." The maximum deceleration for a corner drop is specified as 45g's for the HI-STORM overpack. No carry height limit is specified for the corner drop.</p>	<p>In Chapter 3, the MPC and HI-STORM overpack are evaluated under a 45g radial loading. A 45g axial loading on the MPC is bounded by the analysis presented in the HI-STAR FSAR, Docket 72-1008, under a 60g loading, and is not repeated in this FSAR. In Chapter 3, the HI-STORM overpack is evaluated under a 45g axial loading. Therefore, the HI-STORM overpack and MPC are qualified for a 45g loading as a result of a corner drop. Depending on the design of the lifting device, the type of rigging used, the administrative vertical carry height limit, and the stiffness of the impacted surface, site-specific analyses may be required to demonstrate that the deceleration limit of 45g's is not exceeded.</p>
<p>3.V.2.b.i.(1), Page 3-19, Para. 1, "All concrete used in storage cask system ISFSIs, and subject to NRC review, should be reinforced..."</p> <p>3.V.2.b.i.(2)(b), Page 3-20, Para. 1, "The NRC accepts the use of ACI 349 for the design, material selection and specification, and construction of all reinforced concrete structures that are not addressed within the scope of ACI 359".</p> <p>3.V.2.c.i, Page 3-22, Para. 3, "Materials and material properties used for the design and construction of reinforced concrete structures important to safety but not within the scope</p>	<p><u>Exception:</u> The HI-STORM overpack concrete is not reinforced. However, ACI 349 [1.0.4] is used as guidance for the material selection and specification, and placement of the plain concrete. Appendix 1.D provides the relevant sections of ACI 349 applicable to the plain concrete in the overpack, including clarifications on implementation of this code. ACI 318 [1.0.5] is used for the calculation of the compressive strength of the plain concrete.</p>	<p>Concrete is provided in the HI-STORM overpack primarily for the purpose of radiation shielding during normal operations. During lifting and handling operations and under certain accident conditions, the compressive strength of the concrete (which is not impaired by the absence of reinforcement) is utilized. However, since the structural reliance under loadings which produce section flexure and tension is entirely on the steel structure of the overpack, reinforcement in the concrete will serve no useful purpose.</p> <p>To ensure the quality of the shielding concrete, all relevant provisions of ACI 349 are imposed as clarified in Appendix 1.D. The temperature limits for normal conditions are per Paragraph A.4.3 of Appendix A to ACI 349 and temperature limits for</p>

NUREG-1536 Guidance	Alternate Method to Meet NUREG-1536 Intent	Justification
of ACI 359 should comply with the requirements of ACI 349".		<p>off-normal and accident conditions are per Paragraph A.4.2 of Appendix A to ACI 349.</p> <p>Finally, the Fort St. Vrain ISFSI (Docket No. 72-9) also utilized plain concrete for shielding purposes, which is important to safety.</p>
3.V.3.b.i.(2), Page 3-29, Para. 1, "The NRC accepts the use of ANSI/ANS-57.9 (together with the codes and standards cited therein) as the basic reference for ISFSI structures important to safety that are not designed in accordance with Section III of the ASME B&PV Code."	<u>Clarification:</u> The HI-STORM overpack steel structure is designed in accordance with the ASME B&PV Code, Section III, Subsection NF, Class 3. Any exceptions to the Code are listed in Table 2.2.15.	The overpack structure is a steel weldment consisting of "plate and shell type" members. As such, it is appropriate to design the structure to Section III, Class 3 of Subsection NF. The very same approach has been used in the structural evaluation of the "intermediate shells" in the HI-STAR 100 overpack (Docket Number 72-1008) previously reviewed and approved by the USNRC.
<p>4.IV.5, Page 4-2 "for each fuel type proposed for storage, the DCSS should ensure a very low probability (e.g., 0.5 percent per fuel rod) of cladding breach during long-term storage."</p> <p>4.IV.1, Page 4-3, Para. 1 "the staff should verify that cladding temperatures for each fuel type proposed for storage will be below the expected damage thresholds for normal conditions of storage."</p> <p>4.IV.1, Page 4-3, Para. 2 "fuel cladding limits for each fuel type should be defined in the SAR with thermal restrictions in the DCSS technical specifications."</p> <p>4.V.1, Page 4-3, Para. 4 "the applicant should</p>	<u>Clarification:</u> As described in Section 4.3, all fuel array types authorized for storage are assigned a single peak fuel cladding temperature limit.	As described in Section 4.3, all fuel array types authorized for storage have been evaluated for the peak normal fuel cladding temperature limit of 400°C.

NUREG-1536 Guidance	Alternate Method to Meet NUREG-1536 Intent	Justification
verify that these cladding temperature limits are appropriate for all fuel types proposed for storage, and that the fuel cladding temperatures will remain below the limit for facility operations (e.g., fuel transfer) and the worst-case credible accident."		
4.V.4.a, Page 4-6, Para. 6 "the basket wall temperature of the hottest assembly can then be used to determine the peak rod temperature of the hottest assembly using the Wooten-Epstein correlation."	<u>Clarification:</u> As discussed in Section 4.4, conservative maximum fuel temperatures are obtained directly from the cask thermal analysis. The peak fuel cladding temperatures are then used to determine the corresponding peak basket wall temperatures using a finite-element based model.	The finite-element based thermal conductivity is greater than a Wooten-Epstein based value. This larger thermal conductivity minimizes the fuel-to-basket temperature difference. Since the basket temperature is less than the fuel temperature, minimizing the temperature difference conservatively maximizes the basket wall temperature.
4.V.4.b, Page 4-7, Para. 2 "high burnup effects should also be considered in determining the fuel region effective thermal conductivity."	<u>Exception:</u> All calculations of fuel assembly effective thermal conductivities use nominal fuel design dimensions, neglecting wall thinning associated with high burnup.	The calculated effective thermal conductivities based on nominal design fuel dimensions have been compared with available literature values [1.0.6] and are demonstrated to be conservative.
4.V.4.c, Page 4-7, Para. 5 "a heat balance on the surface of the cask should be given and the results presented."	<u>Clarification:</u> No additional heat balance is performed or provided.	The FLUENT computational fluid dynamics program used to perform evaluations of the HI-STORM Overpack and HI-TRAC transfer cask, which uses a discretized numerical solution algorithm, enforces an energy balance on all discretized volumes throughout the computational domain. This solution method, therefore, ensures a heat balance at the surface of the cask.

NUREG-1536 Guidance	Alternate Method to Meet NUREG-1536 Intent	Justification
4.V.5.a, Page 4-8, Para. 2 "the SAR should include input and output file listings for the thermal evaluations."	<u>Exception:</u> No input or output file listings are provided in Chapter 4.	A complete set of computer program input and output files would be in excess of three hundred pages. All computer files are considered proprietary because they provide details of the design and analysis methods. In order to minimize the amount of proprietary information in the FSAR, computer files are provided in the proprietary calculation packages.
4.V.5.c, Page 4-10, Para. 3 "free volume calculations should account for thermal expansion of the cask internal components and the fuel when subjected to accident temperatures.	<u>Exception:</u> All free volume calculations use nominal confinement boundary dimensions, but the volume occupied by the fuel assemblies is calculated using maximum weights and minimum densities.	Calculating the volume occupied by the fuel assemblies using maximum weights and minimum densities conservatively overpredicts the volume occupied by the fuel and correspondingly underpredicts the remaining free volume.
7.V.4 "Confinement Analysis. Review the applicant's confinement analysis and the resulting annual dose at the controlled area boundary."	<u>Exception:</u> No confinement analysis is performed and no effluent dose at the controlled area boundary is calculated.	<p>The MPC uses redundant closures to assure that there is no release of radioactive materials under all credible conditions. Analyses presented in Chapters 3 and 11 demonstrate that the confinement boundary does not degrade under all normal, off-normal, and accident conditions. Multiple inspection methods are used to verify the integrity of the confinement boundary (e.g., non-destructive examinations in accordance with Chapter 9).</p> <p>Helium leakage testing of the MPC base metals (shell, baseplate, and MPC lid) and MPC shell to baseplate and shell to shell welds is performed on the unloaded MPC.</p> <p>Pursuant to ISG-18, the Holtec MPC is constructed in a manner that supports leakage from the confinement boundary being non-credible. Therefore, no confinement analysis is required.</p>

NUREG-1536 Guidance	Alternate Method to Meet NUREG-1536 Intent	Justification
9.V.1.a, Page 9-4, Para. 4 "Acceptance criteria should be defined in accordance with NB/NC-5330, "Ultrasonic Acceptance Standards"."	<u>Clarification:</u> Section 9.1.1.1 and the Design Drawings specify that the ASME Code, Section III, Subsection NB, Article NB-5332 will be used for the acceptance criteria for the volumetric examination of the MPC lid-to-shell weld.	In accordance with the first line on page 9-4, the NRC endorses the use of "...appropriate acceptance criteria as defined by either the ASME code, or an alternative approach..." The ASME Code, Section III, Subsection NB, Paragraph NB-5332 is appropriate acceptance criteria for pre-service examination.
9.V.1.d, Para. 1 "Tests of the effectiveness of both the gamma and neutron shielding may be required if, for example, the cask contains a poured lead shield or a special neutron absorbing material."	<u>Exception:</u> Subsection 9.1.5 describes the control of special processes, such as neutron shield material installation, to be performed in lieu of scanning or probing with neutron sources.	<p>The dimensional compliance of all shielding cavities is verified by inspection to design drawing requirements prior to shield installation.</p> <p>The Holtite-A shield material is installed in accordance with written, approved, and qualified special process procedures.</p> <p>The composition of the Holtite-A is confirmed by inspection and tests prior to first use.</p> <p>Following the first loading for the HI-TRAC transfer cask and each HI-STORM overpack, a shield effectiveness test is performed in accordance with written approved procedures, as specified in Section 9.1.</p>
13.III, "the application must include, at a minimum, a description that satisfies the requirements of 10 CFR Part 72, Subpart G, 'Quality Assurance'..."	<u>Exception:</u> Section 13.0 incorporates the NRC-approved Holtec International Quality Assurance Program Manual by reference rather than describing the Holtec QA program in detail.	The NRC has approved Revision 13 of the Holtec Quality Assurance Program Manual under 10 CFR 71 (NRC QA Program Approval for Radioactive Material Packages No. 0784, Rev. 3). Pursuant to 10 CFR 72.140(d), Holtec will apply this QA program to all important-to-safety dry storage cask activities. Incorporating the Holtec QA Program Manual by reference eliminates duplicate documentation.

Amendment Revision	Summary of Changes
0	Initial Issue
1	<ul style="list-style-type: none"> • Addition of four new MPCs. The new MPCs include the MPC-24E, MPC-24EF, MPC-32, and MPC-68FF • Addition of the following new Damaged Fuel Containers (DFC) <ul style="list-style-type: none"> ○ TN/D-1 DFC ○ Holtec Generic PWR DFC ○ Holtec Generic BWR DFC • Addition of the HI-STORM 100S, 100A, and 100SA overpacks • Allow for Overpack to be anchored to the ISFSI • Allow for storage of high-burnup fuel • Revision of thermal analysis to include natural convection • Allow helium backfill requirement to use helium density measurement • Allow for the use of a helium drying system (FHD) • Addition of soluble boron requirement for higher enriched fuels • Update surveillance criteria in LCO 3.1.2 (SFSC Heat Removal System) • Update HI-TRAC and Overpack surface dose rate acceptance criteria (LCO 3.2.1 & 3.2.3) • Updated Cask Transport Evaluation Program (Appendix A, Section 5.5) • Editorial change to relocate special requirements for first systems and pre-operational testing and training requirements to the main body of CoC • Allow for storage of these non-fuel hardware: burnable poison rod assemblies (BPRAs), thimble plug devices (TPDs), control rod assemblies (CRAs), axial power shaping rods (APSRs), control element assemblies (CEAs), wet annular burnable absorbers (WABAs), rod cluster control assemblies (RCCAs), water displacement guide tube plugs and orifice rod assemblies • Update Fuel Specifications and Loading Conditions to allow for regionalized fuel loading (Appendix B, Section 2.1)
2	<ul style="list-style-type: none"> • Addition of METAMIC as an alternate neutron poison material • Addition of new MPC-32F as new MPC type • Allow storage of damaged fuel in MPC-32. Allow storage of damaged fuel and damaged fuel debris in MPC-32F <ul style="list-style-type: none"> ○ Addition of soluble boron requirement for MPC-32 and MPC-32F • Revision of MPC cavity drying limits • Removal of Aluminum Heat Conduction Elements (AHCE) from system

Amendment Revision	Summary of Changes
2 (cont'd)	<ul style="list-style-type: none"> • Allow for helium leak test for either (1) lid-to-shell weld or (2) vent and drain port cover plate welds to satisfy ISG-18 requirements • Update CoC to account for changes in ISG-11 Revision 3 • Addition of cavity bulk helium temperature requirement during reflooding operations of the MPC • Addition of Tech Spec Program 5.7 (Radiation Protection) & modified associated LCO • Allow for storage of vibration suppressor inserts (non-fuel hardware) • Increase maximum authorized initial enrichment for PWR damaged fuel and fuel debris to 5.0 wt. % • Revise burn-up as a function of cooling time and fuel array/class • Revise completion times for required action to reflect blocked duct accident analysis and surveillance requirement acceptance criteria for temperature measurement • Revise Appendix B tables for new fuel assembly burnup limits • Revise maximum allowable uranium masses for certain fuel assemblies • Revise maximum allowable burn-up for non-fuel hardware inserts • Updated ASME code edition of record. Added new and revised ASME code alternatives. Incorporated new language related to Code alternatives • Increase off-normal design pressure from 100psig to 110psig • Increase normal temperature limit for overpack lid top plate from 350°F to 450°F • Modify CoC Condition 11 language to address component certification • Allow for maximum boron carbide content in METAMIC to 33.0 wt. % • Incorporated Neutron Absorber Tests (FSAR section 9.1.5.3) to the CoC by reference • Modification of design temperatures of MPC shell, overpack concrete, and Holtite neutron shield material • Addition of Supplemental Cooling system (SCS) as well as Condition 11 in the CoC for the SCS • Addition of FHD and SCS malfunctions as new off normal events • Addition of SCS failure as new accident event • Addition of degraded cask/pad interface friction requirement
3	<ul style="list-style-type: none"> • Remove requirement for MPC cavity cooling prior to reflood with water <ul style="list-style-type: none"> ○ Replace helium exit temperature requirement with MPC cavity pressure

Amendment Revision	Summary of Changes
3 (cont'd)	<ul style="list-style-type: none"> • Allow for linear interpolation between minimum soluble boron concentrations of 4.1 wt% and 5.0 wt% fuel enrichment in MPC-32/32F • Modify definition of: <ul style="list-style-type: none"> ○ Non-fuel hardware to include primary and secondary neutron sources ○ Fuel debris to include containers or structures that provide support to loose fuel assembly parts ○ Damaged fuel to a performance based definition • Allow for storage of neutron source assemblies in MPC-24, 24E, 24EF, 32, 32F • Allow for storage of PWR fuel assemblies with annular fuel pellets in the top and bottom 12 inches of the active fuel length • Addition of water level requirement for cask unloading
4	<ul style="list-style-type: none"> • Addition of site-specific options to permit use of a modified HI-STORM 100S Version B, MPC-32/32F, and HI-TRAC 100D at Indian Point Unit 1 (IP1). Changes include: <ul style="list-style-type: none"> ○ Modification of soluble boron requirements for array/class 14x14E, IP1 fuel ○ Modification of helium gas backfill requirements for array/class 14x14E IP1 fuel ○ Addition of 5th damaged fuel container design (Holtec IP1 DFC) ○ Addition of separate burnup, cooling time, and decay heat limits for array/class 14x14E IP1 fuel for loading in MPC-32 and -32F ○ Addition of antimony-beryllium secondary sources as approved contents ○ Allow for loading of all IP1 fuel assemblies in DFCs ○ Reduction of maximum enrichment for array/class 14x14E IP1 fuel from 5.0 to 4.5 wt.% ²³⁵U
5	<ul style="list-style-type: none"> • Removal of requirement to perform subsequent thermal validations tests on thermal systems (a condition 9 requirement). Condition 9 now requires validation test for overpacks with heat loads equal to or greater than 20 kW • Increase in design basis maximum decay heat loads to: <ul style="list-style-type: none"> ○ 34 kW for uniform loading ○ 36.9 kW for regionalized loading ○ Update to LCO 3.1.1 and 3.1.2 to reflect new heat loads ○ Addition of new decay heat regionalized scheme • Increase in maximum fuel assembly weight for BWR fuel in MPC-68 from 700 to 730 lbs.

Amendment Revision	Summary of Changes
5 (cont'd)	<ul style="list-style-type: none"> • Changes to assembly characteristics of PWR 16x16 fuel assemblies to be qualified for storage. Characteristic changes include: <ul style="list-style-type: none"> ○ Maximum fuel assembly weight for assemblies that do not require upper and lower fuel spacers ○ Fuel Rod Clad Inner Diameter ○ Minimum guide/instrument tube thickness ○ Minimum soluble boron concentration for all intact fuel assemblies • Change in the fuel storage locations in MPC-32 for fuel with Axial Power Shaping Rod Assemblies (APSRs) • Change in fuel storage locations in MPC-24, -24E, and -32 for fuel with Control Rod Assemblies (CRAs), Rod Cluster Control Assemblies (RCAAs), and Control Element Assemblies (CEAs) • Elimination of restriction that fuel debris can only be loaded into the MPC-24EF, -32F, -68F, and 68FF • Requirement for MPC components exposed to spent fuel pool water, or the ambient environment, to be made out of stainless steel or, for MPC internals, neutron absorber, or aluminum • Addition of a threshold heat load below which operation of the SCS is not required <ul style="list-style-type: none"> ○ Modification to SCS design criteria to simplify the system

Amendment Revision	Summary of Changes
11	<ul style="list-style-type: none"> • Increase the per storage location weight limit for cells authorized for DFCs in the MPC-68, -68FF, and 68M. • Modify the surveillance requirements and actions regarding blockage of the overpack vents. • Allow for the storage of low enriched CILC fuel as undamaged fuel assemblies, thereby eliminating the need to place these assemblies into DFCs. • Increase the allowable enrichment limit for BWR 10x10G fuel assemblies to include assemblies currently in use. • Lower the minimum soluble boron concentration limits for PWR 17x17A fuel assemblies. • Increase the allowable burnup limit to accommodate non-fuel hardware consisting of neutron source assemblies (NSAs) in combination with other control components. • Expand the allowable contents of the MPC-68M to include thorium rods/canister. <ul style="list-style-type: none"> ○ Add a second permissible composition of thorium rods allowed for storage in all MPC-68 models, including the MPC-68M. • Clarify that lifting devices and lifting attachments shall be designed in accordance with the applicable stress limits of ANSI N14.6 and/or NUREG-0612.
12	<ul style="list-style-type: none"> • Add new loading patterns for the MPC-68M. • Add an exception to the ASME Code to allow the use of certain duplex stainless steels in the HI-STORM 100 system. • Permit the storage of damaged fuel/ fuel debris in DFCs under the regionalized loading pattern. • Add cyclic vacuum drying for all MPCs.
13	<ul style="list-style-type: none"> • Updated initial uranium weights (kg/assembly) for the 16x16B and 16x16C assembly classes to match the value used for the 16x16A assembly
14	<ul style="list-style-type: none"> • Add three new loading patterns for the MPC-68M • Reduce cooling time to 1 year for all fuel types stored in the MPC-68M • Add Damaged Fuel Isolators for use with damaged fuel stored in the MPC-68M

Amendment Revision	Summary of Changes
15	<ul style="list-style-type: none"> • Addition of three new MPCs: MPC-32M, MPC-32 Version 1, MPC-68 Version 1. • Addition of a new HI-TRAC MS (maximum shielded) transfer cask. • Addition of a new HI-STORM 100S Version E overpack. • Addition of three new BWR fuel types for storage in the MPC-68M: 10x10I, 10x10J, and 11x11A. • Lower the ambient temperature for the HI-STORM 100S Version E from 80°F to 70°F. • Addition of the HI-DRIP and dry ice jacket (DIJ) ancillary system as additional cooling when the MPC is loaded in the HI-TRAC. <ul style="list-style-type: none"> ○ Include DIJ as optional, alternate cooling method for short-term operation of the loaded HI-TRAC • Allow partial gadolinium credit for BWR fuel assembly types 10x10 and 11x11 in MPC-68M. • Allow for storage of MPCs previously loaded using earlier amendments with different helium leak test requirements. • Remove dose rate and consequence analysis from accident analysis for non-mechanistic tipover. • Update DWG 7195 for MPC-68M by removing dimensions which are not used in the safety analysis.

1.1 INTRODUCTION

HI-STORM 100 (acronym for Holtec International Storage Module) is a spent nuclear fuel storage system designed to be in full compliance with the requirements of 10CFR72. The annex "100" is a model number designation which denotes a system weighing over 100 tons. The HI-STORM 100 System consists of a sealed metallic canister, herein abbreviated as the "MPC", contained within an overpack. Its design features are intended to simplify and reduce on-site SNF loading, handling, and monitoring operations, and to provide for radiological protection and maintenance of structural and thermal safety margins.

The HI-STORM 100S and HI-STORM 100S Version B overpack designs are variants of the HI-STORM 100 overpack design and have their own drawings in Section 1.5. The "S" suffix indicates an enhanced overpack design, as described later in this section. "Version B" indicates an enhanced HI-STORM 100S overpack design. The HI-STORM 100S and 100S Version B accept the same MPCs and fuel types as the HI-STORM 100 overpack and the basic structural, shielding, and thermal-hydraulic characteristics remain unchanged. Hereafter in this FSAR reference to HI-STORM 100 System or the HI-STORM overpack is construed to apply to the various models, viz., HI-STORM 100, the HI-STORM 100S, and the HI-STORM 100S Version B. Where necessary, the text distinguishes among the different overpack designs. See Figures 1.1.1A and 1.1.3A for pictorial views of the HI-STORM 100S overpack design. See Figures 1.1.1B and 1.1.3B for pictorial views of the HI-STORM 100S Version B design.

The HI-STORM 100A overpack is a variant of two of the three HI-STORM 100 System overpack designs and is specially outfitted with an extended baseplate and gussets to enable the overpack to be anchored to the ISFSI pad in high seismic applications. In the following, the modified structure of the HI-STORM 100A, in each of four quadrants, is denoted as a "sector lug." The HI-STORM 100A anchor design is applicable to the HI-STORM 100S overpack design, in which case the assembly would be named HI-STORM 100SA. The HI-STORM 100A anchor design is not applicable to the HI-STORM 100S Version B overpack design. Therefore, the HI-STORM 100S Version B overpack cannot be deployed in the anchored configuration at this time. Hereafter in the text, discussion of HI-STORM 100A applies to both the standard (HI-STORM 100A) and HI-STORM 100SA overpacks, unless otherwise clarified.

The axial channels welded to the HI-STORM 100S and HI-STORM 100 S Version B body may be optionally replaced with partial length tubular members aligned with the top lid of the MPC essentially identical to those used in the HI-STORM FW overpack. The tubular members provide significantly lower friction loss on the ventilation air in comparison to the full length channels. The necessary updates to this FSAR to incorporate the above improvement are made to Chapters 2, 3, and 4. Similarly, to reduce tip-over loads an optional girdle beam structural member may be placed circumferentially around the exterior of the overpack body just below the outlet vents.

The HI-STORM 100 System is designed to accommodate a wide variety of spent nuclear fuel assemblies in a single basic overpack design by utilizing different MPCs. The external diameters of

all MPCs are identical to allow the use of a single overpack. Each of the MPCs has different internals (baskets) to accommodate distinct fuel characteristics. Each MPC is identified by the maximum quantity of fuel assemblies it is capable of receiving. The MPC-24, MPC-24E, and MPC-24EF contain a maximum of 24 PWR fuel assemblies; the MPC-32 and MPC-32F contain a maximum of 32 PWR fuel assemblies; and the MPC-68, MPC-68F, and MPC-68FF contain a maximum of 68 BWR fuel assemblies.

The HI-STORM overpack is constructed from a combination of steel and concrete, both of which are materials with long, proven histories of usage in nuclear applications. The HI-STORM overpack incorporates and combines many desirable features of previously-approved concrete and metal module designs. In essence, the HI-STORM overpack is a hybrid of metal and concrete systems, with the design objective of emulating the best features and dispensing with the drawbacks of both. The HI-STORM overpack is best referred to as a METCON™ (metal/concrete composite) system.

Figures 1.1.1, 1.1.1A, and 1.1.1B show the HI-STORM 100 System with two of its major constituents, the MPC and the storage overpack, in a cut-away view. The MPC, shown partially withdrawn from the storage overpack, is an integrally welded pressure vessel designed to meet the stress limits of the ASME Boiler and Pressure Vessel Code, Section III, Subsection NB [1.1.1]. The MPC defines the confinement boundary for the stored spent nuclear fuel assemblies with respect to 10CFR72 requirements and attendant review considerations. The HI-STORM storage overpack provides mechanical protection, cooling, and radiological shielding for the contained MPC.

In essence, the HI-STORM 100 System is the storage-only counterpart of the HI-STAR 100 System (Docket Numbers 72-1008 (Ref. [1.1.2]) and 71-9261 (Ref. [1.1.3])). Both HI-STORM and HI-STAR are engineered to house identical MPCs. Since the MPC is designed to meet the requirements of both 10CFR71 and 10CFR72 for transportation and storage, respectively, the HI-STORM 100 System allows rapid decommissioning of the ISFSI by simply transferring the loaded MPC's directly into HI-STAR 100 overpacks for off-site transport. This alleviates the additional fuel handling steps required by storage-only casks to unload the cask and repackage the fuel into a suitable transportation cask.

In contrast to the HI-STAR 100 overpack, which provides a containment boundary for the SNF during transport, the HI-STORM storage overpack does not constitute a containment or confinement enclosure. The HI-STORM overpack is equipped with large penetrations near its lower and upper extremities to permit natural circulation of air to provide for the passive cooling of the MPC and the contained radioactive material. The HI-STORM overpack is engineered to be an effective barrier against the radiation emitted by the stored materials, and an efficiently configured metal/concrete composite to attenuate the loads transmitted to the MPC during a natural phenomena or hypothetical accident event. Other auxiliary functions of the HI-STORM 100 overpack include isolation of the SNF from abnormal environmental or man-made events, such as impact of a tornado borne missile. As the subsequent chapters of this FSAR demonstrate, the HI-STORM overpack is engineered with large margins of safety with respect to cooling, shielding, and mechanical/structural functions.

The HI-STORM 100 System is autonomous inasmuch as it provides SNF and radioactive material confinement, radiation shielding, criticality control and passive heat removal independent of any

other facility, structures, or components. The surveillance and maintenance required by the plant's staff is minimized by the HI-STORM 100 System since it is completely passive and is composed of materials with long proven histories in the nuclear industry. The HI-STORM 100 System can be used either singly or as the basic storage module in an ISFSI. The site for an ISFSI can be located either at a reactor or away from a reactor.

The information presented in this report is intended to demonstrate the acceptability of the HI-STORM 100 System for use under the general license provisions of Subpart K by meeting the criteria set forth in 10CFR72.236.

The modularity of the HI-STORM 100 System accrues several advantages. Different MPCs, identical in external diameter, manufacturing requirements, and handling features, but different in their SNF arrangement details, are designed to fit a common overpack design. Even though the different MPCs have fundamentally identical design and manufacturing attributes, qualification of HI-STORM 100 requires consideration of the variations in the characteristics of the MPCs. In most cases, however, it is possible to identify the most limiting MPC geometry and the specific loading condition for the safety evaluation, and the detailed analyses are then carried out for that bounding condition. In those cases where this is not possible, multiple parallel analyses are performed.

The HI-STORM overpack is not engineered for transport and, therefore, will not be submitted for 10CFR Part 71 certification. HI-STORM 100, however, is designed to possess certain key elements of flexibility.

For example:

- The HI-STORM overpack is stored at the ISFSI pad in a vertical orientation, which helps minimize the size of the ISFSI and leads to an effective natural convection cooling flow around the MPC.
- The HI-STORM overpack can be loaded with a loaded MPC using the HI-TRAC transfer cask inside the 10CFR50 [1.1.4] facility, prepared for storage, transferred to the ISFSI, and stored in a vertical configuration, or directly loaded using the HI-TRAC transfer cask at or nearby the ISFSI storage pad.

The version of the HI-STORM overpack equipped with sector lugs to anchor it to the ISFSI pad is labeled HI-STORM 100A, shown in Figure 1.1.4. Figure 1.1.5 shows the sector lugs and anchors used to fasten the overpack to the pad in closer view. Details on HI-STORM 100A are presented in the drawing and BOM contained in Section 1.5. Users may employ a double nut arrangement as an option. The HI-STORM 100A overpack will be deployed at those ISFSI sites where the postulated seismic event (defined by the three orthogonal ZPAs) exceeds the maximum limit permitted for free-standing installation. The design of the ISFSI pad and the embedment are necessarily site-specific and the responsibility of the ISFSI owner. These designs shall be in accordance with the requirements specified in Appendix 2.A. The jurisdictional boundary between the anchored cask design and the embedment design is defined in Table 2.0.5. Additional description of the HI-STORM 100A configuration is provided in Subsection 1.2.1.2.1. The anchored design is applicable

to the HI-STORM 100 and the HI-STORM 100S overpack designs only.

The MPC is a multi-purpose SNF storage device both with respect to the type of fuel assemblies and its versatility of use. The MPC is engineered as a cylindrical prismatic structure with square cross section storage cavities. The number of storage locations depends on the type of fuel. Regardless of the storage cell count, the construction of the MPC is fundamentally the same; it is built as a honeycomb of cellular elements positioned within a circumscribing cylindrical canister shell. The manner of cell-to-cell weld-up and cell-to-canister shell interface employed in the MPC imparts extremely high structural stiffness to the assemblage, which is an important attribute for mechanical accident events. Figure 1.1.2 shows an elevation cross section of an MPC.

The MPC enclosure vessel is identical in external diameter to those presented in References [1.1.2] and [1.1.3]. However, certain fuel basket models may not be certified for storage or transportation in the HI-STAR 100 System. The Part 71 and 72 CoCs for HI-STAR 100 should be consulted for the MPC models that are certified for that system. Referencing these documents, as applicable, avoids repetition of information on the MPCs which is comprehensively set forth in the above-mentioned Holtec International documents docketed with the NRC. However, sufficient information and drawings are presented in this report to maintain clarity of exposition of technical data.

The HI-STORM storage overpack is designed to provide the necessary neutron and gamma shielding to comply with the provisions of 10CFR72 for dry storage of SNF at an ISFSI. Cross sectional views of the HI-STORM storage overpacks are presented in Figures 1.1.3, 1.1.3A, and 1.1.3B. A HI-TRAC transfer cask is required for loading of the MPC and movement of the loaded MPC from the cask loading area of a nuclear plant spent fuel pool to the storage overpack. The HI-TRAC is engineered to be emplaced with an empty MPC into the cask loading area of nuclear plant spent fuel pools for fuel loading (or unloading). The HI-TRAC/MPC assembly is designed to preclude intrusion of pool water into the narrow annular space between the HI-TRAC and the MPC while the assembly is submerged in the pool water. The HI-TRAC transfer cask also allows dry loading (or unloading) of SNF into the MPC.

To summarize, the HI-STORM 100 System has been engineered to:

- minimize handling of the SNF;
- provide shielding and physical protection for the MPC;
- permit rapid and unencumbered decommissioning of the ISFSI;
- require minimal ongoing surveillance and maintenance by plant staff;
- minimize dose to operators during loading and handling;
- allow transfer of the loaded MPC to a HI-STAR overpack for transportation.

FIGURE 1.1.5: ANCHORING DETAIL FOR THE HI-STORM 100A AND 100SA OVERPACKS

1.2 GENERAL DESCRIPTION OF HI-STORM 100 System

1.2.1 System Characteristics

The basic HI-STORM 100 System consists of interchangeable MPCs providing a confinement boundary for BWR or PWR spent nuclear fuel, a storage overpack providing a structural and radiological boundary for long-term storage of the MPC placed inside it, and a transfer cask providing a structural and radiological boundary for transfer of a loaded MPC from a nuclear plant spent fuel storage pool to the storage overpack. Figures 1.2.1 and 1.2.1A provide example cross sectional views of the HI-STORM 100 System with an MPC inserted into HI-STORM 100 and HI-STORM 100S storage overpacks, respectively. Figure 1.1.1B provides similar information for the HI-STORM 100 System using a HI-STORM 100S Version B overpack. Each of these components is described below, including information with respect to component fabrication techniques and designed safety features. All structures, systems, and components of the HI-STORM 100 System, which are identified as Important to Safety are specified in Table 2.2.6. This discussion is supplemented with a full set of drawings in Section 1.5.

The HI-STORM 100 System is comprised of three discrete components:

- i. multi-purpose canister (MPC)
- ii. storage overpack (HI-STORM)
- iii. transfer cask (HI-TRAC)

Necessary auxiliaries required to deploy the HI-STORM 100 System for storage are:

- i. vacuum drying (or other moisture removal) system
- ii. helium (He) backfill system with leakage detector (or other system capable of the same backfill condition)
- iii. lifting and handling systems
- iv. welding equipment
- v. transfer vehicles/trailer

Optional auxiliaries to deploy the HI-STORM 100 System for storage are:

- i. HI-DRIP cooling system
- ii. Dry ICE Jacket cooling system

All MPCs have identical external diameters. The outer diameter of the MPC is 68-3/8 inches[†] and the maximum overall length is approximately 190-1/2 inches. See Section 1.5 for the MPC drawings. Due to the differing storage contents of each MPC, the maximum loaded weight differs among MPCs. See Table 3.2.1 for each MPC weight. However, the maximum weight of a loaded MPC is

[†] Dimensions discussed in this section are considered nominal values.

approximately 44-1/2 tons. Tables 1.2.1 and 1.2.2 contain the key system data and parameters for the MPCs.

A single, base HI-STORM overpack design is provided which is capable of storing each type of MPC. The overpack inner cavity is sized to accommodate the MPCs. The inner diameter of the overpack inner shell is 73-1/2 inches and the height of the cavity is 191-1/2 inches. The overpack inner shell is provided with channels (rectangular or cylindrical) distributed around the inner cavity to present an inside diameter of 69-1/2 inches. The channels are intended to offer a flexible medium to absorb some of the impact during a non-mechanistic tip-over, while still allowing the cooling air flow through the ventilated overpack. The outer diameter of the overpack is 132-1/2 inches. The overall height of the HI-STORM 100 overpack is 239-1/2 inches.

There are two variants of the HI-STORM 100S overpack, differing from each other only in height and weight. The HI-STORM 100S(232) is 232 inches high, and the HI-STORM 100S(243) is 243 inches high. The HI-STORM 100S(243) is approximately 10,100 lbs heavier assuming standard density concrete. Hereafter in the text, these two versions of the HI-STORM 100S overpack will only be referred to as HI-STORM 100S and will be discussed separately only if the design feature being discussed is different between the two overpacks. See Section 1.5 for drawings.

There are also variants of the HI-STORM 100S Version B overpack, primarily differing from each other only in height and weight. The HI-STORM 100S-218 is 218 inches high, and the HI-STORM 100S-229 is 229 inches high. The HI-STORM 100S-229 is approximately 8,700 lbs heavier, including standard density concrete. The HI-STORM Version B Type IS is an enhanced HI-STORM 100S Version B overpack design where “IS” stands for Improved Shielding. The Type IS is used with both HI-STORM 100S Version B variants (100S-218 and 100S-229). Hereafter in the text, the versions of the HI-STORM 100S Version B overpack will only be referred to as HI-STORM 100S Version B and will be discussed separately only if the design feature being discussed is different between the overpacks. See Section 1.5 for drawings.

The weight of the overpack without an MPC varies from approximately 135 tons to 160 tons. See Table 3.2.1 for the detailed weights.

Before proceeding to present detailed physical data on the HI-STORM 100 System, it is of contextual importance to summarize the design attributes which enhance the performance and safety of the system. Some of the principal features of the HI-STORM 100 System which enhance its effectiveness as an SNF storage device and a safe SNF confinement structure are:

- the honeycomb design of the MPC fuel basket;
- the effective distribution of neutron and gamma shielding materials within the system;
- the high heat dissipation capability;
- engineered features to promote convective heat transfer;
- the structural robustness of the steel-concrete-steel overpack construction.

The honeycomb design of the MPC fuel baskets renders the basket into a multi-flange plate weldment where all structural elements (i.e., box walls) are arrayed in two orthogonal sets of plates. Consequently, the walls of the cells are either completely co-planar (i.e., no offset) or orthogonal with each other. There is complete edge-to-edge continuity between the contiguous cells.

Among the many benefits of the honeycomb construction is the uniform distribution of the metal mass of the basket over the entire length of the basket. Physical reasoning suggests that a uniformly distributed mass provides a more effective shielding barrier than can be obtained from a nonuniform basket. In other words, the honeycomb basket is a most effective radiation attenuation device. The complete cell-to-cell connectivity inherent in the honeycomb basket structure provides an uninterrupted heat transmission path, making the MPC an effective heat rejection device.

The composite shell construction in the overpack, steel-concrete-steel, allows ease of fabrication and eliminates the need for the sole reliance on the strength of concrete.

A description of each of the components is provided in the following sections, along with information with respect to its fabrication and safety features. This discussion is supplemented with the full set of drawings in Section 1.5.

1.2.1.1 Multi-Purpose Canisters

The MPCs are welded cylindrical structures as shown in cross sectional views of Figures 1.2.2 through 1.2.4. The outer diameter of each MPC is fixed. Each spent fuel MPC is an assembly consisting of a honeycombed fuel basket, a baseplate, canister shell, a lid, and a closure ring, as depicted in the MPC cross section elevation view, Figure 1.2.5. The number of spent nuclear fuel storage locations in each of the MPCs depends on the fuel assembly characteristics.

There are eight MPC models, distinguished by the type and number of fuel assemblies authorized for loading. Section 1.2.3 and Table 1.2.1 summarize the allowable contents for each MPC model. Section 2.1.9 provides the detailed specifications for the contents authorized for storage in the HI-STORM 100 System. Drawings for the MPCs are provided in Section 1.5.

The MPC provides the confinement boundary for the stored fuel. Figure 1.2.6 provides an elevation view of the MPC confinement boundary. The confinement boundary is defined by the MPC baseplate, shell, lid, port covers, and closure ring. The confinement boundary is a strength-welded enclosure of all stainless steel construction.

The PWR MPC-24, MPC-24E and MPC-24EF differ in construction from the MPC-32 (including the MPC-32F) and the MPC-68 (including the MPC-68F and MPC-68FF) in one important aspect: the fuel storage cells in the MPC-24 series are physically separated from one another by a "flux trap", for criticality control. The PWR MPC-32 and -32F are designed similar to the MPC-68 (without flux traps) and its design includes credit for soluble boron in the MPC water during wet fuel loading and unloading operations for criticality control.

The MPC fuel baskets of non-flux trap construction (namely, MPC-68, MPC-68F, MPC-68FF, MPC-32, and MPC-32F) are formed from an array of plates welded to each other at their

intersections. In the flux-trap type fuel baskets (MPC-24, MPC-24E, and MPC-24EF), formed angles are interposed onto the orthogonally configured plate assemblage to create the required flux-trap channels (see MPC-24 and MPC-24E fuel basket drawings in Section 1.5). In both configurations, two key attributes of the basket are preserved:

- i. The cross section of the fuel basket simulates a multi-flanged closed section beam, resulting in extremely high bending rigidity.
- ii. The principal structural frame of the basket consists of co-planar plate-type members (i.e., no offset).

This structural feature eliminates the source of severe bending stresses in the basket structure by eliminating the offset between the cell walls that must transfer the inertia load of the stored SNF to the basket/MPC interface during the various postulated accident events (e.g., non-mechanistic tipover, uncontrolled lowering of a cask during on-site transfer, or off-site transport events, etc.).

The MPC fuel basket is positioned and supported within the MPC shell by a set of basket supports welded to the inside of the MPC shell. In addition, the MPC fuel basket may also be positioned and supported within the MPC shell by a set of basket shims welded directly to the MPC fuel basket or by a set of extruded aluminum shims that are installed in the annular space between the MPC fuel basket and the enclosure vessel. Between the periphery of the basket, the MPC shell, the basket shims, and the basket supports, optional aluminum heat conduction elements (AHCEs) may have been installed in the early vintage MPCs fabricated, certified, and loaded under the original version or Amendment 1 of the HI-STORM 100 System CoC. The presence of these aluminum heat conduction elements is acceptable for MPCs loaded under the original CoC or Amendment 1, since the governing thermal analysis for Amendment 1 conservatively modeled the AHCEs as restrictions to convective flow in the basket, but took no credit for heat transfer through them. The heat loads authorized under Amendment 1 bound those for the original CoC, with the same MPC design. For MPCs loaded under Amendment 2 or a later version of the HI-STORM 100 CoC, the aluminum heat conduction elements shall not be installed. MPCs both with and without aluminum heat conduction elements installed are compatible with all HI-STORM overpacks. If used, these heat conduction elements are fabricated from thin aluminum alloy 1100 in shapes and a design that allows a snug fit in the confined spaces and ease of installation. If used, the heat conduction elements are installed along the full length of the MPC basket except at the drain pipe location to create a nonstructural thermal connection that facilitates heat transfer from the basket to shell. In their operating condition, the heat conduction elements contact the MPC shell and basket walls.

Lifting lugs attached to the inside surface of the MPC canister shell serve to permit placement of the empty MPC into the HI-TRAC transfer cask. The lifting lugs also serve to axially locate the MPC lid prior to welding. These internal lifting lugs are not used to handle a loaded MPC. Since the MPC lid is installed prior to any handling of a loaded MPC, there is no access to the lifting lugs once the MPC is loaded.

The top end of the MPC incorporates a redundant closure system. Figure 1.2.6 shows the MPC closure details. The MPC lid is a circular plate (fabricated from one piece, or two pieces - split top and bottom) edge-welded to the MPC outer shell. If the two-piece lid design is employed, only the

top piece is analyzed as part of the enclosure vessel pressure boundary. The bottom piece acts as a radiation shield and is attached to the top piece with a non-structural, non-pressure retaining weld. The lid is equipped with vent and drain ports that are utilized to remove moisture and air from the MPC, and backfill the MPC with a specified amount of inert gas (helium). The vent and drain ports are covered and seal welded before the closure ring is installed. The closure ring is a circular ring edge-welded to the MPC shell and lid. The MPC lid provides sufficient rigidity to allow the entire MPC loaded with SNF to be lifted by threaded holes in the MPC lid.

For fuel assemblies that are shorter than the design basis length, upper and lower fuel spacers (as appropriate) maintain the axial position of the fuel assembly within the MPC basket. The upper fuel spacers are threaded into the underside of the MPC lid as shown in Figure 1.2.5. The lower fuel spacers are placed in the bottom of each fuel basket cell. The upper and lower fuel spacers are designed to withstand normal, off-normal, and accident conditions of storage. An axial clearance of approximately 2 to 2-1/2 inches is provided to account for the irradiation and thermal growth of the fuel assemblies. The suggested values for the upper and lower fuel spacer lengths are listed in Tables 2.1.9 and 2.1.10 for each fuel assembly type. The actual length of fuel spacers will be determined on a site-specific or fuel assembly-specific basis.

The MPC confinement boundary is constructed entirely from stainless steel alloy materials. All MPC components that may come into contact with spent fuel pool water or the ambient environment (with the exception of neutron absorber, aluminum seals on vent and drain port caps, optional aluminum heat conduction elements, and MPC extruded aluminum shims) must be constructed from stainless steel alloy materials. Concerns regarding interaction of coated carbon steel materials and various MPC operating environments [1.2.1] are not applicable to the MPC. All structural components in a MPC shall be made of Alloy X, a designation which warrants further explanation.

Alloy X is a material that is expected to be acceptable as a Mined Geological Disposal System (MGDS) waste package and which meets the thermophysical properties set forth in this document.

At this time, there is considerable uncertainty with respect to the material of construction for an MPC that would be acceptable as a waste package for the MGDS. Candidate materials being considered for acceptability by the DOE include:

- Type 316
- Type 316LN
- Type 304
- Type 304LN

The DOE material selection process is primarily driven by corrosion resistance in the potential environment of the MGDS. As the decision regarding a suitable material to meet disposal requirements is not imminent, the MPC design allows the use of any one of the four Alloy X materials.

For the MPC design and analysis, Alloy X (as defined in this FSAR) may be one of the following materials. Any steel part in an MPC may be fabricated from any of the acceptable Alloy X materials listed above, except that the steel pieces comprising the MPC shell (i.e., the 1/2" thick cylinder) must

be fabricated from the same Alloy X stainless steel type.

The Fuel Baskets types used in the HI-STORM MPCs can be divided into two discrete categories:

- A. Alloy X Fuel baskets (ASME Code material)
- B. Metamic-HT baskets (Non-Code material)

A. Alloy X Baskets

An alloy X basket is one in which the structural function is rendered by Alloy X (defined below). The neutron absorption function is rendered by the addition of Metamic (classic) or Boral panels to the Alloy X Fuel Basket. As explained in Appendix 1.A, Alloy X (as defined in this FSAR) may be one of the following materials:

- Type 316
- Type 316LN
- Type 304
- Type 304LN

Any stainless steel part in an MPC may be fabricated from any acceptable Alloy X materials listed above. Additional material grades (viz. duplex stainless steel, UNS S31803) are adopted in the Alloy X roster in Appendix 1.A. These duplex steels shall not be used for the fabrication of MPC baskets and internal components. Additional basket material types may be adopted in the Alloy X roster if determined to be acceptable through the §72.48 process.

The Alloy X approach is accomplished by qualifying the MPC for all mechanical, structural, neutronic, radiological, and thermal conditions using material thermophysical properties that are the least favorable for the entire group for the analysis in question. For example, when calculating the rate of heat rejection to the outside environment, the value of thermal conductivity used is the lowest for the candidate material group. Similarly, the stress analysis calculations use the lowest value of the ASME Code allowable stress intensity for the entire group. Stated differently, we have defined a material, which is referred to as Alloy X, whose thermophysical properties, from the MPC design perspective, are the least favorable of the candidate materials.

The evaluation of the candidate Alloy X materials to determine the least favorable properties is provided in Appendix 1.A. The Alloy X approach is conservative because no matter which material is ultimately utilized in the MPC construction, it guarantees that the performance of the MPC will exceed the analytical predictions contained in this document.

In Alloy X baskets, the Metamic or Boral neutron absorber panels are completely enclosed in stainless steel sheathing that is stitch welded to the MPC basket cell walls along their entire periphery. The edges of the sheathing are bent toward the cell wall to make the edge weld. Thus, the neutron absorber is contained in a tight, welded pocket enclosure. The shear strength of the pocket weld joint, which is an order of magnitude greater than the weight of a fuel assembly, guarantees that the neutron absorber and its enveloping sheathing pocket will maintain their as-installed position under all loading, storage, and transient evolutions. Finally, the pocket joint detail ensures that fuel

assembly insertion or withdrawal into or out of the MPC basket will not lead to a disconnection of the sheathing from the cell wall.

B. Metamic HT Baskets

In Metamic HT baskets, both the structural and criticality prevention function is rendered by Metamic HT.

The MPC-68M in Supplement 1.III is a Metamic HT basket. MPC-68M contains a 68 storage cell BWR fuel basket made of co-planar slotted plates of Metamic-HT. The MPC is identified by the maximum number of fuel assemblies it can contain in the fuel basket. The fuel basket is assembled from a rectilinear gridwork of plates so that there are no bends or radii at the cell corners. This structural feature eliminates the source of severe bending stresses in the basket structure by eliminating the offset between the cell walls that must transfer the inertia load of the stored SNF to the basket/MPC interface during the various postulated accident events (e.g., non-mechanistic tipover, uncontrolled lowering of a cask during on-site transfer, or off-site transport accident events, etc.). Heat transfer from the internal basket cells to the canister shell is provided by aluminum basket shims, of which there are two design variations, in the peripheral region between the basket and shell. The standard MPC-68M design consists of loosely installed conformal aluminum shapes that conduct heat from the basket to shell while providing an annular space for natural circulation heat transfer. A continuous basket shim (CBS) design variant consists of aluminum shims bolted to basket panel extensions in the peripheral region, that provide greater natural circulation flow area and increased direct radiant heat transfer from the basket exterior to the canister shell ID. Supplement 1.III describes both MPC-68M designs.

Basket Shims: The HI-STORM 100 MPCs utilize two types of shims that constrain lateral rattling of the basket structures. These are:

1. Alloy X Shims which are characterized by being held in place by welding them to either the MPC Enclosure Vessel or the MPC fuel basket. The Alloy X shims are shaped to provide maximum support to the basket under lateral loading scenarios. They have been primarily used in Alloy X baskets.
2. Extruded Aluminum Shims: These shims are installed in the peripheral space between the fuel basket and the Enclosure Vessel to provide conformal contact surfaces between the Basket Shims and the fuel basket and between the Basket Shims and the Enclosure Vessel shell. The axial holes in the corner basket shims serve as the passageway for the downwards flow of the helium gas under the thermosiphon action, which is intrinsic to the thermal performance of all MPCs in the HI-STORM 100 system. Extruded Aluminum Shims have been allowed in the MPC-68M since the initial licensing by the NRC and have been subsequently evaluated for use in the MPC-32. The extruded aluminum shims used in each MPC type exhibit different characteristics that are unique for its particular MPC. Extruded Aluminum Shims may be used in other Alloy X and Metamic Fuel Baskets after the necessary safety evaluation pursuant to §72.48 is successfully performed.

1.2.1.2 Overpacks

1.2.1.2.1 HI-STORM Overpack

The HI-STORM overpacks are rugged, heavy-walled cylindrical vessels. Figures 1.1.3B, 1.2.7, 1.2.8, and 1.2.8A provide cross sectional views of the HI-STORM 100 System, showing all of the overpack designs. The HI-STORM 100A overpack design is an anchored variant of the HI-STORM 100 and -100S designs and hereinafter is identified by name only when the discussion specifically applies to the anchored overpack. The HI-STORM 100A differs only in the diameter of the overpack baseplate and the presence of bolt holes and associated anchorage hardware (see Figures 1.1.4 and 1.1.5). The main structural function of the storage overpack is provided by carbon steel, and the main shielding function is provided by plain concrete. The overpack plain concrete is enclosed by cylindrical steel shells, a thick steel baseplate, and a top plate. The overpack lid has appropriate concrete shielding to provide neutron and gamma attenuation in the vertical direction.

The storage overpack provides an internal cylindrical cavity of sufficient height and diameter for housing an MPC. The inner shell of the overpack has channels attached to its inner diameter. The channels provide guidance for MPC insertion and removal and a flexible medium to absorb impact loads during the non-mechanistic tip-over, while still allowing the cooling air flow to circulate through the overpack. Shims may be attached to channels to allow the proper inner diameter dimension to be obtained.

The storage system has air ducts to allow for passive natural convection cooling of the contained MPC. A minimum of four air inlets and four air outlets are located at the lower and upper extremities of the storage system, respectively. The location of the air outlets in the HI-STORM 100 and the HI-STORM 100S (including Version B) design differ in that the outlet ducts for the HI-STORM 100 overpack are located in the overpack body and are aligned vertically with the inlet ducts at the bottom of the overpack body. The air outlet ducts in the HI-STORM 100S and -100S Version B are integral to the lid assembly and are not in vertical alignment with the inlet ducts. See the drawings in Section 1.5 for details of the overpack air inlet and outlet duct designs. The air inlets and outlets are covered by a screen to reduce the potential for blockage. Routine inspection of the screens (or, alternatively, temperature monitoring) ensures that blockage of the screens themselves will be detected and removed in a timely manner. Analysis, described in Chapter 11 of this FSAR, evaluates the effects of partial and complete blockage of the air ducts.

The air inlets and air outlets are penetrations through the thick concrete shielding provided by the HI-STORM 100 overpack. The outlet air ducts for the HI-STORM 100S and -100S Version B overpack designs, integral to the lid, present a similar break in radial shielding. Within the air inlets and outlets, an array of gamma shield cross plates are installed (see Figure 5.3.19 for a pictorial representation of the gamma shield cross plate designs). These gamma shield cross plates are designed to scatter any radiation traveling through the ducts. The result of scattering the radiation in the ducts is a significant decrease in the local dose rates around the air inlets and air outlets. The configuration of the gamma shield cross plates is such that the increase in the resistance to flow in the air inlets and outlets is minimized. For the HI-STORM 100 and -100S overpack designs, the shielding analysis conservatively credits only the mandatory version of the gamma shield cross plate design because they provide less shielding than the optional design. Conversely, the thermal

analysis conservatively evaluates the optional gamma shield cross plate design because it conservatively provides greater resistance to flow than the mandatory design. There is only one gamma shield cross plate design employed with the HI-STORM 100S Version B overpack design, which has been appropriately considered in the shielding and thermal analyses.

Four threaded anchor blocks at the top of the overpack are provided for lifting. The anchor blocks are integrally welded to the radial plates, which in turn are full-length welded to the overpack inner shell, outer shell, and baseplate (HI-STORM 100) or the inlet air duct horizontal plates (HI-STORM 100S) (see Figure 1.2.7). The HI-STORM 100S Version B overpack design incorporates partial-length radial plates at the top of the overpack to secure the anchor blocks and uses both gussets and partial-length radial plates at the bottom of the overpack for structural stability. Details of this arrangement are shown in the drawings in Section 1.5.

The four anchor blocks are located on 90° arcs around the circumference of the top of the overpack lid. The overpack may also be lifted from the bottom using specially-designed lifting transport devices, including hydraulic jacks, air pads, Hillman rollers, or other design based on site-specific needs and capabilities. Slings or other suitable devices mate with lifting lugs that are inserted into threaded holes in the top surface of the overpack lid to allow lifting of the overpack lid. After the lid is bolted to the storage overpack main body, these lifting bolts shall be removed and replaced with flush plugs.

The plain concrete between the overpack inner and outer steel shells is specified to provide the necessary shielding properties (dry density) and compressive strength. The concrete shall be in accordance with the requirements specified in Appendix 1.D.

The principal function of the concrete is to provide shielding against gamma and neutron radiation. However, in an implicit manner it helps enhance the performance of the HI-STORM overpack in other respects as well. For example, the massive bulk of concrete imparts a large thermal inertia to the HI-STORM overpack, allowing it to moderate the rise in temperature of the system under hypothetical conditions when all ventilation passages are assumed to be blocked. The case of a postulated fire accident at the ISFSI is another example where the high thermal inertia characteristics of the HI-STORM concrete control the temperature of the MPC. Although the annular concrete mass in the overpack shell is not a structural member, it does act as an elastic/plastic filler of the inter-shell space, such that, while the cracking and crushing under a tip-over accident is not of significant consequence, the deformation characteristics are germane to the analysis of the structural members.

Density and compressive strength are the key parameters that delineate the performance of concrete in the HI-STORM System. The density of concrete used in the inter-shell annulus, pedestal (HI-STORM 100 and –100S overpacks only), and overpack lid has been set as defined in Appendix 1.D. For evaluating the physical properties of concrete for completing the analytical models, conservative formulations of Reference [1.0.5] are used.

To ensure the stability of the concrete at temperature, the concrete composition has been specified in accordance with NUREG-1536, "Standard Review Plan for Dry Cask Storage Systems" [1.0.3]. Thermal analyses, presented in Chapter 4, show that the temperatures during normal storage conditions do not threaten the physical integrity of the HI-STORM overpack concrete.

There are three base HI-STORM overpack designs - HI-STORM 100, HI-STORM 100S, and HI-STORM 100S Version B. The significant differences among the three are overpack height, MPC pedestal height, location of the air outlet ducts, and the vertical alignment of the inlet and outlet air ducts. The HI-STORM 100 overpack is approximately 240 inches high from the bottom of the baseplate to the top of the lid bolts and 227 inches high without the lid installed. There are two variants of the HI-STORM 100S overpack design, differing only in height and weight. The HI-STORM 100S(232) is approximately 232 inches high from the bottom of the baseplate to the top of the lid in its final storage configuration and approximately 211 inches high without the lid installed. The HI-STORM 100S(243) is approximately 243 inches high from the bottom of the baseplate to the top of the lid in its final storage configuration and approximately 222 inches high without the lid installed. There are also variants of the HI-STORM 100S Version B overpack design, differing primarily in height and weight. The HI-STORM 100S-218 is approximately 218 inches high from the bottom of the baseplate to the top of the lid in its final storage configuration and approximately 199 inches high without the lid installed. The HI-STORM 100S-229 is approximately 229 inches high from the bottom of the baseplate to the top of the lid in its final storage configuration and 210 inches high without the lid installed. The HI-STORM Version B Type IS is an enhanced HI-STORM 100S Version B overpack design where “IS” stands for Improved Shielding. The Type IS is used with both HI-STORM 100S Version B variants (100S-218 and 100S-229).

The HI-STORM 100S Version B overpack design does not include a concrete-filled pedestal to support the MPC. Instead, the MPC rests upon a steel plate that maintains the MPC sufficiently above the inlet air ducts to prevent direct radiation shine through the ducts. To facilitate this change, the inlet air ducts for the HI-STORM 100S Version B are shorter in height but larger in width. In addition, the HI-STORM 100S Version B has an optional girdle beam structure that fits around the exterior circumference of the overpack. The girdle beam structure absorbs energy during a non-mechanistic tip-over event, thereby reducing g-loads on the MPC. The HI-STORM 100S Version B Type IS maintains all the Version B design changes, but also uses high density concrete to create the Base-MPC Support, Base-Spacer Block and Base-Shield Blocks. See the drawings in Section 1.5 for HI-STORM 100S Version B details.

The anchored embodiment of the HI-STORM overpack is referred to as HI-STORM 100A or HI-STORM 100SA. The HI-STORM 100S version B overpack design may not be deployed in the anchored configuration at this time. As explained in the foregoing, the HI-STORM overpack is a steel weldment, which makes it a relatively simple matter to extend the overpack baseplate, form lugs, and then anchor the cask to the reinforced concrete structure of the ISFSI. In HI-STORM terminology, these lugs are referred to as “sector lugs.” The sector lugs, as shown in Figure 1.1.5 and the drawing in Section 1.5, are formed by extending the HI-STORM overpack baseplate, welding vertical gussets to the baseplate extension and to the overpack outer shell and, finally, welding a horizontal lug support ring in the form of an annular sector to the vertical gussets and to the outer shell. The baseplate is equipped with regularly spaced clearance holes (round or slotted) through which the anchor studs can pass. The sector lugs are bolted to the ISFSI pad using anchor studs that are made of a creep-resistant, high-ductility, environmentally compatible material. The bolts are pre-loaded to a precise axial stress using a “stud tensioner” rather than a torque wrench. Pre-tensioning the anchors using a stud tensioner eliminates any shear stress in the bolt, which is unavoidable if a torquing device is employed (Chapter 3 of the text “Mechanical Design of Heat Exchangers and

Pressure Vessel Components”, by Arcturus Publishers, 1984, K.P. Singh and A.I. Soler, provides additional information on stud tensioners). The axial stress in the anchors induced by pre-tensioning is kept below 75% of the material yield stress, such that during the seismic event the maximum bolt axial stress remains below the limit prescribed for bolts in the ASME Code, Section III, Subsection NF (for Level D conditions). Figures 1.1.4 and 1.1.5 provide visual depictions of the anchored HI-STORM 100A configuration. This configuration also applies to the HI-STORM 100SA.

The anchor studs pass through liberal clearance holes (circular or slotted) in the sector lugs (0.75” minimum clearance) such that the fastening of the studs to the ISFSI pad can be carried out without mechanical interference from the body of the sector lug. The two clearance hole configurations give the ISFSI pad designer flexibility in the design of the anchor embedment in the ISFSI concrete. The axial force in the anchors produces a compressive load at the overpack/pad interface. This compressive force, F , imputes a lateral load bearing capacity to the cask/pad interface that is equal to μF ($\mu \leq 0.53$ per Table 2.2.8). As is shown in Chapter 3 of this FSAR, the lateral load-bearing capacity of the HI-STORM/pad interface (μF) is many times greater than the horizontal (sliding) force exerted on the cask under the postulated DBE seismic event. Thus, the potential for lateral sliding of the HI-STORM 100A System during a seismic event is precluded, as is the potential for any bending action on the anchor studs.

The seismic loads, however, will produce an overturning moment on the overpack that would cause a redistribution of the compressive contact pressure between the pad and the overpack. To determine the pulsation in the tensile load in the anchor studs and in the interface contact pressure, bounding static analysis of the preloaded configuration has been performed. The results of the static analysis demonstrate that the initial preloading minimizes pulsations in the stud load. A confirmatory non-linear dynamic analysis has also been performed using the time-history methodology described in Chapter 3, wherein the principal nonlinearities in the cask system are incorporated and addressed. The calculated results from the dynamic analysis confirm the static analysis results and that the presence of pre-stress helps minimize the pulsation in the anchor stud stress levels during the seismic event, thus eliminating any concern with regard to fatigue failure under extended and repetitive seismic excitations.

The sector lugs in HI-STORM 100A are made of the same steel material as the baseplate and the shell (SA516- Gr. 70) which helps ensure high quality fillet welds used to join the lugs to the body of the overpack. The material for the anchor studs can be selected from a family of allowable stud materials listed in the ASME Code (Section II). A representative sampling of permitted materials is listed in Table 1.2.7. The menu of materials will enable the ISFSI owner to select a fastener material that is resistant to corrosion in the local ISFSI environment. For example, for ISFSIs located in marine environments (e.g., coastal reactor sites), carbon steel studs would not be recommended without concomitant periodic inspection and coating maintenance programs. Table 1.2.7 provides the chemical composition of several acceptable fastener materials to help the ISFSI owner select the most appropriate material for his site. The two mechanical properties, ultimate strength σ_u and yield strength σ_y are also listed. For purposes of structural evaluations, the lower bound values of σ_u and σ_y from the menu of materials listed in Table 1.2.7 are used (see Table 3.4.10).

As shown in the drawing, the anchor studs are spaced sufficiently far apart such that a practical reinforced concrete pad with embedded receptacles can be designed to carry the axial pull from the

anchor studs without overstressing the enveloping concrete monolith. The design specification and supporting analyses in this FSAR are focused on qualifying the overpack structures, including the sector lugs and the anchor studs. The design of the ISFSI pad, and its anchor receptacle will vary from site to site, depending on the geology and seismological characteristics of the sub-terrain underlying the ISFSI pad region. The data provided in this FSAR, however, provide the complete set of factored loads to which the ISFSI pad, its sub-grade, and the anchor receptacles must be designed within the purview of ACI-349 [1.0.4]. Detailed requirements on the ISFSI pads for anchored casks are provided in Section 2.0.4.

1.2.1.2.2 HI-TRAC (Transfer Cask) - Standard Design

Like the storage overpack, the HI-TRAC transfer cask is a rugged, heavy-walled cylindrical vessel. The main structural function of the transfer cask is provided by carbon steel, and the main neutron and gamma shielding functions are provided by water and lead, respectively. The transfer cask is a steel, lead, steel layered cylinder with a water jacket attached to the exterior. Figure 1.2.9 provides a typical cross section of the standard design HI-TRAC-125 with the pool lid installed. See Section 1.2.1.2.3 for discussion of the optional HI-TRAC 100D and 125D designs, and Section 1.2.1.2.4 for discussion of the optional HI-TRAC 100G design.

The transfer cask provides an internal cylindrical cavity of sufficient size for housing an MPC. The top lid of the HI-TRAC 125 has additional neutron shielding to provide neutron attenuation in the vertical direction (from SNF in the MPC below). The MPC access hole through the HI-TRAC top lid is provided to allow the lowering/raising of the MPC between the HI-TRAC transfer cask, and the HI-STORM or HI-STAR overpacks. The standard design HI-TRAC (comprised of HI-TRAC 100 and HI-TRAC 125) is provided with two bottom lids, each used separately. The pool lid is bolted to the bottom flange of the HI-TRAC and is utilized during MPC fuel loading and sealing operations. In addition to providing shielding in the axial direction, the pool lid incorporates a seal that is designed to hold clean demineralized water in the HI-TRAC inner cavity, thereby preventing contamination of the exterior of the MPC by the contaminated fuel pool water. After the MPC has been drained, dried, and sealed, the pool lid is removed and the HI-TRAC transfer lid is attached (standard design only). The transfer lid incorporates two sliding doors that allow the opening of the HI-TRAC bottom for the MPC to be raised/lowered. Figure 1.2.10 provides a cross section of the HI-TRAC with the transfer lid installed.

In the standard design, trunnions are provided for lifting and rotating the transfer cask body between vertical and horizontal positions. The lifting trunnions are located just below the top flange and the pocket trunnions are located above the bottom flange. The two lifting trunnions are provided to lift and vertically handle the HI-TRAC, and the pocket trunnions provide a pivot point for the rotation of the HI-TRAC for downending or upending.

Two standard design HI-TRAC transfer casks of different weights are provided to house the MPCs. The HI-TRAC-125 weight does not exceed 125 tons during any loading or transfer operation. The HI-TRAC-100 weight does not exceed 100 tons during any loading or transfer operation. The internal cylindrical cavities of the two standard design HI-TRACs are identical. However, the external dimensions are different. The HI-TRAC-100 has a reduced thickness of lead and water shielding and consequently, the external dimensions are different. The structural steel thickness is

identical in the two HI-TRACs. This allows most structural analyses of the HI-TRAC-125 to bound the HI-TRAC-100 design. Additionally, as the two HI-TRACs are identical except for a reduced thickness of lead and water, the HI-TRAC-125 has a larger thermal resistance than the smaller and lighter HI-TRAC-100. Therefore, for normal conditions the HI-TRAC-125 thermal analysis bounds that of the HI-TRAC-100. Separate shielding analyses are performed for each HI-TRAC since the shielding thicknesses are different between the two.

1.2.1.2.3 HI-TRAC 100D and 125D Transfer Casks

As an option to using either of the standard HI-TRAC transfer cask designs, users may choose to use the optional HI-TRAC 100D or 125D designs. Figure 1.2.9A provides a typical cross section of the HI-TRAC-125D with the pool lid installed. The HI-TRAC 100D (figure not shown) is similar to the HI-TRAC 125D except for the top lid (which contains no Holtite). Like the standard designs, the optional designs are designed and constructed in accordance with ASME III, Subsection NF, with certain NRC-approved alternatives, as discussed in Section 2.2.4. Functionally equivalent, the major differences between the HI-TRAC 100D and 125D designs and the standard designs are as follows:

- No pocket trunnions are provided for downending/upending
- The transfer lid is not required
- A new ancillary, the HI-STORM mating device (Figure 1.2.18) is required during MPC transfer operations
- A wider baseplate with attachment points for the mating device is provided
- The baseplate incorporates gussets for added structural strength
- The number of pool lid bolts is reduce

The interface between the MPC and the transfer cask is the same between the standard designs and the optional designs. The optional designs are capable of withstanding all loads defined in the design basis for the transfer cask during normal, off-normal, and accident modes of operation with adequate safety margins. In lieu of swapping the pool lid for the transfer lid to facilitate MPC transfer, the pool lids remain on the HI-TRAC 100D and 125D until MPC transfer is required. The HI-STORM mating device is located between, and secured with bolting (if required by seismic analysis), to the top of the HI-STORM overpack and the HI-TRAC 100D or 125D transfer cask. The mating device is used to remove the pool lid to provide a pathway for MPC transfer between the overpack and the transfer cask. Section 1.2.2.2 provides additional detail on the differences between the standard transfer cask designs and the optional HI-TRAC 100D or 125D designs during operations.

1.2.1.2.4 HI-TRAC 100G Transfer Cask

Users may choose to use the optional HI-TRAC 100G design in place of the standard (100/125) or dual-purpose lid (100D/125D) transfer casks. Figure 1.2.13 provides a typical cross section of the HI-TRAC 100G. Like the other transfer cask designs, the HI-TRAC 100G is designed and constructed in accordance with ASME III, Subsection NF, with certain NRC-approved alternatives, as discussed in Section 2.2.4. Functionally equivalent, the HI-TRAC 100G is defined by the following differences:

- Upper lifting trunnions are now welded to the cask and are positioned lower on the cask

body such that they pass through the water jacket, outer and inner shell; Pocket trunnions of the standard design are replaced with a lower pair of welded rotation trunnions, provided for downending/upending;

- The transfer lid from the standard design is not utilized, so the HI-STORM mating device (Figure 1.2.18) is required during MPC transfer operations;
- The bottom flange mimics that of the dual-purpose lid design, except the diameter is reduced to not significantly protrude outside of water jacket outer diameter;
- The top lid contains Holtite shielding material.
- The pool lid contains increased steel-lead-steel thickness for improved shielding during horizontal handling
- Reduced water jacket outside diameter

The interface between the MPC and the transfer cask is the same between the HI-TRAC 100G and the other designs. The design is capable of withstanding all loads defined in the design basis for the transfer cask during normal, off-normal, and accident modes of operation with adequate safety margins. Section 1.2.2.2 provides additional detail on the differences between the HI-TRAC 100G and the other HI-TRAC designs during operations.

1.2.1.3 Shielding Materials

The HI-STORM 100 System is provided with shielding to ensure the radiation and exposure requirements in 10CFR72.104 and 10CFR72.106 are met. This shielding is an important factor in minimizing the personnel doses from the gamma and neutron sources in the SNF in the MPC for ALARA considerations during loading, handling, transfer, and storage. The fuel basket structure of edge-welded composite boxes and neutron absorber panels attached to the fuel storage cell vertical surfaces provide the initial attenuation of gamma and neutron radiation emitted by the radioactive spent fuel. The MPC shell, baseplate, lid and closure ring provide additional thicknesses of steel to further reduce the gamma flux at the outer canister surfaces.

In the HI-STORM storage overpack, the primary shielding in the radial direction is provided by concrete and steel. In addition, the storage overpack has a thick circular concrete slab attached to the lid, and the HI-STORM 100 and –100S have a thick circular concrete pedestal upon which the MPC rests. This concrete pedestal is not necessary in the HI-STORM 100S Version B overpack design. The HI-STORM 100S Version B Type IS maintains all the Version B design changes, but also uses high density concrete to create the Base-MPC Support, Base-Spacer Block and Base-Shield Blocks. These slabs provide gamma and neutron attenuation in the axial direction. The thick overpack lid and concrete shielding integral to the lid provide additional gamma attenuation in the upward direction, reducing both direct radiation and skyshine. Several steel plate and shell elements provide additional gamma shielding as needed in specific areas, as well as incremental improvements in the overall shielding effectiveness. Gamma shield cross plates, as depicted in Figure 5.3.19, provide attenuation of scattered gamma radiation as it exits the inlet and outlet air ducts.

In the HI-TRAC transfer cask radial direction, gamma and neutron shielding consists of steel-lead-steel and water, respectively. In the axial direction, shielding is provided by the top lid, and the pool or transfer lid, as applicable. In the HI-TRAC pool lid, layers of steel-lead-steel provide an additional measure of gamma shielding to supplement the gamma shielding at the bottom of the

MPC. In the transfer lid, layers of steel-lead-steel provide gamma attenuation. For the HI-TRAC 125 transfer lid, the neutron shield material, Holtite-A, is also provided. The HI-TRAC 125, HI-TRAC 125D, and HI-TRAC 100G top lids are composed of steel-neutron shield-steel, with the neutron shield material being Holtite-A. The HI-TRAC 100 and HI-TRAC 100D top lids are composed of steel only providing gamma attenuation.

1.2.1.3.1 Fixed Neutron Absorbers

1.2.1.3.1.1 BoralTM

Boral is a thermal neutron poison material composed of boron carbide and aluminum (aluminum powder and plate). Boron carbide is a compound having a high boron content in a physically stable and chemically inert form. The boron carbide contained in Boral is a fine granulated powder that conforms to ASTM C-750-80 nuclear grade Type III. The Boral cladding is made of alloy aluminum, a lightweight metal with high tensile strength which is protected from corrosion by a highly resistant oxide film. The two materials, boron carbide and aluminum, are chemically compatible and ideally suited for long-term use in the radiation, thermal, and chemical environment of a nuclear reactor, spent fuel pool, or dry cask.

The documented historical applications of Boral, in environments comparable to those in spent fuel pools and fuel storage casks, dates to the early 1950s (the U.S. Atomic Energy Commission's AE-6 Water-Boiler Reactor [1.2.2]). Technical data on the material was first printed in 1949, when the report "Boral: A New Thermal Neutron Shield" was published [1.2.3]. In 1956, the first edition of the Reactor Shielding Design Manual [1.2.4] was published and it contained a section on Boral and its properties.

In the research and test reactors built during the 1950s and 1960s, Boral was frequently the material of choice for control blades, thermal-column shutters, and other items requiring very good thermal-neutron absorption properties. It is in these reactors that Boral has seen its longest service in environments comparable to today's applications.

Boral found other uses in the 1960s, one of which was a neutron poison material in baskets used in the shipment of irradiated, enriched fuel rods from Canada's Chalk River laboratories to Savannah River. Use of Boral in shipping containers continues, with Boral serving as the poison in current British Nuclear Fuels Limited casks and the Storable Transport Cask by Nuclear Assurance Corporation [1.2.5].

Boral has been licensed by the NRC for use in numerous BWR and PWR spent fuel storage racks and has been extensively used in international nuclear installations.

Boral has been exclusively used in fuel storage applications in recent years. Its use in spent fuel pools as the neutron absorbing material can be attributed to its proven performance and several unique characteristics, such as:

- The content and placement of boron carbide provides a very high removal cross section for thermal neutrons.

- Boron carbide, in the form of fine particles, is homogeneously dispersed throughout the central layer of the Boral panels.
- The boron carbide and aluminum materials in Boral do not degrade as a result of long-term exposure to radiation.
- The neutron absorbing central layer of Boral is clad with permanently bonded surfaces of aluminum.
- Boral is stable, strong, durable, and corrosion resistant.

Boral absorbs thermal neutrons without physical change or degradation of any sort from the anticipated exposure to gamma radiation and heat. The material does not suffer loss of neutron attenuation capability when exposed to high levels of radiation dose.

Holtec International's QA Program ensures that Boral is manufactured under the control and surveillance of a Quality Assurance/Quality Control Program that conforms to the requirements of 10CFR72, Subpart G. Holtec International has procured over 200,000 panels of Boral from AAR Advanced Structures in over 30 projects. Boral has always been purchased with a minimum ^{10}B loading requirement. Coupons extracted from production runs were tested using the wet chemistry procedure. The actual ^{10}B loading, out of thousands of coupons tested, has never been found to fall below the design specification. The size of this coupon database is sufficient to provide reasonable assurance that all future Boral procurements will continue to yield Boral with full compliance with the stipulated minimum loading. Furthermore, the surveillance, coupon testing, and material tracking processes which have so effectively controlled the quality of Boral are expected to continue to yield Boral of similar quality in the future. Nevertheless, to add another layer of insurance, only 75% ^{10}B credit of the fixed neutron absorber is assumed in the criticality analysis consistent with Chapter 6.0, IV, 4.c of NUREG-1536, Standard Review Plan for Dry Cask Storage Systems.

Operating experience in nuclear plants with fuel loading of Boral equipped MPCs as well as laboratory test data indicate that the aluminium used in the manufacture of the Boral may react with water, resulting in the generation of hydrogen. The numerous variables (i.e., aluminium particle size, pool temperature, pool chemistry, etc.) that influence the extent of the hydrogen produced make it impossible to predict the amount of hydrogen that may be generated during MPC loading or unloading at a particular plant. Therefore, due to the variability in hydrogen generation from the Boral-water reaction, the operating procedures in Chapter 8 require monitoring for combustible gases and purging the space beneath the MPC lid during loading and unloading operations when an ignition event could occur (i.e., when the space beneath the MPC lid is open to the welding or cutting operation).

1.2.1.3.1.2 METAMIC®

METAMIC® is a neutron absorber material developed by the Reynolds Aluminum Company in the mid-1990s for spent fuel reactivity control in dry and wet storage applications. Metallurgically, METAMIC® is a metal matrix composite (MMC) consisting of a matrix of 6061 aluminum alloy

reinforced with Type 1 ASTM C-750 boron carbide. METAMIC[®] is characterized by extremely fine aluminum (325 mesh or better) and boron carbide powder. As described in the U.S. patents held by METAMIC, Inc.¹², the high performance and reliability of METAMIC[®] derives from the particle size distribution of its constituents, rendered into a metal matrix composite by the powder metallurgy process. This yields excellent and uniform homogeneity.

The powders are carefully blended without binders or other additives that could potentially adversely influence performance. The maximum percentage of B₄C that can be dispersed in the aluminum alloy 6061 matrix is approximately 40 wt.%, although extensive manufacturing and testing experience is limited to approximately 31 wt.%. The blend of powders is isostatically compacted into a green billet under high pressure and vacuum sintered to near theoretical density.

According to the manufacturer, billets of any size can be produced using this technology. The billet is subsequently extruded into one of a number of product forms, ranging from sheet and plate to angle, channel, round and square tube, and other profiles. For the METAMIC[®] sheets used in the MPCs, the extruded form is rolled down into the required thickness.

METAMIC[®] has been subjected to an extensive array of tests sponsored by the Electric Power Research Institute (EPRI) that evaluated the functional performance of the material at elevated temperatures (up to 900°F) and radiation levels (1E+11 rads gamma). The results of the tests documented in an EPRI report (Ref. [1.2.11]) indicate that METAMIC[®] maintains its physical and neutron absorption properties with little variation in its properties from the unirradiated state. The main conclusions provided in the above-referenced EPRI report are summarized below:

- The metal matrix configuration produced by the powder metallurgy process with a complete absence of open porosity in METAMIC[®] ensures that its density is essentially equal to the theoretical density.
- The physical and neutronic properties of METAMIC[®] are essentially unaltered under exposure to elevated temperatures (750° F - 900° F).
- No detectable change in the neutron attenuation characteristics under accelerated corrosion test conditions has been observed.

In addition, independent measurements of boron carbide particle distribution show extremely small particle-to-particle distance[†] and near-perfect homogeneity.

An evaluation of the manufacturing technology underlying METAMIC[®] as disclosed in the above-referenced patents and of the extensive third-party tests carried out under the auspices of EPRI

¹ U.S. Patent No. 5,965,829, “Radiation Absorbing Refractory Composition”.

² U.S. Patent No. 6,042,779, “Extrusion Fabrication Process for Discontinuous Carbide Particulate Metal Matrix Composites and Super, Hypereutectic Al/Si.”

[†] Medium measured neighbor-to-neighbor distance is 10.08 microns according to the article, “METAMIC Neutron Shielding”, by K. Anderson, T. Haynes, and R. Kazmier, EPRI Boraflex Conference, November 19-20, 1998.

makes METAMIC[®] an acceptable neutron absorber material for use in the MPCs. Holtec's technical position on METAMIC[®] is also supported by the evaluation carried out by other organizations (see, for example, USNRC's SER on NUHOMS-61BT, Docket No. 72-1004).

Consistent with its role in reactivity control, all METAMIC[®] material procured for use in the Holtec MPCs will be qualified as important-to-safety (ITS) Category A item. ITS category A manufactured items, as required by Holtec's NRC-approved Quality Assurance program, must be produced to essentially preclude the potential of an error in the procurement of constituent materials and the manufacturing processes. Accordingly, material and manufacturing control processes must be established to eliminate the incidence of errors, and inspection steps must be implemented to serve as an independent set of barriers to ensure that all critical characteristics defined for the material by the cask designer are met in the manufactured product.

All manufacturing and in-process steps in the production of METAMIC[®] shall be carried out using written procedures. As required by the company's quality program, the material manufacturer's QA program and its implementation shall be subject to review and ongoing assessment, including audits and surveillances as set forth in the applicable Holtec QA procedures to ensure that all METAMIC[®] panels procured meet with the requirements appropriate for the quality genre of the MPCs. Additional details pertaining to the qualification and production tests for METAMIC[®] are summarized in Subsection 9.1.5.3.

Because of the absence of interconnected porosities, the time required to dehydrate a METAMIC[®]-equipped MPC is expected to be less compared to an MPC containing Boral.

NUREG/CR-5661 (Ref. [1.2.14]) recommends limiting poison material credit to 75% of the minimum ¹⁰B loading because of concerns for potential "streaming" of neutrons, and allows for greater percentage credit in criticality analysis "if comprehensive acceptance tests, capable of verifying the presence and uniformity of the neutron absorber, are implemented". The value of 75% is characterized in NUREG/CR-5661 as a very conservative value, based on experiments with neutron poison containing relatively large B₄C particles, such as BORAL with an average particle size in excess of 100 microns. METAMIC[®], however, has a much smaller particle size of typically less than 25 microns on average. Any streaming concerns would therefore be drastically reduced.

Analyses performed by Holtec International show that the streaming due to particle size is practically non-existent in METAMIC[®]. Further, EPRI's neutron attenuation measurements on 31 and 15 B₄C weight percent METAMIC[®] showed that METAMIC[®] exhibits very uniform ¹⁰B areal density. This makes it easy to reliably establish and verify the presence and microscopic and macroscopic uniformity of the ¹⁰B in the material. Therefore, 90% credit is applied to the minimum ¹⁰B areal density in the criticality calculations, i.e. a 10% penalty is applied. This 10% penalty is considered conservative since there are no significant remaining uncertainties in the ¹⁰B areal density. In Chapter 9 the qualification and on production tests for METAMIC[®] to support 90% ¹⁰B credit are specified. With 90% credit, the target weight percent of boron carbide in METAMIC[®] is 31 for all MPCs, as summarized in Table 1.2.8, consistent with the test coupons used in the EPRI evaluations [1.2.11]. The maximum permitted value is 33.0 wt% to allow for necessary fabrication flexibility.

Because METAMIC[®] is a solid material, there is no capillary path through which spent fuel pool water can penetrate METAMIC[®] panels and chemically react with aluminum in the interior of the material to generate hydrogen. Any chemical reaction of the outer surfaces of the METAMIC[®] neutron absorber panels with water to produce hydrogen occurs rapidly and reduces to an insignificant amount in a short period of time. Nevertheless, combustible gas monitoring for METAMIC[®]-equipped MPCs and purging the space under the MPC lid during welding and cutting operations, is required until sufficient field experience is gained that confirms that little or no hydrogen is released by METAMIC[®] during these operations.

Mechanical properties of 31 wt.% METAMIC[®] based on coupon tests of the material in the as-fabricated condition and after 48 hours of an elevated temperature state at 900°F are summarized below from the EPRI report [1.2.11].

Mechanical Properties of 31wt.% B ₄ C METAMIC		
Property	As-Fabricated	After 48 hours of 900°F Temperature Soak
Yield Strength (psi)	32937 ± 3132	28744 ± 3246
Ultimate Strength (psi)	40141 ± 1860	34608 ± 1513
Elongation (%)	1.8 ± 0.8	5.7 ± 3.1

The required flexural strain of the neutron absorber to ensure that it will not fracture when the supporting basket wall flexes due to the worst case lateral loading is 0.2%, which is the flexural strain of the Alloy X basket panel material. The 1% minimum elongation of 31wt.% B₄C METAMIC[®] indicated by the above table means that a large margin of safety against cracking exists, so there is no need to perform testing of the METAMIC[®] for mechanical properties.

EPRI's extensive characterization effort [1.2.11], which was focused on 15 and 31 wt.% B₄C METAMIC[®] served as the principal basis for a recent USNRC SER for 31wt.% B₄C METAMIC for used in wet storage [1.2.12]. Additional studies on METAMIC[®] [1.2.13], EPRI's and others work provide the confidence that 31wt.% B₄C METAMIC[®] will perform its intended function in the MPCs.

1.2.1.3.1.3 Locational Fixity of Neutron Absorbers

Both Boral and METAMIC[®] neutron absorber panels are completely enclosed in Alloy X (stainless steel) sheathing that is stitch welded to the MPC basket cell walls along their entire periphery. The edges of the sheathing are bent toward the cell wall to make the edge weld. Thus, the neutron absorber is contained in a tight, welded pocket enclosure. The shear strength of the pocket weld joint, which is an order of magnitude greater than the weight of a fuel assembly, guarantees that the neutron absorber and its enveloping sheathing pocket will maintain their as-installed position under all loading, storage, and transient evolutions. Finally, the pocket joint detail ensures that fuel assembly insertion or withdrawal into or out of the MPC basket will not lead to a disconnection of the sheathing from the cell wall.

1.2.1.3.2 Neutron Shielding

The specification of the HI-STORM overpack and HI-TRAC transfer cask neutron shield material is predicated on functional performance criteria. These criteria are:

- Attenuation of neutron radiation to appropriate levels;
- Durability of the shielding material under normal conditions, in terms of thermal, chemical, mechanical, and radiation environments;
- Stability of the homogeneous nature of the shielding material matrix;
- Stability of the shielding material in mechanical or thermal accident conditions to the desired performance levels; and
- Predictability of the manufacturing process under adequate procedural control to yield an in-place neutron shield of desired function and uniformity.

Other aspects of a shielding material, such as ease of handling and prior nuclear industry use, are also considered, within the limitations of the main criteria. Final specification of a shield material is a result of optimizing the material properties with respect to the main criteria, along with the design of the shield system, to achieve the desired shielding results.

Neutron attenuation in the HI-STORM overpack is provided by the thick walls of concrete contained in the steel vessel, lid, and pedestal (only for the HI-STORM 100 and –100S overpack designs). Concrete is a shielding material with a long proven history in the nuclear industry. The concrete composition has been specified to ensure its continued integrity at the long term temperatures required for SNF storage.

The HI-TRAC transfer cask is equipped with a water jacket providing radial neutron shielding. Demineralized water will be utilized in the water jacket. To ensure operability for low temperature conditions, ethylene glycol (25% in solution) will be added to reduce the freezing point for low temperature operations (e.g., below 32°F) [1.2.7].

Neutron shielding in the HI-TRAC 125, 125D, and 100G transfer casks in the axial direction is provided by Holtite-A within the top lid. HI-TRAC 125 also contains Holtite-A in the transfer lid. Holtite-A is a poured-in-place solid borated synthetic neutron-absorbing polymer. Holtite-A is specified with a nominal B₄C loading of 1 weight percent for the HI-STORM 100 System. Appendix 1.B provides the Holtite-A material properties germane to its function as a neutron shield. Holtec has performed confirmatory qualification tests on Holtite-A under the company's QA program.

In the following, a brief summary of the performance characteristics and properties of Holtite-A is provided.

Density

The specific gravity of Holtite-A is 1.68 g/cm^3 as specified in Appendix 1.B. To conservatively bound any potential weight loss at the design temperature and any inability to reach the theoretical density, the density is reduced by 4% to 1.61 g/cm^3 . The density used for the shielding analysis is conservatively assumed to be 1.61 g/cm^3 to underestimate the shielding capabilities of the neutron shield.

Hydrogen

The weight concentration of hydrogen is 6.0%. However, all shielding analyses conservatively assume 5.9% hydrogen by weight in the calculations.

Boron Carbide

Boron carbide dispersed within Holtite-A in finely dispersed powder form is present in 1% (nominal) weight concentration. Holtite-A may be specified with a B_4C content of up to 6.5 weight percent. For the HI-STORM 100 System, Holtite-A is specified with a nominal B_4C weight percent of 1%.

Design Temperature

The design temperatures of Holtite-A are provided in Table 1.B.1.. The maximum spatial temperatures of Holtite-A under all normal operating conditions must be demonstrated to be below these design temperatures, as applicable.

Thermal Conductivity

The Holtite-A neutron shielding material is stable below the design temperature for the long term and provides excellent shielding properties for neutrons. A conservative, lower bound conductivity is stipulated for use in the thermal analyses of Chapter 4 (Section 4.2) based on information in the technical literature.

1.2.1.3.3 Gamma Shielding Material

For gamma shielding, the HI-STORM 100 storage overpack primarily relies on massive concrete sections contained in a robust steel vessel. A carbon steel plate, the shield shell, is located adjacent to the overpack inner shell to provide additional gamma shielding (Figure 1.2.7)[†]. Carbon steel supplements the concrete gamma shielding in most portions of the storage overpack, most notably the pedestal (HI-STORM 100 and –100S overpack designs only) and the lid. To reduce the radiation streaming through the overpack air inlets and outlets, gamma shield cross plates are installed in the ducts (Figures 1.2.8 and 1.2.8A) to scatter the radiation. This scattering acts to significantly reduce the local dose rates adjacent to the overpack air inlets and outlets. See Figure 5.3.19 and the drawings in Section 1.5 for more details of the gamma shield cross plate designs for each overpack design.

[†] The shield shell design feature was deleted in June, 2001 after overpack serial number 7 was fabricated.

In the HI-TRAC transfer cask, the primary gamma shielding is provided by lead. As in the storage overpack, carbon steel supplements the lead gamma shielding of the HI-TRAC transfer cask.

1.2.1.4 Lifting Devices

Lifting of the HI-STORM 100 System may be accomplished either by attachment at the top of the storage overpack ("top lift"), as would typically be done with a crane, or by attachment at the bottom ("bottom lift"), as would be effected by a number of lifting/handling devices.

For a top lift, the storage overpack is equipped with four threaded anchor blocks arranged circumferentially around the overpack. These anchor blocks are used for overpack lifting as well as securing the overpack lid to the overpack body. The storage overpack may be lifted with a lifting device that engages the anchor blocks with threaded studs and connects to a crane or similar equipment.

A bottom lift of the HI-STORM 100 storage overpack is affected by the insertion of four hydraulic jacks underneath the inlet vent horizontal plates (Figure 1.2.1). A slot in the overpack baseplate allows the hydraulic jacks to be placed underneath the inlet vent horizontal plate. The hydraulic jacks lift the loaded overpack to provide clearance for inserting or removing a device for transportation.

The standard design HI-TRAC transfer cask is equipped with two lifting trunnions and two pocket trunnions. The HI-TRAC 100G is equipped with two lifting trunnions, as well as two lower rotation trunnions. The HI-TRAC 100D and 125D are equipped with only lifting trunnions. The lifting trunnions for the standard HI-TRAC and the HI-TRAC 100D and 125D are positioned just below the top forging. The two pocket trunnions are located above the bottom forging and attached to the outer shell. Both pairs of trunnions on the HI-TRAC 100G pass through the water jacket shell, outer shell, and inner shell, with welds joining the trunnions to each interfacing shell. The pocket trunnions and lower HI-TRAC 100G trunnions are designed to allow rotation of the HI-TRAC. All trunnions are built from a high strength alloy with proven corrosion and non-galling characteristics. The lifting trunnions are designed in accordance with NUREG-0612 and Reg. Guide 3.61. The lifting trunnions for the standard HI-TRAC and HI-TRAC 100D & 125D are installed by threading into tapped holes just below the top forging.

The top of the MPC lid is equipped with four threaded holes that allow lifting of the loaded MPC. These holes allow the loaded MPC to be raised/lowered through the HI-TRAC transfer cask using lifting cleats. The threaded holes in the MPC lid are designed in accordance with NUREG-0612 and Reg. Guide 3.61.

1.2.1.5 Design Life

The design life of the HI-STORM 100 System is 40 years. This is accomplished by using material of construction with a long proven history in the nuclear industry and specifying materials known to withstand their operating environments with little to no degradation. A maintenance program, as specified in Chapter 9, is also implemented to ensure the HI-STORM 100 System will exceed its design life of 40 years. The design considerations that assure the HI-STORM 100 System performs

as designed throughout the service life include the following:

HI-STORM Overpack and HI-TRAC Transfer Cask

- Exposure to Environmental Effects
- Material Degradation
- Maintenance and Inspection Provisions

MPC

- Corrosion
- Structural Fatigue Effects
- Maintenance of Helium Atmosphere
- Allowable Fuel Cladding Temperatures
- Neutron Absorber Boron Depletion

The adequacy of the HI-STORM 100 System for its design life is discussed in Sections 3.4.11 and 3.4.12.

1.2.1.6 HI-DRIP Auxiliary Cooling System

The HI-DRIP auxiliary cooling system is designed to prevent the water in the loaded MPC from boiling during the interval after it has been lifted out of the fuel pool and prior to the evacuation of water and backfill of helium. Figure 1.2.19 provides an illustration of the HI-DRIP system.

HI-DRIP consists of a tubular ring that girdles the transfer cask above its main cylindrical body. The ring is equipped with small spray nozzles uniformly spaced around its circumference such that the entire circumference of the transfer cask shell can be drenched by the spray from them. The ring is connected to the plant's water supply with a gate valve serving to regulate the flow of water to the ring. The amount of water sprayed should be set such that the entire surface of the cask is wetted by gravity. While some of the water will evaporate, the residual water may be collected in a trough at the bottom of the cask equipped with a provision to drain it out to either the pool or the plant's drainage system. As long as the external surface of the transfer cask remains wet, the water in the canister will remain below boiling. It is noted that the operation of HI-DRIP does not require any pump or electric power; the motive pressure is provided entirely by the plant's water supply system.

1.2.1.7 Dry Ice Jacket (DIJ) Auxiliary Cooling System

For a high heat emitting MPC, a passive means to augment heat removal from the system consists of employing an engineered dry ice chiller ("Chiller") that surrounds all or a portion of the Water Jacket. The chiller's cylindrical external surface is positioned in close proximity (~2 inch) of the Water Jacket surface. The Chiller's outer surface is insulated so that virtually all of the sublimation of dry ice occurs by extracting the heat from the air surrounding the Cask's Water Jacket and by radiant heat delivered to it by the Cask's outer surface. The effect of the passive action Chiller is to lower the temperature of the ambient air adjacent to the Cask's surface and to provide an effective heat extraction means by radiation. The dimensions of the Chiller and the amount of dry ice will

depend on the rate of heat extraction required and the duration of the short-term operation and therefore, must be custom sized for each application. The DIJ can be used for short-term operations at a site. The DIJ can be used with a cask in a vertical, horizontal, or inclined orientation. Figures 1.2.20 and 1.2.21 show the Dry Ice Jacket in the vertical and horizontal orientations.

1.2.2 Operational Characteristics

1.2.2.1 Design Features

The HI-STORM 100 System incorporates some unique design improvements. These design innovations have been developed to facilitate the safe long term storage of SNF. Some of the design originality is discussed in Subsection 1.2.1 and below.

The free volume of the MPCs is inerted with 99.995% pure helium gas during the spent nuclear fuel loading operations. Table 1.2.2 specifies the helium fill requirements for the MPC internal cavity.

The HI-STORM overpack has been designed to synergistically combine the benefits of steel and concrete. The steel-concrete-steel construction of the HI-STORM overpack provides ease of fabrication, increased strength, and an optimal radiation shielding arrangement. The concrete is primarily provided for radiation shielding and the steel is primarily provided for structural functions.

The strength of concrete in tension and shear is conservatively neglected. Only the compressive strength of the concrete is accounted for in the analyses.

The criticality control features of the HI-STORM 100 are designed to maintain the neutron multiplication factor k -effective (including uncertainties and calculational bias) at less than 0.95 under all normal, off-normal, and accident conditions of storage as analyzed in Chapter 6. This level of conservatism and safety margins is maintained, while providing the highest storage capacity.

1.2.2.2 Sequence of Operations

Table 1.2.6 provides the basic sequence of operations necessary to defuel a spent fuel pool using the HI-STORM 100 System. The detailed sequence of steps for storage-related loading and handling operations is provided in Chapter 8 and is supported by the drawings in Section 1.5. A summary of the general actions needed for the loading and unloading operations is provided below. Figures 1.2.16 and 1.2.17 provide a pictorial view of typical loading and unloading operations, respectively.

Loading Operations

At the start of loading operations, the HI-TRAC transfer cask is configured with the pool lid installed. The HI-TRAC water jacket is filled with demineralized water or a 25% ethylene glycol solution depending on the ambient temperature conditions. The lift yoke is used to position HI-TRAC in the designated preparation area or setdown area for HI-TRAC inspection and MPC insertion. The annulus is filled with plant demineralized water, and an inflatable annulus seal is installed. The inflatable seal prevents contact between spent fuel pool water and the MPC shell reducing the possibility of contaminating the outer surfaces of the MPC. The MPC is then filled with water (borated if necessary). Based on the MPC model and fuel enrichment, this may be borated

water or plant demineralized water (see Section 2.1). HI-TRAC and the MPC are lowered into the spent fuel pool for fuel loading using the lift yoke. Pre-selected assemblies are loaded into the MPC and a visual verification of the assembly identification is performed.

While still underwater, a thick shielding lid (the MPC lid) is installed. The lift yoke is remotely engaged to the HI-TRAC lifting trunnions and is used to lift the HI-TRAC close to the spent fuel pool surface. As an ALARA measure, dose rates are measured on the top of the HI-TRAC and MPC prior to removal from the pool to check for activated debris on the top surface. The MPC lift bolts (securing the MPC lid to the lift yoke) are removed. As HI-TRAC is removed from the spent fuel pool, the lift yoke and HI-TRAC are sprayed with demineralized water to help remove contamination.

HI-TRAC is removed from the pool and placed in the designated preparation area. The top surfaces of the MPC lid and the upper flange of HI-TRAC are decontaminated. The inflatable annulus seal is removed, and an annulus shield is installed. The annulus shield provides additional personnel shielding at the top of the annulus and also prevents small items from being dropped into the annulus. The Automated Welding System baseplate shield (if used) is installed to reduce dose rates around the top of the cask. The MPC water level is lowered slightly and the MPC lid is seal-welded using the Automated Welding System (AWS) or other approved welding process. Liquid penetrant examinations are performed on the root and final passes. A multi-layer liquid penetrant or volumetric examination is also performed on the MPC lid-to-shell weld. The MPC water is displaced from the MPC by blowing pressurized helium or nitrogen gas into the vent port of the MPC, thus displacing the water through the drain line. At the appropriate time in the sequence of activities, appropriate non-destructive tests on the MPC Enclosure Vessel as set down in Chapter 9 are performed.

A Vacuum Drying System (VDS) may be used to remove moisture from the MPC cavity. For MPCs containing high burnup fuel, VDS drying operations are to be performed in cycles as described in Section 4.5.3.1. The VDS is connected to the MPC and is used to remove liquid water from the MPC in a stepped evacuation process. The stepped evacuation process is used to preclude the formation of ice in the MPC and Vacuum Drying System lines. The internal pressure is reduced and held for a duration to ensure that all liquid water has evaporated. This process is continued until the pressure in the MPC meets the technical specification limit and can be held there for the required amount of time.

As an option to VDS drying, the reduction of residual moisture in the MPC to trace amounts may be accomplished using a Forced Helium Dehydration (FHD) system, as described in Appendix 2.B. Relatively warm and dry helium is recirculated through the MPC cavity, which helps maintain the SNF in a cooled condition while moisture is being removed. The warm, dry gas is supplied to the MPC drain port and circulated through the MPC cavity where it absorbs moisture. The humidified gas travels out of the MPC and through appropriate equipment to cool and remove the absorbed water from the gas. The dry gas may be heated prior to its return to the MPC in a closed loop system to accelerate the rate of moisture removal in the MPC. This process is continued until the temperature of the gas exiting the demisting module described in Appendix 2.B meets the specified limit.

Following moisture removal, the MPC is backfilled with a predetermined amount of helium gas. The

helium backfill ensures adequate heat transfer during storage and provides an inert atmosphere for long-term fuel integrity. Cover plates are installed and seal-welded over the MPC vent and drain ports with liquid penetrant examinations performed on the root and final passes. The cover plates are helium leakage tested to confirm that they meet the established leakage rate criteria.

The MPC closure ring is then placed on the MPC, aligned, tacked in place, and seal welded, providing redundant closure of the MPC lid and cover plates confinement closure welds. Tack welds are visually examined, and the root and final welds are inspected using the liquid penetrant examination technique to ensure weld integrity. The annulus shield is removed and the remaining water in the annulus is drained. The AWS Baseplate shield is removed. The MPC lid and accessible areas of the top of the MPC shell are smeared for removable contamination and HI-TRAC dose rates are measured. The HI-TRAC top lid is installed and the bolts are torqued. The MPC lift cleats are installed on the MPC lid. The MPC lift cleats are the primary lifting point of the MPC.

Rigging is installed between the MPC lift cleats and the lift yoke. . The rigging supports the MPC within HI-TRAC while the pool lid is replaced with the transfer lid. For the standard design transfer cask, the HI-TRAC is manipulated to replace the pool lid with the transfer lid. The MPC lift cleats and rigging support the MPC during the transfer operations.

MPC transfer from the HI-TRAC transfer cask into the overpack may be performed inside or outside the fuel building. Similarly, HI-TRAC and HI-STORM may be transferred to the ISFSI in several different ways. The loaded HI-TRAC may be handled in the vertical or horizontal orientation. The loaded HI-STORM can only be handled vertically.

For MPC transfers inside the fuel building, the empty HI-STORM overpack is inspected and staged with the lid removed, the alignment device positioned, and, for the HI-STORM 100 overpack, the vent duct shield inserts installed. If using HI-TRAC 100D, 125D, or 100G, the HI-STORM mating device is placed (bolted if required by generic or site specific seismic evaluation) to the top of the empty overpack (Figure 1.2.18). The loaded HI-TRAC is placed using the fuel building crane on top of HI-STORM, or the mating device, as applicable. After the HI-TRAC is positioned atop the HI-STORM or positioned (bolted if required by generic or site specific seismic evaluation) atop the mating device, as applicable, the MPC is raised slightly. With the standard HI-TRAC design, the transfer lid door locking pins are removed and the doors are opened. With the HI-TRAC 100D, 125D, and 100G, the pool lid is removed using the mating device. The MPC is lowered into HI-STORM. Following verification that the MPC is fully lowered, slings are disconnected and lowered onto the MPC lid. For the HI-STORM 100, the doors are closed and the HI-TRAC is prepared for removal from on top of HI-STORM (with HI-TRAC 100D, 125D, and 100G, the transfer cask must first be disconnected from the mating device). For the HI-STORM 100S and HI-STORM 100S Version B, the standard design HI-TRAC may need to be lifted above the overpack to a height sufficient to allow closure of the transfer lid doors without interfering with the MPC lift cleats. The HI-TRAC is then removed and placed in its designated storage location. The MPC lift cleats and slings are removed from atop the MPC. The alignment device, vent duct shield inserts, and/or mating device is/are removed, as applicable. The pool lid is removed from the mating device and re-attached to the HI-TRAC 100D, 125D, or 100G prior to its next use. The HI-STORM lid is installed, and the upper vent screens and gamma shield cross plates are installed. The HI-STORM lid studs are installed and torqued.

For MPC transfers outside of the fuel building, the empty HI-STORM overpack is inspected and staged with the lid removed, the alignment device positioned, and, for the HI-STORM 100, the vent duct shield inserts installed. For HI-TRAC 100D, 125D, and 100G, the mating device is positioned (bolted if required by generic or site specific seismic evaluation) atop the overpack. The loaded HI-TRAC is transported to the cask transfer facility in the vertical or horizontal orientation. A number of methods may be utilized as long as the handling limitations prescribed in the technical specifications are not exceeded.

To place the loaded HI-TRAC in a horizontal orientation, a transport frame or “cradle” is utilized. If the cradle is equipped with rotation features, they are used to engage the HI-TRAC 100 or 125 pocket trunnions or the HI-TRAC 100G lower trunnions. While the loaded HI-TRAC is lifted by the lifting trunnions, the HI-TRAC is lowered onto the cradle rotation features. Then, the crane lowers and the HI-TRAC pivots around the pocket/lower trunnions and is placed in the horizontal position in the cradle.

The HI-TRAC 100D and 125D do not include pocket or lower trunnions in their designs. Therefore, the user must downend the transfer cask onto the transport frame using appropriately designed rigging in accordance with the site’s heavy load control program.

If the loaded HI-TRAC is transferred to the cask transfer facility in the horizontal orientation, the HI-TRAC transport frame and/or cradle are placed on a transport vehicle. The transport vehicle may be an air pad, railcar, heavy-haul trailer, dolly, etc. If the loaded HI-TRAC is transferred to the cask transfer facility in the vertical orientation, the HI-TRAC may be lifted by the lifting trunnions or seated on the transport vehicle. During the transport of the loaded HI-TRAC, standard plant heavy load handling practices shall be applied including administrative controls for the travel path and tie-down mechanisms.

For MPCs containing any HBF and a decay heat load that would yield a peak HBF cladding temperature above the short-term temperature limit, the Supplemental Cooling System (SCS) is required to be operational during the time the loaded and backfilled MPC is in HI-TRAC to ensure fuel cladding temperatures remain within limits. The SCS is discussed in detail in Section 4.5 and the design criteria for the system are provided in Appendix 2.C. The SCS is not required when the MPC is inside the HI-STORM overpack, regardless of decay heat load.

After the loaded HI-TRAC arrives at the cask transfer facility, the HI-TRAC is upended by a crane if the HI-TRAC is in a horizontal orientation. The loaded HI-TRAC is then placed, using the crane located in the transfer area, on top of HI-STORM, which has been inspected and staged with the lid removed, vent duct shield inserts installed, the alignment device positioned, and the mating device installed, as applicable.

After the HI-TRAC is positioned atop the HI-STORM or the mating device, the MPC is raised slightly. In the standard design, the transfer lid door locking pins are removed and the doors are opened. With the HI-TRAC 100D, 125D, and 100G, the pool lid is removed using the mating device. The MPC is lowered into HI-STORM. Following verification that the MPC is fully lowered, slings are disconnected and lowered onto the MPC lid. For the HI-STORM 100, the doors are closed and

HI-TRAC is removed from on top of HI-STORM or disconnected from the mating device, as applicable. For the HI-STORM 100S and the HI-STORM 100S Version B, the standard design HI-TRAC may need to be lifted above the overpack to a height sufficient to allow closure of the transfer lid doors without interfering with the MPC lift cleats. The HI-TRAC is then removed and placed in its designated storage location. The MPC lift cleats and slings are removed from atop the MPC. The alignment device, vent duct shield inserts, and mating device is/are removed, as applicable. The pool lid is removed from the mating device and re-attached to the HI-TRAC 100D, 125D, or 100G prior to its next use. The HI-STORM lid is installed, and the upper vent screens and gamma shield cross plates are installed. The HI-STORM lid studs and nuts are installed.

After the HI-STORM has been loaded either within the fuel building or at a dedicated cask transfer facility, the HI-STORM is then moved to its designated position on the ISFSI pad. The HI-STORM overpack may be moved using a number of methods as long as the handling limitations listed in the technical specifications are not exceeded. The loaded HI-STORM must be handled in the vertical orientation, and may be lifted from the top by the anchor blocks or from the bottom by the inlet vents. After the loaded HI-STORM is lifted, it may be placed on a transport mechanism or continue to be lifted by the lid studs and transported to the storage location. The transport mechanism may be an air pad, crawler, railcar, heavy-haul trailer, dolly, etc. During the transport of the loaded HI-STORM, standard plant heavy load handling practices shall be applied including administrative controls for the travel path and tie-down mechanisms. Once in position at the storage pad, vent operability testing is performed to ensure that the system is functioning within its design parameters.

In the case of HI-STORM 100A, the anchor studs are installed and fastened into the anchor receptacles in the ISFSI pad in accordance with the design requirements.

Unloading Operations

The HI-STORM 100 System unloading procedures describe the general actions necessary to prepare the MPC for unloading, cool the stored fuel assemblies in the MPC, flood the MPC cavity, remove the lid welds, unload the spent fuel assemblies, and recover HI-TRAC and empty the MPC. Special precautions are outlined to ensure personnel safety during the unloading operations, and to prevent the risk of MPC overpressurization and thermal shock to the stored spent fuel assemblies.

The MPC is recovered from HI-STORM either at the cask transfer facility or the fuel building using any of the methodologies described in Section 8.1. The HI-STORM lid is removed, the alignment device positioned, and, for the HI-STORM 100, the vent duct shield inserts are installed, and the MPC lift cleats are attached to the MPC. For HI-TRAC 100D, 125D, and 100G, the mating device is installed. Rigging is attached to the MPC lift cleats. For the HI-STORM 100S and HI-STORM 100S Version B with the standard HI-TRAC design, the transfer doors may need to be opened to avoid interfering with the MPC lift cleats. For the HI-TRAC 100D, 125D, and 100G, the mating device (possibly containing the pool lid) is secured to the top of the overpack. HI-TRAC is raised and positioned on top of HI-STORM or bolted (if necessary) to the mating device, as applicable. For the HI-TRAC 100D, 125D, and 100G, the pool lid is ensured to be out of the transfer path for the MPC. The MPC is raised into HI-TRAC. Once the MPC is raised into HI-TRAC, the standard design HI-TRAC transfer lid doors are closed and the locking pins are installed. For the HI-TRAC 100D, 125D, and 100G, the pool lid is installed and the transfer cask is unsecured from the mating device.

HI-TRAC is removed from on top of HI-STORM. As required based on the presence of high burnup fuel and the decay heat load, the Supplemental Cooling System is installed and placed into operation.

The HI-TRAC is brought into the fuel building and, for the standard design, manipulated for bottom lid replacement. The transfer lid is replaced with the pool lid. The MPC lift cleats and rigging support the MPC during lid transfer operations.

HI-TRAC and its enclosed MPC are returned to the designated preparation area and the rigging, MPC lift cleats, and HI-TRAC top lid are removed. The annulus is filled with plant demineralized water (borated, if necessary). The annulus and HI-TRAC top surfaces are protected from debris that will be produced when removing the MPC lid.

The MPC closure ring and vent and drain port cover plates are core drilled. Local ventilation is established around the MPC ports. The RVOAs are attached to the vent and drain port. The RVOAs allow access to the inner cavity of the MPC, while providing a hermetic seal. The MPC is flooded with borated or unborated water, as required. The MPC lid-to-MPC shell weld is removed. Then, all weld removal equipment is removed with the MPC lid left in place.

The MPC lid is rigged to the lift yoke and the lift yoke is engaged to HI-TRAC lifting trunnions. If weight limitations require, the neutron shield jacket is drained. HI-TRAC is placed in the spent fuel pool and the MPC lid is removed. All fuel assemblies are returned to the spent fuel storage racks and the MPC fuel cells are vacuumed to remove any assembly debris. HI-TRAC and MPC are returned to the designated preparation area where the MPC water is removed. The annulus water is drained and the MPC and HI-TRAC are decontaminated in preparation for re-utilization.

1.2.2.3 Identification of Subjects for Safety and Reliability Analysis

1.2.2.3.1 Criticality Prevention

Criticality is controlled by geometry and neutron absorbing materials in the fuel basket. The MPC-24/24E/24EF (all with lower enriched fuel) and the MPC-68/68F/68FF do not rely on soluble boron credit during loading or the assurance that water cannot enter the MPC during storage to meet the stipulated criticality limits.

Each MPC model is equipped with neutron absorber plates affixed to the fuel cell walls as shown on the drawings in Section 1.5. The minimum ^{10}B areal density specified for the neutron absorber in each MPC model is shown in Table 1.2.2. These values are chosen to be consistent with the assumptions made in the criticality analyses.

The MPC-24, MPC-24E and 24EF (all with higher enriched fuel) and the MPC-32 and MPC-32F take credit for soluble boron in the MPC water for criticality prevention during wet loading and unloading operations. Boron credit is only necessary for these PWR MPCs during loading and unloading operations that take place under water. During storage, with the MPC cavity dry and sealed from the environment, criticality control measures beyond the fixed neutron poisons affixed to the storage cell walls are not necessary because of the low reactivity of the fuel in the dry, helium filled canister and the design features that prevent water from intruding into the canister during

storage.

1.2.2.3.2 Chemical Safety

There are no chemical safety hazards associated with operations of the HI-STORM 100 dry storage system. A detailed evaluation is provided in Section 3.4.

1.2.2.3.3 Operation Shutdown Modes

The HI-STORM 100 System is totally passive and consequently, operation shutdown modes are unnecessary. Guidance is provided in Chapter 8, which outlines the HI-STORM 100 unloading procedures, and Chapter 11, which outlines the corrective course of action in the wake of postulated accidents.

1.2.2.3.4 Instrumentation

As stated earlier, the HI-STORM 100 confinement boundary is the MPC, which is a high integrity pressure vessel designed and constructed to be *leak tight* as discussed in Chapter 7. The HI-STORM 100 is a completely passive system with appropriate margins of safety; therefore, it is not necessary to deploy any instrumentation to monitor the cask in the storage mode. At the option of the user, temperature elements may be utilized to monitor the air temperature of the HI-STORM overpack exit vents in lieu of routinely inspecting the ducts for blockage. See Subsection 2.3.3.2 for additional details.

1.2.2.3.5 Maintenance Technique

Because of their passive nature, the HI-STORM 100 System requires minimal maintenance over its lifetime. No special maintenance program is required. Chapter 9 describes the acceptance criteria and maintenance program set forth for the HI-STORM 100.

1.2.3 Cask Contents

The HI-STORM 100 System is designed to house different types of MPCs. The MPCs are designed to store both BWR and PWR spent nuclear fuel assemblies. Tables 1.2.1 and 1.2.2 provide key system data and parameters for the MPCs. A description of acceptable fuel assemblies for storage in the MPCs is provided in Section 2.1. This includes fuel assemblies classified as damaged fuel assemblies and fuel debris in accordance with the definitions of these terms in the glossary. A summary of the types of fuel authorized for storage in each MPC model is provided below. All fuel assemblies, non-fuel hardware, and neutron sources must meet the fuel specifications provided in Section 2.1. All fuel assemblies classified as damaged fuel or fuel debris must be stored in damaged fuel containers, except damaged fuel meeting the criteria specified below may be stored using Damaged Fuel Isolators (DFIs) (see Figure 2.1.10) when stored in allowed locations. DFIs may be used with damaged fuel assemblies that may have missing or partial fuel rods and/or fuel rods with known or suspected cladding defects greater than hairline cracks or pinhole leaks as long as the fuel assembly can be handled by normal means and where structural integrity is such that geometric rearrangement of fuel is not expected. Damaged fuel that does not meet these conditions must be

stored in a DFC.

MPC-24

The MPC-24 is designed to accommodate up to twenty-four (24) PWR fuel assemblies classified as intact fuel assemblies, with or without non-fuel hardware.

MPC 24E and MPC-24EF

The MPC-24E and MPC-24EF are designed to accommodate up to twenty-four (24) PWR fuel assemblies, with or without non-fuel hardware. Up to four (4) fuel assemblies may be classified as damaged fuel assemblies or fuel debris, with the balance being classified as intact fuel assemblies. Damaged fuel assemblies and fuel debris must be stored in fuel storage locations 3, 6, 19, and/or 22 (see Figure 1.2.4).

MPC-32 and MPC-32F

The MPC-32 and MPC-32F are designed to store up to thirty two (32) PWR fuel assemblies with or without non-fuel hardware. Up to eight (8) of these assemblies may be classified as damaged fuel assemblies or fuel debris, with the balance being classified as intact fuel assemblies. Damaged fuel assemblies and fuel debris must be stored in fuel storage locations 1, 4, 5, 10, 23, 28, 29, and/or 32 (see Figure 1.2.3).

MPC-68F

The MPC-68F is designed to accommodate up to sixty-eight (68) Dresden Unit 1 or Humboldt Bay BWR fuel assemblies (with or without channels) made up of any combination of fuel assemblies classified as intact fuel assemblies, damaged fuel assemblies, and up to four (4) fuel assemblies classified as fuel debris.

MPC-68 and MPC-68FF

The MPC-68 and MPC-68FF are designed to accommodate up to sixty-eight (68) BWR fuel assemblies with or without channels. Any number of these fuel assemblies may be Dresden Unit 1 or Humboldt Bay BWR fuel assemblies classified as intact fuel or damaged fuel. Dresden Unit 1 and Humboldt Bay fuel debris is limited to eight (8) DFCs. DFCs containing Dresden Unit 1 or Humboldt Bay fuel debris may be stored in any fuel storage location. For BWR fuel assemblies from plants other than Dresden Unit 1 and Humboldt Bay, the total number of fuel assemblies classified as damaged fuel assemblies or fuel debris is limited to sixteen (16), with up to eight (8) of the 16 fuel assemblies classified as fuel debris. These fuel assemblies must be stored in fuel storage locations 1, 2, 3, 8, 9, 16, 25, 34, 35, 44, 53, 60, 61, 66, 67, and/or 68 (see Figure 1.2.2). The balance of the fuel storage locations may be filled with intact BWR fuel assemblies,

up to a total of 68.

Table 1.2.1

KEY SYSTEM DATA FOR HI-STORM 100 SYSTEM

ITEM	QUANTITY	NOTES
Types of MPCs	8	5 for PWR 3 for BWR
MPC storage capacity [†] :	MPC-24 MPC-24E MPC-24EF	Up to 24 intact ZR or stainless steel clad PWR fuel assemblies with or without non-fuel hardware. Up to four damaged fuel assemblies and/or fuel assemblies classified as fuel debris may be stored in the MPC-24E or MPC-24EF
	MPC-32 MPC-32F	OR Up to 32 intact ZR or stainless steel clad PWR fuel assemblies with or without non-fuel hardware. Up to 8 damaged fuel assemblies and/or fuel assemblies classified as fuel debris may be stored in the MPC-32 or MPC-32F.

[†] See Section 2.1 for a complete description of authorized cask contents and fuel specifications.

KEY SYSTEM DATA FOR HI-STORM 100 SYSTEM

ITEM	QUANTITY	NOTES
MPC storage capacity:	MPC-68F	Up to 4 damaged fuel containers with ZR clad Dresden Unit 1 (D-1) or Humboldt Bay (HB) BWR fuel debris and the complement damaged ZR clad Dresden Unit 1 or Humboldt Bay BWR fuel assemblies in damaged fuel containers or intact Dresden Unit 1 or Humboldt Bay BWR intact fuel assemblies.
	MPC-68	OR
	MPC-68FF	Up to 68 Dresden Unit 1 or Humboldt Bay intact fuel or damaged fuel and up to 8 damaged fuel containers containing D-1 or HB fuel debris. For other BWR plants, up to 16 damaged fuel containers containing BWR damaged fuel and/or fuel debris with the complement intact fuel assemblies, up to a total of 68. The number of damaged fuel containers containing BWR fuel debris is limited to eight (8) for all BWR plants.

Table 1.2.2

KEY PARAMETERS FOR HI-STORM 100 MULTI-PURPOSE CANISTERS

	PWR	BWR
Pre-disposal service life (years)	40	40
Design temperature, max./min. (°F)	725 ^{o†} /-40 ^{o††}	725 ^{o†} /-40 ^{o††}
Design internal pressure (psig)		
Normal conditions	100	100
Off-normal/Short-term conditions	110	110
Accident Conditions	200	200
Total heat load, max. (kW) ^{††††}	36.9	36.9
Maximum permissible peak fuel cladding temperature:		
Long Term Normal (°F)	752	752
Short Term Operations (°F)	752 or 1058 ^{†††}	752 or 1058 ^{†††}
Off-normal and Accident (°F)	1058	1058

† Maximum normal condition design temperatures for the MPC fuel basket. A complete listing of design temperatures for all components is provided in Table 2.2.3.

†† Temperature based on off-normal minimum environmental temperatures specified in Section 2.2.2.2 and no fuel decay heat load.

††† See Section 4.5 for discussion of the applicability of the 1058°F temperature limit during MPC drying.

†††† Maximum heat load shown is for regionalized loading.

KEY PARAMETERS FOR HI-STORM 100 MULTI-PURPOSE CANISTERS

NOTE:

1. All MPC-68F canisters are equipped with Boral neutron absorber.
2. Refer to Section 4.4.5.1 for detailed information on heat load values.

Table 1.2.6

HI-STORM 100 OPERATIONS SEQUENCE

Site-specific handling and operations procedures will be prepared, reviewed, and approved by each owner/user.	
1	HI-TRAC and MPC lowered into the fuel pool without lids
2	Fuel assemblies transferred into the MPC fuel basket
3	MPC lid lowered onto the MPC
4	HI-TRAC/MPC assembly moved to the decon pit and MPC lid welded in place, volumetrically or multi-layer PT examined, and pressure and leakage tested
5	MPC dewatered, moisture removed, backfilled with helium, and the closure ring welded
6	HI-TRAC annulus drained and external surfaces decontaminated
7	MPC lifting cleats installed and MPC weight supported by rigging
8	HI-TRAC pool lid removed and transfer lid attached (not applicable to HI-TRAC 100D, 125D, or 100G)
9	MPC lowered and seated on HI-TRAC transfer lid (not applicable to HI-TRAC 100D, 125D, or 100G)
9a	HI-STORM mating device secured to top of empty HI-STORM overpack (HI-TRAC 100D, 125D, and 100G only)
10	HI-TRAC/MPC assembly transferred to atop the HI-STORM overpack or mating device, as applicable
11	MPC weight supported by rigging and transfer lid doors opened (standard design HI-TRAC) or pool lid removed (HI-TRAC 100D, 125D, and 100G)
12	MPC lowered into HI-STORM overpack, and HI-TRAC removed from atop the HI-STORM overpack/mating device
12a	HI-STORM mating device removed (HI-TRAC 100D, 125D, and 100G only)
13	HI-STORM overpack lid installed and bolted in place
14	HI-STORM overpack placed in storage at the ISFSI pad
15	For HI-STORM 100A (or 100SA) users, the overpack is anchored to the ISFSI pad by installation of nuts onto studs and torquing to the minimum required torque.

17Cr-4Ni-4Cu	SA-564	630 (H-1100)	140	115	
17Cr-4Ni-4Cu	SA-564	630 (H-1075)	145	125	
25Ni-15Cr-2Ti	SA-638	660	130	85	
22CR-13Ni-5Mn	SA-479	XM-19 (S20910)	135	105	

Note: The materials listed in this table are representative of acceptable materials and have been abstracted from the ASME Code, Section II, Part D, Table 3. Other materials listed in the Code are also acceptable as long as they meet the size requirements, the minimum requirements on yield and ultimate strength (see Table 2.0.4), and are suitable for the environment.

[†] Nominal diameter of the bolt (or rod) as listed in the Code tables. Two-inch diameter studs/rods are specified for the HI-STORM 100A.

Table 1.2.8

METAMIC[®] DATA FOR HOLTEC MPCs

MPC Type	Min. B-10 areal density required by criticality analysis (g/cm ²)	Nominal Weight Percent of B ₄ C and Reference <i>METAMIC</i> [®] Panel Thickness			
		100% Credit	90% Credit	75% Credit	Ref. Thickness (inch) (see note)
MPC-24	0.020	27.6	31	37.2	0.075
MPC-68, -68FF, -32, -32F, -24E, and -24EF	0.0279	27.8	31	37.4	0.104

Note: The drawings in Section 1.5 show slightly larger thickness to ensure that the minimum B-10 areal density is conservative under all conditions.

1.3 IDENTIFICATION OF AGENTS AND CONTRACTORS

This section contains the necessary information to fulfill the requirements pertaining to the qualifications of the applicant pursuant to 10 CFR72.2(a)(1),(b) and 72.230(a). Holtec International, based in Marlton, NJ and Jupiter Florida is the system designer and applicant for certification of the HI-STORM 100 system.

Holtec International is an engineering technology company with a principal focus on the power industry. Holtec International Nuclear Power Division (NPD) specializes in spent fuel storage technologies. NPD has carried out turnkey wet storage capacity expansions (engineering, licensing, fabrication, removal of existing racks, performance of underwater modifications, volume reduction of the old racks and hardware, installation of new racks, and commissioning of the fuel pool for increased storage capacity) in numerous nuclear plants around the world. Over 90 plants in the U.S., Britain, Brazil, Korea, Mexico, China and Taiwan have utilized the Company's wet storage technology to establish their state-of-the-art in-pool storage capacities.

Holtec's NPD is also a turnkey provider of dry storage and transportation technologies to nuclear plants around the globe. The company is contracted by over 50 nuclear plants in the U.S. to provide the company's vertical ventilated dry storage technology. Utilities in Belgium, China, Korea, Mexico, Spain, Sweden, Ukraine, the United Kingdom and Switzerland are also active users of Holtec International's dry storage and transport systems.

Four U.S. commercial plants, namely, Dresden Unit 1, Trojan, Indian Point Unit 1, and Humboldt Bay have thus far been completely defueled using Holtec International's technology. For many of its dry storage clients, Holtec International provides all phases of dry storage including: the required site-specific safety evaluations; ancillary designs; manufacturing of all capital equipment; preparation of site construction procedures; personnel training; dry runs; and fuel loading. The USNRC dockets in parts 71 and 72 currently maintained by the Company are listed in Table 1.3.1. Holtec International's corporate engineering consists of professional engineers and experts with extensive experience in every discipline germane to the fuel storage technologies, namely structural mechanics, heat transfer, computational fluid dynamics, and nuclear physics. Virtually all engineering analyses for Holtec's fuel storage projects (including the HI-STORM UMAX and HI-STORM FW systems) are carried out by the company's full-time staff. The Company is actively engaged in a continuous improvement program of the state-of-the-art in dry storage and transport of spent nuclear fuel. The active patents and patent applications in the areas of dry storage and transport of SNF held by the Company (ca. October 2015) are listed in Table 1.3.2.

Holtec International's quality assurance (QA) program was originally developed to meet NRC requirements delineated in 10CFR50 Appendix B, and was expanded to include provisions of 10CFR71 Subpart H, and 10CFR72, Subpart G, for structures, systems, and components designated as important to safety. The Holtec quality assurance program, which satisfies all 18 criteria in 10CFR72, Subpart G, that apply to the design, fabrication, construction, testing, operation, modification, and decommissioning of structures, systems, and components important to safety is incorporated by reference into this FSAR. Holtec International's QA program has been certified by the USNRC (Certificate No. 71-0784).

The HI-STORM System will be fabricated by the Holtec International Manufacturing Division (HMD) located in Pittsburgh, Pennsylvania with subcontract services from the NPD- affiliated plant, Orrvilon in Orrville, Ohio. HMD is a long-term ASME N-Stamp holder and fabricator of nuclear components. In particular, HMD has been manufacturing HI-STORM and HI-STAR system components since the inception of Holtec International's dry storage and transportation program in the 1990s. HMD routinely manufactures ASME code components for use in the U.S. and overseas nuclear plants. Holtec International's engineering organization, based in Marlton, NJ and the HMD subsidiary in Pittsburgh, PA have been subject to triennial inspections by the USNRC. If another fabricator is to be used for the fabrication of any part of the HI-STORM 100 System, the proposed fabricator will be evaluated and audited in accordance with Holtec International's QA program approved by the USNRC.

Holtec International's Nuclear Power Division (NPD) also carries out site services for dry storage deployments at nuclear power plants. Several nuclear plants, such as Trojan, Waterford 3, Pilgrim and Comanche Peak have deployed dry storage at their sites using a turnkey contract with Holtec International.

Table 1.3.1

USNRC DOCKETS ASSIGNED TO HOLTEC INTERNATIONAL

System Name	Docket Number
HI-STORM 100 (Storage)	72-1014
HI-STAR 100 (Storage)	72-1008
HI-STAR 100 (Transportation)	71-9261
HI-STAR 180 (Transportation)	71-9325
HI-STAR 60 (Transportation)	71-9336
Holtec Quality Assurance Program	71-0784
HI-STORM FW (Storage)	72-1032
HI-STORM UMAX	72-1040
HI-STAR 80 (Transportation)	71-9374
HI-STAR 330 (ATB-1T) (Transportation)	71-9375

1.4 GENERIC CASK ARRAYS

The HI-STORM 100 System is stored in a vertical configuration. The required center-to-center spacing between the modules (layout pitch) is guided by operational considerations. Tables 1.4.1 and 1.4.2 provide the nominal layout pitch information. Site-specific pitches are determined by practical operation with supporting heat transfer calculations in Chapter 4. The pitch values in Tables 1.4.1 and 1.4.2 are nominal and may be varied to suit the user's specific needs.

Table 1.4.1 provides recommended cask spacing data for array(s) of two by N casks. The pitch between adjacent rows of casks and between each adjacent column of casks are denoted by P_1 and P_2 in Table 1.4.1. There may be an unlimited number of rows. The distance between adjacent arrays of two by N casks (P_3) shall be as specified in Table 1.4.1. See Figure 1.4.1 for further clarification. The pattern of required pitches and distances may be repeated for an unlimited number of columns.

For a square array of casks the pitch between adjacent casks may be in accordance with Table 1.4.2. See Figure 1.4.2 for further clarification. The data in Table 1.4.2 provide nominal values for large ISFSIs (i.e., those with hundreds of casks in a uniform layout), where access of feed air to the centrally located casks may become a matter of thermal consideration. From a thermal standpoint, regardless of the size of the ISFSI, the casks should be arrayed in such a manner that the tributary area for each cask (open ISFSI area attributable to a cask) is a minimum of 225 ft². For specific sites, a smaller tributary area can be utilized after appropriate thermal evaluations for the site-specific conditions are performed.

Table 1.4.1

CASK LAYOUT PITCH DATA FOR 2 BY N ARRAYS

Orientation	Nominal Cask Pitch (ft.)
Between adjacent rows, P1, and adjacent columns, P2	13.5
Between adjacent sets of two columns, P3	38

Table 1.4.2

CASK LAYOUT PITCH DATA FOR SQUARE ARRAYS

Orientation	Nominal Cask Pitch (ft.)
Between adjacent casks	18' - 8"

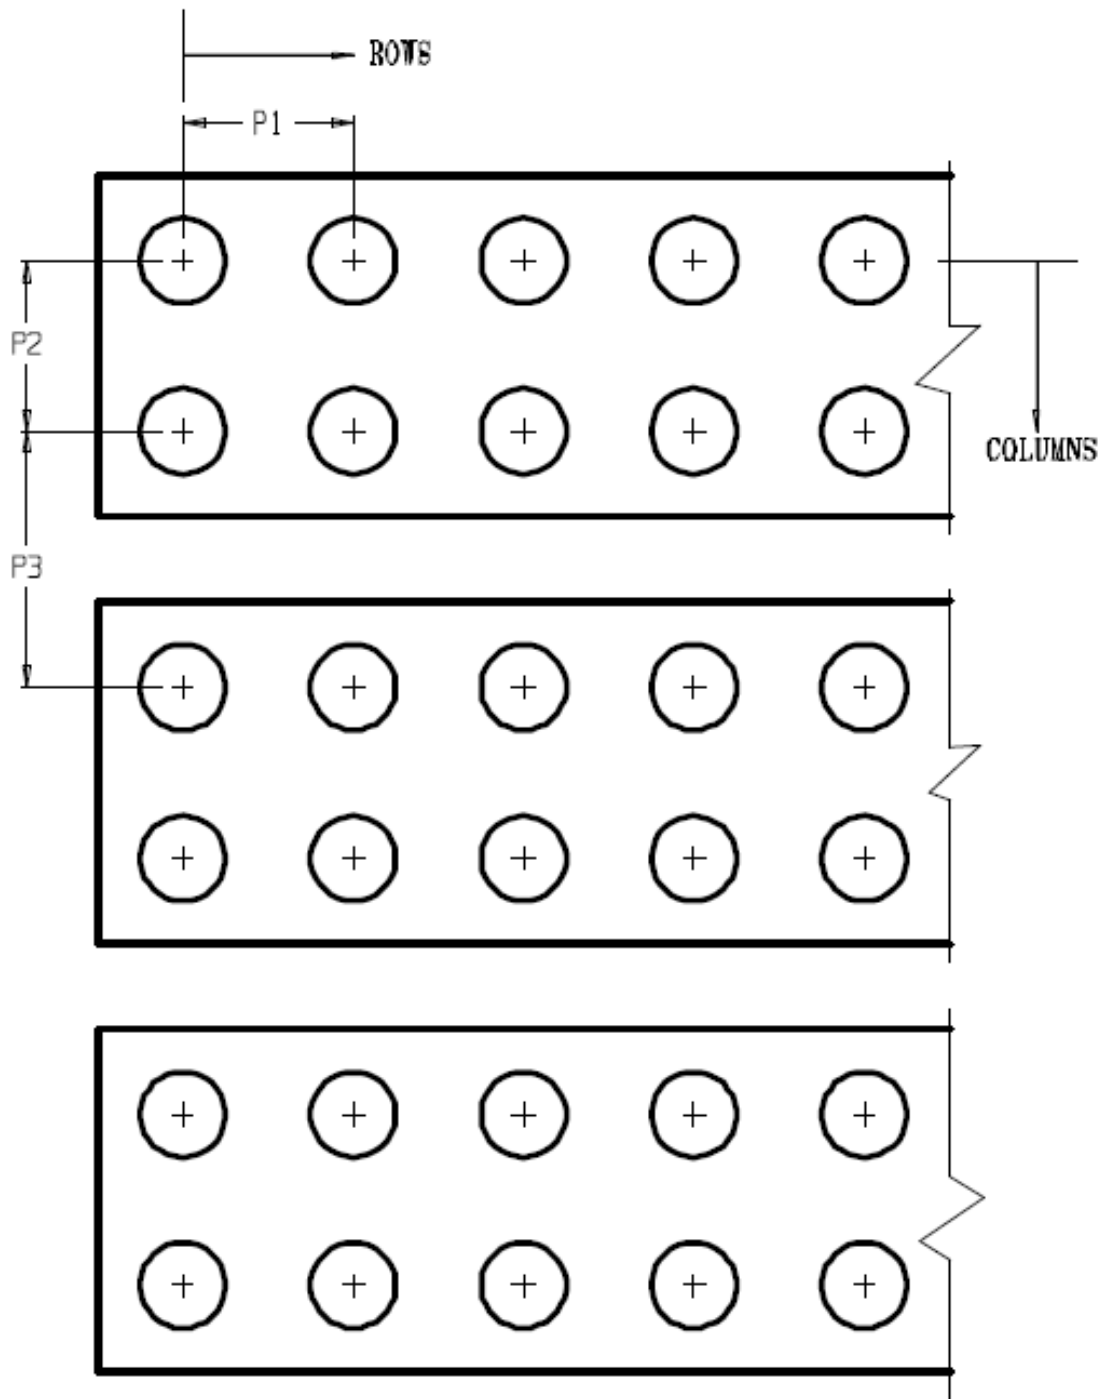

FIGURE 1.4.1: CASK LAYOUT PITCH REQUIREMENTS BASED ON 2 BY N ARRAY(S)

FIGURE 1.4.2: CASK LAYOUT PITCH REQUIREMENTS BASED ON A SQUARE ARRAY

APPENDIX 1.A: ALLOY X DESCRIPTION

1.A ALLOY X DESCRIPTION

1.A.1 Alloy X Introduction

Alloy X is used within this licensing application to designate a group of stainless steel alloys. Alloy X can be any one of the following alloys:

- Type 316
- Type 316LN
- Type 304
- Type 304LN
- Duplex Stainless Alloy S31803 [1.A.3]

Qualification of structures made of Alloy X is accomplished by using the least favorable mechanical and thermal properties of the entire group for all MPC mechanical, structural, neutronic, radiological, and thermal conditions. The Alloy X approach is conservative because no matter which material is ultimately utilized, the Alloy X approach guarantees that the performance of the MPC will meet or exceed the analytical predictions.

Duplex stainless steels (DSS) are sensitive to the manufacturing processes employed in welding operations. Control of microstructure stability plays a vital role. The intermetallic microstructure is a complex function of the attendant parameters. For example, Cr and Mo promote ferrite and intermetallic phases, whereas N and Ni promote austenite.

During welding the balance between the ferritic and austenitic phases may be disturbed due to ferritization at high temperatures associated with welding operations. Ferrite content over 70% will lead to lower ductility and reduced corrosion resistance. Coarse ferritic grains are harmful for DSS toughness besides of impairing the austenite reformation at the heat affected zone (HAZ) [1.A.5]. The best metallurgical condition for welding is achieved by the most rapid quenching from the annealing temperature that produces a fine grained DSS structure with the required ferrite content (less than 70%).

Besides the austenite-ferrite phase balance, the second major concern with duplex steels and their chemical composition is the formation of detrimental intermetallic phases, precipitating preferentially in the ferrite, at elevated temperatures in the range of approximately 600 - 1750°F reaching an uncertain state of fragility at 887°F [1.A.4] and above. The mechanical (toughness) and corrosion properties of the weld and HAZ are deteriorated due to the presence of intermetallic phases.

Welding of DSS is associated with problems in HAZ which can be loss of corrosion, toughness, or post-weld cracking. The heat input and cooling rates in welding are important as they control ferrite to austenite transformation. Exceedingly low heat input may result in fusion zones and HAZ which are excessively ferritic (above 70%) [1.A.6]. Exceedingly high heat input increases

the danger of forming intermetallic phases [1.A.6]. In both cases the impact toughness and corrosion resistance of the DSS will be seriously affected. Hence, heat input must be 0.6 – 2.6 kJ/mm to retain the phase balance, limit the width of the HAZ, and obtain a sigma phase free product [1.A.5]. Further, cooling rate from the solution annealing temperature must exceed 0.3°C/s to avoid sigma phase and satisfy the generally accepted toughness requirements [1.A.8]. The maximum interpass temperature is limited to 150°C (302°F) [1.A.6].

DSS have chloride stress corrosion cracking (CSCC) resistance significantly greater than that of the austenitic stainless steels, but they are not completely immune. Experimental results indicate that DSS is prone to stress corrosion cracking at temperatures above 100°C [1.A.9]. Poor welding practice, a low pH, presence of Hydrogen in welds, and/or high ferrite (>70%) can contribute to failures at temperatures below 100°C.

Holtec will make sure that this material shall be used *only* if the metal temperature of the MPC shell can be assured to remain below the limit in Table 1.A.6 under all *normal operating* modes [1.A.3]. Likewise, under short term and accident conditions, such as the “inlet duct blockage” scenario, the maximum metal temperature of duplex stainless steel must be held below the limit in Table 1.A.6.

To confirm that the required properties are achieved in production, Holtec will implement a test program to insure that the weldments are tested for the absence of detrimental intermetallic phases. The test program will comply with ASTM A923 and will use metallographic examination, impact testing and corrosion testing to demonstrate the absence of such detrimental phases. The test will be intended to determine the presence or absence of intermetallic phase to the extent that it is detrimental to the toughness and corrosion resistance of the material. The test *shall* be implemented to products during weld procedure qualification as well as during fabrication which will provide the assurance that the weldments are *free* from detrimental intermetallic phases, and *provide* the required corrosion resistance and fracture toughness [1.A.7].

It is noted that DSS material shall not be used for the fabrication of MPC baskets and MPC internal components. For other stainless steels listed as members of Alloy X above, the design temperature limits in Table 2.2.3 remain unmodified. It is also noted that DSS shall be used only in aboveground systems.

This appendix defines the least favorable material properties of Alloy X.

1.A.2 Alloy X Common Material Properties

Several material properties do not vary significantly from one Alloy X constituent to the next. These common material properties are as follows:

- density
- specific heat
- Young's Modulus (Modulus of Elasticity)
- Poisson's Ratio

The comparative values for Modulus of Elasticity at different temperatures are provided in Table 1.A.7. The values utilized for this licensing application are provided in their appropriate chapters.

1.A.3 Alloy X Least Favorable Material Properties

The following material properties vary between the Alloy X constituents:

- Design Stress Intensity (S_m)
- Tensile (Ultimate) Strength (S_u)
- Yield Strength (S_y)
- Coefficient of Thermal Expansion (α)
- Coefficient of Thermal Conductivity (k)

Each of these material properties are provided in the ASME Code Section II [1.A.10]. Tables 1.A.1 through 1.A.5 provide the ASME Code values for each constituent of Alloy X along with the least favorable value utilized in this licensing application. The ASME Code only provides values from -20°F. The design temperature of the MPC is -40°F, below -20°F, as stated in Table 1.2.2. Most of the above-mentioned properties improve as the temperature drops. For this reason, the values at the lowest design temperature for the HI-STORM 100 System have been assumed to be equal to the lowest value stated in the ASME Code. The lone exceptions are the coefficient of thermal expansion and thermal conductivity. As they decrease with decreasing temperature, its value for -40°F is linearly extrapolated from the 70°F value with the slope based on data from 70°F to 100°F.

The Alloy X material properties are the minimum values of the group for the design stress intensity, tensile strength, yield strength, and coefficient of thermal conductivity. Using minimum values of design stress intensity is conservative because lower design stress intensities lead to lower allowables that are based on design stress intensity. Similarly, using minimum values of tensile strength and yield strength is conservative because lower values of tensile strength and yield strength lead to lower allowables that are based on tensile strength and yield strength. When compared to calculated values, these lower allowables result in factors of safety that are conservative for any of the constituent materials of Alloy X. Using the minimum value of thermal conductivity has the effect of reducing the heat rejection rate from the canister which is conservative. The maximum and minimum values are used for the coefficient of thermal expansion of Alloy X. The maximum and minimum coefficients of thermal expansion are used as appropriate in this submittal to support a conservative safety evaluation. However, for any internal interference assessment the actual values of coefficients of thermal expansion from the ASME Code or Table 1.A.4 will be used.

APPENDIX 1.B: HOLTITE™ NEUTRON SHIELD MATERIAL

The shielding against neutron fluence in Holtec's dry storage casks is provided by Holtite™, which is a boron carbide impregnated, hydrogen rich, radiation resistant, neutron shield material initially developed by Holtec International in the 1990s as a part of the company's HI-STAR 100 design development program. The classical Holtite product, labeled Holtite-A, utilizes Aluminum Tri-hydrate (ATH) in a hydrogen rich epoxy compound. A mixing machine, developed by Holtec, is used in the cask manufacturing facility to mix and then pour the Holtite-A slurry into the cask's cavities. The shielding material cures *in-situ*, ensuring that no gaps or voids will exist. Holtite-A was subjected to extensive studies of its critical characteristics (viz., radiation resistance, physical stability at service temperature and homogeneity) during its evaluation and validation program [1B.1, 1B.2] which led to its regulatory approval in the HI-STAR 100 dockets by the USNRC (dockets 71-9261 and 72-1008) in the 1990s and subsequent use in the manufactured HI-STAR 100 casks, many of which have been deployed around the world. The key physical properties including the Design Temperature of Holtite-A is provided in Table 1.B.1.

In addition to Holtite-A, Holtec also utilizes Holtite-B [1.B.3.]. Holtite-B is the combination of a hydrogen rich polymer, Nylon plus a neutron capture agent, B₄C and an optional thermal conductivity enhancing agent, aluminum. Holtite-B's physical properties are provided in Table 1.B.2. Holtite B is particularly suitable for use in elevated temperature applications (Table 1.B.3). As Table 1.B.4 indicates, both Holtite A and Holtite B are NRC-reviewed neutron shield materials, having been licensed and used in several cask models by different regulatory agencies.

APPENDIX 1.C: MISCELLANEOUS MATERIAL DATA
(Total of 1 Page Including This Page)

The information provided in this appendix specifies the paint properties and demonstrates their suitability for use in spent nuclear fuel storage casks.

Thermaline 450 or functionally equivalent paint/coating is specified to coat the overpack to the maximum extent practical and the inner cavity of the HI-TRAC transfer cask. Carboline 890 or functionally equivalent paint/coating is specified to coat external surfaces of the HI-TRAC transfer cask. The paints are suitable for the design temperatures (see Table 2.2.3) and the environment.

APPENDIX 1.D: Requirements on HI-STORM 100 Shielding Concrete

1.D.1 Introduction

The HI-STORM 100 overpack utilizes plain concrete for neutron and gamma shielding. Plain concrete used in the HI-STORM overpack provides only a compressive strength structural function due to the fact that both the primary and secondary load bearing members of the overpack are made of carbon steel. While most of the shielding concrete used in the HI-STORM 100 overpack is installed in the annulus between the concentric structural shells, smaller quantities of concrete are also present in the pedestal shield and the overpack lid. Because plain concrete has little ability to withstand tensile stresses, but is competent in withstanding compressive and bearing loads, the design of the HI-STORM 100 overpack places no reliance on the tension-competence of the shielding concrete.

During normal operations of the HI-STORM, the stresses in the concrete continuum are negligible, arising solely from its self-weight. ACI 318.1-89(92) provides formulas for permissible compressive and bearing stresses in plain concrete, which incorporate a penalty over the corresponding permissible values in reinforced concrete. The formulas for permissible compressive and bearing stresses set forth in ACI 318.1-89(92) are used in calculations supporting this FSAR in load cases involving compression or bearing loads on the overpack concrete. However, since the overpack concrete is designated as an ITS Category B material, it is appropriate to ensure that all “*critical characteristics*” of the concrete, as defined herein, are fully satisfied. During normal storage operations, the overpack concrete is completely enclosed by the overpack steel structure, protecting it from the deleterious effects of direct exposure to the environment, typical of most concrete structures governed by the ACI codes.

The “*critical characteristics*” of the plain concrete in the HI-STORM overpack are: (i) its density and (ii) its compressive strength. This appendix provides the criteria applicable to the plain concrete in the HI-STORM 100 overpack.

1.D.2 Design Requirements

The paragraphs applicable to plain concrete (not reinforced concrete) in American Concrete Institute (ACI) 349-85 provide the governing requirements for HI-STORM overpack concrete to ensure that the key parameters that bear upon the performance of concrete in the HI-STORM overpack, (namely, density and compressive strength) are in compliance with the design basis values specified for the storage system.

This Appendix uses US national consensus standards, such as ASTM and ACI, for providing succinct design and operational guidelines. Equivalent foreign or international national norms and standards may be employed instead in overseas jurisdictions if determined to be acceptable through the 72.48 change process.

The primary function of the plain concrete is to provide neutron and gamma shielding. As plain concrete is structurally competent in compression, the plain concrete’s effect on the performance of

the HI-STORM overpack under compression loadings is considered and modeled in the structural analyses, as necessary. The formulas for permissible compressive and bearing stresses set forth in ACI 318.1-89(92) are used. However, as plain concrete has very limited capabilities in tension, no tensile strength capability is allotted to the HI-STORM concrete. Because the plain concrete is not considered to be bonded to the HI-STORM steel shell and plate structure, it cannot participate in resisting primary loads exerted on the overpack. Therefore, the HI-STORM concrete is termed *non-structural* concrete.

The steel structure of the HI-STORM overpack provides the strength to meet all load combinations specified in Chapters 2 and 3, due to the fact that both the primary and secondary load bearing members (as defined in the ASME Code, Section III, Subsection NF-1215) of the HI-STORM overpack are made from carbon steel. Credit for the structural strength of the plain concrete is only taken to enhance the compressive load carrying capability of the concrete in calculations appropriate to handling and transfer operations, and to demonstrate that the HI-STORM 100 System continues to provide functional performance in a post-accident environment. Therefore, the load combinations provided in ACI 349 and NUREG-1536, Table 3-1 are not applicable to the plain concrete in the HI-STORM overpack.

The shielding performance of the plain concrete is maintained by ensuring that the minimum concrete density is met during its placement and the allowable concrete temperature limits are not exceeded. The thermal analyses for normal and off-normal conditions utilize the temperature limits provided in Table 1.D.1. The temperature limits for transient conditions (such as under partial or full duct blockage and fire) are set down in reference [1.D.4] in conformance with the guidelines set forth in the ACI code, supplemented by data from the published permanent literature. A state-of-the-art review paper [1.D.5], which contains the information in other industry publications listed in the reference section, provides extensive test data on the temperature dependence of plain concrete. In reference [1.D.4] the guidance from ACI and the published archival data on plain concrete has been used to establish temperature limits for normal and transient conditions listed in Table 1.D.1 herein.

1.D.2.1 Temperature Effects on HI-STORM Concrete

The principal function of the concrete is to provide shielding against gamma and neutron radiation. However, the massive bulk of concrete imparts a large thermal inertia to the HI-STORM FW overpack, allowing it to moderate the rise in temperature of the system under hypothetical conditions when all ventilation passages are assumed to be blocked. During the postulated fire accident, the high thermal inertia characteristics of the HI-STORM overpack concrete control the temperature of the MPC. Although the annular concrete mass in the overpack shell is not a structural member, it does act as an elastic/plastic filler of the inter-shell space buttressing the steel shells.

Because HI-STORM concrete has no rebars and is not relied on to bond with the overpack's steel weldment, its allowable temperatures under normal and other operating conditions are guided by considerations of loss of entrained hydrogen which is important to neutron attenuation. Likewise, the differential thermal expansion between the concrete and interfacing steel is not a significant parameter because the thermal stresses produced by any mismatch belong to the class of secondary stresses which are alleviated by the deformations required to establish compatibility.

Exposure of concrete to elevated temperatures can affect its properties due to the dehydration or loss of absorbed and chemically combined water. With respect to concrete shielding performance at local temperatures above 300°F, [1.D.4] examined weight loss and thermal degradation mechanisms of concrete at elevated temperatures.

Using the data in [1.D.4], to address a postulated accident that may occur during the 30-day vent blockage condition (i.e. a tornado borne missile impact), the compressive strength of the concrete is conservatively reduced by 50% even though the maximum temperature experienced by concrete during 30-day vent blockage accident is less than 450°F and is about 300°F during long term normal condition. The evaluations (Supplements 15 and 25 of HI-2012769) conclude that the concrete in overpack, post 50% strength reduction, is acceptable during and after the 30-day vent blockage accident, and during the long-term normal condition.

To evaluate the effect of hydrogen loss on the shielding performance of the HI-STORM 100, it was assumed that entire hydrogen is lost from the concrete. This is a conservative estimate of an upper bound dose rate effect. Water and hydrogen is present in concrete in two forms, chemically bound water/hydrogen, and physically bound water. The material properties for the concrete in the HI-STORM 100 assume hydrogen content that is less than or equal to that in the chemically bound water. As the entire weight loss is attributed to water loss, the total amount of hydrogen in concrete is expected to be no less than 0.8 wt%. The assumed hydrogen content in concrete composition listed in Table 5.3.2 of the FSAR is only 0.6 wt%, which is used for shielding analyses. The analyses results show that shielding performance with such reductions in hydrogen content is negligible. Additionally, the results demonstrate that the hypothetical HI-STORM 100% duct blockage accident condition is bounded by the HI-TRAC accident condition discussed in Section 5.1.2 of the FSAR.

1.D.3 Material Requirements

Table 1.D.1 provides the material limitations and requirements applicable to the overpack plain concrete. These requirements, drawn from ACI 349-85 and supplemented by the provisions of NUREG 1536 (page 3-21), are intended to ensure that the “critical characteristics” of the concrete placed in the HI-STORM overpack comply with the requirements of this Appendix and standard good practice.

ACI 349 was developed to govern the design and construction of steel reinforced concrete structures for the entire array of nuclear power plant applications, except for concrete reactor vessels and containment structures. As such, ACI 349 contains many requirements not germane to the plain concrete installed within and completely enclosed by the steel HI-STORM overpack structure. For

example, the overpack concrete is not exposed to the environment, so provisions in the standard for protecting concrete from the environment would not be applicable to the concrete contained in the overpack.

In accordance with the requirement in Section 3.3 of Appendix B of the HI-STORM 100 CoC, Section 1.D.4, Table 1.D.1 and Table 1.D.2 were developed using the guidance of ACI 349-85, to the extent applicable to the unique application of placing unreinforced concrete inside the steel enclosure of the HI-STORM overpack. Other concrete standards were used, as appropriate, to provide the controls necessary to assure that the *critical characteristics* of the overpack concrete will be achieved and that the concrete will perform its design function.

Aggregate is an important constituent material in the shielding concrete installed in the HI-STORM unit. The critical criteria that the aggregate must fulfill to support the HI-STORM's service life are its chemical inertness in the concrete's environment, absence of large concentration of deleterious materials such as chlorides, and appropriate specific gravity. Because the mass of the shielding in a HI-STORM module is customized to meet shielding requirements for a particular application, several candidate materials are available for a particular application from which a locally available material can be sourced. Broadly speaking, the aggregates may be placed in two categories, namely, standard, and heavy aggregate.

- (a) Standard aggregates pre-approved for HI-STORM application are limestone, marble, basalt, granite, gabbro, or rhyolite. The thermal expansion coefficient limit does not apply when these aggregates are used. Careful consideration shall be given to the potential of long-term degradation of concrete due to chemical reactions between the aggregate and cement selected for HI-STORM overpack concrete. Unlike reinforced concrete where the differential thermal expansion between the rebars and the concrete may weaken their adhesive bond resulting in loss of strength, thermal expansion coefficient of the aggregate is not a critical characteristic in plain concrete.
- (b) Heavy aggregates pre-approved for HI-STORM applications are the following selected from [1.D.2]: They are Hematite, Magnetite (FeFe_2O_4), and Barite (BaSO_4).

In addition to the pre-approved aggregates, locally available natural or synthetic aggregates may be considered for a site-specific application if they meet the acceptance criteria summarized above.

1.D.3.1 Essential Requirements for Concrete Supplier and Lab Testing Support

The material used in HI-STORM related concrete shall be procured to satisfy Holtec's QA program for ITS Category B materials. The QA surveillance record on the concrete supplier must be current at the time of concrete placement. The surveillance shall be performed in accordance with written procedures that include activities that are crucial to insure that all required *critical characteristics* shall be met such as, confirmation that scales used in the batching process are calibrated, delivery trucks are inspected to confirm working condition, and aggregate material stored at the facility is properly stored and segregated.

With respect to the test lab services, the written procedures describing the surveillance of the lab shall ensure that the equipment used in testing of aggregates and concrete compression samples is calibrated. Additionally, the procedure will address the inspection of the concrete cylinder storage facilities as well as basic material controls. With these controls in place, the results of any aggregate testing or concrete cylinder testing can be confirmed to be accurate and reliable.

1.D.3.2 Concrete Mix Design and Material Requirements

A concrete mix design shall be developed in accordance with written procedures to determine the necessary quantity of constituent materials (the recipe) to produce a HI-STORM concrete that meets the *critical characteristics* of the HI-STORM as specified in this section. Holtec Standard Procedures provide detailed requirements and testing logistics to comply with this appendix.

With respect to individual aggregate testing, those provisions from ACI 349 that are germane to the plain concrete installed in and completely enclosed by the steel HI-STORM overpack structure are summarized herein. For example, the overpack concrete is not exposed to the environment, so provisions in the ACI standards for protecting concrete from the environment would not be applicable to the concrete contained in the overpack.

For the standard use local coarse and fine aggregates supplied by the local batch, a high level of confidence based on continued use in area concrete obviates the need for many of the aggregate testing recommended by ASTM C33. However, certain testing relevant to confirming the acceptability of the aggregate is required by this FSAR. For both the local fine and coarse aggregate, laboratory testing shall be carried out to confirm grading per ASTM C33 as well as the ASTM C117 test to determine materials finer than 200 sieve. A laboratory technician shall also visually inspect the source pile to evaluate the aggregates for any deleterious substances or organic impurities. If this visual inspection reveals any evidence of deleterious substances or organic impurities, additional aggregate testing that addresses deleterious substances per ASTM C33 for both fine and coarse aggregates as well as organic impurities testing per ASTM C40 for the local fine aggregate shall be conducted.

High density aggregate that is supplied from an outside source, shall also be tested to confirm grading per ASTM C33 and for material finer than a 200 sieve .

1.D.3.3 Shielding Enhancer Additives

Shielding Enhancer Additives may be used to enhance the shielding effectiveness or neutron capture effectiveness of the plain concrete. To enhance the gamma shielding effectiveness, it is permissible to use a higher density conventional aggregate and/or to incorporate suitable high specific gravity non-organic material as additives. To improve the neutron capture effectiveness, granules of material with high neutron absorption cross-sections may also be dispersed in the plain concrete. The Shielding Enhancer Additives shall meet the product performance criteria set forth in Table 1.D.3. The use of Shielding Enhancer Additives requires consideration be given to the effects on Chapter 4 thermal evaluations and Chapter 5 shielding evaluations concerning the plain concrete on a site-

specific basis. If the use of Shielding Enhancer Additives causes the overpack to exceed the bounding weight used in Chapter 2 structural qualifications, the HI-STORM shell and/or lid “steel structure”, as applicable, shall be evaluated to insure that all structural requirements set forth in Chapter 2 are satisfied. It is noted that any specific material selected for use as a Shielding Enhancer Additive may require additional consideration under the §72.48 process.

1.D.4 Construction Requirements

As is true of all SSCs in this FSAR, the design, construction and commissioning principles set down in this Appendix for plain concrete are implemented through Holtec Standard Procedures (HSPs) prepared and adopted under the Company’s quality assurance program.

1.D.5 Testing Requirements

Fresh concrete tests and compressive testing shall be performed in accordance with written procedures meeting the requirements of the applicable ASTM standard. Concrete may be tested for temperature, slump, and density for each truck prior to placement in the HI-STORM for informational purposes. Official samples, as required by the applicable written procedure will become the sample of record for slump, temperature, and density. Additionally, compressive test cylinder samples shall be taken of a quantity to support required break tests as detailed in the governing Holtec procedure and will ensure a representative sample of the concrete is tested in accordance with ACI 349-85. At a minimum one set of samples must be taken for each HI-STORM. All test samples shall be prepared, stored, and tested in accordance with written procedures. Compressive break strengths of the official concrete cylinder samples taken shall be tested for the required minimum concrete strength. Based upon the fact that compressive strength of concrete is known to increase monotonically with the time of curing, break tests resulting in a compressive strength exceeding the minimum required compressive strength earlier than 28 days may be used as the official concrete break data in lieu of waiting for 28-day breaks.

Table 1.D.1
Requirements for Plain Concrete

ITEM	APPLICABLE LIMIT OR REFERENCE
Density in overpack body (Minimum) (see Table 3.2.1 for information on maximum concrete density)	140 lb/ft ³ (170 lb/ft ³ for HI-STORM 100S Version B Type IS)
Density in lid and pedestal (Minimum) (See Table 3.2.1 for information on maximum concrete density)	140 lb/ft ³ (HI-STORM 100S Version B does not have a concrete-filled pedestal) 170 lb/ft ³ for HI-STORM 100S Version B Type IS lid
Density in HI-STORM 100S Version B Type IS Base-MPC Support, Base-Spacer Block and Base-Shield Blocks (Minimum).	200 lb/ft ³
Specified Compressive Strength	3,300 psi (Note 5)
Compressive and Bearing Stress Limit	Per ACI 318.1-89(92)
Cement Type and Mill Test Report	Type II; (ASTM C 150)
Aggregate Type	Fine and coarse aggregate as required (Note 2)
Nominal Maximum Aggregate Size	1-1/2 (inch)
Water Quality	Deleted
Material Testing	See Note 4.
Admixtures	Deleted
Maximum Water to Cement Ratio	0.5 (Table 4.5.2)
Maximum Water Soluble Chloride Ion Cl in Concrete	1.00 percent by weight of cement (Table 4.5.4) (See Table 1.D.2, Note 1)
Concrete Quality	Deleted
Mixing and Placing	See Note 6.
Consolidation	Deleted
Quality Assurance	Per Holtec Quality Assurance Manual, 10 CFR Part 72, Appendix G commitments
Through-Thickness Section Average [†] Temperature Limit Under Long Term Conditions	300°F (See Note 3)
Local Temperature Limit Under 30-Day 100% Vent Blockage Accident Condition	See Table 2.2.3
Local Temperature Limit Under Short Term, Off Normal, and Accident Conditions	See Table 2.2.3
Aggregate Maximum Value of Coefficient of Thermal Expansion (tangent in the range of 70°F to 100°F)	6E-06 inch/inch/°F (See Note 1) (NUREG-1536, 3.V.2.b.i.(2)(c)2.b)

[†] The through-thickness section average is the same quantity as that defined in Paragraph A.4.3 of Appendix A to ACI 349 as the mean temperature distribution. A formula for determining this value, consistent with the inner and outer surface averaging used in this FSAR, is presented in Figure A-1 of the commentary on ACI 349. Use of this quantity as an acceptance criterion is, therefore, in accordance with the governing ACI code.

Table 1.D.1 (continued)
Requirements for Plain Concrete

Notes:

1. The following aggregate types are a priori acceptable: limestone, marble, basalt, granite, gabbro, rhyolite, hematite, magnetite, or barite. Careful consideration shall be given to the potential of long-term degradation of concrete due to chemical reactions between the aggregate and cement selected for HI-STORM overpack concrete.
2. The coarse aggregate shall meet the requirements of ASTM C33 for class designation 1S from Table 3. However, if the requirements of ASTM C33 cannot be met, concrete aggregates that have been shown by special tests or actual service to produce concrete of adequate strength, unit weight, and durability meeting the requirements of Tables 1.D.1 and 1.D.2 are acceptable in accordance with ACI 349 Section 3.3.2. The high-density coarse aggregate percentage of Material Finer than No. 200 Sieve may be increased to 10 % if the material is essentially free of clay or shale.
3. The 300°F long term temperature limit is specified in accordance with Paragraph A.4.3 of Appendix A to ACI 349 for normal conditions considering the very low maximum stresses calculated and discussed in Section 3.4 of this FSAR for normal conditions. In accordance with this paragraph of the governing code, the specified concrete compressive strength is supported by test data and the concrete is shown not to deteriorate, as evidenced by a lack of reduction in concrete density or durability.
4. Tests of materials and concrete, as required, shall be made in accordance with standards of the American Society for Testing and Materials (ASTM) as specified here, to ensure that the *critical characteristics* for the HI-STORM concrete are achieved. ASTM Standards to be used include: C 31, C 33, C 39, C 88, C 131, C 138, C 143, C 150, C 172, C 192, C 494, C 637. Equivalent standards may be approved for use after a 10CFR72.48 safety evaluation by Holtec.
5. The compressive strength of HI-STORM concrete is used in determining the extent of penetration into the cask by a medium or small Design Basis Missile treated in this FSAR. For sites subject to more severe missiles, the minimum concrete strength may be increased, as necessary, to meet site specific requirements. Lower than the reference strength is seldom required to improve safety margins at a site; however, if required, a lower concrete compressive strength than the nominal value in the table may be employed with Holtec structural engineering approval.
6. Water and admixtures may be added at the job site as specified in the procedure to bring both the slump and wet unit weight of the concrete within the mix design limits. The tolerance for individual and combined aggregate weights in the concrete batch may be outside of tolerances specified in ASTM C94, provided that the wet unit weight of the concrete is tested prior to placement and confirmed to be within the approved range.

Table 1.D.2: Testing Requirements for Plain Concrete

TEST	SPECIFICATION
Compression Test	ASTM C31, ASTM C39, ASTM C192
Unit Weight (Density)	ASTM C138
Maximum Water Soluble Chloride Ion Concentration	ASTM C1218(See Note 1)

Notes:

1. If the concrete or concrete aggregates are suspected of containing excessive amounts of chlorides, they will be tested to ensure that their contribution will not cause the water-soluble chloride concentration to exceed the required maximum. Factors to be considered will consist of the source of the aggregates (proximity to a salt water source, brackish area, etc.) and service history of the concrete made from aggregates originating from the same source. No specific tests are required unless the aggregates or water source are suspected of containing an excessive concentration of chloride ions.

Table 1.D.3: Required Properties of Shielding Enhancer Additives (“Aggregate”)

ITEM	REQUIRED PROPERTY
1	The Aggregate does not chemically react extensively with the other constituents in the concrete.
2	The concrete meets the minimum compressive strength requirement specified for the specific HI-STORM application.
3	The Aggregate remains physically stable at the maximum permissible normal and short term temperatures set down in Table 1.D.1.
4	The maximum Aggregate size is bounded by the limit in Table 1.D.1.
5	The concrete mixing process is qualified to ensure the additive aggregate is evenly distributed with a maximum permissible distribution difference of 10%.

SUPPLEMENT 1.I

GENERAL DESCRIPTION OF HI-STORM 100U SYSTEM

1.I.0 GENERAL INFORMATION

The HI-STORM 100U System is an alternative Vertical Ventilated Module (VVM) design to be used with the Holtec International Multi-purpose Canisters (MPCs) for dry storage of spent nuclear fuel at an Independent Spent Fuel Storage Installation (ISFSI). Information pertaining to the HI-STORM 100U System is generally contained in the “I” supplements to each chapter of this FSAR. Certain sections of the main FSAR are also affected and are appropriately modified for continuity with the “I” supplements. Unless superseded or specifically modified by information in the “I” supplements, the information in the main FSAR is applicable to the HI-STORM 100U System. Drawings specific to the HI-STORM 100U VVM are in Subsection 1.I.5. The Glossary has been appropriately augmented to include the terms particular to the HI-STORM 100U VVM.

1.I.1 INTRODUCTION

HI-STORM 100U, like HI-STORM 100³ and HI-STORM 100S⁴, is a vertical, ventilated dry spent fuel storage system engineered to be fully compatible with the presently certified HI-TRAC transfer casks and MPCs. HI-STORM 100U is an underground vertical ventilated module (VVM) designed to accept all MPC models for storage at an ISFSI (see Figure 1.I.1). ISFSIs employing the VVM may be designed for any number of MPCs and expanded to add additional storage modules as the need arises. Each VVM stores one MPC.

The design and operational attributes of the HI-STORM 100U VVM, described in the following paragraphs pursuant to the provisions of 10CFR72.24(b), are subject to intellectual property rights in the U.S. and abroad under the patent laws governing the respective jurisdictions.

1.I.2 GENERAL DESCRIPTION OF HI-STORM 100U SYSTEM

1.I.2.1 HI-STORM 100U Vertical Ventilated Module

The VVM provides for storage of MPCs in a vertical configuration inside a subterranean cylindrical cavity entirely below the top-of-the-grade (TOG) of the ISFSI (Figure 1.I.2 provides identification of the TOG). The MPC Storage Cavity is defined by the Cavity Enclosure Container (CEC), consisting of the Container Shell integrally welded to the Bottom Plate. The top of the Container Shell is stiffened by the Container Flange (a ring shaped flange), which is also integrally welded. As shown in licensing basis drawings provided in Section 1.I.5, all of the constituent parts of the CEC are made of thick low carbon steel plate (See Table 2.I.8 for component materials). In its installed configuration, the CEC is interfaced with the surrounding subgrade for most of its height except for the top region where it is girdled by the ISFSI pad. The ISFSI pad serves several purposes in the HI-STORM 100U storage system, such as:

3 U.S. Patent No. 6,064,710 dated May 16, 2000.

4 U.S. Patent No. 6,718,000 dated April 6, 2004.

- It provides an essentially impervious barrier of reinforced concrete against seepage of water from rain/snow into the subgrade.
- It provides the interface surface for the CEC flange.
- It helps maintain a clean, debris-free region around the VVMs.
- It provides the necessary riding surface for the cask transporter (see Figure 1.I.7).

The ISFSI pad is actually composed of two distinct regions separated by suitably engineered expansion joints. These are referred to as (see Figure 1.I.3):

- i. the VVM Interface Pad (VIP) and
- ii. the Top Surface Pad (TSP).

As its name implies, the VIP is in close contact with the Container Flange and the upper part of the Container Shell for sealing and shielding purposes. In Figures 1.I.1 and 1.I.2, the elevated portion of the ISFSI pad is the VIP.

The balance of the ISFSI pad, lower in elevation than the VIP, is the top surface pad (TSP). The TSP carries no significant loads except during the movement of the cask transporter over portions of its surface. The substantial difference in the dead load patterns on the two regions of the ISFSI pad warrants that the two regions be physically disconnected so that differential settlement between the two do not produce (undesirable) flexural and shear loadings. Governing codes for the ISFSI pad design and construction are described (see Supplement 2.I) to ensure a high integrity design. Expansion joints are placed between the two pads where necessary to ensure that vertical movements are independent. As discussed in Supplement 3.I, an optional concrete encasement around the coated external surface of the CEC may be added to control the pH at the CEC-to-subgrade interface.

Corrosion mitigation measures commensurate with site-specific conditions are implemented on below-grade external surfaces of the CEC. A corrosion allowance (metal wastage) equal to 1/8" on the external surfaces of the VVM in contact with the subgrade is nevertheless assumed in the structural evaluation in Supplement 3.I. All external and internal surfaces of the VVM are coated with an appropriate surface preservative. The top surfaces of the MPC Bearing Pads are equipped with stainless steel liners so that the MPC is not resting directly on carbon steel components. Details of corrosion mitigation measures are described in Section 3.I.4.

With the Closure Lid removed, the CEC is a closed bottom, open top, thick walled cylindrical vessel that has no penetrations or openings. Thus, groundwater has no path for intrusion into the interior space of the MPC storage cavity. Likewise, any water that may be introduced into the MPC storage cavity through the air passages in the top lid will not drain out on its own. The Bottom Plate of the CEC is round and slightly larger in diameter than the Container Shell to accommodate an all around weld between the plate and the shell.

The Support Foundation has circular VVM Lateral Support Recessed Regions to locate and contain lateral motion of each VVM with respect to the Support Foundation. The VVM Support Foundation and the underlying substrate must be sufficiently strong to prevent significant long-term settlement under the weight of the loaded storage cavities. The appropriate requirements on the Support Foundation's structural strength and the applicable industry code are specified in Supplement 2.I of this FSAR. Like the ISFSI pad above, the Support Foundation is classified as an "interfacing structure" in this FSAR.

The MPC Bearing Pads and the Divider Shell, two parts internal to the CEC, are important to the VVM's thermal performance. The Divider Shell, as its name implies, is a vertical cylindrical shell concentrically situated in the CEC. The Divider Shell creates an outer annular coolant air or intake plenum and an inner annular coolant air space around the MPC. The bottom end of the Divider Shell has cutouts to enable incoming air streaming down the intake plenum to enter the inner coolant air space from around the circumference of the Divider Shell in a symmetric manner (Figures 1.I.2 and 1.I.4). The sectors of the Divider Shell that rest on the CEC Bottom Plate are also the locations where MPC Bearing Pads provide for a Bottom Plenum underneath the MPC for access of coolant air. The cutouts in the Divider Shell are sufficiently tall to ensure that if the cavity were to be filled with water, the bottom region of the MPC would be submerged for several inches before the water level reaches the top edge of the cutouts. This design feature is important to ensure uncompromised thermal performance of the system under any conceivable accidental flooding of the cavity by any means whatsoever. The Divider Shell is laterally restrained in the horizontal plane at its bottom end by the Divider Shell Restraints and rotationally restrained in the horizontal plane by the MPC Bearing Pads. The Divider Shell is not attached to the CEC; this allows convenient removal for decommissioning, for unplanned in-service maintenance, or for any other unforeseeable reason. The Divider Shell's interface with the Closure Lid features a small gap to permit the Divider Shell to expand freely from heating by ventilation air.

In addition to the lateral restraints at the bottom, the Divider Shell is also restrained against lateral movement at the top by the cylindrical protrusion in the Closure Lid. In addition, the Divider Shell is equipped with Upper and Lower MPC Guides. The Upper MPC Guides are radially symmetric and located at the elevation of the MPC's top lid. The Upper MPC Guides serve to guide the MPC down to the Lower MPC Guides and MPC Bearing Pads during the MPC's lowering operation, as well as to limit the MPC's lateral movement relative to the CEC, during an earthquake event, to a fraction of an inch.

The cylindrical surface of the Divider Shell is equipped with insulation to ensure that the heated air streaming up around the MPC in the inner coolant air space causes minimal preheating of the air streaming down the intake plenum. As discussed in Supplement 3.I.4, the insulation material is selected to be water and radiation resistant and non-degradable under accidental wetting.

Finally, the Closure Lid shown in Figure 1.I.6 completes the physical embodiment to the VVM. The Closure Lid is a steel structure filled with shielding concrete. The design of the top lid fulfills the following principal performance objectives:

- i. Both the inlet and outlet air passages are located in the Closure Lid, so there are no lateral radiation leakage paths during the MPC lowering or raising operation. The need for shield blocks (necessary to close off vents in some aboveground HI-STORM 100 overpacks) is eliminated.

- ii. Both inlet and outlet passages are radially symmetric so that the air cooling action in the system is not affected by the change in the horizontal direction of the wind.
- iii. By locating the air inlet at the periphery of the Closure Lid and the air outlet at its top central axis, mixing of entering and exiting air streams is essentially eliminated.
- iv. The inlet and outlet air passages are made of “formed and flued” heads (i.e., surfaces of revolution) that serve three major design objectives as noted below.
 - a. The curved passages eliminate any direct line of sight to the MPC storage space and serve as an effective means to scatter the photons streaming from the stored fuel.
 - b. The curved steel plates significantly increase the load bearing capacity of the Closure Lid much in the manner as a curved beam exhibits considerably greater lateral load bearing capacity in comparison to its straight counterpart. This design feature is a valuable attribute if a “beyond-the-design basis” impact scenario involving a large and energetic missile needs to be evaluated for a particular ISFSI site.
 - c. The curved passages, as is well known in classical hydraulics, provide for minimum loss of pressure in the coolant air stream, resulting in a more vigorous ventilation action.
- v. The Closure Lid rests on the Container Flange and is gasketed to minimize foreign material intrusion.
- vi. The top surface of the Closure Lid is also curved and extended beyond the air inlet perimeter to efficiently drain off rainwater.
- vii. The Container Flange restrains the Closure Lid against horizontal movement, during a Design Basis Earthquake event or a tornado missile strike.
- viii. The radially symmetric air inlet passage in the lid is geometrically aligned with the annular opening formed between by the Divider Shell and the CEC Shell.
- ix. Because the inlet opening extends around the circumference of the Closure Lid, the hydraulic resistance to the incoming airflow, a common limitation in ventilated modules, is minimized. A similar airflow resistance minimization facility is built into the pathway for the exiting air. A circumferentially circumscribing vent opening is also quite obviously less apt to be completely blocked under even most extreme environmental phenomena involving substantial quantities of debris.
- x. To minimize the VVM’s height, a portion of the Closure Lid extends into the cylindrical space above the MPC. This cylindrical below-surface extension of the Closure Lid is also

made of steel filled with shielding concrete to maximize the blockage of skyward radiation issuing from the MPC.

- xi. All inlet and outlet air passages are equipped with screens, as in the aboveground HI-STORM overpacks, to prevent debris, insects, and small animals from entering the VVM. Although the screen is a non-structural member, it is designed for long-term durability and easy maintainability to ensure that its installation, removal, and maintenance are ALARA.

Finally, particular attention is paid to the design of the exit vent assembly (at the top of the outlet air passages in Figure 1.I.2) to ensure that wind-driven rain at up to 45° inclination from the vertical will not have a direct line of sight to the vertically oriented portion of the air passage in the Closure Lid.

- xii. As can be seen from the drawings in Section 1.I.5, the Closure Lid is substantially larger in diameter than the Divider Shell in the CEC and the MPC is positioned to be at a significant vertical depth below the top of the Container Flange. These geometric provisions ensure that the Closure Lid will not fall into the MPC storage cavity space and strike the MPC if it were accidentally dropped during its handling. An accidental drop of the MPC, however, can lead to a collision with the top of the Divider Shell. The Divider Shell, if damaged due to a handling accident, can be readily removed and repaired or replaced without affecting any other parts of the VVM. Because the Closure Lid is the only removable heavy load, the carefully engineered design features to facilitate recovery from its accidental drop provide added assurance that a handling accident at the ISFSI will not lead to radiological release. This additional measure against accidental Closure Lid drop does not replace the drop prevention features mandated in this FSAR on heavy load lifting devices such as the cask transporter (illustrated in Figure 1.I.7) that have been a standard and established requirement in the HI-STORM 100 docket.

From a jurisdictional standpoint, the CEC, the Container Flange, and the Closure Lid, constitute the body of the VVM. The Support Foundation on which the VVM rests, however, must be designed to meet certain structural criteria to minimize long-term settlement and physical degradation from aggressive attack of the materials in the surrounding subgrade. Likewise, the Top Surface Pad serves to augment shielding, but is mainly needed to provide a sufficiently stiff roadway for the transporter. Similarly, the VVM Interface Pad (Figure 1.I.2) serves to augment shielding, as a barrier against gravity induced seepage of rain or floodwater around the VVM body, and as a barrier against a missile directed towards the underground portion of the CEC structure. The essential structural requirements applicable to the design of the Support Foundation, the VVM Interface Pad, and the Top Surface Pad for proper functioning of the VVM are provided in Supplement 2.I (Principal Design Criteria). Similarly, typical physical characteristics of the surrounding substrate are provided in Supplement 2.I. This data is intended to provide guidelines for the design of SSCs proximate to the VVM to ensure that the VVM, regardless of the wide variations in the properties at an ISFSI site, will render its intended function for the duration of its Design Life.

The foregoing description of the VVM clearly indicates that the principal function of the VVM structure is to provide the biological shield and cooling facility. However, for conservatism, stress limits of the

“Level A” service condition in Subsection NF of the ASME Code are applied to establish the embedded structural margins of safety in the primary load bearing parts of the VVM under normal conditions of storage. For short term and accident conditions (i.e., earthquakes, missile strike, etc.), the continued functional adequacy of the system is the appropriate criterion. For the VVM, continued functional adequacy under accident or extreme environmental events demands absence of a complete blockage of the ventilation passages and a non-significant amount of loss of shielding. Supplement 2.I provides complete details on the applicable design criteria.

All MPC types certified for storage in the aboveground overpacks can be stored in the below ground VVM. The chief distinguishing features of the VVM are its low profile and subterranean configuration. The Container Shell is buried below the ISFSI Pad for virtually its entire height, resulting in a near complete blockage of laterally emanating radiation from the stored fuel.

In summary, the notable design and operational features of the HI-STORM 100U System are:

- i. The MPC is supported on MPC Bearing Pads to provide an inlet air plenum at the bottom of the storage cavity (Figure 1.I.2). The bottom of the MPC, however, will be in contact with water if the cutouts at the bottom of the Divider Shell were to be filled with water cutting off feed air. As long as the MPC is wetted with water, the peak cladding temperature of the stored spent fuel will not exceed the regulatory off-normal condition temperature limit. Thus, the VVM configuration provides a built-in protection against flood events.
- ii. Like the HI-STORM 100A and 100SA models, tipover of the canister in storage is not possible.
- iii. Although the modules may be closely spaced, as illustrated in Figure 1.I.5, the design permits any MPC located in any cavity to be independently accessed and retrieved using a HI-TRAC transfer cask.
- iv. A cask transporter typical of those used in numerous Holtec ISFSI projects for on-site transport of loaded HI-TRACs and HI-STORMs can provide the means to deliver the loaded HI-TRAC to the HI-STORM 100U VVM and to carry out the MPC lowering operation (Figure 1.I.7). The same cask transporter can also be used to remove an MPC from storage and place it in a recipient HI-TRAC transfer cask.
- v. To exploit the biological shielding provided by the surrounding soil subgrade, the MPC is entirely situated well below the top-of-grade level. The open plenum above the MPC also acts to boost the ventilation action of the coolant air.
- vi. Because the VVM is rendered into an integral part of the subgrade, it cannot be translocated to another ISFSI site. It also cannot be lifted and, therefore, is not subject to the potential for a handling accident.
- vii. Removal of water from the bottom of the storage cavity can be carried out by the simple expedient use of a flexible hose inserted through either the inlet or the outlet passageway.

- viii. As discussed in Supplement 3.I.4, all exposed surfaces of the VVM are coated with proven surface preservatives that meet the toxicological and extraction test requirements of ANSI/NSF Standard 61.
- ix. The VVM is a formed metallic welded structure with a removable Closure Lid. The Closure Lid is also a formed metallic welded structure but filled with shielding concrete. The requirements on the shielding concrete are specified in Appendix 1.D.

As can be readily deduced from the above description of the VVM, the MPC storage cavity (consisting of the Container Shell and Bottom Plate) is at or near ambient temperature during normal operations. The only portions of the VVM in contact with heated ventilation air are the Divider Shell and the domed annular outlet in the Closure Lid, neither of which is in contact with the subgrade soil.

It should be recognized that the depth of the MPC Storage cavity determines the height of the hot air column in the annular region during the system's operation. Therefore, deepening the cavity has the beneficial effect of increasing the quantity of the ventilation air and, thus, enhancing the rate of heat rejection from the stored MPC. Further, lowering the MPC in the MPC Storage cavity will increase the subterranean depth of the radiation source, making the site boundary dose even more miniscule. To ensure that the thermal and shielding performance is the bounding minimum, the top of the MPC is assumed to be at its maximum permissible elevation with respect to the Top-of-the-Grade and the MPC Storage Cavity depth is assumed to be accordingly at its permitted minimum in all thermal and shielding analyses reported in Supplements 4.I and 5.I, respectively, and in the drawings provided in Section 1.I.5. At a specific ISFSI site, the user has the latitude to deepen the VVM cavity and situate the MPC at a deeper depth using the §72.48 process.

The VVM implements seals or gaskets at the Closure Lid. The outer seal is a weather seal (between the Closure Lid and the top of the Divider Shell), which facilitates maintenance by minimizing foreign material intrusion into the MPC storage cavity. The inner seal (between the Closure Lid skirt and the Divider Shell (not shown on the licensing drawing 4501)) provides an enhanced barrier against mixing of inlet and outlet air in the annular space between the Divider Shell and the cylindrical protrusion in the Closure Lid (even though the pressure differential between the two sides is extremely low – less than a few inches of water). The outer seal relies on the weight of the Closure Lid to insure sealing. A polymeric gasket made from EPDM⁵ is preferred for this purpose. The inner seal is made of a durable radiation and heat resistant material and designed to have no credible mechanism for significant degradation or detachment from its sealing location. The seals do not provide a safety function because their loss during operation would not have an effect on safe operation of the system.

Finally, the physical hardening of the VVM against impulsive and impactive loadings is a major consideration in the embodiment of the HI-STORM 100U System. Quite obviously, the low physical profile of the VVM reduces the probability of impact from a missile or a projectile. In addition, to impute maximum margin against extreme environmental phenomena loads, the Closure Lid is a METCON[®] (metal/concrete) structure engineered to possess considerably greater strength reserve than that required to prevent design basis missiles from penetrating into the MPC storage cavity, as demonstrated by

⁵ Radiation resistant polymeric gasket materials are available from the Presray and Pawling Corporations, for example.

analysis in Supplement 3.I. Another design consideration is protection against intrusion of rainwater and other liquid matter into the MPC storage cavity. In contrast to typical ventilated modules, the VVM air passages are elevated above the Top-of-the-Grade, providing a physical barrier against the intrusion of any accumulating pool of fluid (including combustibles) on the ISFSI surfaces into the module cavity. A significantly enhanced level of protection against incident missiles and an improved barrier against ingress of rainwater or spilled fluids into the module cavity space, and a design that is ideally configured for a flood event, are among the many distinguishing features of the HI-STORM 100U System.

1.I.2.2 HI-STORM 100U System Sequence of Operations

Fuel loading operations and MPC preparation are identical for the VVM as they are with the other HI-STORM overpack designs. The HI-TRAC transfer cask is used for on-site transport of the loaded MPC from the MPC preparation area to the VVM at the ISFSI. The Closure Lid will have been previously removed from the VVM. The cask transporter carrying the transfer cask and the MPC moves over the top of the open VVM where the HI-STORM mating device (shown beneath the HI-TRAC in Figure 1.I.7) is in place. The MPC inside the transfer cask is lifted slightly by the cask transporter (or an equivalent heavy load handling device) to allow the transfer cask pool lid to be removed. Once the pool lid is removed, the heavy load handling device is used to lower the MPC into the VVM. The transfer cask and mating device are removed from the top of the VVM, the MPC lift connectors are removed, and the VVM Closure Lid is installed. Supplement 8.I provides a more detailed discussion of operations involving the HI-STORM 100U System. (The “mating device” aided MPC transfer operation is an exclusive intellectual property of Holtec International under U.S. Patent No. 6,853,797 B2 dated February 8, 2005.)

1.I.3 IDENTIFICATION OF AGENTS AND CONTRACTORS

Same as in Section 1.3.

1.I.4 GENERIC CASK ARRAYS

An ISFSI deploying the HI-STORM 100U System may use an unlimited number of VVMs. The preferred embodiment of the VVM array is a rectangular grid as illustrated in Figure 1.I.5. The minimum pitch between the VVM cavities is shown on the licensing drawing in Subsection 1.I.5. In either or both directions, the spacing can be increased by the site to ensure that any of the commercially available cask transporters can traverse the VVM arrays to provide autonomous access to each stored MPC. This minimum spacing also serves to provide adequate shielding around each storage cavity.

No limit is placed on the maximum spacing. Multiple VVMs in an ISFSI shall be founded on a continuous support foundation to prevent an unacceptable level of differential settlement between adjacent VVMs and to enhance the seismic response characteristics of the ISFSI.

The design of the expansion joints between the VVM Interface Pad and the Top Surface Pad regions of the ISFSI Pad is guided by the need to physically decouple the settlement of the two regions due to long term creep effects.

Additional VVMs may be built adjacent to existing VVMs without imparting excessive dose to the construction crew, if a sufficient distance to loaded VVMs is kept. To ensure that this distance is kept, a “Radiation Protection Space” (RPS) boundary is specified in the drawing package in Section 1.I.5. This boundary shall not be encroached upon during any site construction effort. Subsection 2.I.6(xii) contains additional requirements on the design and qualification of the RPS to insure that the earthen shielding in the RPS shall be protected against a significant loss due to human error or natural events such as earthquakes and tornado borne missiles.

1.I.5 FIGURES AND DRAWINGS

Figures associated with Supplement 1.I and the licensing drawing package of the HI-STORM 100U VVM, pursuant to the requirements of 10CFR72.24(c)(3), are provided in this subsection. The material in the licensing drawing package in this section contains sufficient information to articulate major design features and general operational characteristics of the HI-STORM 100U VVM. Further, it is intended to serve as the control information to guide the preparation of the documents required to manufacture the components under the company’s quality assurance system. Some key document types needed for manufacturing in the factory under the company’s fail-safe configuration control protocol are:

- Purchasing Specifications (PSs)
- Manufacturing Drawing Package
- Holtec Standard Procedures (HSPs)
- Holtec Project Procedures (HPPs)
- Bill-of-Materials
- Fabrication and NDE Procedures
- Shop Travelers

Holtec’s Quality Assurance Program requires that the entire array of manufacturing documents must remain in complete consonance with the Licensing Drawing Package (and other provisions in this FSAR) at all times.

SUPPLEMENT 1.II: GENERAL DESCRIPTION OF HI-STORM 100 SYSTEM WITH VERSION E VERTICAL VENTILATED MODULE¹², HI-TRAC MS, MPC-32M, MCP-32 VERSION 1 AND MPC-68 VERSION 1

1.II.0 General Information

The HI-STORM 100 system consists of several *vertical ventilated module* (VVM) and *multi-purpose canister* (MPC) models. The various above-ground VVM and MPC models are analyzed in the main body of this SAR which supports their certification through the CoCs issued under Docket # 1014. The certified components include the first subterranean storage module HI-STORM 100U and MPC-68M (the first Metamic HT Fuel Basket containing MPC for the HI-STORM 100 system) added in Supplements I and III, respectively, to the certified line-up of Canisters³ and storage modules. This supplement adds a VVM model referred to as HI-STORM 100S Version E (including the HI-STORM 100S Version E1), new HI-TRAC Version MS and a new Canister model referred to as MPC-32M, as well as the MPC-32MCBS variant.

In addition, updated safety analyses of Version 1 designs of MPC-32 and MPC-68 (Alloy X MPCs -as described in the Glossary) are also included in this Supplement.

The HI-STORM 100S Version E is an enhanced version of the HI-STORM 100S Version B that has been in use since the mid-2000s. The HI-STORM 100S Version E1 is a design variant of the Version E, with a few key noted differences: a modified inlet vent assembly which features additional shielding material attached to the outside of the vent assembly; an additional "inner base plate" that adds shielding material to the bottom of the overpack enhancing shielding capabilities; MPC support guides are replaced with stainless steel tiles effectively lowering the MPC base structure; and a reduced cask height. The HI-STORM 100S Common Lid is to be used in combination with the HI-STORM 100S Version E1 overpack body. MPC-32M is the PWR counterpart of MPC-68M analyzed in Supplement III and certified for use in this docket previously. Information pertaining to the HI-STORM 100S Version E and E1 VVM and associated safety analyses are generally contained in the "II" supplements to each chapter of this FSAR. The "II" supplements are written to be autonomous with respect to the safety analyses; however, reference to the main body of this SAR is made for common data such as material properties, stress limits and safety considerations. Content in this Supplement II supersedes corresponding safety analysis material in the main body of this SAR. Drawings specific to the HI-STORM 100S Version E and E1 VVM, HI-TRAC MS, MPC-32M, and MPC-32MCBS can be found in Section 1.II.5. The Glossary has been appropriately augmented to include the specific terms germane to the components and operations introduced in Supplement II.

To identify each figure and table uniquely within the set of supplements that constitute Supplement II, all figures and tables cited are identified by the triple decimal system m.n.i.j, where m is the chapter number to which this supplement applies, n is the Supplement number (II), i is the Section number and j is the sequential number. Thus, for example, Figure 1.II.2-3 is the third figure in Section 1.II.2 of Supplement II to Chapter 1. Figures and tables are placed at the end of each section. Thus, the presence of the Roman numeral II in any section, subsection, table or figure identifier indicates that its native location is in Supplement II.

References follow a dual decimal system m.n.i where m is the Chapter number in the main report, n is the

1 Supplement 1.II means it is the supplement to Chapter 1 of the FSAR which along with other such supplements to other chapters constitute Supplement II to the FSAR

2 The novel design features of HI-STORM Version E are subject to intellectual property protection under USPTO EFS #33681217, Application #62729482, Confirmation #9872

3 The term Canister is used interchangeable with MPC in this FSAR

Supplement number (II) and j is the sequential number. References are located at the end of each supplement.

1.II.1 Introduction

The HI-STORM Version E (including the Version E1) overpack along with the MPC-32M or MPC-32MCBS variant where specified constitutes the HI-STORM 100 vertical ventilated system whose safety evaluation is documented in the set of supplements denoted as Supplement II. The HI-STORM 100 System with HI-STORM Version E and the Version E1 as the VVM can accept all previously licensed MPC models in Docket #1014 for storage at an ISFSI. This is because the Version E and Version E1 VVM are akin to HI-STORM Version B with slightly better or equal mechanical, thermal and nucleonic properties germane to MPC storage. ISFSIs employing the VVM may be designed for any number of different MPCs and expanded to add additional storage modules as the need arises. Each VVM stores one MPC. The safety analyses for the new MPC model, MPC-32M or MPC-32MCBS variant where specified are explicitly performed in this FSAR. In addition, enhanced versions of the classical canisters, MPC-32 and MPC-68, are also introduced in this Supplement II with the identifier “Version 1” appended to differentiate them from their base designs. Drawings for the MPC-32 Version 1 and MPC-68 Version 1 can be found in Section 1.II.5.

Like other HI-STORM 100 systems, previously certified in this docket, both sheltered and unsheltered storage at an ISFSI is permitted. Likewise, the system can be arrayed in a free standing, anchored or restrained configuration provided the structural criteria set down in Supplement 2.II are satisfied.

1.II.2 General Description

1.II.2.1 HI-STORM Version E VVM

The HI-STORM Version E vertical ventilated module (VVM) (Figure 1.II.2-1 for the Version E and Figure 1.II.2-4 for the Version E1), like other HI-STORM overpacks previously qualified in this Safety Analysis Report, is a buttressed dual-shell structure with shielding concrete placed in the inter-shell annulus. The HI-STORM Version E and HI-STORM Version E1 (also called “Version E” and “Version E1” for brevity) casks are anatomically similar to the widely deployed “Version B” in most respects, such as:

- a. A solid Bottom Plate defines the bottom extremity of the VVM.
- b. Vertically disposed Threaded Anchor Locations (TALs) welded to the inter-shell connectors, used in every HI-STORM 100 overpack, are also used in Version E.
- c. The OD of the Top Lid is nominally equal to the OD of the cask body to more effectively block the skywards radiation emanating from the Canister.
- d. The overpack supports the MPC without any lateral contact with the MPC shell which, along with the vertical disposition of the MPC, protects against the risk of crevice corrosion attack on the MPC shell.
- e. Like all other versions, Version E can be deployed in an unsheltered or sheltered storage mode. However, if the sheltered configuration is used then site specific evaluations should be performed to ensure that the temperature profile (time averaged, as applicable) of the ventilation air entering the cask complies with the normal storage temperature limit set forth in Supplement 2.II (Principal Design Criteria) herein.
- f. Like all other above-ground HI-STORM 100 models, a loaded Version E is not authorized to be transported horizontally. Tilting the cask to clear an overhead obstruction; however, is permissible if the applicable safety case can be demonstrated.
- g. Because, like all HI-STORM overpack models, Version E is a steel structural weldment, it can be readily secured to the ISFSI pad, if required, using a set of lugs and anchor bolts. The anchoring option is typically utilized only if the site’s Design Basis Earthquake (DBE) is determined to be severe enough to topple the free-standing loaded cask or cause inter-cask collisions.

The Licensing drawing package in Section 1.II.5 provide essential design features.

Version E improves upon its forerunner “Version B” in certain respects, viz.:

- a. The inlet duct system of Version E is comprised of eight circumferentially separated ducts in lieu of four ducts in Version B. The Version E1 inlet duct system is comprised of four circumferentially separated ducts, but has a greater flow area than that of the Version B. The outlet flow is designed to be radially symmetric at the cask body to lid interface. The flow areas of both the inlet and outlet flow passages are enlarged to facilitate increased ventilation flow.
- b. A set of inlet vents is designed to take air suction from all around the circumference of the cask at a slightly elevated penetration in the outer shell and deliver it to the MPC cavity space through penetrations in the inner shell located near the cask’s Bottom Plate. An oblique stainless-steel rectangular tube joins the upper penetration in the outer shell with the lower penetration in the inner shell providing a well-

defined pathway for the incoming ventilation air. Each oblique tube is in a radial plane substantially separated from each other to minimize local increase in the accreted radiation from the cask typical of inlet ducts.

An important benefit of the inlet vent system employed in Version E is the ability it imputes to the canister to continue to reject its decay heat in the event of a flood event that blocks the flow of incoming air. Because blocking of the elevated inlet vent with flood water will partially wet the MPC, which has recirculating helium from internal thermo-siphon effects, an effective means for heat rejection to the surrounding flood water is established without any operator action.

- c. Directing the inlet air flow towards the bottom of the MPC serves to slightly pre-heat the incoming air, alleviating the stress-corrosion risk to the lower portion of the MPC shell (where it is most vulnerable).
- d. As a key design objective, while the air flow areas are enlarged to facilitate increased ventilation flow, the design ensures that the flow regime throughout the VVM will continue to be fully turbulent at the system's Design Basis Heat Load (DBHT).
- e. The MPC sits on a thin stainless liner (MPC support guides replaced with stainless steel tiles for the Version E1) welded to the Bottom Plate so that it is not in direct contact with the carbon steel bottom plate of the overpack
- f. The density of the shielding concrete (Appendix 1.D) in the overpack body and Top Lid has been increased to enhance dose attenuation (See Table 1.II.2.4.) [1.II.2]
- g. The massive Top Lid, which is held in place by four large anchor bolts has been designed such that during the non-mechanistic tip-over event, the lid will impact the ISFSI pad independently of the cask body because of the large clearances around each bolt hole. This feature has the beneficial effect of ameliorating internal stresses in the cask from the tip-over event.

Table 1.II.2.5 provides the essential design data required for the safety analysis of Version E overpack cask in the subsequent chapters. Table 1.II.2.1 lists the sections from the main body of the FSAR used to evaluate the improved features of Version E as analyzed in the supplement II to each chapter.

1.II.2.2 Multi-Purpose Canister (MPC)

The MPC for all HI-STORM/HI-STAR systems consists of two principal components, namely (i) The Enclosure Vessel (EV) which is an all-welded pressure vessel of the highest ASME Code pedigree, and (ii) The Fuel Basket. MPC-32M, MPC-32MCBS, MPC-32 Version 1 and MPC-68 Version 1 utilize Enclosure Vessel Version 1 listed in section 1.II.5. For reference purposes, a listing of MPCs allowed for storage in the Version E and Version E1 is provided in Table 1.II.2.2. MPC-32M, including the MPC-32MCBS variant, along with version 1 of MPC-32 and MPC-68 are the subject of the safety analysis in this Supplement II.

- (i) MPC-32M (including MPC-32MCBS): Certain design attributes of MPC-32M are summarized below, most of which it shares with all other MPC models:
 - a. Like all MPCs, MPC-32M and its MPC-32MCBS variant will be handled by a set of Lift Cleats" (under "Special lifting devices" in the regulatory literature) that engages with threaded anchor locations (TALs) in the top lid. The lifting appurtenances of the Enclosure Vessel body must meet the stress margin criteria of NUREG-0612 and ANSI 3.61.

- b. In all MPCs, the Enclosure Vessel is made from one of the previously approved stainless-steel alloy materials denoted as Alloy X in this FSAR (See Appendix 1.A).
- c. Like MPC-68M (described in Supplement III), the gap between the Enclosure Vessel shell and the Fuel Basket is occupied by the so-called Basket Shims made of an aluminum alloy qualified for their thermal environment. As in MPC-68M, the basket body and the Basket Shims are non-Code. For the standard MPC-32M, the Basket Shims are loosely installed conformal aluminum shapes that feature axial flow holes to facilitate helium recirculation. The continuous basket shim (CBS) variant consists of aluminum shims bolted to basket panel extensions in the peripheral region, that provide greater natural circulation flow area and increased direct radiant heat transfer from the basket exterior to the canister shell ID.
- d. Axial Spacers are utilized to limit longitudinal movement of the fuel during handling evolutions in the case that there is an excessive gap between the fuel assembly (with its control components) and the top of its storage cavity. The Axial Spacers may be installed at the MPC's baseplate location or in the top region defined by the Top Lid. The Axial Spacers are non-code and are sized to leave a small axial clearance between the fuel and the cavity to account for the (not-amenable-to-accurate-prediction-of) in-core irradiation growth of the fuel.
- e. In the case of MPC-32M (Figure 1.II.2-3), like the previously certified MPC-68M, the Fuel Basket is made entirely from Metamic-HT. The properties of Metamic-HT and key characteristics are presented in Section 1.III.2.4.

(ii) Version 1 of MPC-32 and MPC-68: Version 1 of MPC-32 and MPC-68 are slightly modified updates of their classical counterparts wherein the cell openings are slightly enlarged to improve the ability to store Damaged Fuel Containers" and the Baseplate is slightly thickened to increase its pressure and load bearing capacity. The basket material, as before, is made of Alloy X (Appendix 1.A)

The nominal length of all HI-STORM MPCs has been standardized to accept the vast majority of commercial nuclear fuel produced by western light water reactors. However, the MPC length can be increased or reduced to accord with its intended used fuel content for a specific host site using the provisions of 10CFR72.48.

1.II.2.3 The HI-TRAC MS Transfer Cask

The HI-TRAC transfer cask is required to perform all short-term loading operations on the MPC, beginning with fuel loading and ending with the emplacement of the MPC in the storage overpack. The HI-TRAC transfer cask is also used for short term unloading operations beginning with the removal of the MPC from the storage overpack and ending with fuel unloading.

The HI-TRAC MS (acronym for **m**aximum **s**hielded) transfer cask is anatomically similar to the HI-TRAC 100 and HI-TRAC 125 transfer cask models described in this FSAR and previously certified for use. The safety analyses in Supplement II justifies addition of HI-TRAC MS to the list of acceptable transfer casks. It is a smaller diameter counterpart of HI-TRAC VW Version V in HI-STORM FW FSAR. The HI-TRAC MS transfer cask contains a natural ventilation feature by adding an air inlet on the HI-TRAC's bottom lid. The HI-TRAC MS licensing drawing (see Section 1.II.5) shows the natural ventilation passages that enable ventilation of air to passively reject the MPC's decay heat.

HI-TRAC MS (Figure 1.II.2-2) is designed to meet the following specific performance objectives that are centered on ALARA and physical safety of the plant's operations staff.

- a. Provide maximum shielding to the plant personnel engaged in conducting short-term operations.

- b. Provide protection of the MPC against extreme environmental phenomena loads, such as tornado-borne missiles, during short-term operations.
- c. Serve as the container equipped with the appropriate lifting appurtenances in accordance with NUREG-0612 to lift, move, and handle the MPC, as required, to perform the short-term operations.
- d. Provide the means to restrain the MPC from sliding and protruding beyond the shielding envelope of the transfer cask under a (postulated) handling accident.
- e. Facilitate ALARA transfer of a loaded MPC to or from the HI-STORM VVM (or another physically compatible storage or transfer cask) by vertical movement of the MPC without any risk of damage to the canister by friction.

The above performance demands on the HI-TRAC MS are met by its design configuration as summarized below and presented in the licensing drawings in Section 1.II.5.

Like all other transfer cask models, HI-TRAC MS is principally made of carbon steel and lead. The cask consists of two major parts, namely (a) a multi-shell cylindrical cask body, and (b) a quick connect/disconnect bottom lid. The cylindrical cask body is made of three concentric shells joined to a solid annular top flange and a solid annular bottom flange by circumferential welds. The innermost and the middle shells are fixed in place by longitudinal ribs which serve as radial connectors between the two shells. The radial connectors provide a continuous path for radial heat transfer and render the dual shell configuration into a stiff beam under flexural loadings. The space between these two shells is occupied by lead, which provides the bulk of the transfer cask's gamma radiation shielding capability and accounts for a major portion of its weight.

Between the middle shell and the outermost shell is the weldment that is referred to as the "water jacket." The water jacket is filled with water and may contain ethylene glycol fortified water, if warranted by the environmental conditions at the time of use. The water jacket provides most of the neutron shielding capability to the cask. The water jacket is outfitted with pressure relief devices to prevent over-pressurization in the case of an off-normal or accident event that causes the water mass inside of it to boil.

When required, cooling water is placed in the water jacket to serve as the principal neutron shield. When the cask is being removed from the pool and the MPC is full of water, the water jacket can be empty. This will minimize weight, if for example, crane capacities are limited, since the water within the MPC cavity is providing the neutron shielding during this time. However, the water jacket must be filled before the MPC is emptied of water. This keeps the load on the crane (i.e., weight of the loaded transfer cask) nearly constant between the lifts before and after MPC processing. Furthermore, the amount of shielding provided by the transfer cask is maximized at all times within crane capacity constraints. The water jacket concept is disclosed in a Holtec Patent [6,587,536 B1]. Those plants that have ample crane capacity may keep the water jacket filled at all times.

Depending on the nuclear plant's crane architecture, the transfer cask is equipped with a set of trunnions or a pair of lift blocks that are anchored into the top forging of the transfer cask using a set of high strength bolts. An optional device which prevents the MPC from sliding out of the transfer cask is attached to the lift blocks. The lifting appurtenance must meet the stress margins specified in NUREG-0612.

The bottom of the transfer cask is equipped with a thick lid. It is provided with a gasket seal against the machined face of the bottom flange creating a watertight (open top) container. A set of bolts that tap into the machined holes in the bottom lid provide the required physical strength to meet the structural margin requirements of NUREG-0612 as well as bolt pull to maintain joint integrity. The bottom lid can be fastened and released from the cask body by accessing its bolts from above the transfer cask bottom flange, which is an essential design feature to

permit MPC transfer operations with minimal dose and personnel safety.

To optimize the shielding in the body of HI-TRAC MS, the thickness of the lead in the transfer cask shall be customized for the host site. The thickness of the lead cylinder and the water jacket can be varied to meet the shielding demand of the MPCs being loaded. This design approach permits the quantity of shielding around the body of the transfer cask to be maximized for a given length and weight of fuel in keeping with the best ALARA practices. A 10CFR72.48 evaluation will be needed to demonstrate the safety of the proposed Change to a different height.

Table 1.II.2.5 provides the essential design data required for the safety analysis of the transfer cask in the subsequent chapters.

1.II.2.4 Topical Areas Addressed in the Main Body of the SAR

For convenience of reference, Table 1.II.2.1 below provides the subsection/paragraph number for the topical areas that are germane to the safety evaluation of the components being added though Supplement II.

1.II.2.5 MPC Contents and Parameters

The fuel types approved for storage in the HI-STORM 100 system in this FSAR also apply to MPC-32M introduced in this supplement, but are fully detailed in Supplement 2.II.

Table 1.II.2.1
Index of Topical Areas in Chapter Main Body

Topical Area/Subject	Location in Chapter 1 addressed in the FSAR	Comment
Locational fixity of neutron absorber material	1.2.1.3.1.2	In Metamic HT basket the entire cell wall is “poisoned”.
Neutron shielding materials	1.2.1.3.2	Applies to HI-STORM casks and the HI-TRAC transfer cask
Gamma Shielding materials	1.2.1.3.3	The text matter applies without exception
Lifting appurtenances	1.2.1.4	
Design Life	1.2.1.5	
Operational characteristics	1.2.2	
Criticality prevention	1.2.2.3.1	
Chemical safety	1.2.2.3.2	
Operation shutdown modes	1.2.2.3.3	
Instrumentation	1.2.2.3.4	
Maintenance Techniques	1.2.2.3.5	

Table 1.II.2.2
MPC Models Allowable for Storage in the HI-STORM 100 Version E (including the Version E1)

MPC Model Number	Applicable SNF Type	Number of Storage Cells	Fuel Basket's Structural material
MPC-68 and MPC-68 Version 1	BWR	68	Alloy X (stainless steel)
MPC-68M and MPC-68MCBS	BWR	68	Metamic HT
MPC-24	PWR	24	Alloy X
MPC-24E	PWR	24	Alloy X
MPC-32 & MPC-32 Version 1	PWR	32	Alloy X
MPC-32M and MPC-32MCBS	PWR	32	Metamic HT

SUPPLEMENT 1.III: GENERAL DESCRIPTION OF THE MPC-68M

1.III.0 GENERAL INFORMATION

The list of MPC models for use in the HI-STORM 100 System is expanded to include the MPC-68M model which consists of a Metamic-HT BWR fuel basket inside the existing MPC enclosure vessel. Information pertaining to the MPC-68M is contained in the “III” supplements to each chapter of this FSAR. Unless superseded or specifically modified by information in the “III” supplements, the information in the main FSAR is applicable to the HI-STORM 100 System with the MPC-68M.

Each chapter in the HI-STORM FSAR has been updated by the addition of a supplement labeled n.III (n = chapter number) that contains all necessary information in support of Licensing Amendment Request #1014-8 to the HI-STORM 100 CoC. This series of supplements is focused solely on incorporating one specific MPC model containing a new BWR fuel basket design into the HI-STORM 100 system.

1.III.1 INTRODUCTION

The safety evaluation in the “III” Supplements supports the use of an alternate fuel basket, made entirely of Metamic-HT, for use within the current MPC Enclosure Vessel. The canister is referred to as MPC-68M. The same design/service life applied to the current MPC models applies to the MPC-68M.

NUREG-1536 Revision 1 Section 8.4.17 provides guidance on fuel classification which is focused on the functional and performance based requirements of the fuel assembly. The following definitions, consistent with this guidance, are added and are specific to the “III” Supplements:

Undamaged Fuel Assembly is defined as: a) a fuel assembly without known or suspected cladding defects greater than pinhole leaks and hairline cracks, and which can be handled by normal means; or b) a BWR fuel assembly with an intact channel, a maximum planar average initial enrichment of 3.3 wt% U-235, without known or suspected **grossly breached spent fuel rods**, and which can be handled by normal means. An **undamaged fuel assembly** may be a **repaired/reconstituted fuel assembly**.

Grossly breached spent fuel rod is a spent nuclear fuel rod with a cladding defect that could lead to the release of fuel particulate greater than the average size fuel fragment for that particular assembly. A gross cladding breach may be confirmed by visual examination, through a review of reactor operating records indicating the presence of heavy metal isotopes, or other acceptable inspection means.

Repaired/reconstituted fuel assembly is a spent nuclear fuel assembly which contains dummy fuel rod(s) that displaces an amount of water greater than or equal to the original fuel rod(s) and/or which contains structural repairs so it can be handled by normal means.

1.III.2 GENERAL DESCRIPTION OF THE MPC-68M

1.III.2.1 MPC-68M Characteristics

The MPC-68M contains a 68 storage cell BWR fuel basket made of co-planar slotted plates of Metamic-HT (See Figure 1.III.1). The MPC is identified by the maximum number of fuel assemblies it can contain in the fuel basket. The Metamic-HT in the MPC-68M serves as the structural material of the basket and provides the necessary neutron absorption for maintaining the fuel in a sub-critical condition. The following design characteristics of MPC-68M are important to its function:

- i. The fuel basket is assembled from a rectilinear gridwork of plates so that there are no bends or radii at the cell corners. This structural feature eliminates the source of severe bending stresses in the basket structure by eliminating the offset between the cell walls that must transfer the inertia load of the stored SNF to the basket/MPC interface during the various postulated accident events (e.g., non-mechanistic tipover, uncontrolled lowering of a cask during on-site transfer, or off-site transport accident events, etc.).
- ii. Extruded aluminum shims (the so-called “*Basket Shims*”) are installed in the peripheral space between the fuel basket and the Enclosure Vessel to provide conformal contact surfaces between the Basket Shims and the fuel basket and between the Basket Shims and the Enclosure Vessel shell. The standard MPC-68M design consists of loosely installed conformal aluminum shapes that conduct heat from the basket to shell. The axial holes in the corner basket shims serve as the passageway for the downwards flow of the helium gas under the thermosiphon action, which is intrinsic to the thermal performance of all MPCs in the HI-STORM 100 system. A continuous basket shim (CBS) design variant consists of aluminum shims bolted to basket panel extensions in the peripheral region, that provide greater natural circulation flow area and increased direct radiant heat transfer from the basket exterior to the canister shell ID. The CBS design variant provides equivalent overall heat transfer to the standard design.
- iii. To facilitate an effective convective circulation inside the Canister, the Enclosure Vessel is pressurized to the same pressure level specified for the MPC-68 model. See Table 1.III.1.
- iv. The fuel basket consists of adjacent square openings (cells) separated by one wall of neutron absorber.

The mechanical and thermophysical properties of Metamic-HT presented in Section 1.III.2.4 are supported by the Metamic-HT Sourcebook[1.III.3]. The basket shims are made from creep resistant aluminum alloy similar to those used in HI-STAR 180 (Docket No. 71-9325) [2.III.6.2]. All design aspects of the MPC enclosure vessel (confinement boundary), including the vent and drain port arrangements in the MPC lid, are unchanged. The MPC-68M may be loaded in all licensed aboveground HI-STORM 100 overpacks.

1.III.2.2 Operational Characteristics

The MPC-68M canister is loaded in exactly the same manner as all other MPCs certified in the HI-STORM 100 docket, and uses the same ancillary equipment, (viz., lift cleats, lift yokes, Lid Welding Machine, Weld Removal Machine, Cask Transporter, Mating Device, Low Profile transporter or Zero Profile Transporter, Canister Upender, the Forced Helium Dehydrator system and the like). The operational characteristics of the HI-STORM overpack are unaffected.

All short-term operations, including draining of the MPC, welding of the lid, drying and filling of the MPC cavity with inert gas, and handling of the MPC remain unchanged from the existing practice, except that the dried and helium filled MPC-68M may reside indefinitely in the HI-TRAC transfer cask without the aid of the supplemental cooling system. The increased thermal conductivity of the Metamic-HT basket maintains the steady state fuel cladding temperatures below the ISG-11, Revision 3 [2.0.8] limits; thus eliminating the need for the supplemental cooling system. All other loading and unloading procedures and operations described in Chapter 8 apply to MPC-68M with the clarifications and limitations presented in Supplement 8.III.

1.III.2.2.1 Criticality Prevention

Metamic-HT is the designated neutron absorber and structural material in the MPC-68M. The properties of Metamic-HT and key characteristics, necessary for ensuring nuclear reactivity control, thermal, and structural performance of the basket, are presented in Section 1.III.2.4.

The entire basket is made of Metamic-HT, incorporating in the fuel basket a much greater B-10 areal density than is available in the fuel baskets designs with “attached” neutron absorber. This accrues three major safety and reliability advantages:

- (i) The BWR basket may store high enrichment fuel (i.e., fuel with up to 4.8 wt% U-235 initial planar enrichment) without reliance on gadolinium or burn-up credit.
- (ii) The neutron absorber cannot detach from the basket or displace within it.
- (iii) Axial movement of the fuel with respect to the basket due to internal clearances has no reactivity consequence because the entire length of the basket contains the same concentration of the B-10 isotope.

During storage, criticality control measures beyond the integral neutron poison in the storage cell walls are not necessary because of the low reactivity of the fuel in the dry helium-filled canister and the design features that prevent water from intruding into the canister fuel storage space.

1.III.2.2.2 Structural Considerations

Due to the low density of the Metamic-HT material and the optimized fuel basket design, the loaded weight of the MPC-68M (see Supplement 3.III) is less than the loaded weight of the MPC-68. Therefore, the lifting features on the MPC are unchanged and all of the lifting and handling equipment used to lift and handle the loaded MPC-68 may also be used to lift and handle the loaded MPC-68M.

1.III.2.2.3 Thermal Considerations

The MPC-68M, for an identical heat load, is intrinsically capable of more cooling effectiveness than the MPC-68, due to the higher thermal conductivity of Metamic-HT (approximately 1 order of magnitude greater than the thermal conductivity of Alloy X), the use of full length aluminum basket shims, and the hard-anodizing of the basket and basket shim materials to obtain high emissivities. Thus satisfaction of the ISG-11 temperature limits with acceptable margins is assured.

1.III.2.2.4 Shielding Considerations

The MPC68M basket consists of homogeneously dispersed boron carbide (10% minimum by weight). The B-10 areal density of the Metamic-HT panels which make up the basket is consistent with the areal density of the Metamic classic neutron poison panels in the MPC-68, therefore provides equivalent neutron shielding. From an overall shielding perspective the MPC-68M is expected to provide similar, if not better, shielding characteristics as the MPC-68. The MPC enclosure vessel, overpack, and transfer cask shielding properties are not modified.

1.III.2.3 Cask Contents

The MPC-68M is designed to accommodate up to sixty-eight undamaged BWR fuel assemblies. Up to sixteen damaged fuel assemblies in DFCs/DFIs and/or up to eight DFCs containing fuel debris may be stored in the following fuel storage locations: 1, 2, 3, 8, 9, 16, 25, 34, 35, 44, 53, 60, 61, 66, 67, and/or 68 (Figure 1.III.2), with the remaining fuel storage locations filled with undamaged BWR fuel assemblies. Damaged fuel assemblies in DFCs/DFIs and/or fuel debris in DFCs may be stored in fuel storage locations indicated in Figure 2.III.4 with remaining fuel storage locations filled with undamaged BWR fuel assemblies. Fuel classified as damaged fuel assemblies will be loaded into damaged fuel containers (DFCs) or basket cell locations with DFIs installed at the upper and lower ends. Damaged fuel assemblies stored using DFIs may contain missing or partial fuel rods and/or fuel rods with known or suspected cladding defect greater than hairline cracks or pinhole leaks as long as the fuel assembly can be handled by normal means and whose structural integrity is such that geometric rearrangement of fuel is not expected. Damaged fuel that does not meet these conditions must be stored in a DFC. Table 1.2.2 as supplemented by Table 1.III.1 provides the key system data and parameters for the MPC-68M.

(b) Thermo-Physical Properties of Metamic-HT

Metamic-HT was subject to an exhaustive test program prior to its certification by the USNRC in the HI-STAR 180 transport package. The results of the tests provide the authoritative information on the characteristics of Metamic-HT and are archived in the Metamic-HT Sourcebook [1.III.3] which is the source of much of the information summarized in this sub-section. As defined in this SAR, a *critical characteristic* of a material is one that is significant to its safety function. For purposes of manufacturing control, those *critical characteristics* that play a direct role in the ability of the fuel basket to render an essential safety function and are subject to minor variation in production are defined as Primary properties. Those properties that are not used in any of the safety analyses in this SAR are termed “ancillary” properties. Finally, those properties that bear upon the safety analysis but are essentially non-variant (such as density, heat capacity etc.) are denoted as “Invariant” properties. Primary properties are differentiated from the ancillary and invariant properties by the following two key characteristics which require them to be subjected to an extensive statistical in-production testing protocol (set down in Chapter 9).

- (i) They are used in the safety analysis simulations, and
- (ii) They are subject to lot-to-lot variability due to variation in the manufacturing parameters.

Thermal and inertia properties of Metamic-HT, such as density, heat capacity, thermal expansion coefficient, thermal conductivity and emissivity are stable properties that are not subject to significant variations among different lots in the production cycle. Therefore, following the practice similarly used in the ASME codes, such properties are treated as “invariant” and their reference values are excerpted from the Sourcebook and provided in Table 1.III.3 for analysis purposes. Properties that are not used in this safety analysis are elongation, charpy impact strength and lateral expansion. In accordance with the definition above these are ancillary properties.

Primary Properties

Tensile strength, yield strength, young's modulus and percent area reduction are properties that directly bear upon the structural strength of the basket. Therefore, their minimum guaranteed values (MGVs) specified in this report must be used in the strength and deflection analyses performed on the basket and reported in Supplement 3.III herein. The specified MGVs are subject to a programmatic confirmatory test regimen during production as described in Supplement 9.III.

Young's modulus is the slope of the stress/strain curve in the elastic range of the material. The deflection of a structure, such as a laterally loaded beam, is inversely proportional to the material's Young's modulus (Classical Kirchoff's Equation). Because the structural acceptance criterion for the Metamic-HT panels is deflection based, the lower bound value of E (i.e. MGV) should be used in the analysis models.

Area reduction measured in the tensile test coupons enables the "true strain" to be correlated to the "engineering strain". This property is needed for defining the stress-strain curve of the material in the structural analysis model.

The MGVs of all primary properties identified in the foregoing are provided in Table 1.III.2 and are either equal to or less than their corresponding values derived from the test program [1.III.3].

Finally, as is well known in the literature [1.III.10], the yield and ultimate strength of aluminum alloys, like all metals, may be substantially greater than the static values (reported as MGVs) because of dynamic effects that arise from rapid strain rates associated with impactive or impulsive loads. For conservatism, contrary to the standard practice for stainless steel baskets, *credit for strain rate effects on Metamic-HT's strength properties has not been taken in this SAR*. This additional conservatism has been deliberately incorporated to amplify the computed strains and deflections in the basket panels, which has the direct effect of reducing the computed safety margins.

Ancillary Properties

Ancillary properties are those that are not required in the safety analysis in this FSAR. Properties that are not used in this safety analysis are elongation, charpy impact strength and lateral expansion. Elongation is not utilized in the structural model because it is a redundant property, subsumed in the mechanical properties discussed above. Therefore, it is an ancillary property.

Creep of the basket panel under extended lateral loading from the basket under normal service condition was another subject of investigation in the Metamic-HT qualification program. If the basket is horizontal (which is the case under transport) then the lateral deflection of the basket panels due to creep would impact the criticality control characteristics. Therefore, it is necessary to ensure that the total deformation due to creep will remain within a specified (tolerable) limit. To make the generic safety determination for Metamic-HT panels in the fuel basket, creep tests were carried out for a significant length of time (approximately 20,000 hours) at different temperatures and stress levels to permit a correlation to be developed. As shown in the Metamic-HT sourcebook, the design basis creep equation developed therein bounds all creep data from the test program with large margins. Because the fuel basket is always in the

vertical orientation in HI-STORM, creep is not an operative mechanism for basket deformation. Therefore, creep strength qualifies as an ancillary property.

The data on charpy strength and lateral expansion were compiled in the Metamic-HT evaluation program (2005-2008) to study crack propagation in material containing internal flaws or pre-existing defects to ensure that any flaw in the Metamic-HT panels will not grow and propagate due to stress encountered during service. A bounding crack propagation study in the Metamic-HT Sourcebook using lowerbound properties from the test program confirmed that the Metamic-HT panels in the baskets are not vulnerable to crack propagation under transport service conditions (which entails repetitive impactive loadings). In storage, where there are no significant impactive loads under any of the operating modes, C_v and λ are not germane to any safety analysis in this FSAR making them as ancillary properties (i.e. not essential to safety analysis). Authoritative test based values of the above ancillary properties can be obtained from the Metamic-HT sourcebook [1.III.3], if needed.

Invariant Properties

Thermal and inertia properties of Metamic-HT, such as density, heat capacity, thermal expansion coefficient, thermal conductivity and emissivity are stable properties that are not subject to significant variations among different lots in the production cycle. Therefore, following the practice similarly used in the ASME codes, such properties are treated as “invariant” and their reference values are excerpted from the Sourcebook and provided in Table 1.III.3 for analysis purposes. The significance of invariant properties in the thermal design of Metamic-HT equipped casks is evaluated below.

Thermal Conductivity and Emissivity

The thermal performance of the cask is a direct function of emissivity and thermal conductivity properties. Therefore, to obtain a lowerbound thermal performance, it is necessary to define a lowerbound value for analysis. To this end suitable lowerbound emissivity and conductivity values supported by Metamic-HT test data are adopted in Table 1.III.3. The use of lowerbound thermal conductivity and emissivity in the thermal analysis ensures that for any given heat load, the computed metal temperatures will be upperbound values. Because the mechanical strength properties of metals decrease with increasing temperature, the over prediction of temperatures in the thermal analysis also ensures conservatism in the structural analysis by requiring the use of smaller-than-actual strength values.

Specific Gravity, Coefficient of Thermal Expansion and Specific Heat

As justified below these properties have a second order effect on the thermal design of Metamic-HT equipped casks.

Specific gravity is used to establish the weight of the cask. Because the fuel basket is constructed of a light weight material (90% is aluminum) its weight is a small fraction of the host cask. Minor variations in specific gravity do not affect the weight of the cask. Therefore, the use of nominal (average) specific gravity of Metamic-HT is appropriate in cask design and analysis. Accordingly, suitable mean specific gravity properties are computed from test data and tabulated in Table 1.III.3.

Coefficient of Thermal Expansion is used to compute the growth of the basket and to ensure that a condition of “restraint of free expansion” would not exist. Because the clearances engineered in the cask

design are quite liberal, as a practical matter, restraint of free expansion is not an issue. Therefore, the use of a mean value in cask design work is appropriate. Accordingly, suitable mean thermal expansion properties are computed from test data and tabulated in Table 1.III.3.

Specific Heat is used in the thermal transient analysis under a fire event. Even in this case, variation in C_p will have a minor effect on the results because of the small thermal inertia of the fuel basket relative to other items such as the stored fuel in the cask. Therefore the Specific Heat value of Metamic-HT should be pegged to the average measured value from test data. Accordingly, suitable mean heat capacity properties are computed from test data and tabulated in Table 1.III.3.

(e) Welding of Metamic-HT

Welding of Metamic-HT is conducted in accordance with Holtec approved procedures. As Metamic-HT is a non-code material, weld requirements are specified to meet the required safety and structural function of the basket. Weld acceptance criteria is stated in the licensing drawings provided in Section 1.5. In accordance with practice of joining metal-matrix composites, Friction Stir Welding (FSW) technique was adopted and qualified by Holtec for welding Metamic-HT. This process yields stronger joint strength on a repeatable basis compared to classical welding methods such as metal inert gas or tungsten inert gas welding. The FSW process implemented in the manufacturing of Metamic-HT basket require that the welding procedure and welders are appropriately qualified. This is accomplished by tensile testing of weld coupons (emulating ASME Section IX) to meet the weld strength requirements and conducting visual examinations, and bend testing or radiography testing to verify soundness of the weld (bend testing emulates ASME Section IX). The above procedure qualification protocol, provided in the Metamic-HT Manufacturing Manual [1.III.4], has been established to accord with the unique bonding characteristics of Metamic-HT and to ensure that the required minimum joint strength is realized with full assurance in the production of the fuel baskets.

APPENDIX 1.III.A: Intentionally Deleted

APPENDIX 1.III.B: Intentionally Deleted

CHAPTER 2[†]: PRINCIPAL DESIGN CRITERIA

This chapter contains a compilation of design criteria applicable to the HI-STORM 100 System. The loadings and conditions prescribed herein for the MPC, particularly those pertaining to mechanical accidents, are far more severe in most cases than those required for 10CFR72 compliance. The MPC is designed to be in compliance with both 10CFR72 and 10CFR71 and therefore certain design criteria are overly conservative for storage. This chapter sets forth the loading conditions and relevant acceptance criteria; it does not provide results of any analyses. The analyses and results carried out to demonstrate compliance with the design criteria are presented in the subsequent chapters of this report.

This chapter is in full compliance with NUREG-1536, except for the exceptions and clarifications provided in Table 1.0.2. Table 1.0.2 provides the NUREG-1536 review guidance, the justification for the exception or clarification, and the Holtec approach to meet the intent of the NUREG-1536 guidance.

2.0 PRINCIPAL DESIGN CRITERIA

The design criteria for the MPC, HI-STORM overpack, and HI-TRAC transfer cask are summarized in Tables 2.0.1, 2.0.2, and 2.0.3, respectively, and described in the sections that follow.

2.0.1 MPC Design Criteria

General

The MPC is designed for 40 years of service, while satisfying the requirements of 10CFR72. The adequacy of the MPC design for the design life is discussed in Section 3.4.12.

Structural

The MPC is classified as important to safety. The MPC structural components include the internal fuel basket and the enclosure vessel. The fuel basket is designed and fabricated as a core support structure, in accordance with the applicable requirements of Section III, Subsection NG of the ASME Code, with certain NRC-approved alternatives, as discussed in Section 2.2.4. The enclosure vessel is designed and fabricated as a Class 1 component pressure vessel in accordance with Section III, Subsection NB of the ASME Code, with certain NRC-approved alternatives, as discussed in Section 2.2.4. The principal exception is the MPC lid, vent and drain port cover plates, and closure ring welds to the MPC lid and shell, as discussed in Section 2.2.4. In addition, the threaded holes in

[†] This chapter has been prepared in the format and section organization set forth in Regulatory Guide 3.61. However, the material content of this chapter also fulfills the requirements of NUREG-1536. Pagination and numbering of sections, figures, and tables are consistent with the convention set down in Chapter 1, Section 1.0, herein. Finally, all terms-of-art used in this chapter are consistent with the terminology of the glossary and component nomenclature of the drawings (Section 1.5).

the MPC lid are designed in accordance with the requirements of NUREG-0612 and Regulatory Guide 3.61 for critical lifts to facilitate vertical MPC transfer.

Helium leakage testing of the MPC base metals (shell, baseplate, and MPC lid) and MPC shell to baseplate and shell to shell welds is performed on the unloaded MPC. MPCs that were loaded under CoC Amendments 7 and prior are subject to the requirements of those amendments, which may differ.

The MPC closure welds are partial penetration welds that are structurally qualified by analysis, as presented in Chapter 3. The MPC lid and closure ring welds are inspected by performing a liquid penetrant examination of the root pass and/or final weld surface (if more than one weld pass was required), in accordance with the drawings contained in Section 1.5. The integrity of the MPC lid weld is further insured by the non-destructive tests set forth in Chapter 9 and by a rigorous stress analysis described in Chapter 3.

Compliance with the ASME Code as it is applied to the design and fabrication of the MPC and the associated justification are discussed in Section 2.2.4. The MPC is designed for all design basis normal, off-normal, and postulated accident conditions, as defined in Section 2.2. These design loadings include postulated drop accidents while in the cavity of the HI-STORM overpack or the HI-TRAC transfer cask. The load combinations for which the MPC is designed are defined in Section 2.2.7. The maximum allowable weight and dimensions of a fuel assembly to be stored in the MPC are limited in accordance with Section 2.1.5.

Thermal

The design and operation of the HI-STORM 100 System meets the intent of the review guidance contained in ISG-11, Revision 3 [2.0.8]. Specifically, the ISG-11 provisions that are explicitly invoked and satisfied are:

- i. The thermal acceptance criteria for all commercial spent fuel (CSF) authorized by the USNRC for operation in a commercial reactor are unified into one set of requirements.
- ii. The maximum value of the *calculated* temperature for all CSF (including ZR and stainless steel fuel cladding materials) under long-term normal conditions of storage must remain below 400°C (752°F). For short-term operations, including canister drying, helium backfill, and on-site cask transport operations, the fuel cladding temperature must not exceed 400°C (752°F) for high burnup fuel and 570°C (1058°F) for moderate burnup fuel.
- iii. The maximum fuel cladding temperature as a result of an off-normal or accident event must not exceed 570°C (1058°F).
- iv. For High Burnup Fuel (HBF), operating restrictions are imposed to limit the maximum temperature excursion during short-term operations to 65°C (117°F).

To achieve compliance with the above criteria, certain design and operational changes are necessary, as summarized below.

- i. The peak fuel cladding temperature limit (PCT) for long term storage operations and short term operations is generally set at 400°C (752°F). However, for MPCs containing all moderate burnup fuel, the fuel cladding temperature limit for short-term operations is set at 570°C (1058°F) because fuel cladding stress is shown to be less than approximately 90 MPa per Reference [2.0.9]. Appropriate analyses have been performed as discussed in Chapter 4 and operating restrictions added to ensure these limits are met (see Section 4.5).
- ii. For MPCs containing at least one high burnup fuel (HBF) assembly or if the MPC heat load is greater than the threshold heat load defined in Table 4.5.1, the forced helium dehydration (FHD) method or the cyclic vacuum drying method of MPC cavity drying must be used to meet the normal operations PCT limit and satisfy the 65°C temperature excursion criterion for HBF.
- iii. The off-normal and accident condition PCT limit remains unchanged (1058°F).
- iv. For MPCs loaded with one or more high burnup fuel assemblies and the MPC heat load is greater than threshold heat load defined in Table 4.5.4, the Supplemental Cooling System (SCS) is required to ensure fuel cladding temperatures remain below the applicable temperature limit (see Section 4.5). The design criteria for the SCS are provided in Appendix 2.C.

The MPC cavity is dried using either a vacuum drying system, or a forced helium dehydration system (see Appendix 2.B). The MPC is backfilled with 99.995% pure helium in accordance with the limits in Table 1.2.2 during canister sealing operations to promote heat transfer and prevent cladding degradation.

The normal condition design temperatures for the structural steel components of the MPC are based on the temperature limits provided in ASME Section II, Part D, tables referenced in ASME Section III, Subsection NB and NG, for those load conditions under which material properties are relied on for a structural load combination. The specific design temperatures for the components of the MPC are provided in Table 2.2.3.

The MPCs are designed for a bounding thermal source term, as described in Section 2.1.6. The maximum allowable fuel assembly heat load for each MPC is limited as specified in Section 2.1.9.

Each MPC model, except MPC-68F, allows for two fuel loading strategies. The first is uniform fuel loading, wherein any authorized fuel assembly may be stored in any fuel storage location up to a maximum specific heat emission rate, subject to other restrictions, such as location requirements for damaged fuel containers (DFCs) and fuel with integral non-fuel hardware (e.g., APSR). The second is regionalized fuel loading, wherein the basket is segregated into two regions. Regionalized loading allows for storage of fuel assemblies with higher heat emission rates than would otherwise be authorized for uniform loading. Regionalized loading strategies must also comply with other

requirements, such as those for DFCs and non-fuel hardware. Specific fuel assembly cooling time, burnup, and decay heat limits for regionalized loading are presented in Section 2.1.9. The two fuel loading regions are defined by fuel storage location number in Table 2.1.27 (refer to Figures 1.2.2 through 1.2.4). For MPC-68F, only uniform loading is permitted.

Shielding

The allowable doses for an ISFSI using the HI-STORM 100 System are delineated in 10CFR72.104 and 72.106. Compliance with these regulations for any particular array of casks at an ISFSI is necessarily site-specific and is to be demonstrated by the licensee, as discussed in Chapters 5 and 12.

Compliance with these regulations for a single cask and several representative cask arrays is demonstrated in Chapters 5 and 10.

The MPC provides axial shielding at the top and bottom ends to maintain occupational exposures ALARA during canister closure and handling operations. The occupational doses are controlled in accordance with plant-specific procedures and ALARA requirements (discussed in Chapter 10).

The MPCs are designed for design basis fuel as described in Sections 2.1.7 and 5.2. The radiological source term for the MPCs is limited based on the burnup and cooling times specified in Section 2.1.9. Calculated dose rates for each MPC are provided in Section 5.1. These dose rates are used to perform an occupational exposure evaluation, as discussed in Chapter 10.

Criticality

The MPCs provide criticality control for all design basis normal, off-normal, and postulated accident conditions, as discussed in Section 6.1. The effective neutron multiplication factor is limited to $k_{eff} < 0.95$ for fresh unirradiated fuel with optimum water moderation and close reflection, including all biases, uncertainties, and MPC manufacturing tolerances.

Criticality control is maintained by the geometric spacing of the fuel assemblies, fixed borated neutron absorbing materials incorporated into the fuel basket assembly, and, for certain MPC models, soluble boron in the MPC water. The minimum specified boron concentration verified during neutron absorber manufacture is further reduced by 25% for criticality analysis for Boral-equipped MPCs and by 10% for METAMIC[®]-equipped MPCs. No credit is taken for burnup. The maximum allowable initial enrichment for fuel assemblies to be stored in each MPC is limited. Enrichment limits and soluble boron concentration requirements are delineated in Section 2.1.9 consistent with the criticality analysis described in Chapter 6.

Confinement

The MPC provides for confinement of all radioactive materials for all design basis normal, off-normal, and postulated accident conditions. As discussed in Section 7.1, the Holtec MPC design meets the guidance in Interim Staff Guidance 18 to classify confinement boundary leakage as non-credible. Therefore, no confinement dose analysis is performed. The confinement function of the MPC is verified through appropriate non-destructive examinations performed in accordance with the

acceptance test program in Chapter 9.

Helium leakage testing of the MPC base metal (shell, baseplate and MPC Lid) and MPC shell to baseplate welds and shell to shell weld is performed on the unloaded MPC. MPCs that were loaded under CoC Amendments 7 and prior are subject to the requirements of those amendments, which may differ.

Operations

There are no radioactive effluents that result from storage or transfer operations. Effluents generated during MPC loading are handled by the plant's radwaste system and procedures.

Generic operating procedures for the HI-STORM 100 System are provided in Chapter 8. Detailed operating procedures will be developed by the licensee based on Chapter 8, site-specific requirements that comply with the 10CFR50 Technical Specifications for the plant, and the HI-STORM 100 System CoC.

Acceptance Tests and Maintenance

The fabrication acceptance basis and maintenance program to be applied to the MPCs are described in Chapter 9. The operational controls and limits to be applied to the MPCs are discussed in Chapter 12. Application of these requirements will assure that the MPC is fabricated, operated, and maintained in a manner that satisfies the design criteria defined in this chapter.

Decommissioning

The MPCs are designed to be transportable in the HI-STAR overpack and are not required to be unloaded prior to shipment off-site. Decommissioning of the HI-STORM 100 System is addressed in Section 2.4.

2.0.2 HI-STORM Overpack Design Criteria

General

The HI-STORM overpack is designed for 40 years of service, while satisfying the requirements of 10CFR72. The adequacy of the overpack design for the design life is discussed in Section 3.4.11.

Structural

The HI-STORM overpack includes both concrete and structural steel components that are classified as important to safety.

The concrete material is defined as important to safety because of its importance to the shielding analysis. The primary function of the HI-STORM overpack concrete is shielding of the gamma and neutron radiation emitted by the spent nuclear fuel.

Unlike other concrete storage casks, the HI-STORM overpack concrete is enclosed in steel inner and outer shells connected to each other by radial ribs, and top and bottom plates. Where typical concrete storage casks are reinforced by rebar, the HI-STORM overpack is supported by the inner and outer shells connected by radial ribs. As the HI-STORM overpack concrete is not reinforced, the structural analysis of the overpack only credits the compressive strength of the concrete. Providing further conservatism, the structural analyses for normal conditions demonstrate that the allowable stress limits of the structural steel are met even with no credit for the strength of the concrete. During accident conditions (e.g., tornado missile, tip-over, end drop, and earthquake), only the compressive strength of the concrete is accounted for in the analysis to provide an appropriate simulation of the accident condition. Where applicable, the compressive strength of the concrete is calculated in accordance with ACI-318.1-89 (92) [2.0.1].

In recognition of the conservative assessment of the HI-STORM overpack concrete strength and the primary function of the concrete being shielding, the applicable requirements of ACI-349 [2.0.2] are invoked in the design and construction of the HI-STORM overpack concrete as clarified in Appendix 1.D.

Steel components of the storage overpack are designed and fabricated in accordance with the requirements of ASME Code, Section III, Subsection NF for Class 3 plate and shell components with certain NRC-approved alternatives.

The overpack is designed for all normal, off-normal, and design basis accident condition loadings, as defined in Section 2.2. At a minimum, the overpack must protect the MPC from deformation, provide continued adequate performance, and allow the retrieval of the MPC under all conditions. These design loadings include a postulated drop accident from the maximum allowable handling height, consistent with the analysis described in Section 3.4.10. The load combinations for which the overpack is designed are defined in Section 2.2.7. The physical characteristics of the MPCs for which the overpack is designed are defined in Chapter 1.

Thermal

The allowable long-term through-thickness section average temperature limit for the overpack concrete is established in accordance with Paragraph A.4.3 of Appendix A to ACI 349, which allows the use of elevated temperature limits if test data supporting the compressive strength is available and an evaluation to show no concrete deterioration provided. Appendix 1.D specifies the cement and aggregate requirements to allow the utilization of the temperature limits in Table 2.2.3. The allowable temperatures for the structural steel components are based on the maximum temperature for which material properties and allowable stresses are provided in Section II of the ASME Code. The specific allowable temperatures for the structural steel components of the overpack are provided in Table 2.2.3.

The overpack is designed for extreme cold conditions, as discussed in Section 2.2.2.2. The structural steel materials used for the storage cask that are susceptible to brittle fracture are discussed in Section 3.1.2.3.

The overpack is designed for the maximum allowable heat load for steady-state normal conditions, in accordance with Section 2.1.6. The thermal characteristics of the MPCs for which the overpack is designed are defined in Chapter 4.

Shielding

The off-site dose for normal operating conditions to a real individual beyond the controlled area boundary is limited by 10CFR72.104(a) to a maximum of 25 mrem/year whole body, 75 mrem/year thyroid, and 25 mrem/year for other critical organs, including contributions from all nuclear fuel cycle operations. Since these limits are dependent on plant operations as well as site-specific conditions (e.g., the ISFSI design and proximity to the controlled area boundary, and the number and arrangement of loaded storage casks on the ISFSI pad), the determination and comparison of ISFSI doses to this limit are necessarily site-specific. Dose rates for a single cask and a range of typical ISFSIs using the HI-STORM 100 System are provided in Chapter 5. The determination of site-specific ISFSI dose rates at the site boundary and demonstration of compliance with regulatory limits is to be performed by the licensee in accordance with 10CFR72.212.

The overpack is designed to limit the calculated surface dose rates on the cask for all MPCs as defined in Section 2.3.5. The overpack is also designed to maintain occupational exposures ALARA during MPC transfer operations, in accordance with 10CFR20. The calculated overpack dose rates are determined in Section 5.1. These dose rates are used to perform a generic occupational exposure estimate for MPC transfer operations and a dose assessment for a typical ISFSI, as described in Chapter 10.

Confinement

The overpack does not perform any confinement function. Confinement during storage is provided by the MPC and is addressed in Chapter 7. The overpack provides physical protection and biological shielding for the MPC confinement boundary during MPC dry storage operations.

Operations

There are no radioactive effluents that result from MPC transfer or storage operations using the overpack. Effluents generated during MPC loading and closure operations are handled by the plant's radwaste system and procedures under the licensee's 10CFR50 license.

Generic operating procedures for the HI-STORM 100 System are provided in Chapter 8. The licensee is required to develop detailed operating procedures based on Chapter 8, site-specific conditions and requirements that also comply with the applicable 10CFR50 technical specification requirements for the site, and the HI-STORM 100 System CoC.

Acceptance Tests and Maintenance

The fabrication acceptance basis and maintenance program to be applied to the overpack are

described in Chapter 9. The operational controls and limits to be applied to the overpack are contained in Chapter 12. Application of these requirements will assure that the overpack is fabricated, operated, and maintained in a manner that satisfies the design criteria defined in this chapter.

Decommissioning

Decommissioning considerations for the HI-STORM 100 System, including the overpack, are addressed in Section 2.4.

2.0.3 HI-TRAC Transfer Cask Design Criteria

General

The HI-TRAC transfer cask is designed for 40 years of service, while satisfying the requirements of 10CFR72. The adequacy of the HI-TRAC design for the design life is discussed in Section 3.4.11.

Structural

The HI-TRAC transfer cask includes both structural and non-structural biological shielding components that are classified as important to safety. The structural steel components of the HI-TRAC, with the exception of the lifting trunnions, are designed and fabricated in accordance with the applicable requirements of Section III, Subsection NF, of the ASME Code with certain NRC-approved alternatives, as discussed in Section 2.2.4. The lifting trunnions and associated attachments are designed in accordance with the requirements of NUREG-0612 and Regulatory Guide 3.61 for non-redundant lifting devices.

The HI-TRAC transfer cask is designed for all normal, off-normal, and design basis accident condition loadings, as defined in Section 2.2. At a minimum, the HI-TRAC transfer cask must protect the MPC from deformation, provide continued adequate performance, and allow the retrieval of the MPC under all conditions. These design loadings include a side drop from the maximum allowable handling height, consistent with the technical specifications (Not applicable for HI-TRAC 100G). The load combinations for which the HI-TRAC is designed are defined in Section 2.2.7. The physical characteristics of each MPC for which the HI-TRAC is designed are defined in Chapter 1.

Thermal

The allowable temperatures for the HI-TRAC transfer cask structural steel components are based on the maximum temperature for material properties and allowable stress values provided in Section II of the ASME Code. The top lids of the HI-TRAC 125, HI-TRAC 125D, and HI-TRAC 100G incorporate Holtite-A shielding material. This material has a maximum allowable temperature in accordance with the manufacturer's test data. The specific allowable temperatures for the structural steel and shielding components of the HI-TRAC are provided in Table 2.2.3. The HI-TRAC is designed for off-normal environmental cold conditions, as discussed in Section 2.2.2.2. The structural steel materials susceptible to brittle fracture are discussed in Section 3.1.2.3.

The HI-TRAC is designed for the maximum heat load analyzed for storage operations. When the MPC contains any high burnup fuel assemblies and the MPC decay heat is greater than the threshold heat load defined in Table 4.5.4, the Supplemental Cooling System (SCS) will be required for certain time periods while the MPC is inside the HI-TRAC transfer cask (see Section 4.5). The design criteria for the SCS are provided in Appendix 2.C. The HI-TRAC water jacket maximum allowable temperature is a function of the internal pressure. To preclude over pressurization of the water jacket due to boiling of the neutron shield liquid (water), the maximum temperature of the water is limited to less than the saturation temperature at the shell design pressure. In addition, the water is precluded from freezing during off-normal cold conditions by limiting the minimum allowable temperature and adding ethylene glycol. The thermal characteristics of the fuel for each MPC for which the transfer cask is designed are defined in Section 2.1.6. The working area ambient temperature limit for loading operations is limited in accordance with the design criteria established for the transfer cask.

Shielding

The HI-TRAC transfer cask provides shielding to maintain occupational exposures ALARA in accordance with 10CFR20, while also maintaining the maximum load on the plant's crane hook to below either 125 tons or 100 tons, or less, depending on whether the HI-TRAC 125 or HI-TRAC 100 transfer cask is utilized. The HI-TRAC calculated dose rates are reported in Section 5.1. These dose rates are used to perform a generic occupational exposure estimate for MPC loading, closure, and transfer operations, as described in Chapter 10. A postulated HI-TRAC accident condition, which includes the loss of the liquid neutron shield (water), is also evaluated in Section 5.1.2. In addition,

HI-TRAC dose rates are controlled in accordance with plant-specific procedures and ALARA requirements (discussed in Chapter 10).

The HI-TRAC 125 and 125D provide better shielding than the HI-TRAC 100, 100D, or 100G. Provided the licensee is capable of utilizing the 125-ton HI-TRAC, ALARA considerations would normally dictate that the 125-ton HI-TRAC should be used. However, sites may not be capable of utilizing the 125-ton HI-TRAC due to crane capacity limitations, floor loading limits, or other site-specific considerations. As with other dose reduction-based plant activities, individual users who cannot accommodate the 125-ton HI-TRAC should perform a cost-benefit analysis of the actions (e.g., modifications), which would be necessary to use the 125-ton HI-TRAC. The cost of the action(s) would be weighed against the value of the projected reduction in radiation exposure and a decision made based on each plant's particular ALARA implementation philosophy.

The HI-TRAC provides a means to isolate the annular area between the MPC outer surface and the HI-TRAC inner surface to minimize the potential for surface contamination of the MPC by spent fuel pool water during wet loading operations. The HI-TRAC surfaces expected to require decontamination are coated. The maximum permissible surface contamination for the HI-TRAC is in accordance with plant-specific procedures and ALARA requirements (discussed in Chapter 10).

Confinement

The HI-TRAC transfer cask does not perform any confinement function. Confinement during MPC transfer operations is provided by the MPC, and is addressed in Chapter 7. The HI-TRAC provides physical protection and biological shielding for the MPC confinement boundary during MPC closure and transfer operations.

Operations

There are no radioactive effluents that result from MPC transfer operations using HI-TRAC. Effluents generated during MPC loading and closure operations are handled by the plant's radwaste system and procedures.

Generic operating procedures for the HI-STORM 100 System are provided in Chapter 8. The licensee will develop detailed operating procedures based on Chapter 8, plant-specific requirements including the Part 50 Technical Specifications, and the HI-STORM 100 System CoC.

Acceptance Tests and Maintenance

The fabrication acceptance basis and maintenance program to be applied to the HI-TRAC Transfer Cask are described in Chapter 9. The operational controls and limits to be applied to the HI-TRAC are contained in Chapter 12. Application of these requirements will assure that the HI-TRAC is fabricated, operated, and maintained in a manner that satisfies the design criteria defined in this chapter.

Decommissioning

Decommissioning considerations for the HI-STORM 100 Systems, including the HI-TRAC Transfer Cask, are addressed in Section 2.4.

2.0.4 Principal Design Criteria for the ISFSI Pad

2.0.4.1 Design and Construction Criteria

In compliance with 10CFR72, Subpart F, “General Design Criteria”, the HI-STORM 100 cask system is classified as “important-to-safety” (ITS). This final safety analysis report (FSAR) explicitly recognizes the HI-STORM 100 System as an assemblage of equipment containing numerous ITS components. The reinforced concrete pad, on which the cask is situated, however, is designated as a non-ITS structure. This is principally because, in most cases, cask systems for storing spent nuclear fuel on reinforced concrete pads are installed as free-standing structures. The lack of a physical connection between the cask and the pad permits the latter to be designated as not important-to-safety.

However, if the ZPAs at the surface of an ISFSI pad exceed the threshold limit for free-standing HI-STORM installation set forth in this FSAR, then the cask must be installed in an anchored configuration (HI-STORM 100A).

In contrast to an ISFSI containing free-standing casks, a constrained-cask installation relies on the structural capacity of the pad to ensure structural safety. The Part 72 regulations require consideration of natural phenomenon in the design. Since an ISFSI pad in an anchored cask installation participates in maintaining the stability of the cask during “natural phenomena” on the cask and pad, it is an ITS structure. The procedure suggested in Regulatory Guide 7.10 [2.0.4] and the associated NUREG [2.0.5] indicates that an ISFSI pad used to secure anchored casks should be classified as a Category C ITS structure.

Because tipover of a cask installed in an anchored configuration is not feasible, the pad does not need to be engineered to accommodate this non-mechanistic event. However, the permissible carry height for a loaded HI-STORM 100A overpack must be established for the specific ISFSI pad using the methodology described in this FSAR, if the load handling device is not designed in accordance with ANSI N 14.6 and does not have redundant drop protection design features. These requirements are specified in the CoC. However, to serve as an effective and reliable anchor, the pad must be made appropriately stiff and suitably secured to preclude pad uplift during a seismic event.

Because the geological conditions vary widely across the United States, it is not possible to, a’piori, define the detailed design of the pad. Accordingly, in this FSAR, the limiting requirements on the design and installation of the pad are provided. The user of the HI-STORM 100A System bears the responsibility to ensure that all requirements on the pad set forth in this FSAR are fulfilled by the pad design. Specifically, the ISFSI owner must ensure that:

- The pad design complies with the structural provisions of this report. In particular, the requirements of ACI-349-97 [2.0.2] with respect to embedments must be assured.
- The material of construction of the pad (viz., the additives used in the pad concrete), and the attachment system are compatible with the ambient environment at the ISFSI site.
- The pad is designed and constructed in accordance with a Part 72, Subpart G-compliant QA program.
- The design and manufacturing of the cask attachment system are consistent with the provisions of this report.
- Evaluations are performed (e.g., per 72.212) to demonstrate that the seismic and other inertial loadings at the site are enveloped by the respective bounding loadings defined in this report.

A complete listing of design and construction requirements for an ISFSI pad on which an anchored HI-STORM 100A will be deployed is provided in Appendix 2.A. A sample embedment design is depicted in Figure 2.A.1.

2.0.4.2 Applicable Codes

Factored load combinations for ISFSI pad design are provided in NUREG-1536 [2.1.5], which is consistent with ACI-349-85. The factored loads applicable to the pad design consist of dead weight of the cask, thermal gradient loads, impact loads arising from handling and accident events, external missiles, and bounding environmental phenomena (such as earthquakes, wind, tornado, and flood). Codes ACI 360R-92, “Design of Slabs on Grade”; ACI 302.1R, “Guide for Concrete Floor and Slab Construction”; and ACI 224R-90, “Control of Cracking in Concrete Structures” should be used in the design and construction of the concrete pad, as applicable. The embedment design for the HI-STORM 100A (and 100SA) are the responsibility of the ISFSI owner and shall comply with Appendix B to ACI-349-97 as described in Appendix 2.A. A later Code edition may be used provided a written reconciliation is performed.

The factored load combinations presented in Table 3-1 of NUREG 1536 are reduced in the following to a bounding set of load combinations that are applied to demonstrate adherence to its acceptance criteria.

a. Definitions

D =	dead load including the loading due to pre-stress in the anchor studs
L =	live load
W =	wind load
W_t =	tornado load
T =	thermal load
F =	hydrological load
E =	DBE seismic load
A =	accident load
H =	lateral soil pressure
T_a =	accident thermal load
U_c =	reinforced concrete available strength

Note that in the context of a complete ISFSI design, the DBE seismic load includes both the inertia load on the pad due to its self mass plus the interface loads transmitted to the pad to resist the inertia loads on the cask due to the loaded cask self mass. It is only these interface loads that are provided herein for possible use in the ISFSI structural analyses. The inertia load associated with the seismic excitation of the self mass of the slab needs to be considered in the ISFSI owner’s assessment of overall ISFSI system stability in the presence of large uplift, overturning, and sliding forces at the base of the ISFSI pad. Such considerations are site specific and thus beyond the purview of this document.

b. Load Combinations for the Concrete Pad

The notation and acceptance criteria of NUREG-1536 apply.

Normal Events

$$U_c > 1.4D + 1.7L$$

$$U_c > 1.4D + 1.7 (L+H)$$

Off-Normal Events

$$U_c > 1.05D + 1.275 (L+H+T)$$

$$U_c > 1.05D + 1.275 (L+H+T+W)$$

Accident-Level Events

$$U_c > D+L+H+T+F$$

$$U_c > D+L+H+T_a$$

$$U_c > D+L+H+T+E$$

$$U_c > D+L+H+T+W_t$$

$$U_c > D+L+H+T+A$$

In all of the above load combinations, the loaded cask weight is considered as a live load L on the pad. The structural analyses presented in Chapter 3 provide the interface loads contributing to “E”, “F” and “W_t”, which, for high-seismic sites, are the most significant loadings. The above set of load combinations can be reduced to a more limited set by recognizing that the thermal loads acting on the ISFSI slab are small because of the low decay heat loads from the cask. In addition, standard construction practices for slabs serve to ensure that extreme fluctuations in environmental temperatures are accommodated without extraordinary design measures. Therefore, all thermal loads are eliminated in the above combinations. Likewise, lateral soil pressure load “H” will also be bounded by “F” (hydrological) and “E” (earthquake) loads. Accident loads “A”, resulting from a tipover, have no significance for an anchored cask. The following three load combinations are therefore deemed sufficient for structural qualification of the ISFSI slab supporting an anchored cask system.

Normal Events

$$U_c > 1.4D + 1.7 (L)$$

Off-Normal Events

$$U_c > 1.05D + 1.275 (L+F)$$

Accident-Level Events

$$U_c > D+L+E \text{ (or } W_t)$$

c. Load Combination for the Anchor Studs

The attachment bolts are considered to be governed by the ASME Code, Section III, Subsection NF and Appendix F [2.0.7]. Therefore, applicable load combinations and allowable stress limits for the attachment bolts are as follows:

Event Class and Load Combination	Governing ASME Code Section III Article for Stress Limits
<u>Normal Events</u>	
D	NF-3322.1, 3324.6
<u>Off-Normal Events</u>	
D+F	NF-3322.1, 3324.6 with all stress limits increased by 1.33
<u>Accident-Level Events</u>	
D+E and D+W _t	Appendix F, Section F-1334, 1335

2.0.4.3 Limiting Design Parameters

Since the loaded HI-STORM overpack will be carried over the pad, the permissible lift height for the cask must be determined site-specifically to ensure the integrity of the storage system in the event of a handling accident (uncontrolled lowering of the load). To determine the acceptable lift height, it is necessary to set down the limiting ISFSI design parameters. The limiting design parameters for an anchored cask ISFSI pad and the anchor studs, as applicable, are tabulated in Table 2.0.4. The design of steel embedments in reinforced concrete structures is governed by Appendix B of ACI-349-97. Section B.5 in that appendix states that “anchorage design shall be controlled by the strength of embedment steel...”. Therefore, limits on the strength of embedment steel and on the anchor studs must be set down not only for the purposes of quantifying structural margins for the design basis load combinations, but also for the use of the ISFSI pad designer to establish the appropriate embedment anchorage in the ISFSI pad. The anchored cask pad design parameters presented in Table 2.0.4 allow for a much stiffer pad than the pad for free-standing HI-STORMs (Table 2.2.9). This increased stiffness has the effect of reducing the allowable lift height. However, a lift height for a loaded HI-STORM 100 cask (free-standing or anchored) is not required to be established if the cask is being lifted with a lift device designed in accordance with ANSI N14.6 having redundant drop protection design features.

In summary, the requirements for the ISFSI pad for free-standing and anchored HI-STORM deployment are similar with a few differences. Table 2.0.5 summarizes their commonality and differences in a succinct manner with the basis for the difference fully explained.

2.0.4.4 Anchored Cask/ISFSI Interface

The contact surface between the baseplate of overpack and the top surface of the ISFSI pad defines the structural interface between the HI-STORM overpack and the ISFSI pad. When HI-STORM is deployed in an anchored configuration, the structural interface also includes the surface where the nuts on the anchor studs bear upon the sector lugs on the overpack baseplate. The anchor studs and their fastening arrangements into the ISFSI pad are outside of the structural boundary of the storage cask. While the details of the ISFSI pad design for the anchored configuration, like that for the free-standing geometry, must be custom engineered for each site, certain design and acceptance criteria are specified herein (Appendix 2.A) to ensure that the design and construction of the pad fully comports with the structural requirements of the HI-STORM System.

TABLE 2.0.4
LIMITING DESIGN PARAMETERS FOR ISFSI PADS AND ANCHOR STUDS FOR HI-STORM 100A

Item	Maximum Permitted Value [†]	Minimum Permitted Value
ISFSI PAD		
Pad Thickness	---	48 inches
Subgrade Young's Modulus from Static Tests (needed if pad is not founded on rock)	---	10,000 psi
Concrete compressive strength at 28 days	---	4,000 psi
ANCHOR STUDS		
Yield Strength at Ambient Temperature	None	80,000 psi
Ultimate Strength at Ambient Temperature	None	125,000 psi
Initial Stud Tension	65 ksi	55 ksi

[†] Pad and anchor stud parameters to be determined site-specifically, except where noted.

Item	Free-Standing	Anchored	Comments
1. Interface between cask and ISFSI	Contact surface between cask and top surface of ISFSI pad	Same as free-standing with the addition of the bearing surface between the anchor stud nut and the overpack baseplate. (The interface between the anchor stud and the anchor receptacle is at the applicable threaded or bearing surface).	All components below the top surface of the ISFSI pad and in contact with the pad concrete are part of the pad design. A non-integral component such as the anchor stud is not part of the embedment even though it may be put in place when the ISFSI pad is formed. The embedment for the load transfer from the anchor studs to the concrete ISFSI pad shall be exclusively cast-in-place.
2. Applicable ACI Code	At the discretion of the ISFSI owner. ACI-318 and ACI-349 are available candidate codes.	ACI-349-97. A later edition of this Code may be used if a written reconciliation is performed.	ACI-349-97 recognizes increased structural role of the ISFSI pad in an anchored cask storage configuration and imposes requirements on embedment design.
3. Limitations on the pad design parameters	Per Table 2.2.9	Per Table 2.0.4	In free-standing cask storage, the non-mechanistic tipover requirement limits the stiffness of the pad. In the anchored storage configuration, increased pad stiffness is permitted; however, the permissible HI-STORM carry height is reduced.
4. HI-STORM Carry Height	11 inches (for ISFSI pad parameter Set A or Set B) or, otherwise, site-specific. Not applicable if the cask is lifted with a device designed in accordance with ANSI N14.6 and having redundant drop protection features.	Determined site-specifically. Not applicable if the cask is lifted with a device designed in accordance with ANSI N14.6 and having redundant drop protection features.	Appendix 3.A provides the technical basis for free-standing installation. Depending on the final ISFSI pad configuration (thickness, concrete strength, subgrade, etc.), and the method of transport, an allowable carry height may need to be established.

Item	Free-Standing	Anchored	Comments
5. Maximum seismic input on the pad/cask contact surface. G_H is the vectorial sum of the two horizontal ZPAs and G_V is the vertical ZPA	$G_H + \mu G_V \leq \mu$ (see note 1 below)	$G_H \leq 2.12$ AND $G_V \leq 1.5$	
6. Required minimum value of cask to pad static coefficient of friction (μ , must be confirmed by testing if a value greater than 0.53 is used).	Greater than or equal to 0.53 (per Table 2.2.9).	Not applicable	
7. Applicable Wind and Large Missile Loads	Per Table 2.2.4, missile and wind loading different from the tabulated values, require 10CFR 72.48 evaluation	The maximum overturning moment at the base of the cask due to lateral missile and/or wind action must be less than 1×10^7 ft-lb.	The bases are provided in Section 3.4.8 for free-standing casks; the limit for anchored casks ensures that the anchorage system will have the same structural margins established for seismic loading.
8. Small and medium missiles (penetrant missile)	Per Table 2.2.5, missiles and wind loading different from the tabulated value, require 10CFR 72.48 evaluation.	Same as for free-standing cask construction.	
9. Design Loadings for the ISFSI Pad	Per load combinations in Section 2.0.4 using site-specific load.	Same as for free-standing cask.	

Note 1 – G_H and G_V may be the coincident values of the instantaneous horizontal and vertical accelerations, and the inequality shall be evaluated at each time step.

2.1 SPENT FUEL TO BE STORED

2.1.1 Determination of The Design Basis Fuel

The HI-STORM 100 System is designed to store most types of fuel assemblies generated in the commercial U.S. nuclear industry. Boiling-water reactor (BWR) fuel assemblies have been supplied by The General Electric Company (GE), Siemens, Exxon Nuclear, ANF, UNC, ABB Combustion Engineering, and Gulf Atomic. Pressurized-water reactor (PWR) fuel assemblies are generally supplied by Westinghouse, Babcock & Wilcox, ANF, and ABB Combustion Engineering. ANF, Exxon, and Siemens are historically the same manufacturing company under different ownership. Within this report, SPC is used to designate fuel manufactured by ANF, Exxon, or Siemens. Publications such as Refs. [2.1.1] and [2.1.2] provide a comprehensive description of fuel discharged from U.S. reactors. A central object in the design of the HI-STORM 100 System is to ensure that a majority of SNF discharged from the U.S. reactors can be stored in one of the MPCs.

The cell openings and lengths in the fuel basket have been sized to accommodate the BWR and PWR assemblies listed in Refs. [2.1.1] and [2.1.2] except as noted below. Similarly, the cavity lengths of the multi-purpose canisters have been set at dimensions which permit storing most types of PWR fuel assemblies and BWR fuel assemblies with or without fuel channels. The one exception is as follows:

- i. The South Texas Units 1 & 2 SNF, and CE 16x16 System 80 SNF are too long to be accommodated in the available MPC cavity lengths.

In addition to satisfying the cross sectional and length compatibility, the active fuel region of the SNF must be enveloped in the axial direction by the neutron absorber located in the MPC fuel basket. Alignment of the neutron absorber with the active fuel region is ensured by the use of upper and lower fuel spacers suitably designed to support the bottom and restrain the top of the fuel assembly. The spacers axially position the SNF assembly such that its active fuel region is properly aligned with the neutron absorber in the fuel basket. Figure 2.1.5 provides a pictorial representation of the fuel spacers positioning the fuel assembly active fuel region. Both the upper and lower fuel spacers are designed to perform their function under normal, off-normal, and accident conditions of storage.

In summary, the geometric compatibility of the SNF with the MPC designs does not require the definition of a design basis fuel assembly. This, however, is not the case for structural, confinement, shielding, thermal-hydraulic, and criticality criteria. In fact, a particular fuel type in a category (PWR or BWR) may not control the cask design in all of the above-mentioned criteria. To ensure that no SNF listed in Refs. [2.1.1] and [2.1.2] which is geometrically admissible in the MPC is precluded, it is necessary to determine the governing fuel specification for each analysis criterion. To make the necessary determinations, potential candidate fuel assemblies for each qualification criterion were considered. Table 2.1.1 lists the PWR fuel assemblies that were evaluated. These fuel assemblies were evaluated to define the governing design criteria for PWR fuel. The BWR fuel assembly designs evaluated are listed in Table 2.1.2. Tables 2.1.3 and 2.1.4 provide the fuel characteristics determined to be acceptable for storage in the HI-STORM 100 System. Section 2.1.9 summarizes the authorized contents for the HI-STORM 100 System. Any fuel assembly that has fuel characteristics

within the range of Tables 2.1.3 and 2.1.4 and meets the other limits specified in Section 2.1.9 is acceptable for storage in the HI-STORM 100 System. Tables 2.1.3 and 2.1.4 present the groups of fuel assembly types defined as “array/classes” as described in further detail in Chapter 6. Table 2.1.5 lists the BWR and PWR fuel assembly designs which are found to govern for three qualification criteria, namely reactivity, shielding, and thermal. Additional information on the design basis fuel definition is presented in the following subsections.

2.1.2 Intact SNF Specifications

Intact fuel assemblies are defined as fuel assemblies without known or suspected cladding defects greater than pinhole leaks and hairline cracks, and which can be handled by normal means. The design payload for the HI-STORM 100 System is intact ZR or stainless steel (SS) clad fuel assemblies with the characteristics listed in Tables 2.1.17 through 2.1.24.

Intact fuel assemblies without fuel rods in fuel rod locations cannot be loaded into the HI-STORM 100 unless dummy fuel rods, which occupy a volume greater than or equal to the original fuel rods, replace the missing rods prior to loading. Any intact fuel assembly that falls within the geometric, thermal, and nuclear limits established for the design basis intact fuel assembly, as defined in Section 2.1.9 can be safely stored in the HI-STORM 100 System. If irradiated dummy stainless steel rods are present in the fuel assembly, the dummy/replacement rods will be considered in the site specific dose calculations.

The range of fuel characteristics specified in Tables 2.1.3 and 2.1.4 have been evaluated in this FSAR and are acceptable for storage in the HI-STORM 100 System within the decay heat, burnup, and cooling time limits specified in Section 2.1.9 for intact fuel assemblies.

2.1.3 Damaged SNF and Fuel Debris Specifications

Damaged fuel and fuel debris are defined in the glossary.

Damaged fuel assemblies and fuel debris will be loaded into stainless steel damaged fuel containers (DFCs) provided with mesh screens having between 40x40 and 250x250 openings per inch, for storage in the HI-STORM 100 System (see Figures 2.1.1 and 2.1.2B, C, and D. Note: Figures 2.1.2B, C, and D are for illustrative purposes only). The MPC-24, MPC-24EF, MPC-32 and MPC-32F are designed to accommodate PWR damaged fuel and fuel debris. The MPC-68, MPC-68F and MPC-68FF are designed to accommodate BWR damaged fuel and fuel debris. The appropriate structural, thermal, shielding, criticality, and confinement analyses have been performed to account for damaged fuel and fuel debris and are described in their respective chapters that follow. For damaged fuel assemblies that can be handled by normal means and whose structural integrity is such that geometric rearrangement of fuel is not expected, the use of Damaged Fuel Isolators (DFIs) (see Figure 2.1.10) can be substituted for the use of the DFC for storage in allowed locations. Damaged fuel that does not meet this criteria must be stored using DFCs. The DFI is a set of specially designed barriers at the top and bottom of a storage cell space used to prevent the migration of fissile material from those cells. DFI storage locations are limited to the same locations allowed for DFCs in the MPC-68M. The limiting design characteristics for damaged fuel assemblies and restrictions on the number and location of damaged fuel containers authorized for loading in each MPC model

are provided in Section 2.1.9. Dresden Unit 1 fuel assemblies contained in Transnuclear-designed damaged fuel canisters and one Dresden Unit 1 thoria rod canister have been approved for storage directly in the HI-STORM 100 System without re-packaging (see Figures 2.1.2 and 2.1.2A).

MPC contents classified as fuel debris are required to be stored in DFCs. The basket designs for the standard and “F” model MPCs are identical. The lid and shell designs of the “F” models are unique in that the upper shell portion of the canister is thickened for additional strength needed to qualify as a secondary containment, which used to be required under hypothetical accident conditions of transportation under 10 CFR 71. Figure 2.1.9 shows the details of the differences between the standard and “F” model MPC shells. These details are common for both the PWR and BWR series MPC models.

2.1.3.1 Damaged Fuel Isolator

For the MPC-68M, if the damaged fuel assembly can be handled by normal means and its structural integrity is such that geometric rearrangement of fuel is not expected, then the device known as the Damaged Fuel Isolator (DFI) can be used in place of the DFC. Like the DFC, the DFI prevents the migration of fissile material in bulk or coarse particulate form from the nuclear fuel stored in its cellular storage cavity. The DFI can be used only if the fuel can be handled by normal means but is classified as damaged because of physical defect, viz., a breach in the fuel cladding or a structural failure in the grid strap assembly, etc., as explained in ISG-1. Damaged fuel stored utilizing the DFI may contain missing or partial fuel rods and/or fuel rods with known or suspected cladding defects greater than hairline cracks or pinhole leaks as long as the fuel assembly can be handled by normal means.

The DFI is made up of two end caps that, along with the four basket cell walls, comprise the fuel isolation space. The essential attributes of the DFI are:

1. The bottom cap is an open prismatic box with a flat baseplate which fits inside the storage cell space with a small clearance (for ease of installation). Once installed, the bottom of the DFI is flush with the MPC baseplate. The orientation of the bottom DFI is such that the DFI opening faces upward to allow the fuel assembly to rest inside of the DFI. The sidewalls of the bottom cap have perforations or wire mesh to permit transmigration of gases but not fuel fragments or gross particulates and is equipped with a permeable barrier against the storage cell walls for sequestration of coarse particulate matter. Figure 2.1.10 illustrates the features of the DFI end cap.
2. The top cap is anatomically similar to the bottom cap as illustrated in Figure 2.1.10. The length of the side walls of the top DFI is sized dependent upon the fuel geometry. The top DFI shall extend far enough into the top of the basket cell such that if the fuel shifts upwards, the DFI top cap can contact the MPC lid and still maintain a particulate barrier within the basket cell. The length of the side walls is at least 2 inches greater than the gap between the top of the fuel basket and the underside of the MPC lid. The orientation of the top DFI is such that the DFI opening faces downward. During installation, the top DFI will be pushed down on top of the fuel assembly until contact is made.
3. Both caps have engineered features to enable them to be remotely installed in any storage cell in which a fuel assembly needs to be isolated. Both caps are

- geometrically constrained to prevent their ejection from the storage cavity during a postulated accident event.
4. The design configuration of the DFI is common for all Light Water Reactor fuel.
 5. The DFI is constructed entirely from stainless steel or nickel alloy suitable for use within the high temperature environment of the MPC. (see Table 2.2.6) Per Figure 2.1.10, the cap walls shall have perforation with a maximum size of 1mm. This allows flow through the walls while keeping gross particulate fissile material inside the basket cell.
 6. The DFI includes perforated plates at the top and bottom to allow for flow through the basket cell while keeping gross particulate fissile material inside the basket cell.
 7. All load bearing members of the DFI, including the interfacing lift points, must be designed to satisfy Level A limits per ASME Code, Section III, Subsection NF under normal conditions. The most limiting accident conditions are the non-mechanistic tip over and vertical end drop. For these accident loadings, all load bearing members of the DFI must be able to support their amplified self-weight, considering the maximum design basis horizontal and vertical decelerations in Table 3.1.2, without suffering a gross structural failure. A conservative approach is to design all load bearing members of the DFI to satisfy Level D stress limits per ASME Code, Section III, Appendix F.

The fuel weight is not included as a load acting on the DFI, under normal or accident conditions, because the DFI, by design, does not play a role in supporting or resisting the weight of the fuel. Since the DFI top and bottom caps are not physically connected to each other nor to the basket cell walls, they are free to move in the longitudinal direction within the confines of the basket cell that they are installed. This means that, if the stored fuel assembly were to shift inside the basket cell due to a tip over event, the DFI would move together with the fuel assembly until the DFI top plate bottomed out against the underside of the MPC lid. At that moment, the inertia load from the fuel assembly would be fully resisted by the MPC lid with the DFI top plate acting merely as a shim plate. The behavior of the DFI bottom cap at the base of the cell is similar, with the DFI bottom plate acting as a thin shim plate between the stored fuel assembly and the MPC base plate.

2.1.4 Deleted

2.1.5 Structural Parameters for Design Basis SNF

The main physical parameters of an SNF assembly applicable to the structural evaluation are the fuel assembly length, envelope (cross sectional dimensions), and weight. These parameters, which define the mechanical and structural design, are specified in Section 2.1.9. The centers of gravity reported in Section 3.2 are based on the maximum fuel assembly weight. Upper and lower fuel spacers (as appropriate) maintain the axial position of the fuel assembly within the MPC basket and, therefore, the location of the center of gravity. The upper and lower fuel spacers are designed to withstand normal, off-normal, and accident conditions of storage. An axial clearance of approximately 2 to 2-1/2 inches is provided to account for the irradiation and thermal growth of the fuel assemblies. The suggested upper and lower fuel spacer lengths are listed in Tables 2.1.9 and 2.1.10. In order to qualify for storage in the MPC, the SNF must satisfy the physical parameters listed in Section 2.1.9.

2.1.6 Thermal Parameters for Design Basis SNF

The principal thermal design parameter for the stored fuel is the peak fuel cladding temperature, which is a function of the maximum heat generation rate per assembly and the decay heat removal capabilities of the HI-STORM 100 System. No attempt is made to link the maximum allowable decay heat per fuel assembly with burnup, enrichment, or cooling time. Rather, the decay heat per fuel assembly is adjusted to yield peak fuel cladding temperatures with an allowance for margin to the temperature limit.

To ensure the permissible fuel cladding temperature limits are not exceeded, Section 2.1.9 specifies the allowable decay heat per assembly for each MPC model. For both uniform and regionalized loading of moderate and high burnup fuel assemblies, the allowable decay heat per assembly is presented in Section 2.1.9.

Section 2.1.9 also includes separate cooling time, burnup, and decay heat limits for uniform fuel loading and regionalized fuel loading. Regionalized loading allows higher heat emitting fuel assemblies to be stored in the center fuel storage locations than would otherwise be authorized for storage under uniform loading conditions.

The fuel cladding temperature is also affected by the heat transfer characteristics of the fuel assemblies. The bounding fuel assembly design for thermal calculations for each fuel type is provided in Table 2.1.5.

Finally, the axial variation in the heat generation rate in the design basis fuel assembly is defined based on the axial burnup distribution. For this purpose, the data provided in Refs. [2.1.7] and [2.1.8] are utilized and summarized in Table 2.1.11 and Figures 2.1.3 and 2.1.4 for reference. These distributions are representative of fuel assemblies with the design basis burnup levels considered. These distributions are used for analyses only, and do not provide a criteria for fuel assembly acceptability for storage in the HI-STORM 100 System.

Except for MPC-68F, fuel may be stored in the MPC using one of two storage strategies, namely, uniform loading and regionalized loading. Uniform loading allows storage of any fuel assembly in any fuel storage location, subject to additional restrictions, such as those for loading of fuel assemblies containing non-fuel hardware as defined in the glossary. Regionalized fuel loading allows for higher heat emitting fuel assemblies to be stored in some storage locations with lower heat emitting fuel assemblies in the remaining fuel storage locations. Regionalized loading allows storage of higher heat emitting fuel assemblies than would otherwise be permitted using the uniform loading strategy. The definition of the regions for each MPC model is provided in Table 2.1.27. Regionalized fuel loading is not permitted in MPC-68F.

2.1.7 Radiological Parameters for Design Basis SNF

The principal radiological design criteria for the HI-STORM 100 System are the 10CFR72.104 site boundary dose rate limits and maintaining operational dose rates as low as reasonably achievable (ALARA). The radiation dose is directly affected by the gamma and neutron source terms of the

SNF assembly.

The gamma and neutron sources are separate and are affected differently by enrichment, burnup, and cooling time. It is recognized that, at a given burnup, the radiological source terms increase monotonically as the initial enrichment is reduced. The shielding design basis fuel assembly, therefore, is evaluated at conservatively high burnups, low cooling times, and low enrichments, as discussed in Chapter 5. The shielding design basis fuel assembly thus bounds all other fuel assemblies.

The design basis dose rates can be met by a variety of burnup levels and cooling times. Section 2.1.9 provides the procedure for determining burnup and cooling time limits for all of the authorized fuel assembly array/classes for both uniform fuel loading and regionalized loading. Table 2.1.11 and Figures 2.1.3 and 2.1.4 provide the axial distribution for the radiological source terms for PWR and BWR fuel assemblies based on the axial burnup distribution. The axial burnup distributions are representative of fuel assemblies with the design basis burnup levels considered. These distributions are used for analyses only, and do not provide a criteria for fuel assembly acceptability for storage in the HI-STORM 100 System.

Thoria rods placed in Dresden Unit 1 Thoria Rod Canisters meeting the requirements of Table 2.1.12 and Dresden Unit 1 fuel assemblies with one Antimony-Beryllium neutron source have been qualified for storage. Up to one Thoria Rod Canister is authorized for storage in combination with other intact and damaged fuel, and fuel debris as specified in Section 2.1.9.

Non-fuel hardware, as defined in the glossary, has been evaluated and is authorized for storage in the PWR MPCs as specified in Section 2.1.9.

2.1.8 Criticality Parameters for Design Basis SNF

As discussed earlier, the MPC-68, MPC-68F, MPC-68FF, MPC-32 and MPC-32F feature a basket without flux traps. In the aforementioned baskets, there is one panel of neutron absorber between two adjacent fuel assemblies. The MPC-24, MPC-24E, and MPC-24EF employ a construction wherein two neighboring fuel assemblies are separated by two panels of neutron absorber with a water gap between them (flux trap construction).

The minimum ^{10}B areal density in the neutron absorber panels for each MPC model is shown in Table 2.1.15.

For all MPCs, the ^{10}B areal density used for the criticality analysis is conservatively established below the minimum values shown in Table 2.1.15. For Boral, the value used in the analysis is 75% of the minimum value, while for METAMIC, it is 90% of the minimum value. This is consistent with NUREG-1536 [2.1.5] which suggests a 25% reduction in ^{10}B areal density credit when subject to standard acceptance tests, and which allows a smaller reduction when more comprehensive tests of the areal density are performed.

The criticality analyses for the MPC-24, MPC-24E and MPC-24EF (all with higher enriched fuel) and for the MPC-32 and MPC-32F were performed with credit taken for soluble boron in the MPC

water during wet loading and unloading operations. Table 2.1.14 and 2.1.16 provide the required soluble boron concentrations for these MPCs.

2.1.9 Summary of Authorized Contents

Tables 2.1.3, 2.1.4, 2.1.12, and 2.1.17 through 2.1.29 together specify the limits for spent fuel and non-fuel hardware authorized for storage in the HI-STORM 100 System. The limits in these tables are derived from the safety analyses described in the following chapters of this FSAR. Table 2.1.32 identifies allowable foreign materials to be stored in the HI-STORM 100 system. The foreign materials have been evaluated and are shown to have negligible impacts to the design functions of the HI-STORM system.

Fuel classified as damaged fuel assemblies or fuel debris must be stored in damaged fuel containers for storage in the HI-STORM 100 System, except for damaged fuel which can be handled by normal means whose structural integrity is such that geometric rearrangement of fuel is not expected can be stored using DFIs in allowed locations. For damaged fuel assemblies which can be handled by normal means and whose structural integrity is such that geometric rearrangement of fuel is not expected, the damaged fuel assemblies may be stored in basket cell locations with DFIs installed at the upper and lower ends, in place of storage in a DFC when using the MPC-68M. Damaged fuel stored using DFIs may contain missing or partial fuel rods and/or fuel rods with known or suspected cladding defects greater than hairline cracks or pinhole leaks as long as the fuel assembly can be handled by normal means. Damaged fuel not meeting these requirements must be stored using DFCs. Fuel classified as fuel debris must be stored in damaged fuel containers for storage in all MPCs in the HI-STORM 100 System.

Tables 2.1.17 through 2.1.24 are the baseline tables that specify the fuel assembly limits for each of the MPC models, with appropriate references to the other tables in this section for certain other limits. Tables 2.1.17 through 2.1.24 refer to Section 2.1.9.1 for ZR-clad fuel limits on minimum cooling time, maximum decay heat, and maximum burnup for uniform and regionalized fuel loading.

2.1.9.1 Decay Heat, Burnup, and Cooling Time Limits for ZR-Clad Fuel

Each ZR-clad fuel assembly and any PWR integral non-fuel hardware (NFH) to be stored in the HI-STORM 100 System must meet the following limits, in addition to meeting the physical limits specified elsewhere in this section, to be authorized for storage in the HI-STORM 100 System. The contents of each fuel storage location (fuel assembly and NFH) to be stored must be verified to have, as applicable:

- A decay heat less than or equal to the maximum allowable value.
- A burnup less than or equal to the maximum allowable value.
- A cooling time greater than or equal to the minimum allowable value.

The maximum allowable ZR-clad fuel storage location decay heat values are determined using the

methodology described in Section 2.1.9.1.1 or 2.1.9.1.2 depending on whether uniform fuel loading or regionalized fuel loading is being implemented[†]. The total permissible MPC heat load, for both uniform and regionalized loading, is determined in the following two subsections 2.1.9.1.1 and 2.1.9.1.2. The decay heat limits are independent of burnup, cooling time, or enrichment and are based strictly on the thermal analysis described in Chapter 4. Decay heat limits must be met for all contents in a fuel storage location (i.e., fuel and PWR non-fuel hardware, as applicable).

2.1.9.1.1 Uniform Fuel Loading Decay Heat Limits for ZR-Clad Fuel

Table 2.1.26 provides the maximum allowable decay heat per fuel storage location for ZR-clad fuel in uniform fuel loading for each MPC model in aboveground storage*. Even if the limits in Table 2.1.26 are met, the user must follow the instructions in the next section to calculate Q_{CoC} to determine if certain operational steps are required per the CoC. If the user needs to load fuel assemblies with a decay heat higher than the limits in Table 2.1.26, a regionalized loading pattern discussed in the next section may be considered.

2.1.9.1.2 Design Heat Load for ZR-Clad Fuel

The discussion in this section provides the approach to determine the maximum permitted per cell heat load for long term-storage in a regionalized pattern. In addition, this section also provides the approach to determine the allowed per cell heat load for those operations that are dependent on the total MPC heat load. These include helium backfill pressure, supplemental cooling, drying method, and time requirements for clearing blockage on HI-STORM inlet vents.

The Design Basis heat load for the aboveground HI-STORM System, Q_d , is 34 kW. Q_d is based on the assumption that every storage cell in the MPC is generating an equal amount of heat. In other words, the specific heat generation rate, q , of each storage location is considered equal. Thus, in an MPC with n storage locations,

$$Q_d = n q \quad \text{Equation a}$$

In reality, however, the population of SNF and associated NFH loaded in the MPC invariably has unequal decay heat. If we consider the loaded decay heat in a cell as r , and r_i denotes the loaded decay heat in location i , then the aggregate MPC heat load, Q_t , is given by a simple summation, i.e.,

$$Q_t = \sum_i^n r_i \quad \text{Equation b}$$

For purposes of the CoC compliance for operations where the total MPC heat load needs to be calculated, the total MPC heat load is,

[†] Note that the stainless steel-clad fuel decay heat limits apply to all fuel in the MPC, if a mixture of stainless steel and ZR-clad fuel is stored in the same MPC. The stainless steel-clad fuel assembly decay heat limits may be found in Table 2.1.17 through 2.1.24

* Maximum allowable heat loads in 100U underground storage are defined in Supplement 2.I; however the discussion in Section 2.1.9.1 also applies to the 100U.

$$Q_{CoC} = r_{max} n \quad \text{Equation c}$$

where r_{max} is the largest value of r_i in the population of SNF loaded in the MPC, i.e.,

$$r_{max} = \max \text{ of } [r_i, i = 1, 2, \dots, n] \quad \text{Equation d}$$

In all cases, the aggregate MPC heat load, Q_t , is less than or equal to Q_{CoC} or Q_d . In some cases this difference can be quite large. This scenario can be illustrated by considering the example of a MPC-32 that has 31 cells containing 0.5kW and one cell containing 1 kW. The aggregate MPC heat load is $(31)(0.5) + 1 = 16.5\text{kW}$. However, because $r_{max} = 1 \text{ kW}$, $Q_{CoC} = (32)(1) = 32\text{kW}$. Thus, $Q_{CoC} \gg Q_t$. This condition prevails in all loaded MPCs to a varying degree.

Even though Q_t may be significantly less than Q_{CoC} , Q_{CoC} must be used to establish certain operational procedures and the pre-analyzed conditions. The aggregate total heat load Q_t may be used for time to boil calculations, when determining if the air mass flow rate test on a loaded system, per Condition 9 of the CoC, needs to be performed and when considering if time limits need to be applied to vacuum drying. It should be noted that equation c is used to determine Q_{CoC} when following the heat load limits for uniform loading (Table 2.1.26).

To utilize more of the design basis heat load and allow for more loading flexibility, the MPC is divided into two regions. This is referred to as “regionalized loading”. The inner region (Region 1) and the outer region (Region 2) have maximum permitted heat load of q_1 and q_2 , respectively. The maximum permitted values of q_1 and q_2 are related through the ratio X , where $X = q_1/q_2$. The ratio X is NOT the ratio of the maximum values of the as-loaded storage locations in Region 1 and Region 2. The case where q_1 and q_2 are equal ($X = 1$) is referred to as “uniform storage”. Q_{CoC} for regionalized loading is computed by:

$$Q_{CoC} = n_1 q_1 + n_2 q_2 \quad \text{Equation e}$$

where n_1 and n_2 are the number of cells in Regions 1 and 2, respectively.

A functional relationship between Q and X was determined by performing an iterative thermal analysis. This led to the functional relationship $Q(X)$:

$$Q(X) = \frac{2Q_d}{1 + X^y} \quad \text{Equation f}$$

where X is a value greater than or equal to 0.5 and less than or equal to 3 and where y is also a function of X as defined below:

$$y(X) = \frac{0.23}{X^{0.1}} \quad \text{Equation g}$$

Table 2.1.30 is provided to give a list of permissible q_1 and q_2 for discrete values of X for all MPC

types. The table was determined using the following approach:

- (i) Choose a value of X in the permissible range ($0.5 \leq X \leq 3$)
- (ii) Calculate q_2 using the following equation:

$$q_2 = \frac{2 \times Q_d}{(1 + X^y) \times (n_1 \times X + n_2)} \quad \text{Equation h}$$

where:

$$y = 0.23/X^{0.1}$$

q_2 = Maximum allowable decay heat per fuel storage location in Region 2 (kW)

Q_d = Maximum uniform storage MPC decay heat (34 kW)

X = Ratio of q_1 to q_2 chosen in Step (i)

n_1 = Number of fuel storage locations in Region 1 from Table 2.1.27

n_2 = Number of fuel storage locations in Region 2 from Table 2.1.27

- (iii) Calculate q_1 using the following equation:

$$q_1 = X \times q_2 \quad \text{Equation i}$$

Using the steps provided above we find for $X=2$ that $q_1 = 1.43$ kW and $q_2 = 0.715$ kW for MPC-32. The user can follow Table 2.1.30 for discrete values of X to determine q_1 and q_2 or calculate q_1 and q_2 for a specific value of X using the steps above. It should be noted that equation e is used to determine Q_{CoC} when following the heat load limits for regionalized loading.

It should be emphasized that the variable two-region scheme of storage does not introduce any new complication in the dry storage implementation. As compared to uniform loading in MPC-32, where $q = 1.0625$ kW for all cells, the regionalized loading gives the user the flexibility to load the MPC with more varying heat loads. It is noted that for $X < 1$ Q_{CoC} is greater than Q_d , for $X = 1$ Q_{CoC} equals Q_d , and for $X > 1$ Q_{CoC} is less than Q_d . For ALARA and regardless of which loading pattern is used, a plant should always seek to preferentially locate the fuel with the higher heat loads toward the center of the MPC. If the need arises to place younger fuel into dry storage a regionalized pattern with $X < 1$ may be more appropriate.

2.1.9.1.3 Burnup Limits as a Function of Cooling Time for ZR-Clad Fuel

The maximum allowable ZR-clad fuel assembly average burnup varies with the following parameters, based on the shielding analysis in Chapter 5:

- Minimum required fuel assembly cooling time
- Maximum allowable fuel assembly decay heat
- Minimum fuel assembly average enrichment

The calculation described in this section is used to determine the maximum allowable fuel assembly burnup for minimum cooling times between 2 and 40 years, using maximum decay heat and

minimum enrichment as input values. This calculation may be used to create multiple burnup versus cooling time tables for a particular fuel assembly array/class and different minimum enrichments. The allowable maximum burnup for a specific fuel assembly may be calculated based on the assembly's particular enrichment and cooling time.

- (i) Choose a fuel assembly minimum enrichment, E_{235} .
- (ii) Calculate the maximum allowable fuel assembly average burnup for a minimum cooling time between 2 and 40 years using the equation below:

$$Bu = (A \times q) + (B \times q^2) + (C \times q^3) + [D \times (E_{235})^2] + (E \times q \times E_{235}) + (F \times q^2 \times E_{235}) + G$$

Equation j

Where:

Bu = Maximum allowable assembly average burnup (MWD/MTU)

q = Maximum allowable decay heat per fuel storage location determined in Section 2.1.9.1.1 or 2.1.9.1.2 (kW)

E_{235} = Minimum fuel assembly average enrichment (wt. % ^{235}U)
(e.g., for 4.05 wt. %, use 4.05)

A through G = Coefficients from Tables 2.1.28 or 2.1.29 for the applicable fuel assembly array/class and minimum cooling time.

2.1.9.1.4 Other Considerations

In computing the allowable maximum fuel storage location decay heats and fuel assembly average burnups, the following requirements apply:

- Calculated burnup limits shall be rounded down to the nearest integer
- Calculated burnup limits greater than 68,200 MWD/MTU for PWR fuel and 65,000 MWD/MTU for BWR fuel must be reduced to be equal to these values.
- Linear interpolation of calculated burnups between cooling times for a given fuel assembly maximum decay heat and minimum enrichment is permitted. For example, the allowable burnup for a minimum cooling time of 4.5 years may be interpolated between those burnups calculated for 4 and 5 years.
- ZR-clad fuel assemblies must have a minimum enrichment, as defined in the glossary, greater than or equal to the value used in determining the maximum allowable burnup per Section 2.1.9.1.3 to be authorized for storage in the MPC.

- When complying with the maximum fuel storage location decay heat limits, users must account for the decay heat from both the fuel assembly and any PWR non-fuel hardware, as applicable for the particular fuel storage location, to ensure the decay heat emitted by all contents in a storage location does not exceed the limit.
- There are two options for helium backfill range (shown in Table 1.2.2). The lower helium backfill range has different per cell heat load limits given in Table 2.1.31.

Section 12.2.10 provides a practical example of determining fuel storage location decay heat, burnup, and cooling time limits and verifying compliance for a set of example fuel assemblies.

2.1.9.1.5 Supplemental Cooling Threshold Heat Loads

Fuel loading operations involving the handling of High Burnup Fuel (HBF) in a dewatered MPC emplaced in a HI-TRAC transfer cask require additional cooling under certain thermal loads to address reduced heat dissipation relative to the normal storage condition. To address this requirement the Supplemental Cooling System (SCS) defined in Appendix 2.C is mandated under threshold heat loads defined in Section 4.5 and Table 2.1.30. The specific design of a SCS must accord with site-specific needs and resources, including the availability of plant utilities. However, a set of specifications to ensure that the performance objectives of the SCS are satisfied by plant-specific designs are set forth in Appendix 2.C.

Table 2.1.3 (continued)
PWR FUEL ASSEMBLY CHARACTERISTICS

Notes:

1. All dimensions are design nominal values. Maximum and minimum dimensions are specified to bound variations in design nominal values among fuel assemblies within a given array/class.
2. See glossary for the definition of “ZR.”
3. Design initial uranium weight is the nominal uranium weight specified for each assembly by the fuel manufacturer or reactor user. For each PWR fuel assembly, the total uranium weight limit specified in this table may be increased up to 2.0 percent for comparison with users’ fuel records to account for manufacturer’s tolerances.
4. Each guide tube replaces four fuel rods.
5. Soluble boron concentration per Tables 2.1.14 and 2.1.16, as applicable.
6. This fuel assembly array/class includes only the Indian Point Unit 1 fuel assembly. This fuel assembly has two pitches in different sectors of the assembly. These pitches are 0.441 inches and 0.453 inches.
7. For those MPCs loaded with both intact fuel assemblies and damaged fuel assemblies or fuel debris, the maximum initial enrichment of the intact fuel assemblies, damaged fuel assemblies and fuel debris is 4.0 wt.% ^{235}U .
8. Annular fuel pellets are allowed in the top and bottom 12” of the active fuel length.
9. This fuel assembly array/class can only be loaded in MPC-32.
10. One Instrument Tube and eight Guide Bars (Solid Zr).

Table 2.1.4 (continued)
BWR FUEL ASSEMBLY CHARACTERISTICS

NOTES:

1. All dimensions are design nominal values. Maximum and minimum dimensions are specified to bound variations in design nominal values among fuel assemblies within a given array/class.
2. See glossary for the definition of “ZR.”
3. Design initial uranium weight is the nominal uranium weight specified for each assembly by the fuel manufacturer or reactor user. For each BWR fuel assembly, the total uranium weight limit specified in this table may be increased up to 1.5 percent for comparison with users’ fuel records to account for manufacturer tolerances.
4. ≤ 0.635 wt. % ^{235}U and ≤ 1.578 wt. % total fissile plutonium (^{239}Pu and ^{241}Pu), (wt. % of total fuel weight, i.e., UO_2 plus PuO_2)
5. This assembly class contains 74 total rods; 66 full length rods and 8 partial length rods.
6. Square, replacing nine fuel rods.
7. Variable.
8. This assembly contains 92 total fuel rods; 78 full length rods and 14 partial length rods.
9. This assembly class contains 91 total fuel rods; 83 full length rods and 8 partial length rods.
10. One diamond-shaped water rod replacing the four center fuel rods and four rectangular water rods dividing the assembly into four quadrants.
11. These rods may also be sealed at both ends and contain Zr material in lieu of water.
12. This assembly is known as “QUAD+.” It has four rectangular water cross segments dividing the assembly into four quadrants.
13. For the SPC 9x9-5 fuel assembly, each fuel rod must meet either the 9x9E or the 9x9F set of limits or clad O.D., clad I.D., and pellet diameter.
14. For those MPCs loaded with both intact fuel assemblies and damaged fuel assemblies or fuel debris, the maximum planar average initial enrichment for the intact fuel assemblies is limited to 3.7 wt.% ^{235}U , as applicable.

Table 2.1.5

DESIGN BASIS FUEL ASSEMBLY FOR EACH DESIGN CRITERION

Criterion	BWR Fuel	PWR Fuel
Reactivity (Criticality)	GE12/14 10x10 with Partial Length Rods (Array/Class 10x10A)	B&W 15x15 (Array/Class 15x15F)
Shielding	GE 7x7	B&W 15x15
Thermal-Hydraulic	GE-12/14 10x10	<u>W</u> 17x17 OFA
Structural	730 lbs. for intact fuel 830 lbs. for canisterized fuel (intact and canisterized fuel include channels)	1680 lbs. including any control components

Tables 2.1.6 through 2.1.8

Indian Point 1	137.2	17.705	101.5	18.75	20.0

Note: Each user shall specify the fuel spacer length based on their fuel assembly length and presence of a DFC. Fuel spacers shall be sized to ensure that the active fuel region of intact fuel assemblies remains within the neutron poison region of the MPC basket with water in the MPC. For all fuel assemblies loaded into MPCs, with or without DFC/DFIs, the sum of the free axial space above the top of the fuel assembly (free axial space does not include DFC/DFI hardware) shall be less than 6". Additionally, any designed gap between the top of the DFC/DFI and the MPC lid to account for free axial thermal expansion shall not exceed 1.5".

¹ NFH is an abbreviation for non-fuel hardware, including control components. Fuel assemblies with control components may require shorter fuel spacers.

Table 2.1.10

SUGGESTED BWR UPPER AND LOWER FUEL SPACER LENGTHS

Fuel Assembly Type	Assembly Length (in.)	Location of Active Fuel from Bottom (in.)	Max. Active Fuel Length (in.)	Upper Fuel Spacer Length (in.)	Lower Fuel Spacer Length (in.)

[INTENTIONALLY DELETED]

Table 2.1.14

Soluble Boron Requirements for MPC-24/24E/24EF Fuel Wet Loading and Unloading Operations

MPC MODEL	FUEL ASSEMBLY MAXIMUM AVERAGE ENRICHMENT (wt % ²³⁵U)	MINIMUM SOLUBLE BORON CONCENTRATION (ppmb)
MPC-24	All fuel assemblies with initial enrichment ¹ less than the prescribed value for soluble boron credit	0
MPC-24	One or more fuel assemblies with an initial enrichment ¹ greater than or equal to the prescribed value for no soluble boron credit and ≤ 5.0 wt. %	≥ 400
MPC-24E/24EF	All fuel assemblies with initial enrichment ¹ less than the prescribed value for soluble boron credit	0
MPC-24E/24EF	All fuel assemblies classified as intact fuel assemblies and one or more fuel assemblies with an initial enrichment ¹ greater than or equal to the prescribed value for no soluble boron credit and ≤ 5.0 wt. %	≥ 300
MPC-24E/24EF	One or more fuel assemblies classified as damaged fuel or fuel debris and one or more fuel assemblies with initial enrichment > 4.0 wt.% and ≤ 5.0 wt. %	≥ 600

Table 2.1.15

¹Refer to Table 2.1.3 for these enrichments.

MINIMUM BORAL ^{10}B LOADING IN NEUTRON ABSORBER PANELS

MPC MODEL	MINIMUM ^{10}B LOADING (g/cm ²)	
	Boral Neutron Absorber Panels	METAMIC Neutron Absorber Panels
MPC-24	0.0267	0.0223
MPC-24E and MPC-24EF	0.0372	0.0310
MPC-32/32F	0.0372	0.0310
MPC-68 and MPC-68FF	0.0372	0.0310
MPC-68F	0.01	N/A (Note 1)

Notes:

1. All MPC-68F canisters are equipped with Boral neutron absorber panels.

Table 2.1.16

Soluble Boron Requirements for MPC-32 and MPC-32F Wet Loading and Unloading Operations

Fuel Assembly Array/Class	All Intact Fuel Assemblies		One or More Damaged Fuel Assemblies or Fuel Debris	
	Max. Initial Enrichment ≤ 4.1 wt.% ^{235}U (ppmb)	Max. Initial Enrichment 5.0 wt.% ^{235}U (ppmb)	Max. Initial Enrichment ≤ 4.1 wt.% ^{235}U (ppmb)	Max. Initial Enrichment 5.0 wt.% ^{235}U (ppmb)
14x14A/B/C/D/E	1,300	1,900	1,500	2,300
15x15A/B/C/G/I	1,800	2,500	1,900	2,700
15x15D/E/F/H	1,900	2,600	2,100	2,900
16x16A	1,400	2,000	1,500	2,300
17x17A	1,600	2,200	1,800	2,600
17x17B/C	1,900	2,600	2,100	2,900

Note:

1. For maximum initial enrichments between 4.1 wt% and 5.0 wt% ^{235}U , the minimum soluble boron concentration may be determined by linear interpolation between the minimum soluble boron concentrations at 4.1 wt% and 5.0 wt% ^{235}U .

Table 2.1.17

LIMITS FOR MATERIAL TO BE STORED IN MPC-24

PARAMETER	VALUE
Fuel Type	Uranium oxide, PWR intact fuel assemblies meeting the limits in Table 2.1.3 for the applicable array/class
Cladding Type	ZR or Stainless Steel (SS) as specified in Table 2.1.3 for the applicable array/class
Maximum Initial Enrichment per Assembly	As specified in Table 2.1.3 for the applicable array/class
Post-irradiation Cooling Time and Average Burnup per Assembly	ZR clad: As specified in Section 2.1.9.1 SS clad: ≥ 8 years and $\leq 40,000$ MWD/MTU
Decay Heat Per Fuel Storage Location	ZR clad: As specified in Section 2.1.9.1 SS clad: ≤ 710 Watts
Non-Fuel Hardware Burnup and Cooling Time	As specified in Table 2.1.25
Fuel Assembly Length	≤ 176.8 in. (nominal design)
Fuel Assembly Width	≤ 8.54 in. (nominal design)
Fuel Assembly Weight	$\leq 1,720$ lbs (including non-fuel hardware) for array/classes that do not require fuel spacers, otherwise $\leq 1,680$ lbs (including non-fuel hardware)
Other Limitations	<ul style="list-style-type: none"> ▪ Quantity is limited to up to 24 PWR intact fuel assemblies. ▪ Damaged fuel assemblies and fuel debris are not permitted for loading in MPC-24. ▪ One NSA is authorized to be loaded with a fuel assembly in fuel storage location 9, 10, 15, or 16. ▪ BPRAs, TPDs, WABAs, water displacement guide tube plugs, orifice rod assemblies, and/or vibration suppressor inserts, with or without ITTRs, may be stored with fuel assemblies in any fuel cell location. ▪ APSRs may be loaded with fuel assemblies in fuel cell locations 9, 10, 15, and/or 16 ▪ CRAs, RCCAs and/or CEAs may be stored with fuel assemblies in fuel cell locations 4, 5, 8 through 11, 14 through 17, 20, and/or 21. ▪ Soluble boron requirements during wet loading and unloading are specified in Table 2.1.14.

≥ 9	$\leq 78,784$	-	$\leq 111,000$
≥ 10	$\leq 101,826$	-	$\leq 180,000$
≥ 11	$\leq 141,982$	-	$\leq 630,000$
≥ 12	$\leq 360,000$	-	-

NOTES:

1. Burnups for non-fuel hardware are to be determined based on the burnup and uranium mass of the fuel assemblies in which the component was inserted during reactor operation.
2. Linear interpolation between points is permitted, except that APSR burnups $> 180,000$ MWD/MTU and $\leq 630,000$ MWD/MTU must be cooled ≥ 11 years.
3. Applicable to uniform loading and regionalized loading.
4. Includes Burnable Poison Rod Assemblies (BPRAs), Wet Annular Burnable Absorbers (WABAs), vibration suppressor inserts, and Neutron Source Assemblies (NSAs) in combination with other control components (i.e., BPRAs, TPDs, and/or RCCAs).
5. Includes Thimble Plug Devices (TPDs), water displacement guide tube plugs, orifice rod assemblies, Control Rod Assemblies (CRAs), Control Element Assemblies (CEAs), Rod Cluster Control Assemblies (RCCAs), and NSAs without other forms of control components.
6. N/A means not authorized for loading at this cooling time.
7. Non-fuel hardware burnup and cooling time limits are not applicable to Instrument Tube Tie Rods (ITTRs), since they are installed post-irradiation.

Table 2.1.32

FOREIGN MATERIALS ALLOWED FOR STORAGE

Foreign Material	Bounding Volume (in ³) (Note 2)	Bounding Dimension (in) (Note 3)	Bounding Cross-Sectional Area (in ²) (Note 4)
Duct Tape	1	5	N/A
Paper		5	
Common String		24	
Plastic/Nylon Tie Wraps	5	24	
Glue		N/A	
Tungsten (Note 1)	See Note 2	2	1.4
Rocks (Note 1)			
Zircaloy Metal (Note 1)			
Stainless Steel (Note 1)			
Glass			
Rust or Boron Flakes			
Rubber			
Wood			
Cotton			
Nuclear Grade Paint Chips	5		
Common Plastic	5		

Note 1: If the foreign material is located inside or is attached to a SFA such that the SFA could rest on the foreign material when the MPC is in the horizontal orientation, a site-specific evaluation must be performed to determine the impact on spent fuel cladding.

Note 2: A cumulative solid volume of up to 10 cubic inches of foreign materials may be stored in a single MPC. Each individual piece of foreign material must still comply with bounding cross-sectional area and dimensional requirements stated herein.

Note 3: Maximum permissible dimension applies to length, width, or height for a given foreign material. Foreign materials that exhibit dimensions greater than allowable may still be acceptable for storage provided that it is demonstrated that the given foreign material cannot completely block fluid flow through the MPC drain line or MPC basket flow holes.

Note 4: Foreign materials that exhibit a cross-sectional area greater than what is specified herein may still be acceptable for storage, provided that it is demonstrated that the given foreign material cannot completely block fluid flow through the MPC drain line or MPC basket flow holes.

* Note: The height of the top DFI (X) is determined by:

$$X \text{ (inches)} \geq (\text{gap between the MPC lid and top of the fuel basket}) + 2$$

FIGURE 2.1.10 (CONTINUED): DAMAGED FUEL ISOLATOR IN BASKET CELL (TYPICAL)

2.2 HI-STORM 100 DESIGN CRITERIA

The HI-STORM 100 System is engineered for unprotected outside storage for the duration of its design life. Accordingly, the cask system is designed to withstand normal, off-normal, and environmental phenomena and accident conditions of storage. Normal conditions include the conditions that are expected to occur regularly or frequently in the course of normal operation. Off-normal conditions include those infrequent events that could reasonably be expected to occur during the lifetime of the cask system. Environmental phenomena and accident conditions include events that are postulated because their consideration establishes a conservative design basis.

Normal condition loads act in combination with all other loads (off-normal or environmental phenomena/accident). Off-normal condition loads and environmental phenomena and accident condition loads are not applied in combination. However, loads that occur as a result of the same phenomena are applied simultaneously. For example, the tornado winds loads are applied in combination with the tornado missile loads.

In the following subsections, the design criteria are established for normal, off-normal, and accident conditions for storage. Loads that require consideration under each condition are identified and the design criteria discussed. Based on consideration of the applicable requirements of the system, the following loads are identified:

Normal (Long-Term Storage) Condition: Dead Weight, Handling, Pressure, Temperature, Snow

Off-Normal Condition: Pressure, Temperature, Leakage of One Seal, Partial Blockage of Air Inlets, Off-Normal Handling of HI-TRAC, Malfunction of Forced Helium Dehydrator System, Supplemental Cooling System Power Failure

Accident Condition: Handling Accident, Tip-Over, Fire, Partial Blockage of MPC Basket Vent Holes, Tornado, Flood, Earthquake, Fuel Rod Rupture, Confinement Boundary Leakage, Explosion, Lightning, Burial Under Debris, 100% Blockage of Air Inlets, Extreme Environmental Temperature, Supplemental Cooling System Operational Failure

Short-Term Operations: This loading condition is defined to accord with ISG-11, Revision 3 guidance [2.0.8]. This includes those normal operational evolutions necessary to support fuel loading or unloading activities. These include, but are not limited to MPC cavity drying, helium backfill, MPC transfer, and on-site handling of a loaded HI-TRAC transfer cask.

Each of these conditions and the applicable loads are identified with applicable design criteria established. Design criteria are deemed to be satisfied if the specified allowable limits are not exceeded.

2.2.1 Normal Condition Design Criteria

2.2.1.1 Dead Weight

The HI-STORM 100 System must withstand the static loads due to the weights of each of its components, including the weight of the HI-TRAC with the loaded MPC atop the storage overpack.

2.2.1.2 Handling

The HI-STORM 100 System must withstand loads experienced during routine handling. Normal handling includes:

- i. vertical lifting and transfer to the ISFSI of the HI-STORM overpack with loaded MPC
- ii. lifting, upending/downending, and transfer to the ISFSI of the HI-TRAC with loaded MPC in the vertical or horizontal position
- iii. lifting of the loaded MPC into and out of the HI-TRAC, HI-STORM, or HI-STAR overpack

The loads shall be increased by 15% to include any dynamic effects from the lifting operations as directed by CMAA #70 [2.2.16].

Handling operations of the loaded HI-TRAC transfer cask or HI-STORM overpack are limited to working area ambient temperatures greater than or equal to 0°F. This limitation is specified to ensure that a sufficient safety margin exists before brittle fracture might occur during handling operations. Subsection 3.1.2.3 provides the demonstration of the adequacy of the HI-TRAC transfer cask and the HI-STORM overpack for use during handling operations at a minimum service temperature of 0° F.

Special lifting devices shall meet the requirements of ANSI N14.6[†] [2.2.3]. Lifting attachments or interfacing lift points shall meet the requirements of NUREG-0612 and/or Regulatory Guide 3.61.

2.2.1.3 Pressure

The MPC internal pressure is dependent on the initial volume of cover gas (helium), the volume of fill gas in the fuel rods, the fraction of fission gas released from the fuel matrix, the number of fuel rods assumed to have ruptured, and temperature.

The normal condition MPC internal design pressure bounds the cumulative effects of the maximum fill gas volume, normal environmental ambient temperatures, the maximum MPC heat load, and an assumed 1% of the fuel rods ruptured with 100% of the fill gas and 30% of the significant radioactive gases (e.g., H³, Kr, and Xe) released in accordance with NUREG-1536.

[†] Yield and ultimate strength values used in the stress compliance demonstration per ANSI N14.6 shall utilize confirmed material test data through either independent coupon testing or material suppliers= CMTR or COC, as appropriate. To ensure consistency between the design and fabrication of a lifting component, compliance with ANSI N14.6 in this FSAR implies that the guidelines of ASME Section III, Subsection NF for Class 3 structures are followed for material procurement and testing, fabrication, and for NDE during manufacturing.

Table 2.2.1 provides the pressure limits for the HI-STORM 100 System.

For the storage of damaged fuel assemblies or fuel debris in a damaged fuel container, it is conservatively assumed that 100% of the fuel rods are ruptured with 100% of the rod fill gas and 30% of the significant radioactive gases (e.g., H^3 , Kr, and Xe) released for both normal and off-normal conditions. For PWR assemblies stored with non-fuel hardware, it is assumed that 100% of the gasses in the non-fuel hardware (e.g., BPRAs) is also released. This condition is bounded by the pressure calculation for design basis intact fuel with 100% of the fuel rods ruptured in all of the fuel assemblies. It is shown in Chapter 4 that the accident condition design pressure is not exceeded with 100% of the fuel rods ruptured in all of the design basis fuel assemblies. Therefore, rupture of 100% of the fuel rods in the damaged fuel assemblies or fuel debris will not cause the MPC internal pressure to exceed the accident design pressure.

The MPC internal design pressure under accident conditions is discussed in Subsection 2.2.3.

The HI-STORM overpack and MPC external pressure is a function of environmental conditions, which may produce a pressure loading. The normal and off-normal condition external design pressure is set at ambient standard pressure (1 atmosphere).

The HI-STORM overpack is not capable of retaining internal pressure due to its open design, and, therefore, no analysis is required or provided for the overpack internal pressure.

The HI-TRAC is not capable of retaining internal pressure due to its open design and, therefore, ambient and hydrostatic pressures are the only pressures experienced. Due to the thick steel walls of the HI-TRAC transfer cask, it is evident that the small hydrostatic pressure can be easily withstood; no analysis is required or provided for the HI-TRAC internal pressure. However, the HI-TRAC water jacket does experience internal pressure due to the heat-up of the water contained in the water jacket. Analysis is presented in Chapter 3 that demonstrates that the design pressure in Table 2.2.1 can be withstood by the water jacket and Chapter 4 demonstrates by analysis that the water jacket design pressure will not be exceeded. To provide an additional layer of safety, a pressure relief device set at the design pressure is provided, which ensures the pressure will not be exceeded.

2.2.1.4 Environmental Temperatures

To evaluate the long-term effects of ambient temperatures on the HI-STORM 100 System, an upper bound value on the annual average ambient temperatures for the continental United States is used. The normal temperature specified in Table 2.2.2 is bounding for all reactor sites in the contiguous United States. The "normal" temperature set forth in Table 2.2.2 is intended to ensure that it is greater than the annual average of ambient temperatures at any location in the continental United States. In the northern region of the U.S., the design basis "normal" temperature used in this FSAR will be exceeded only for brief periods, whereas in the southern U.S., it may be straddled daily in summer months. Inasmuch as the sole effect of the "normal" temperature is on the computed fuel cladding temperature to establish long-term fuel integrity, it should not lie below the time averaged yearly mean for the ISFSI site. Previously licensed cask systems have employed lower "normal" temperatures (viz. 75° F in Docket 72-1007) by utilizing national meteorological data.

Likewise, within the thermal analysis, a conservatively assumed soil temperature of the value specified in Table 2.2.2 is utilized to bound the annual average soil temperatures for the continental United States. The 1987 ASHRAE Handbook (HVAC Systems and Applications) reports average earth temperatures, from 0 to 10 feet below grade, throughout the continental United States. The highest reported annual average value for the continental United States is 77° F for Key West, Florida. Therefore, this value is specified in Table 2.2.2 as the bounding soil temperature.

Confirmation of the site-specific annual average ambient temperature and soil temperature is to be performed by the licensee, in accordance with 10CFR72.212. The annual average temperature is combined with insolation in accordance with 10CFR71.71 averaged over 24 hours to establish the normal condition temperatures in the HI-STORM 100 System.

2.2.1.5 Design Temperatures

The ASME Boiler and Pressure Vessel Code (ASME Code) requires that the value of the vessel design temperature be established with appropriate consideration for the effect of heat generation internal or external to the vessel. The decay heat load from the spent nuclear fuel is the internal heat generation source for the HI-STORM 100 System. The ASME Code (Section III, Paragraph NCA-2142) requires the design temperature to be set at or above the maximum through thickness mean metal temperature of the pressure part under normal service (Level A) condition. Consistent with the terminology of NUREG-1536, we refer to this temperature as the "Design Temperature for Normal Conditions". Conservative calculations of the steady-state temperature field in the HI-STORM 100 System, under assumed environmental normal temperatures with the maximum decay heat load, result in HI-STORM component temperatures at or below the normal condition design temperatures for the HI-STORM 100 System defined in Table 2.2.3. The temperature limits in Table 2.2.3 have been set down for the various parts in the MPC, HI-STORM and HI-TRAC to ensure that the subject part will not degrade if subject to the limiting temperature under long term storage. The normal condition temperature limit may be used as the reference temperature for defining the applicable part's allowable stress levels or for estimating the free expansion of the part if the actual computed service condition temperature is not available.

Except for the MPC Confinement Boundary, there are no Section III Subsection NB components in the HI-STORM system. Therefore, computation of secondary stresses (i.e., those that arise from thermal gradients at gross structural discontinuities) is not required for any component except the MPC pressure boundary. It should be noted that a HI-STORM MPC is uniquely protected against a sharp thermal gradient anywhere within its pressure boundary because of the continuously circulating helium gas which sweeps the canister's internal surfaces by the thermos-siphon action. As a result, the thermal stresses in the pressure boundary of the MPC are quite small. However, if required, the actual metal temperatures under the applicable service condition must be used to compute the Secondary stresses; the limiting temperatures listed in Table 2.2.3 can't be used.

Maintaining fuel rod cladding integrity is also a design consideration. The fuel rod peak cladding temperature (PCT) limits for the long-term storage and short-term normal operating conditions meet the intent of the guidance in ISG-11, Revision 3 [2.0.8]. For moderate burnup fuel, the previously licensed PCT limit of 570°C (1058°F) may be used [2.0.9] (see also Section 4.5).

2.2.1.6 Snow and Ice

The HI-STORM 100 System must be capable of withstanding pressure loads due to snow and ice. ASCE 7-88 (formerly ANSI A58.1) [2.2.2] provides empirical formulas and tables to compute the effective design pressure on the overpack due to the accumulation of snow for the contiguous U.S. and Alaska. Typical calculated values for heated structures such as the HI-STORM 100 System range from 50 to 70 pounds per square foot. For conservatism, the snow pressure loading is set at a level in Table 2.2.8 which bounds the ASCE 7-88 recommendation.

2.2.1.7 Dry Ice Jacket Supplemental Cooling System

The DIJ can be used to cool a Cask during short term operations at a site; it is not intended for long haul of loaded casks. Calculations show that the DIJ can be sized for transfer casks to maintain their cooling function for up to 12 hours. For longer short-term operations, intermediate replenishment of the dry ice in the jacket will be required. No safety analysis is required because there is no credible failure mode for malfunction of the passive dry-ice chiller.

2.2.1.8 HI-DRIP Supplemental Cooling System

The HI-DRIP supplemental cooling system is used for the short-term operations when the loaded transfer cask is out of the pool but the MPC contains water. It is not intended for long term operation. No safety analysis is required because there is no credible failure mode for the malfunction of the system since it relies only on the motive pressure provided by the plant's water supply system. If the plant's water supply system were to fail, the time-to-boil of the transfer cask is monitored.

2.2.2 Off-Normal Conditions Design Criteria

As the HI-STORM 100 System is passive, loss of power and instrumentation failures are not defined as off-normal conditions. The off-normal condition design criteria are defined in the following subsections.

A discussion of the effects of each off-normal condition is provided in Section 11.1. Section 11.1 also provides the corrective action for each off-normal condition. The location of the detailed analysis for each event is referenced in Section 11.1.

2.2.2.1 Pressure

The HI-STORM 100 System must withstand loads due to off-normal pressure. The off-normal condition MPC internal design pressure bounds the cumulative effects of the maximum fill gas volume, off-normal environmental ambient temperatures, the maximum MPC heat load, and an assumed 10% of the fuel rods ruptured with 100% of the fill gas and 30% of the significant radioactive gases (e.g., H^3 , Kr, and Xe) released in accordance with NUREG-1536.

2.2.2.2 Environmental Temperatures

The HI-STORM 100 System must withstand off-normal environmental temperatures. The off-normal environmental temperatures are specified in Table 2.2.2. The lower bound temperature occurs with no solar loads and the upper bound temperature occurs with steady-state insolation. Each bounding temperature is assumed to persist for a duration sufficient to allow the system to reach steady-state temperatures.

Limits on the peaks in the time-varying ambient temperature at an ISFSI site is recognized in the FSAR in the specification of the off-normal temperatures. The lower bound off-normal temperature is defined as the minimum of the 72-hour average of the ambient temperature at an ISFSI site. Likewise, the upper bound off-normal temperature is defined by the maximum of 72-hour average of the ambient temperature. The lower and upper bound off-normal temperatures listed in Table 2.2.2 are intended to cover all ISFSI sites in the continent U.S. The 72-hour average of temperature used in the definition of the off-normal temperature recognizes the considerable thermal inertia of the HI-STORM 100 storage system which reduces the effect of undulations in instantaneous temperature on the internals of the multi-purpose canister.

2.2.2.3 Design Temperatures

In addition to the normal condition design temperatures, which apply to the long-term storage condition, we also define an "off-normal/accident condition temperature" pursuant to the provisions of NUREG-1536 and Regulatory Guide 3.61. This is, in effect, the temperature, which may exist during a transient event (an example of such an instance is the overpack blocked air duct off-normal event). The off-normal/accident design temperatures of Table 2.2.3 are set down to bound the maximax (maximum in time and space) value of the thru-thickness average temperature of the structural or non-structural part, as applicable, during the transient event. These enveloping values, therefore, will bound the maximum temperature reached anywhere in the part, excluding skin effects during or immediately after, a transient event. Additionally, temperature limits are also defined for short-term normal operating conditions which include but are not limited to MPC drying operations and onsite transport operations.

The off-normal/accident design temperatures for stainless steel and carbon steel components are chosen such that the material's ultimate tensile strength does not fall below 30% of its room temperature value, based on data in published references [2.2.12 and 2.2.13]. This ensures that the material will not fail due to creep rupture during these short duration transient events. In addition, the off-normal and accident condition temperature limits in Table 2.2.3 have been set down for the various parts in the MPC, HI-STORM and HI-TRAC to ensure that the subject part will continue to render its intended function if subject to the limiting temperature under the applicable service condition. The limiting service condition temperature may be used as the reference temperature for defining the applicable part's allowable stress levels (for stress analysis purposes) or for estimating the free expansion of the part if the actual computed service condition temperature is not available.

2.2.2.4 Leakage of One Seal

The MPC enclosure vessel is designed to have no credible leakage under all normal, off-normal, and

hypothetical accident conditions of storage.

The confinement boundary is defined by the MPC shell, baseplate, MPC lid, port cover plates, closure ring, and associated welds. MPC shell welds and shell to baseplate weld are subject to helium leakage testing. Most confinement boundary welds are inspected by radiography or ultrasonic examination. Field welds are examined by the liquid penetrant method as specified in Chapter 9 using proven inspection and testing techniques to verify the integrity of the confinement boundary.

2.2.2.5 Partial Blockage of Air Inlets

The HI-STORM 100 System must withstand the partial blockage of the overpack air inlets. This event is defined in Table 2.0.2 as 50% blockage of the four air inlets. Because the overpack air inlets and outlets are covered by screens, located 90° apart, and inspected routinely (or alternatively, exit vent air temperature monitored), significant blockage of all vents by blowing debris, animals, etc. is very unlikely. To demonstrate the inherent thermal stability of the HI-STORM 100 System all four air inlets are assumed to be 50% blocked.

2.2.2.6 Off-Normal HI-TRAC Handling

During upending and/or downending of the HI-TRAC 100, HI-TRAC 125, or HI-TRAC 100G transfer cask, the total lifted weight is distributed among both the upper lifting trunnions and the lower pair of trunnions. Each of the four trunnions on the HI-TRAC therefore supports approximately one-quarter of the total weight. This even distribution of the load would continue during the entire rotation operation. The HI-TRAC 100D and 125D transfer cask designs do not include a lower pair of trunnions. Therefore, the entire load is held by the lifting trunnions.

If the lifting device cables begin to “go slack” while upending or downending the HI-TRAC 100, HI-TRAC 125, or HI-TRAC 100G, the eccentricity of the lower trunnions would immediately cause the cask to pivot, restoring tension on the cables. Nevertheless, the lower trunnions are conservatively analyzed to support 100% of the total weight with cask in vertical orientation, doubling the load per trunnion. This condition is analyzed to demonstrate that the lower trunnions in the standard and 100G HI-TRAC designs possess sufficient strength to support the increased load under this off-normal condition. In addition, the region in the vicinity of bottom trunnions in HI-TRAC 100G is also conservatively analyzed to support 75% of the total weight with cask in horizontal orientation. This off-normal condition is analyzed to demonstrate that any intermediate orientation is bounded by the two cases evaluated.

2.2.2.7 Malfunction of Forced Helium Dehydrator (FHD)

The FHD system is a forced helium circulation device used to effectuate moisture removal from loaded MPCs. For circulating helium, the FHD system is equipped with active components requiring external power for normal operation.

Initiating events of FHD malfunction are: (i) a loss of external power to the FHD System and (ii) an active component trip. In both cases a stoppage of forced helium circulation occurs and heat

dissipation in the MPC transitions to natural convection cooling.

Although the FHD System is monitored during its operation, stoppage of FHD operations does not require actions to restore forced cooling for adequate heat dissipation. This is because the condition of natural convection cooling evaluated in Section 4.5 shows that the fuel temperatures remain below off-normal limits. An FHD malfunction is detected by operator response to control panel visual displays and alarms.

2.2.2.8 Supplemental Cooling System (SCS) Power Failure

The SCS system is a fluid circulation device used to provide supplemental HI-TRAC cooling. For fluid circulation, the SCS system is equipped with active components requiring power for normal operation. The SCS is normally operated from an external source of power such as from site utilities or a feed from a heavy haul vehicle carrying the HI-TRAC. Occasional interruption in power supply is possible.

2.2.3 Environmental Phenomena and Accident Condition Design Criteria

Environmental phenomena and accident condition design criteria are defined in the following subsections.

The minimum acceptance criteria for the evaluation of the accident conditions are that the MPC confinement boundary maintains radioactive material confinement, the MPC fuel basket structure maintains the fuel contents subcritical, the stored SNF can be retrieved by normal means, and the system provides adequate shielding.

A discussion of the effects of each environmental phenomenon and accident condition is provided in Section 11.2. The consequences of each accident or environmental phenomenon are evaluated against the requirements of 10CFR72.106 and 10CFR20. Section 11.2 also provides the corrective action for each event. The location of the detailed analysis for each event is referenced in Section 11.2.

2.2.3.1 Handling Accident

The HI-STORM 100 System must withstand loads due to a handling accident. Even though the loaded HI-STORM 100 System will be lifted in accordance with approved, written procedures and may use special lifting devices which comply with ANSI N14.6-1993 [2.2.3], certain drop events are considered herein to demonstrate the defense-in-depth features of the design.

The loaded HI-STORM overpack will be lifted so that the bottom of the cask is at a height less than the vertical lift limit (see Table 2.2.8) above the ground. For conservatism, the postulated drop event assumes that the loaded HI-STORM 100 overpack falls freely from the vertical lift limit height before impacting a thick reinforced concrete pad. The deceleration of the cask must be maintained below 45 g's. Additionally, the overpack must continue to suitably shield the radiation emitted from the loaded MPC. The use of special lifting devices designed in accordance with ANSI N14.6 having redundant drop protection features to lift the loaded overpack will eliminate the lift height limit. The

lift height limit is dependent on the characteristics of the impacting surface, which are specified in Table 2.2.9, and the number of fuel assemblies being stored (full or partially loaded MPC). For site-specific conditions including impact surfaces not encompassed by Table 2.2.9 or handling a partially loaded MPC, the licensee shall evaluate the site-specific conditions to ensure that the drop accident loads do not exceed 45 g's. The methodology used in this alternative analysis shall be commensurate with the analyses in Appendix 3.A and shall be reviewed by the Certificate Holder.

The loaded HI-TRAC will be lifted so that the lowest point on the transfer cask (i.e., the bottom edge of the cask/lid assemblage) is at a height less than the calculated horizontal lift height limit (see Table 2.2.8) above the ground, when lifted horizontally outside of the reactor facility. For conservatism, the postulated drop event assumes that the loaded HI-TRAC falls freely from the horizontal lift height limit before impact. The postulated drop event is not applicable for the HI-TRAC 100G and is excluded from further discussion below.

Analysis is provided that demonstrates that the HI-TRAC continues to suitably shield the radiation emitted from the loaded MPC, and that the HI-TRAC end plates (top lid and transfer lid for HI-TRAC 100 and HI-TRAC 125 and the top lid and pool lid for HI-TRAC 100D and 125D) remain attached. Furthermore, the HI-TRAC inner shell is demonstrated by analysis to not deform sufficiently to hinder retrieval of the MPC. The horizontal lift height limit is dependent on the characteristics of the impacting surface, which are specified in Table 2.2.9, and the number of fuel assemblies being stored (full or partially loaded MPC). For site-specific conditions including impact surfaces not encompassed by Table 2.2.9 or handling a partially loaded MPC, the licensee shall evaluate the site-specific conditions to ensure that the drop accident loads do not exceed 45 g's. The methodology used in this alternative analysis shall be commensurate with the methodology described in this FSAR and shall be reviewed by the Certificate Holder. The use of lifting devices designed in accordance with ANSI N14.6 having redundant drop protection features during horizontal lifting of the loaded HI-TRAC outside of the reactor facilities eliminate the need for a horizontal lift height limit.

The loaded HI-TRAC, when lifted in the vertical position outside of the Part 50 facility shall be lifted with devices designed in accordance with ANSI N14.6 and having redundant drop protection features unless a site-specific analysis has been performed to determine a lift height limit. For vertical lifts of HI-TRAC with suitably designed lift devices, a vertical drop is not a credible accident for the HI-TRAC transfer cask and no vertical lift height limit is required to be established. Likewise, while the loaded HI-TRAC is positioned atop the HI-STORM 100 overpack for transfer of the MPC into the overpack (outside the Part 50 facility), the lifting equipment will remain engaged with the lifting trunnions of the HI-TRAC transfer cask or suitable restraints will be provided to secure the HI-TRAC. This ensures that a tip-over or drop from atop the HI-STORM 100 overpack is not a credible accident for the HI-TRAC transfer cask. The design criteria and conditions of use for MPC transfer operations from the HI-TRAC transfer cask to the HI-STORM 100 overpack at a Cask Transfer Facility are specified in Subsection 2.3.3.1 of this FSAR.

The loaded MPC is lowered into the HI-STORM or HI-STAR overpack or raised from the overpack using the HI-TRAC transfer cask and a MPC lifting system designed in accordance with ANSI N14.6 and having redundant drop protection features. Therefore, the possibility of a loaded MPC falling freely from its highest elevation during the MPC transfer operations into the HI-STORM or

HI-STAR overpacks is not credible.

The magnitude of loadings imparted to the HI-STORM 100 System due to drop events is heavily influenced by the compliance characteristics of the impacted surface. Two “pre-approved” concrete pad designs for storing the HI-STORM 100 System are presented in Table 2.2.9. Other ISFSI pad designs may be used provided the designs are reviewed by the Certificate Holder to ensure that impactive and impulsive loads under accident events such as cask drop and non-mechanistic tip-over are less than the design basis limits when analyzed using the methodologies established in this FSAR.

2.2.3.2 Tip-Over

The free-standing HI-STORM 100 System is demonstrated by analysis to remain kinematically stable under the design basis environmental phenomena (tornado, earthquake, etc.). However, the HI-STORM 100 overpack and MPC shall also withstand impacts due to a hypothetical tip-over event. The structural integrity of a loaded HI-STORM 100 System after a tip-over onto a reinforced concrete pad is demonstrated by analysis. The cask tip-over is not postulated as an outcome of any environmental phenomenon or accident condition. The cask tip-over is a non-mechanistic event.

The ISFSI pad for deploying a free-standing HI-STORM overpack must possess sufficient structural stiffness to meet the strength limits set forth in the ACI Code selected by the ISFSI owner. At the same time, the pad must be sufficiently compliant such that the maximum deceleration under a tip-over event is below the limit set forth in Table 3.1.2 of this FSAR.

During original licensing for the HI-STORM 100 System, a single set of ISFSI pad and subgrade design parameters (now labeled Set A) was established. Experience has shown that achieving a maximum concrete compressive strength (at 28 days) of 4,200 psi can be difficult. Therefore, a second set of ISFSI pad and subgrade design parameters (labeled Set B) has been developed. The Set B ISFSI parameters include a thinner concrete pad and less stiff subgrade, which allow for a higher concrete compressive strength. Cask deceleration values for all design basis drop and tipover events with the HI-STORM 100, HI-STORM 100S, HI-STORM 100S Version B, and HI-STORM 100S Version B Type IS overpacks have been verified to be less than or equal to the design limit of 45 g's for both sets of ISFSI pad parameters.

The original set and the new set (Set B) of acceptable ISFSI pad and subgrade design parameters are specified in Table 2.2.9. Users may design their ISFSI pads and subgrade in compliance with either parameter Set A or Set B. Alternatively, users may design their site-specific ISFSI pads and subgrade using any combination of design parameters resulting in a structurally competent pad that meets the provisions of ACI-318 and also limits the deceleration of the cask to less than or equal to 45 g's for the design basis drop and tip-over events for the HI-STORM 100, HI-STORM 100S, and HI-STORM 100S Version B overpacks. The structural analyses for site-specific ISFSI pad design shall be performed using methodologies consistent with those described in this FSAR, as applicable.

The interaction with the overpack and the ISFSI pad is heavily dependent on the compressive strengths of the concrete in the overpack and of the ISFSI pad. An increase in the concrete's compressive strength occurs monotonically as the system ages. A HI-STORM 100S Version B

overpack may include a flexible medium, designed similar to the overpacks internal channels or guide tubes, to absorb some of the energy during a non-mechanistic tip-over impact. The use of this flexible medium running along the top of the overpack circumferentially, would aid in reducing the g-loads of the event and improving the safety margin for re-certification of the overpack.

If the HI-STORM 100 System is deployed in an anchored configuration (HI-STORM 100A), then tip-over of the cask is structurally precluded along with the requirement of target compliance, which warrants setting specific limits on the concrete compressive strength and subgrade Young's Modulus. Rather, at the so-called high seismic sites (ZPAs greater than the limit set forth in the CoC for free standing casks), the ISFSI pad must be sufficiently rigid to hold the anchor studs and maintain the integrity of the fastening mechanism embedded in the pad during the postulated seismic event. The ISFSI pad must be designed to minimize a physical uplift during extreme environmental event (viz., tornado missile, DBE, etc.). The requirements on the ISFSI pad to render the cask anchoring function under long-term storage are provided in Section 2.0.4.

2.2.3.3 Fire

The possibility of a fire accident near an ISFSI site is considered to be extremely remote due to the absence of significant combustible materials. The only credible concern is related to a transport vehicle fuel tank fire engulfing the loaded HI-STORM 100 overpack or HI-TRAC transfer cask while it is being moved to the ISFSI.

The HI-STORM 100 System must withstand temperatures due to a fire event. The HI-STORM overpack and HI-TRAC transfer cask fire accidents for storage are conservatively postulated to be the result of the spillage and ignition of 50 gallons of combustible transporter fuel. The HI-STORM overpack and HI-TRAC transfer cask surfaces are considered to receive an incident radiation and forced convection heat flux from the fire. Table 2.2.8 provides the fire durations for the HI-STORM overpack and HI-TRAC transfer cask based on the amount of flammable materials assumed. The temperature of fire is assumed to be 1475° F in accordance with 10CFR71.73.

The accident condition design temperatures for the HI-STORM 100 System and the fuel rod cladding limits are specified in Table 2.2.3. The specified fuel cladding temperature limits are based on the temperature limits specified in ISG-11, Rev. 3 [2.0.9].

2.2.3.4 Partial Blockage of MPC Basket Vent Holes

The HI-STORM 100 System is designed to withstand reduction of flow area due to partial blockage of the MPC basket vent holes. As the MPC basket vent holes are internal to the confinement barrier, the only events that could partially block the vents are fuel cladding failure and debris associated with this failure, or the collection of crud at the base of the stored SNF assembly. The HI-STORM 100 System maintains the SNF in an inert environment with fuel rod cladding temperatures below accepted values (Table 2.2.3). Therefore, there is no credible mechanism for gross fuel cladding degradation during storage in the HI-STORM 100. For the storage of damaged BWR fuel assemblies or fuel debris, the assemblies and fuel debris will be placed in damaged fuel containers. The damaged fuel container is equipped with mesh screens which ensure that the damaged fuel and fuel debris will not escape to block the MPC basket vent holes. In addition, each MPC will be loaded

once for long-term storage and, therefore, buildup of crud in the MPC due to numerous loadings is precluded. Using crud quantities reported in an Empire State Electric Energy Research Corporation Report [2.2.6], a layer of crud of conservative depth is assumed to partially block the MPC basket vent holes. The crud depths for the different MPCs are listed in Table 2.2.8.

2.2.3.5 Tornado

The HI-STORM 100 System must withstand pressures, wind loads, and missiles generated by a tornado. The prescribed design basis tornado and wind loads for the HI-STORM 100 System are consistent with NRC Regulatory Guide 1.76 [2.2.7], ANSI 57.9 [2.2.8], and ASCE 7-88 [2.2.2]. Table 2.2.4 provides the wind speeds and pressure drops which the HI-STORM 100 overpack must withstand while maintaining kinematic stability. The pressure drop is bounded by the accident condition MPC external design pressure.

The kinematic stability of the HI-STORM overpack, and continued integrity of the MPC confinement boundary, while within the storage overpack or HI-TRAC transfer cask, must be demonstrated under impact from tornado-generated missiles in conjunction with the wind loadings. Standard Review Plan (SRP) 3.5.1.4 of NUREG-0800 [2.2.9] stipulates that the postulated missiles include at least three objects: a massive high kinetic energy missile that deforms on impact (large missile); a rigid missile to test penetration resistance (penetrant missile); and a small rigid missile of a size sufficient to pass through any openings in the protective barriers (micro-missile). SRP 3.5.1.4 suggests an automobile for a large missile, a rigid solid steel cylinder for the penetrant missile, and a solid sphere for the small rigid missile, all impacting at 35% of the maximum horizontal wind speed of the design basis tornado. Table 2.2.5 provides the missile data used in the analysis, which is based on the above SRP guidelines. The effects of a large tornado missile are considered to bound the effects of a light general aviation airplane crashing on an ISFSI facility.

During horizontal handling of the loaded HI-TRAC transfer cask outside the Part 50 facility, tornado missile protection shall be provided to prevent tornado missiles from impacting either end of the HI-TRAC. The tornado missile protection shall be designed such that the large tornado missile cannot cause damage to the bottom or top of the loaded HI-TRAC beyond acceptable limits, while in the horizontal position. Also, the missile protection for the top of the HI-TRAC shall be designed to preclude the penetrant missile and micro-missile from passing through the penetration in the HI-TRAC top lid, while in the horizontal position. With the tornado missile protection in place, the impacting of a large tornado missile on either end of the loaded HI-TRAC or the penetrant missile or micro-missile entering the penetration of the top lid is not credible. Therefore, no analyses of these impacts are provided.

2.2.3.6 Flood

The HI-STORM 100 System must withstand pressure and water forces associated with a flood. Resultant loads on the HI-STORM 100 System consist of buoyancy effects, static pressure loads, and velocity pressure due to water velocity. The flood is assumed to deeply submerge the HI-STORM 100 System (see Table 2.2.8). The flood water depth is based on the hydrostatic pressure which is bounded by the MPC external pressure stated in Table 2.2.1.

It must be shown that the MPC does not collapse, buckle, or allow water in-leakage under the hydrostatic pressure from the flood.

The flood water is assumed to be nonstagnant. The maximum allowable flood water velocity is determined by calculating the equivalent pressure loading required to slide or tip over the HI-STORM 100 System. The design basis flood water velocity is stated in Table 2.2.8. Site-specific safety reviews by the licensee must confirm that flood parameters do not exceed the flood depth, slide, or tip-over forces.

If the flood water depth exceeds the elevation of the top of the HI-STORM overpack inlet vents, then the cooling air flow would be blocked. The flood water may also carry debris which may act to block the air inlets of the overpack. Blockage of the air inlets is addressed in Subsection 2.2.3.13.

Most reactor sites are hydrologically characterized as required by Paragraph 100.10(c) of 10CFR100 and further articulated in Reg. Guide 1.59, "Design Basis Floods for Nuclear Power Plants" and Reg. Guide 1.102, "Flood Protection for Nuclear Power Plants." It is assumed that a complete characterization of the ISFSI's hydrosphere including the effects of hurricanes, floods, seiches and tsunamis is available to enable a site-specific evaluation of the HI-STORM 100 System for kinematic stability. An evaluation for tsunamis[†] for certain coastal sites should also be performed to demonstrate that sliding or tip-over will not occur and that the maximum flood depth will not be exceeded.

Analysis for each site for such transient hydrological loadings must be made for that site. It is expected that the plant licensee will perform this evaluation under the provisions of 10CFR72.212.

2.2.3.7 Seismic Design Loadings

The HI-STORM 100 System must withstand loads arising due to a seismic event and must be shown not to tip over during a seismic event. Subsection 3.4.7 contains calculations based on conservative static "incipient tipping" calculations which demonstrate static stability. The calculations in Section 3.4.7 result in the values reported in Table 2.2.8, which provide the maximum horizontal zero period acceleration (ZPA) versus vertical acceleration multiplier above which static incipient tipping would occur. This conservatively assumes the peak acceleration values of each of the two horizontal earthquake components and the vertical component occur simultaneously. The maximum horizontal ZPA provided in Table 2.2.8 is the vector sum of two horizontal earthquakes.

For anchored casks, the limit on zero period accelerations (ZPA) is set by the structural capacity of the sector lugs and anchoring studs. Table 2.2.8 provides the limits for HI-STORM 100A for the maximum vector sum of two horizontal earthquake peak ZPA's along with the coincident limit on the vertical ZPA.

2.2.3.8 100% Fuel Rod Rupture

[†] A tsunami is an ocean wave from seismic or volcanic activity or from submarine landslides. A tsunami may be the result of nearby or distant events. A tsunami loading may exist in combination with wave splash and spray, storm surge and tides.

The HI-STORM 100 System must withstand loads due to 100% fuel rod rupture. For conservatism, 100 percent of the fuel rods are assumed to rupture with 100 percent of the fill gas and 30% of the significant radioactive gases (e.g., H³, Kr, and Xe) released in accordance with NUREG-1536. All of the fill gas contained in non-fuel hardware, such as Burnable Poison Rod Assemblies (BPRAs) is also assumed to be released in analyzing this event.

2.2.3.9 Confinement Boundary Leakage

No credible scenario has been identified that would cause failure of the confinement system. Section 7.1 provides a discussion as to why leakage of any magnitude from the MPC is not credible, based on the materials and methods of fabrication and inspection.

2.2.3.10 Explosion

The HI-STORM 100 System must withstand loads due to an explosion. The accident condition MPC external pressure and overpack pressure differential specified in Table 2.2.1 bounds all credible external explosion events. There are no credible internal explosive events since all materials are compatible with the various operating environments, as discussed in Section 3.4.1, or appropriate preventive measures are taken to preclude internal explosive events (see Section 1.2.1.3.1.1). The MPC is composed of stainless steel, neutron absorber material, and prior to CoC Amendment 2, possibly optional aluminum alloy 1100 heat conduction elements. For these materials, and considering the protective measures taken during loading and unloading operations there is no credible internal explosive event.

2.2.3.11 Lightning

The HI-STORM 100 System must withstand loads due to lightning. The effect of lightning on the HI-STORM 100 System is evaluated in Chapter 11.

2.2.3.12 Burial Under Debris

The HI-STORM 100 System must withstand burial under debris. Such debris may result from floods, wind storms, or mud slides. Mud slides, blowing debris from a tornado, or debris in flood water may result in duct blockage, which is addressed in Subsection 2.2.3.13. The thermal effects of burial under debris on the HI-STORM 100 System are evaluated in Chapter 11. Siting of the ISFSI pad shall ensure that the storage location is not located near shifting soil. Burial under debris is a highly unlikely accident, but is analyzed in this FSAR.

2.2.3.13 100% Blockage of Air Inlets

For conservatism, this accident is defined as a complete blockage of all four bottom air inlets. Such a blockage may be postulated to occur during accident events such as a flood or tornado with blowing debris. The HI-STORM 100 System must withstand the temperature rise as a result of 100% blockage of the air inlets and outlets. The fuel cladding temperature must be shown to remain below the off-normal/accident temperature limit specified in Table 2.2.3.

2.2.3.14 Extreme Environmental Temperature

The HI-STORM 100 System must withstand extreme environmental temperatures. The extreme accident level temperature is specified in Table 2.2.2. The extreme accident level temperature occurs with steady-state insolation. This temperature is assumed to persist for a duration sufficient to allow the system to reach steady-state temperatures. The HI-STORM overpack and MPC have a large thermal inertia. Therefore, this temperature is assumed to persist over three days (3-day average).

2.2.3.15 Bounding Hydraulic, Wind, and Missile Loads for HI-STORM 100A

In the anchored configuration, the HI-STORM 100A System is clearly capable of withstanding much greater lateral loads than a free-standing overpack. Coastal sites in many areas of the world, particularly the land mass around the Pacific Ocean, may be subject to severe fluid inertial loads. Several publications [2.2.10, 2.2.11] explain and quantify the nature and source of such environmental hazards.

It is recognized that a lateral fluid load may also be accompanied by an impact force from a fluid borne missile (debris). Rather than setting specific limits for these loads on an individual basis, a limit on the static overturning base moment on the anchorage is set. This bounding overturning moment is given in Table 2.2.8 and is set at a level that ensures that structural safety margins on the sector lugs and on the anchor studs are essentially equal to the structural safety margins of the same components under the combined effect of the net horizontal and vertical seismic load limits in Table 2.2.8. The ISFSI owner bears the responsibility to establish that the lateral hydraulic, wind, and missile loads at his ISFSI site do not yield net overturning moments, when acting separately or together, that exceed the limit value in Table 2.2.8. If loadings are increased above those values for free-standing casks, their potential effect on the other portions of the cask system must be considered.

2.2.3.16 Supplemental Cooling System (SCS) Failure

The SCS system is a forced fluid circulation device used to provide supplemental HI-TRAC cooling. For fluid circulation, the SCS system is equipped with active components requiring power for normal operation.

Although an SCS System failure is highly unlikely, for defense-in-depth an accident condition that renders it inoperable for an extended duration is postulated. Possible causes of SCS failure are: (a) Simultaneous loss of external and backup power, or (b) Complete loss of annulus water from an uncontrolled leak or line break.

2.2.4 Applicability of Governing Documents

The ASME Boiler and Pressure Vessel Code (ASME Code), 1995 Edition, with Addenda through 1997 [2.2.1], is the governing code for the structural design of the MPC, the metal structure of the HI-STORM 100 overpack, and the HI-TRAC transfer cask, except for Sections V and IX. The latest effective editions of ASME Section V and IX may be used, provided a written reconciliation of the

later edition against the 1995 Edition, including addenda, is performed by the certificate holder. The MPC enclosure vessel and fuel basket are designed in accordance with Section III, Subsections NB Class 1 and NG Class 1, respectively. The metal structure of the overpack and the HI-TRAC transfer cask are designed in accordance with Section III, Subsection NF Class 3. The ASME Code is applied to each component consistent with the function of the component.

ACI 349 is the governing code for the plain concrete in the HI-STORM 100 overpack. ACI 318.1-85(92) is the applicable code utilized to determine the allowable compressive strength of the plain concrete credited during structural analysis. Appendix 1.D provides the sections of ACI 349 and ACI 318.1-85(92) applicable to the plain concrete.

Table 2.2.6 provides a summary of each structure, system and component (SSC) of the HI-STORM 100 System that is identified as important to safety, along with its function and governing Code. Some components perform multiple functions and in those cases, the most restrictive Code is applied. In accordance with NUREG/CR-6407, "Classification of Transportation Packaging and Dry Spent Fuel Storage System Components", and according to importance to safety, components of the HI-STORM 100 System are classified as A, B, C, or NITS (not important to safety) in Table 2.2.6. Section 13.1 provides the criteria used to classify each item. The classification of necessary auxiliary equipment is provided in Table 8.1.6.

Table 2.2.7 lists the applicable governing Code for material procurement, design, fabrication and inspection of the components of the HI-STORM 100 System. The ASME Code section listed in the design column is the section used to define allowable stresses for structural analyses.

Table 2.2.15 lists the alternatives to the ASME Code for the HI-STORM 100 System and the justification for those alternatives.

The MPC enclosure vessel and certain fuel basket designs utilized in the HI-STORM 100 System are identical to the MPC components described in the SARs for the HI-STAR 100 System for storage (Docket 72-1008) and transport (Docket 71-9261). To avoid unnecessary repetition of the large numbers of stress analyses, this document refers to those SARs, as applicable, if the MPC loadings for storage in the HI-STORM 100 System do not exceed those computed in the HI-STAR documents. Many of the loadings in the HI-STAR applications envelope the HI-STORM loadings on the MPC, and, therefore, a complete re-analysis of the MPC is not provided in the FSAR. Certain individual MPC analyses may have been required to license a particular MPC fuel basket design for HI-STORM that was not previously licensed for HI-STAR. These unique analyses are summarized in the appropriate location in this FSAR.

Table 2.2.16 provides a summary comparison between the loading elements. Table 2.2.16 shows that most of the loadings remain unchanged and several are less than the HI-STAR loading conditions. In addition to the magnitude of the loadings experienced by the MPC, the application of the loading must also be considered. Therefore, it is evident from Table 2.2.16 that the MPC stress limits can be ascertained to be qualified a priori if the HI-STAR analyses and the thermal loadings under HI-STORM storage are not more severe compared to previously analyzed HI-STAR conditions. In the analysis of each of the normal, off-normal, and accident conditions, the effect on the MPC is evaluated and compared to the corresponding condition analyzed in the HI-STAR 100 System SARs

[2.2.4 and 2.2.5]. If the HI-STORM loading is greater than the HI-STAR loading or the loading is applied differently, the analysis of its effect on the MPC is evaluated in Chapter 3.

2.2.5 Service Limits

In the ASME Code, plant and system operating conditions are commonly referred to as normal, upset, emergency, and faulted. Consistent with the terminology in NRC documents, this FSAR utilizes the terms normal, off-normal, and accident conditions.

The ASME Code defines four service conditions in addition to the Design Limits for nuclear components. They are referred to as Level A, Level B, Level C, and Level D service limits, respectively. Their definitions are provided in Paragraph NCA-2142.4 of the ASME Code. The four levels are used in this FSAR as follows:

- a. Level A Service Limits: Level A Service Limits are used to establish allowables for normal condition load combinations.
- b. Level B Service Limits: Level B Service Limits are used to establish allowables for off-normal condition load combinations.
- c. Level C Service Limits: Level C Service Limits are not used.
- d. Level D Service Limits: Level D Service Limits are used to establish allowables for accident condition load combinations.

The ASME Code service limits are used in the structural analyses for definition of allowable stresses and allowable stress intensities. Allowable stresses and stress intensities for structural analyses are tabulated in Chapter 3. These service limits are matched with normal, off-normal, and accident condition loads combinations in the following subsections.

The MPC confinement boundary is required to meet Section III, Class 1, Subsection NB stress intensity limits. Table 2.2.10 lists the stress intensity limits for Design and Service Levels A, B, and D for Class 1 structures extracted from the ASME Code (1995 Edition). The limits for the MPC fuel basket, required to meet the stress intensity limits of Subsection NG of the ASME Code, are listed in Table 2.2.11. Table 2.2.12 lists allowable stress limits for the steel structure of the HI-STORM overpack and HI-TRAC which are analyzed to meet the stress limits of Subsection NF, Class 3. Only Service Levels A, B, and D (normal, off-normal, and accident conditions, respectively) are applicable.

2.2.6 Loads

Subsections 2.2.1, 2.2.2, and 2.2.3 describe the design criteria for normal, off-normal, and accident conditions, respectively. Table 2.2.13 identifies the notation for the individual loads that require consideration. The individual loads listed in Table 2.2.13 are defined from the design criteria. Each load is assigned a symbol for subsequent use in the load combinations.

The loadings listed in Table 2.2.13 fall into two broad categories; namely, (i) those that primarily affect kinematic stability, and (ii) those that produce significant stresses. The loadings in the former category are principally applicable to the overpack. Tornado wind (W'), earthquake (E), and tornado-borne missile (M) are essentially loadings which can destabilize a cask. Analyses reported in Chapter 3 show that the HI-STORM 100 overpack structure will remain kinematically stable under these loadings. Additionally, for the missile impact case (M), analyses that demonstrate that the overpack structure remains unbreached by the postulated missiles are provided in Chapter 3.

Loadings in the second category produce global stresses that must be shown to comply with the stress intensity or stress limits, as applicable. The relevant loading combinations for the fuel basket, the MPC, the HI-TRAC and the HI-STORM overpack are different because of differences in their function. For example, the fuel basket does not experience a pressure loading because it is not a pressure vessel. The specific load combination for each component is specified in Subsection 2.2.7.

2.2.7 Load Combinations

To demonstrate compliance with the design requirements for normal, off-normal, and accident conditions of storage, the individual loads, identified in Table 2.2.13, are combined into load combinations. In the formation of the load combinations, it is recognized that the number of combinations requiring detailed analyses is reduced by defining bounding loads. Analyses performed using bounding loads serve to satisfy the requirements for analysis of a multitude of separately identified loads in combination.

For example, the values established for internal and external pressures (P_i and P_o) are defined such that they bound other surface-intensive loads, namely snow (S), tornado wind (W'), flood (F), and explosion (E^*). Thus, evaluation of pressure in a load combination established for a given storage condition enables many individual load effects to be included in a single load combination.

Table 2.2.14 identifies the combinations of the loads that are required to be considered in order to ensure compliance with the design criteria set forth in this chapter. Table 2.2.14 presents the load combinations in terms of the loads that must be considered together. A number of load combinations are established for each ASME Service Level. Within each loading case, there may be more than one analysis that is required to demonstrate compliance. Since the breakdown into specific analyses is most applicable to the structural evaluation, the identification of individual analyses with the applicable loads for each load combination is found in Chapter 3. Tables 3.1.3 through 3.1.5 define the particular evaluations of loadings that demonstrate compliance with the load combinations of Table 2.2.14.

For structural analysis purposes, Table 2.2.14 serves as an intermediate classification table between the definition of the loads (Table 2.2.13 and Section 2.2) and the detailed analysis combinations (Tables 3.1.3 through 3.1.5).

Finally, it should be noted that the load combinations identified in NUREG-1536 are considered as applicable to the HI-STORM 100 System. The majority of load combinations in NUREG-1536 are directed toward reinforced concrete structures. Those load combinations applicable to steel structures are directed toward frame structures. As stated in NUREG-1536, Page 3-35 of Table 3-1,

“Table 3-1 does not apply to the analysis of confinement casks and other components designed in accordance with Section III of the ASME B&PV Code.” Since the HI-STORM 100 System is a metal shell structure, with concrete primarily employed as shielding, the load combinations of NUREG-1536 are interpreted within the confines and intent of the ASME Code.

2.2.8 Allowable Stresses

The stress intensity limits for the MPC confinement boundary for the design condition and the service conditions are provided in Table 2.2.10. The MPC confinement boundary stress intensity limits are obtained from ASME Code, Section III, Subsection NB. The stress intensity limits for the MPC fuel basket are presented in Table 2.2.11 (governed by Subsection NG of Section III). The steel structure of the overpack and the HI-TRAC meet the stress limits of Subsection NF of ASME Code, Section III for plate and shell components. Limits for the Level D condition are obtained from Appendix F of ASME Code, Section III for the steel structure of the overpack. The ASME Code is not applicable to the HI-TRAC transfer cask for accident conditions, service level D conditions. The HI-TRAC transfer cask has been shown by analysis to not deform sufficiently to apply a load to the MPC, have any shell rupture, or have the top lid, pool lid, or transfer lid (as applicable) detach.

The following definitions of terms apply to the tables on stress intensity limits; these definitions are the same as those used throughout the ASME Code:

- S_m : Value of Design Stress Intensity listed in ASME Code Section II, Part D, Tables 2A, 2B and 4
- S_y : Minimum yield strength at temperature
- S_u : Minimum ultimate strength at temperature

2.2.9 Requirements on Lifting and Special Lifting Devices

- 2.2.9.1 Definitions: The lifting and handling systems used in Holtec’s used fuel management program are made up of individual components or devices. These components can be further classified as either “*lifting devices*” or “*special lifting devices*.” (See Glossary)

The term *special lifting device* refers to components to which ANSI N14.6 applies. As stated in ANSI N14.6 (both 1978 and 1993 versions), “This standard shall apply to *special lifting devices* that transmit the load from lifting attachments, which are structural parts of a container to the hook(s) of an overhead hoisting system.” Examples of special lifting devices used with Holtec’s systems include MPC lift cleats, lift brackets, and lift yokes

The term *lifting device* refers to components of a lifting and handling system that are not classified as *special lifting devices*. ANSI N14.6 is not applicable to these *lifting devices*. These include non-active structural components (components that bear the primary load but are not a constituent of a moving part, e.g., gear train, hydraulic cylinder) of the system. Examples of lifting devices used with

Holtec's systems include: a vertical cask transporter's overhead beam, the structural members (viz. the main girder) of a gantry crane or a cask crane used to handle the MPC inside a part 50 structure.

The design of all lifting devices is governed by a Purchasing Specification prepared under the system designer's QA program which shall contain appropriate interpretations of the applicable codes and standards, required material properties, extreme environmental loadings (viz., earthquakes) and the like. The qualification for seismic and other applicable environmental loads is not required for transient states such as when the load is being emplaced and fastened or the lifting device is in motion.

2.2.9.2 Stress compliance criteria applicable to *Lifting Devices and Special Lifting Devices*:

The stress compliance criteria for *lifting devices* are taken from the code applicable to the specific component defined in the system designer's Purchasing Specification. For example, slings are required to meet the guidelines of ANSI B30.9 and overhead beams are required to meet the guidelines of an applicable consensus national standard selected by the designer, such as AISC, CMAA, or ASME Code (Subsection NF). Where a suitable consensus standard does not exist, the system designer is required to specify the necessary stress and strength requirements appropriate to the hardware.

The stress compliance criteria for *special lifting devices* are taken directly from ANSI N14.6, which requires safety factors of three against the yield strength and five times against ultimate strength under the dead load to be lifted.

2.2.9.3 Single Failure Proof Criteria

In order for a *lifting device* or *special lifting device* to be considered *single failure proof*, the design must also follow the guidance in NUREG-0612, which requires that a single failure proof device have twice the normal safety margin. This designation can be achieved by either providing redundant devices or providing twice the design safety factor as required by the applicable code. Therefore, for a *lifting device* to be considered single failure proof, the applicable code requirements should be doubled, or a redundant *lifting device* should be provided. The load drop protection feature incorporated in the vertical towers of a cask transporter is an example of redundant lifting part.

The horizontal transporters, referred to as Hauling transporter, Low Profile transporter, etc., are characterized by the absence of a lifting feature. Such ground supported equipment is considered single failure proof if the stresses developed under the design basis dead load are <50% of the allowable limit set down in the system designer's specification.

Likewise, for cask handling purposes, a plant's main crane can be treated as single failure proof if the structural factors of safety against the applicable code limit are a minimum of 2.

Similarly for a *special lifting device* to be considered *single failure proof*, the design safety factors in ANSI N14.6 should be doubled, or a redundant *special lifting device* should be provided.

Alternatively, the designer may perform a load drop analysis (permitted by both NUREG-0612 and ANSI N14.6). If the analyses support the conclusion that, after the physically admissible drop accident, the permissible dose rate from the cask does not exceed the plant's accident condition dose limit and the MPC meets the sub-criticality criterion of §72.124 then the increased safety factors are not required. In addition, for a drop scenario involving a loaded MPC, the confinement integrity of the MPC must remain intact and the MPC must remain retrievable subsequent to the drop event.

Table 2.2.1

PRESSURE LIMITS

Pressure Location	Condition	Pressure (psig)
MPC Internal Pressure	Design / Long-Term Normal	100
	Off-Normal/Short-Term Normal	110
	Accident	200
MPC External Pressure	Normal	(0) Ambient
	Off-Normal	(0) Ambient
	Accident	60
Overpack External Pressure	Normal	(0) Ambient
	Off-Normal	(0) Ambient
	Accident	10 (differential pressure for 1 second maximum)* or 5 (differential pressure steady state)
HI-TRAC Water Jacket	Normal	60
	Off-normal	60
	Accident	N/A (Under accident conditions, the water jacket is assumed to have lost all water thru the pressure relief valves)

* The overpack is also qualified to sustain without tip-over a lateral impulse load of 60 psi (differential pressure for 85 milliseconds maximum) [3.4.5].

Table 2.2.2

ENVIRONMENTAL TEMPERATURES

Condition	Temperature (°F)	Comments
HI-STORM 100 Overpack		
Normal Ambient (Bounding Annual Average)	80	
Normal Soil Temperature (Bounding Annual Average)	77	
Off-Normal Ambient (3-Day Average)	-40 and 100	-40°F with no insolation 100°F with insolation
Extreme Accident Level Ambient (3-Day Average)	125	125°F with insolation starting at steady-state off-normal high environment temperature
HI-TRAC Transfer Cask		
Inside Building Short-Term Operations (3-Day Average)	110	110°F with no insolation
Outside Building Short-Term Operations (3-Day Average)	90	90°F with insolation

Note:

- 2) Handling operations with the loaded HI-STORM overpack and HI-TRAC transfer cask are limited to working area ambient temperatures greater than or equal to 0°F as specified in Subsection 2.2.1.2.

Sub-component or Part**	Long Term, Normal Condition Temperature Limits (Long-Term Events) (° F)	Short-Term Events^{††} Temperature Limits (° F)	Off-Normal and Accident Condition Temperature Limits (° F)	30-Day Accident Condition Temperature Limit (° F) ^{†††}
MPC shell	600 [‡]	775 [‡]	775	572
MPC basket	752	1058	1058	752
MPC Extruded Aluminum shims ^{‡‡}	752	932	932	752
MPC Neutron Absorber	752	1058	1058	752
MPC lid	600 [‡]	775 [‡]	775	572
MPC closure ring	500 [‡]	775 [‡]	775	572
MPC baseplate	400 [‡]	775 [‡]	775	572
HI-TRAC inner shell	-	500	800	-
HI-TRAC transfer lid	-	350	800	-
HI-TRAC pool lid	-	400	800	-
HI-TRAC top lid	-	400	800	-
HI-TRAC top flange	-	400	700	-
HI-TRAC pool lid seals	-	400	N/A	-
HI-TRAC bottom lid bolts	-	350	800	-
HI-TRAC bottom flange	-	350	800	-

** Wherever applicable, the limiting temperatures under all service conditions in this table for each sub-component or part have been aligned with the corresponding values in Table 2.2.3 of the HI-STORM FW FSAR [2.2.17].

††† 30-day accident event is defined as 100% blocked vent condition at threshold heat loads defined in Section 4.6.

†† Normal short term operations includes MPC drying and onsite transport per Reference [2.0.8]. The 1058°F temperature limit applies to MPCs containing all moderate burnup fuel as discussed in Reference [2.0.9]. The limit for MPCs containing one or more high burnup fuel assemblies is 752°F. See also Section 4.3.

‡ Temperature limits in Table 1.A.6 shall take precedence if duplex stainless steels are used for the fabrication of confinement boundary components as described in Appendix 1.A

‡‡ Structural evaluations of extruded aluminum shims in Chapter 3 are based on temperatures that bound those computed in Chapter 4. Site-specific evaluations shall be performed when adopted values are exceeded. During horizontal transfer of the HI-TRAC, the short-term event temperature is limited to 752°F.

Sub-component or Part**	Long Term, Normal Condition Temperature Limits (Long-Term Events) (° F)	Short-Term Events^{††} Temperature Limits (° F)	Off-Normal and Accident Condition Temperature Limits (° F)	30-Day Accident Condition Temperature Limit (° F) ^{†††}
HI-TRAC top lid neutron shielding	-	300	350	-
HI-TRAC radial neutron shield	-	307	N/A	-
HI-TRAC radial lead gamma shield	-	350	600	-
Remainder of HI-TRAC	-	350	800	-
Fuel Cladding	752	752 or 1058 ^{††}	1058	752
Overpack concrete	300 [†]	572 (on local temperature of shielding concrete)	572 (on local temperature of shielding concrete except under fire*)	450 (on local temperature of shielding concrete)
Overpack Lid Top and Bottom Plate	450	700	800 [†]	450

General note: All short-term, off-normal and accident condition structural evaluations are based on bounding temperatures from thermal evaluations presented in Chapter 4. If the actual computed service condition temperature is not available for a particular sub-component or part, the normal condition temperature limit can be used conservatively in the design basis structural evaluations for MPC and HI-STORM. Similarly, the short-term condition temperature limits can be used for HI-TRAC. The thermal evaluations presented in Chapter 4 must comply with the above temperature limits as well as the temperatures used to inform the structural design basis calculations, which in some cases use actual computed temperatures as opposed to the above limit values. Changes to these computed temperatures should be evaluated under 10CFR72.48 as necessary.

† For accident conditions that involve heating of the steel structures and no mechanical loading (such as the blocked air duct accident), the permissible metal temperature of the steel parts is defined by Table 1A of ASME Section II (Part D) for Section III, Class 3 materials as 700°F. For fire accident conditions, steel structure is required to remain structurally stable. The term “remain structurally stable” shall mean that there will be no risk of structural instability such as gross buckling. Structural stability is ensured if the average vertical compressive stress in the composite steel shell structure (the Component) at every elevation is below the total axial compressive strength of the Component across the cross section at the instant of its most heated state. Based on yield strength vs. temperature data for structural steel and the heaviest HI-STORM overpack design this requirement is satisfied up to at least 800°C (1475°F). For a fire event, the local temperature limit of HI-STORM concrete is 1100°F (HI-STORM 100 FSAR Appendix 1.D) and concrete that exceeds this temperature shall be considered unavailable for shielding of the overpack.

Sub-component or Part**	Long Term, Normal Condition Temperature Limits (Long-Term Events) (° F)	Short-Term Events^{††} Temperature Limits (° F)	Off-Normal and Accident Condition Temperature Limits (° F)	30-Day Accident Condition Temperature Limit (° F) ^{†††}
Remainder of overpack steel structure	400	700	800*	450

Table 2.2.4

TORNADO CHARACTERISTICS

Condition	Value
Rotational wind speed (mph)	290
Translational speed (mph)	70
Maximum wind speed (mph)	360
Pressure drop (psi)	3.0

Table 2.2.5

TORNADO-GENERATED MISSILES

Missile Description	Mass (kg)	Velocity (mph)
Automobile	1800	126
Rigid solid steel cylinder (8 in. diameter)	125	126
Solid sphere (1 in. diameter)	0.22	126

Primary Function	Component ⁽³⁾	Safety Class ⁽⁴⁾	Codes/Standards (as applicable to component)	Material	Strength (ksi)	Special Surface Finish/Coating	Contact Matl. (if dissimilar)
Confinement	Shell	A	ASME Section III; Subsection NB	Alloy X ⁽⁵⁾	See Appendix 1.A	NA	Aluminum ⁽⁷⁾
Confinement	Baseplate	A	ASME Section III; Subsection NB	Alloy X	See Appendix 1.A	NA	Aluminum ⁽⁷⁾

Table 2.2.8

ADDITIONAL DESIGN INPUT DATA FOR NORMAL, OFF-NORMAL, AND
ACCIDENT CONDITIONS

Item	Condition	Value
Snow Pressure Loading (lb./ft ²)	Normal	100
Constriction of MPC Basket Vent Opening By Crud Settling (Depth of Crud, in.)	Accident	0.85 (MPC-68) 0.36 (MPC-24 and MPC-32)
Cask Environment During the Postulated Fire Event (Deg. F)	Accident	1475
HI-STORM Overpack Fire Duration (seconds)	Accident	217
HI-TRAC Transfer Cask Fire Duration (minutes)	Accident	4.8
Maximum submergence depth due to flood (ft)	Accident	125
Flood water velocity (ft/s)	Accident	15
Interaction Relation for Horizontal & Vertical acceleration for HI-STORM	Accident	$G_H + 0.53G_V = 0.53^{\dagger\dagger}$ (HI-STORM 100, 100S, and 100S Version B) $G_H = 2.12; G_V = 1.5$ (HI-STORM 100A)
Net Overturning Moment at base of HI-STORM 100A (ft-lb)	Accident	18.7×10^6
HI-STORM 100 Overpack Vertical Lift Height Limit (in.)	Accident	$11^{\dagger\dagger\dagger}$ (HI-STORM 100 and 100S), OR By Users (HI-STORM 100A)
HI-TRAC Transfer Cask Horizontal Lift Height Limit (in.)	Accident	$42^{\dagger\dagger\dagger}$

^{††} See Subsection 3.4.7.1 for definition of G_H and G_V . The coefficient of friction may be increased above 0.53 based on testing described in Subsection 3.4.7.1

^{†††} For ISFSI and subgrade design parameter Sets A and B and fully loaded MPC. Users may also develop a site-specific lift height limit.

Table 2.2.9

EXAMPLES OF ACCEPTABLE ISFSI PAD DESIGN PARAMETERS

PARAMETER	PARAMETER SET "A" [†]	PARAMETER SET "B"
Concrete thickness, t_p , (inches)	≤ 36	≤ 28
Concrete Compressive Strength (at 28 days), f_c' , (psi)	$\leq 4,200$	$\leq 6,000$ psi
Reinforcement Top and Bottom (both directions)	Reinforcing bar shall be 60 ksi Yield Strength ASTM Material	Reinforcing bar shall be 60 ksi Yield Strength ASTM Material
Subgrade Effective Modulus of Elasticity ^{††} (measured prior to ISFSI pad installation), E , (psi)	$\leq 28,000$	$\leq 16,000$

NOTE: A static coefficient of friction of 0.53 between the ISFSI pad and the bottom of the overpack shall be used. If for a specific ISFSI a higher value of the coefficient of friction is used, it shall be verified by test. The test procedure shall follow the guidelines included in the Sliding Analysis in Subsection 3.4.7.1.

[†] The characteristics of this pad are identical to the pad considered by Lawrence Livermore Laboratory (see Appendix 3.A).

^{††} An acceptable method of defining the soil effective modulus of elasticity applicable to the drop and tipover analysis is provided in Table 13 of NUREG/CR-6608 with soil classification in accordance with ASTM-D2487 Standard Classification of Soils for Engineering Purposes (Unified Soil Classification System USCS) and density determination in accordance with ASTM-D1586 Standard Test Method for Penetration Test and Split/Barrel Sampling of Soils.

Table 2.2.10
MPC CONFINEMENT BOUNDARY STRESS INTENSITY LIMITS
FOR DIFFERENT LOADING CONDITIONS (ELASTIC ANALYSIS PER NB-3220)[†]

STRESS CATEGORY	DESIGN	LEVELS A & B ^{†††}	LEVEL D ^{††}
Primary Membrane, P_m	S_m	S_m	AMIN ($2.4S_m$, $0.7S_u$)
Local Membrane, P_L	$1.5S_m$	$1.5S_m$	150% of P_m Limit
Membrane plus Primary Bending	$1.5S_m$	$1.5S_m$	150% of P_m Limit
Primary Membrane plus Primary Bending	$1.5S_m$	$1.5S_m$	150% of P_m Limit
Membrane plus Primary Bending plus Secondary	N/A	$3S_m$	N/A
Average Shear Stress ^{††††}	$0.6S_m$	$0.6S_m$	$0.42S_u$

[†] Stress combinations including F (peak stress) apply to fatigue evaluations only.

^{††} Governed by Appendix F, Paragraph F-1331 of the ASME Code, Section III.

^{†††} For stress intensities generated by Level B Service Loadings, allowable stress intensity values are 110% of Level A limits per NB-3223.

^{††††} Governed by NB-3227.2 or F-1331.1(d).

Table 2.2.11

**MPC BASKET STRESS INTENSITY LIMITS
FOR DIFFERENT LOADING CONDITIONS (ELASTIC ANALYSIS PER NG-3220)**

STRESS CATEGORY	DESIGN	LEVELS A & B	LEVEL D[†]
Primary Membrane, P_m	S_m	S_m	$AMIN(2.4S_m, 0.7S_u)^{††}$
Primary Membrane plus Primary Bending	$1.5S_m$	$1.5S_m$	150% of P_m Limit
Primary Membrane plus Primary Bending plus Secondary	$N/A^{†††}$	$3S_m$	N/A

[†] Governed by Appendix F, Paragraph F-1331 of the ASME Code, Section III.

^{††} Governed by F-1331.1(a).

^{†††} No specific stress intensity limit applicable.

Table 2.2.12
STRESS LIMITS FOR DIFFERENT
LOADING CONDITIONS FOR THE STEEL STRUCTURE OF THE OVERPACK AND HI-TRAC
(ELASTIC ANALYSIS PER NF-3260)

		SERVICE CONDITION	
STRESS CATEGORY	DESIGN + LEVEL A	LEVEL B	LEVEL D [†]
Primary Membrane, P_m	S	1.33S	AMAX ($1.2S_y$, $1.5S_m$) but $< .7S_u$
Primary Membrane, P_m , plus Primary Bending, P_b	1.5S	1.995S	150% of P_m
Shear Stress (Average)	0.6S	0.6S	$< 0.42S_u$

Definitions:

S = Allowable Stress Value for Table 1A, ASME Section II, Part D.

S_m = Allowable Stress Intensity Value from Table 2A, ASME Section II, Part D

S_u = Ultimate Strength

[†] Governed by Appendix F, Paragraph F-1332 of the ASME Code, Section III.

Table 2.2.13

NOTATION FOR DESIGN LOADINGS FOR NORMAL, OFF-NORMAL, AND
ACCIDENT CONDITIONS

NORMAL CONDITION	
LOADING	NOTATION
Dead Weight	D
Handling Loads	H
Design Pressure (Internal)	P_i
Short-Term Normal Pressure (Internal)	P_{st}
Design Pressure (External) [†]	P_o
Snow	S
Operating Temperature	T
OFF-NORMAL CONDITION	
Loading	Notation
Off-Normal Pressure (Internal)	P_i'
Off-Normal Pressure (External) [†]	P_o
Off-Normal Temperature	T'
Off-Normal HI-TRAC Handling	H'

ACCIDENT CONDITIONS	
LOADING	NOTATION
Handling Accident	H'
Earthquake	E
Fire	T*
Tornado Missile	M
Tornado Wind	W'
Flood	F
Explosion	E*
Accident Pressure (Internal)	P _i *
Accident Pressure (External)	P _o *

Table 2.2.14
APPLICABLE LOAD CASES AND COMBINATIONS FOR EACH CONDITION AND COMPONENT^{†, ††}

CONDITION	LOADING CASE	MPC	OVERPACK	HI-TRAC
Design (ASME Code Pressure Compliance)	1	P_i, P_o	N/A	N/A
Normal (Level A)	1	D, T, H, P_i, P_{st}	D, T, H	$D, T^{\dagger\dagger\dagger}, H, P_{i \text{ (water jacket)}}$
	2	D, T, H, P_o	N/A	N/A
Off-Normal (Level B)	1	D, T', H, P_i'	D, T', H	$N/A^{\dagger\dagger\dagger}$ (H' pocket trunnion)
	2	D, T', H, P_o	N/A	N/A
Accident (Level D)	1	D, T, P_i, H'	D, T, H'	D, T, H'
	2	D, T^*, P_i^*	N/A	N/A
	3	$D, T, P_o^{*\dagger\dagger\dagger}$	$D, T, P_o^{*\dagger\dagger\dagger}$	$D, T, P_o^{*\dagger\dagger\dagger}$
	4	N/A	$D, T, (E, M, F, W')^{\dagger\dagger\dagger\dagger}$	$D, T, (M, W')^{\dagger\dagger\dagger\dagger}$

[†] The loading notations are given in Table 2.2.13. Each symbol represents a loading type and may have different values for different components. The different loads are assumed to be additive and applied simultaneously.

^{††} N/A stands for “Not Applicable.”

^{†††} T (normal condition) for the HI-TRAC is 100°F and $P_{i \text{ (water jacket)}}$ is 60 psig and, therefore, there is no off-normal temperature or load combination because Load Case 1, Normal (Level A), is identical to Load Case 1, Off-Normal (Level B). Only the off-normal handling load on the pocket trunnion is analyzed separately.

^{††††} P_o^* bounds the external pressure due to explosion.

^{†††††} (E, M, F, W') means loads are considered separately in combination with D, T. E and F not applicable to HI-TRAC.

Table 2.2.15
LIST OF ASME CODE ALTERNATIVES FOR HI-STORM 100 SYSTEM

Component	Reference ASME Code Section/Article	Code Requirement	Alternative, Justification & Compensatory Measures
MPC, MPC basket assembly, HI-STORM overpack steel structure, and HI-TRAC transfer cask steel structure.	Subsection NCA	General Requirements. Requires preparation of a Design Specification, Design Report, Overpressure Protection Report, Certification of Construction Report, Data Report, and other administrative controls for an ASME Code stamped vessel.	<p>Because the MPC, overpack, and transfer cask are not ASME Code stamped vessels, none of the specifications, reports, certificates, or other general requirements specified by NCA are required. In lieu of a Design Specification and Design Report, the HI-STORM FSAR includes the design criteria, service conditions, and load combinations for the design and operation of the HI-STORM 100 System as well as the results of the stress analyses to demonstrate that applicable Code stress limits are met. Additionally, the fabricator is not required to have an ASME-certified QA program. All important-to-safety activities are governed by the NRC-approved Holtec QA program.</p> <p>Because the cask components are not certified to the Code, the terms “Certificate Holder” and “Inspector” are not germane to the manufacturing of NRC-certified cask components. To eliminate ambiguity, the responsibilities assigned to the Certificate Holder in the various articles of Subsections NB, NG, and NF of the Code, as applicable, shall be interpreted to apply to the NRC Certificate of Compliance (CoC) holder (and by extension, to the component fabricator) if the requirement must be fulfilled. The Code term “Inspector” means the QA/QC personnel of the CoC holder and its vendors assigned to oversee and inspect the manufacturing process.</p>

Component	Reference ASME Code Section/Article	Code Requirement	Alternative, Justification & Compensatory Measures
MPC	NB-1100	Statement of requirements for Code stamping of components.	MPC enclosure vessel is designed and will be fabricated in accordance with ASME Code, Section III, Subsection NB to the maximum practical extent, but Code stamping is not required.
MPC basket supports and lift lugs	NB-1130	<p>NB-1132.2(d) requires that the first connecting weld of a nonpressure - retaining structural attachment to a component shall be considered part of the component unless the weld is more than 2t from the pressure-retaining portion of the component, where t is the nominal thickness of the pressure-retaining material.</p> <p>NB-1132.2(e) requires that the first connecting weld of a welded nonstructural attachment to a component shall conform to NB-4430 if the connecting weld is within 2t from the pressure-retaining portion of the component.</p>	<p>The MPC basket supports (nonpressure - retaining structural attachment) and lift lugs (nonstructural attachments (relative to the function of lifting a loaded MPC) that are used exclusively for lifting an empty MPC) are welded to the inside of the pressure-retaining MPC shell, but are not designed in accordance with Subsection NB. The basket supports and associated attachment welds are designed to satisfy the stress limits of Subsection NG and the lift lugs and associated attachment welds are designed to satisfy the stress limits of Subsection NF, as a minimum. These attachments and their welds are shown by analysis to meet the respective stress limits for their service conditions. Likewise, non-structural items, such as shield plugs, spacers, etc. if used, can be attached to pressure-retaining parts in the same manner.</p>

Component	Reference ASME Code Section/Article	Code Requirement	Alternative, Justification & Compensatory Measures
MPC	NB-2000	Requires materials to be supplied by ASME-approved material supplier.	Materials will be supplied by Holtec approved suppliers with Certified Material Test Reports (CMTRs) in accordance with NB-2000 requirements.
MPC	NB-2121	Provides permitted material specification for pressure-retaining material, which must conform to Section II, Part D, Tables 2A and 2B	Certain duplex stainless steels are not included in Section II, Part D, Tables 2A and 2B. UNS S31803 duplex stainless steel alloy is evaluated in the HI-STORM 100 FSAR and meet the required design criteria for use in the HI-STORM 100 system per ASME Code Case N-635-1. Appendix 1.A provides the required property data for the necessary safety analysis
MPC, MPC basket assembly, HI-STORM overpack, and HI-TRAC transfer cask	NB-3100 NG-3100 NF-3100	Provides requirements for determining design loading conditions, such as pressure, temperature, and mechanical loads.	These requirements are not applicable. The HI-STORM FSAR, serving as the Design Specification, establishes the service conditions and load combinations for the storage system.

Component	Reference ASME Code Section/Article	Code Requirement	Alternative, Justification & Compensatory Measures
MPC	NB-3350	NB-3352.3 requires, for Category C joints, that the minimum dimensions of the welds and throat thickness shall be as shown in Figure NB-4243-1.	<p>Due to MPC basket-to-shell interface requirements, the MPC shell-to-baseplate weld joint design (designated Category C) does not include a reinforcing fillet weld or a bevel in the MPC baseplate, which makes it different than any of the representative configurations depicted in Figure NB-4243-1. The transverse thickness of this weld is equal to the thickness of the adjoining shell (1/2 inch). The weld is designed as a full penetration weld that receives VT and RT or UT, as well as final surface PT examinations. Because the MPC shell design thickness is considerably larger than the minimum thickness required by the Code, a reinforcing fillet weld that would intrude into the MPC cavity space is not included. Not including this fillet weld provides for a higher quality radiographic examination of the full penetration weld.</p> <p>From the standpoint of stress analysis, the fillet weld serves to reduce the local bending stress (secondary stress) produced by the gross structural discontinuity defined by the flat plate/shell junction. In the MPC design, the shell and baseplate thicknesses are well beyond that required to meet their respective membrane stress intensity limits.</p>

Component	Reference ASME Code Section/Article	Code Requirement	Alternative, Justification & Compensatory Measures
MPC, MPC basket assembly, HI-STORM overpack steel structure, and HI-TRAC transfer cask steel structure	NB-4120 NG-4120 NF-4120	NB-4121.2, NG-4121.2, and NF-4121.2 provide requirements for repetition of tensile or impact tests for material subjected to heat treatment during fabrication or installation.	<p>In-shop operations of short duration that apply heat to a component, such as plasma cutting of plate stock, welding, machining, coating, and pouring of lead are not, unless explicitly stated by the Code, defined as heat treatment operations.</p> <p>For the steel parts in the HI-STORM 100 System components, the duration for which a part exceeds the off-normal temperature limit defined in Chapter 2 of the FSAR shall be limited to 24 hours in a particular manufacturing process (such as the HI-TRAC lead pouring process).</p>
MPC, HI-STORM overpack steel structure, HI-TRAC transfer cask steel structure	NB-4220 NF-4220	Requires certain forming tolerances to be met for cylindrical, conical, or spherical shells of a vessel.	The cylindricity measurements on the rolled shells are not specifically recorded in the shop travelers, as would be the case for a Code-stamped pressure vessel. Rather, the requirements on inter-component clearances (such as the MPC-to-transfer cask) are guaranteed through fixture-controlled manufacturing. The fabrication specification and shop procedures ensure that all dimensional design objectives, including inter-component annular clearances are satisfied. The dimensions required to be met in fabrication are chosen to meet the functional requirements of the dry storage components. Thus, although the post-forming Code cylindricity requirements are not evaluated for compliance directly, they are indirectly satisfied (actually exceeded) in the final manufactured components.

Component	Reference ASME Code Section/Article	Code Requirement	Alternative, Justification & Compensatory Measures
MPC Lid and Closure Ring Welds	NB-4243	Full penetration welds required for Category C Joints (flat head to main shell per NB-3352.3)	MPC lid and closure ring are not full penetration welds. They are welded independently to provide a redundant seal. Additionally, a weld efficiency factor of 0.45 has been applied to the analyses of these welds.
MPC Closure Ring, Vent and Drain Cover Plate Welds	NB-5230	Radiographic (RT) or ultrasonic (UT) examination required.	Root (if more than one weld pass is required) and final liquid penetrant examination to be performed in accordance with NB-5245. The closure ring provides independent redundant closure for vent and drain cover plates. Vent and drain port cover plate welds are helium leakage tested.
MPC Lid to Shell Weld	NB-5230	Radiographic (RT) or ultrasonic (UT) examination required.	Only UT or multi-layer liquid penetrant (PT) examination is permitted. If PT examination alone is used, at a minimum, it will include the root and final weld layers and each approx. 3/8" of weld depth.
MPC Enclosure Vessel and Lid	NB-6111	All completed pressure retaining systems shall be pressure tested.	The MPC vessel is seal welded in the field following fuel assembly loading. The MPC vessel shall then be pressure tested as defined in Chapter 9. Accessibility for leakage inspections precludes a Code compliant pressure test. Since the shell welds of the MPC cannot be checked for leakage during this pressure test, the shop leakage test to 10^{-7} ref cc/sec (as described in Chapter 9) provides reasonable assurance as to its leak tightness. All MPC vessel welds (except closure ring and vent/drain cover plate) are inspected by volumetric examination, except the MPC lid-to-shell weld shall be verified by volumetric or multi-layer PT examination. If PT alone is used, at a minimum, it must include the root and final layers and each approximately 3/8 inch of weld depth. For either UT or PT, the maximum undetectable flaw size must be demonstrated to be less than the critical flaw size. The critical flaw size must be determined in accordance with ASME Section XI methods. The critical flaw size shall not cause the primary stress limits

Component	Reference ASME Code Section/Article	Code Requirement	Alternative, Justification & Compensatory Measures
			<p>of NB-3000 to be exceeded.</p> <p>The inspection results, including relevant findings (indications) shall be made a permanent part of the user's records by video, photographic, or other means which provide an equivalent record of weld integrity. The video or photographic records should be taken during the final interpretation period described in ASME Section V, Article 6, T-676. The vent/drain cover plate and the closure ring welds are confirmed by liquid penetrant examination. The inspection of the weld must be performed by qualified personnel and shall meet the acceptance requirements of ASME Code Section III, NB-5350 for PT or NB-5332 for UT.</p>
MPC Enclosure Vessel	NB-7000	Vessels are required to have overpressure protection.	No overpressure protection is provided. Function of MPC enclosure vessel is to contain radioactive contents under normal, off-normal, and accident conditions of storage. MPC vessel is designed to withstand maximum internal pressure considering 100% fuel rod failure and maximum accident temperatures.
MPC Enclosure Vessel	NB-8000	States requirements for nameplates, stamping and reports per NCA-8000.	The HI-STORM 100 System is to be marked and identified in accordance with 10CFR71 and 10CFR72 requirements. Code stamping is not required. QA data package to be in accordance with Holtec approved QA program.
MPC Basket Assembly	NG-2000	Requires materials to be supplied by ASME approved Material Supplier.	Materials will be supplied by Holtec approved supplier with CMTRs in accordance with NG-2000 requirements.

Component	Reference ASME Code Section/Article	Code Requirement	Alternative, Justification & Compensatory Measures
MPC Basket Assembly	NG-4420	NG-4427(a) requires a fillet weld in any single continuous weld may be less than the specified fillet weld dimension by not more than 1/16 inch, provided that the total undersize portion of the weld does not exceed 10 percent of the length of the weld. Individual undersize weld portions shall not exceed 2 inches in length.	<p>Modify the Code requirement (intended for core support structures) with the following text prepared to accord with the geometry and stress analysis imperatives for the fuel basket: For the longitudinal MPC basket fillet welds, the following criteria apply: 1) The specified fillet weld throat dimension must be maintained over at least 92 percent of the total weld length. All regions of undersized weld must be less than 3 inches long and separated from each other by at least 9 inches. 2) Areas of undercuts and porosity beyond that allowed by the applicable ASME Code shall not exceed 1/2 inch in weld length. The total length of undercut and porosity over any 1-foot length shall not exceed 2 inches. 3) The total weld length in which items (1) and (2) apply shall not exceed a total of 10 percent of the overall weld length. The limited access of the MPC basket panel longitudinal fillet welds makes it difficult to perform effective repairs of these welds and creates the potential for causing additional damage to the basket assembly (e.g., to the neutron absorber and its sheathing) if repairs are attempted. The acceptance criteria provided in the foregoing have been established to comport with the objectives of the basket design and preserve the margins demonstrated in the supporting stress analysis.</p> <p>From the structural standpoint, the weld acceptance criteria are established to ensure that any departure from the ideal, continuous fillet weld seam would not alter the primary bending stresses on which the design of the fuel baskets is predicated. Stated differently, the permitted weld discontinuities are limited in size to ensure that they remain classifiable as local stress elevators (“peak stress”, F, in the ASME Code for which specific stress intensity limits do not apply).</p>

Component	Reference ASME Code Section/Article	Code Requirement	Alternative, Justification & Compensatory Measures
MPC Basket Assembly	NG-8000	States requirements for nameplates, stamping and reports per NCA-8000.	The HI-STORM 100 System is to be marked and identified in accordance with 10CFR71 and 10CFR72 requirements. No Code stamping is required. The MPC basket data package is to be in conformance with Holtec's QA program.
Overpack Steel Structure	NF-2000	Requires materials to be supplied by ASME approved Material Supplier.	Materials will be supplied by Holtec approved supplier with CMTRs in accordance with NF-2000 requirements.
HI-TRAC Steel Structure	NF-2000	Requires materials to be supplied by ASME approved Material Supplier.	Materials will be supplied by Holtec approved supplier with CMTRs in accordance with NF-2000 requirements.
Overpack Baseplate and Lid Top Plate	NF-4441	Requires special examinations or requirements for welds where a primary member thickness of 1" or greater is loaded to transmit loads in the through thickness direction.	The margins of safety in these welds under loads experienced during lifting operations or accident conditions are quite large. The overpack baseplate welds to the inner shell, pedestal shell, and radial plates are only loaded during lifting conditions and have large safety factors during lifting. Likewise, the top lid plate to lid shell weld has a large structural margin under the inertia loads imposed during a non-mechanistic tipover event.

Component	Reference ASME Code Section/Article	Code Requirement	Alternative, Justification & Compensatory Measures
Overpack Steel Structure	NF-3256 NF-3266	Provides requirements for welded joints.	<p>Welds for which no structural credit is taken are identified as “Non-NF” welds in the design drawings by an “*”. These non-structural welds are specified in accordance with the pre-qualified welds of AWS D1.1. These welds shall be made by welders and weld procedures qualified in accordance with AWS D1.1 or ASME Section IX.</p> <p>Welds for which structural credit is taken in the safety analyses shall meet the stress limits for NF-3256.2, but are not required to meet the joint configuration requirements specified in these Code articles. The geometry of the joint designs in the cask structures are based on the fabricability and accessibility of the joint, not generally contemplated by this Code section governing supports.</p>

Component	Reference ASME Code Section/Article	Code Requirement	Alternative, Justification & Compensatory Measures
HI-STORM Overpack and HI-TRAC Transfer Cask	NF-3320 NF-4720	NF-3324.6 and NF-4720 provide requirements for bolting	<p>These Code requirements are applicable to linear structures wherein bolted joints carry axial, shear, as well as rotational (torsional) loads. The overpack and transfer cask bolted connections in the structural load path are qualified by design based on the design loadings defined in the FSAR. Bolted joints in these components see no shear or torsional loads under normal storage conditions. Larger clearances between bolts and holes may be necessary to ensure shear interfaces located elsewhere in the structure engage prior to the bolts experiencing shear loadings (which occur only during side impact scenarios).</p> <p>Bolted joints that are subject to shear loads in accident conditions are qualified by appropriate stress analysis. Larger bolt-to-hole clearances help ensure more efficient operations in making these bolted connections, thereby minimizing time spent by operations personnel in a radiation area. Additionally, larger bolt-to-hole clearances allow interchangeability of the lids from one particular fabricated cask to another.</p>

Table 2.2.16

COMPARISON BETWEEN HI-STORM MPC LOADINGS WITH HI-STAR MPC LOADINGS[†]

Loading Condition	Difference Between MPC Loadings Under HI-STAR and HI-STORM Conditions
Dead Load	Unchanged
Design Internal Pressure (normal, off-normal, & accident)	Unchanged
Design External Pressure (normal, off-normal, & accident)	HI-STORM normal and off-normal external pressure is ambient which is less than the HI-STAR 40 psig. The accident external pressure is unchanged.
Thermal Gradient (normal, off-normal, & accident)	Determined by analysis in Chapters 3 and 4
Handling Load (normal)	Unchanged
Earthquake (accident)	Inertial loading increased less than 0.1g's (for free-standing overpack designs).
Handling Load (accident)	HI-STORM vertical and horizontal deceleration loadings are less than those in HI-STAR, but the HI-STORM cavity inner diameter is different and therefore the horizontal loading on the MPC is analyzed in Chapter 3.

[†] HI-STAR MPC loadings are those specified in the HI-STAR SAR under docket number 71-9261, which does not impose any off-normal condition loadings.

2.3 SAFETY PROTECTION SYSTEMS

2.3.1 General

The HI-STORM 100 System is engineered to provide for the safe long-term storage of spent nuclear fuel (SNF). The HI-STORM 100 will withstand all normal, off-normal, and postulated accident conditions without any uncontrolled release of radioactive material or excessive radiation exposure to workers or members of the public. Special considerations in the design have been made to ensure long-term integrity and confinement of the stored SNF throughout all cask operating conditions. The design considerations, which have been incorporated into the HI-STORM 100 System to ensure safe long-term fuel storage are:

1. The MPC confinement barrier is an enclosure vessel designed in accordance with the ASME Code, Subsection NB with confinement welds inspected by radiography (RT) or ultrasonic testing (UT). Where RT or UT is not possible, a redundant closure system is provided with field welds, which are tested as specified in Section 9.1.
2. The MPC confinement barrier is surrounded by the HI-STORM overpack which provides for the physical protection of the MPC.
3. The HI-STORM 100 System is designed to meet the requirements of storage while maintaining the safety of the SNF.
4. The SNF once initially loaded in the MPC does not require opening of the canister for repackaging to transport the SNF.
5. The decay heat emitted by the SNF is rejected from the HI-STORM 100 System through passive means. No active cooling systems are employed.

It is recognized that a rugged design with large safety margins is essential, but that is not sufficient to ensure acceptable performance over the service life of any system. A carefully planned oversight and surveillance plan, which does not diminish system integrity but provides reliable information on the effect of passage of time on the performance of the system is essential. Such a surveillance and performance assay program will be developed to be compatible with the specific conditions of the licensee's facility where the HI-STORM 100 System is installed. The general requirements for the acceptance testing and maintenance programs are provided in Chapter 9. Surveillance requirements are specified in the Technical Specifications in Appendix A to the CoC. .

The structures, systems, and components of the HI-STORM 100 System designated as important to safety are identified in Table 2.2.6. Similar categorization of structures, systems, and components, which are part of the ISFSI, but not part of the HI-STORM 100 System, will be the responsibility of the 10CFR72 licensee. For HI-STORM 100A, the ISFSI pad is designated ITS, Category C as discussed in Subsection 2.0.4.1.

2.3.2 Protection by Multiple Confinement Barriers and Systems

2.3.2.1 Confinement Barriers and Systems

The radioactivity which the HI-STORM 100 System must confine originates from the spent fuel assemblies and, to a lesser extent, the contaminated water in the fuel pool. This radioactivity is confined by multiple confinement barriers.

Radioactivity from the fuel pool water is minimized by preventing contact, removing the contaminated water, and decontamination.

An inflatable seal in the annular gap between the MPC and HI-TRAC, and the elastomer seal in the HI-TRAC pool lid prevent the fuel pool water from contacting the exterior of the MPC and interior of the HI-TRAC while submerged for fuel loading. The fuel pool water is drained from the interior of the MPC and the MPC internals are dried. The exterior of the HI-TRAC has a painted surface which is decontaminated to acceptable levels. Any residual radioactivity deposited by the fuel pool water is confined by the MPC confinement boundary along with the spent nuclear fuel.

The HI-STORM 100 System is designed with several confinement barriers for the radioactive fuel contents. Intact fuel assemblies have cladding which provides the first boundary preventing release of the fission products. Fuel assemblies classified as damaged fuel or fuel debris are placed in a damaged fuel container which restricts the release of fuel debris. The MPC is a seal welded enclosure which provides the confinement boundary. The MPC confinement boundary is defined by the MPC baseplate, shell, lid, closure ring, and port cover plates.

The MPC confinement boundary has been designed to withstand any postulated off-normal operations, internal change, or external natural phenomena. The MPC is designed to endure normal, off-normal, and accident conditions of storage with the maximum decay heat loads without loss of confinement. Designed in accordance with the ASME Code, Section III, Subsection NB, with certain NRC-approved alternatives, the MPC confinement boundary provides assurance that there will be no release of radioactive materials from the cask under all postulated loading conditions. Redundant closure of the MPC is provided by the MPC closure ring welds which provide a second barrier to the release of radioactive material from the MPC internal cavity. Therefore, no monitoring system for the confinement boundary is required.

Confinement is discussed further in Chapter 7. MPC shop and field weld examinations using non-destructive methods as specified in Chapters 8 and 9 are performed to ensure the confinement function. Fabrication inspections and tests are also performed, as discussed in Chapter 9, to confirm the confinement boundary maintains its integrity.

2.3.2.2 Cask Cooling

To facilitate the passive heat removal capability of the HI-STORM 100, several thermal design criteria are established for normal and off-normal conditions. They are as follows:

- The heat rejection capacity of the HI-STORM 100 System is deliberately understated

by conservatively determining the design basis fuel that maximizes thermal resistance (see Section 2.1.6). Additional margin is built into the calculated cask cooling rate by using the design basis fuel assembly that offers maximum resistance to MPC internal helium circulation.

- The MPC fuel basket is formed by a honeycomb structure of stainless steel plates with full-length edge-welded intersections, which allows the unimpaired conduction of heat.
- The MPC confinement boundary ensures that the helium atmosphere inside the MPC is maintained during normal, off-normal, and accident conditions of storage and transfer. The MPC confinement boundary maintains the helium confinement atmosphere below the design temperatures and pressures stated in Table 2.2.3 and Table 2.2.1, respectively.
- The MPC thermal design maintains the fuel rod cladding temperatures below the values stated in Chapter 4 such that fuel cladding is not degraded during the long term storage period.
- The HI-STORM is optimally designed with cooling vents and an MPC to overpack annulus which maximize air flow, while providing superior radiation shielding. The vents and annulus allow cooling air to circulate past the MPC removing the decay heat.

2.3.3 Protection by Equipment and Instrumentation Selection

2.3.3.1 Equipment

Design criteria for the HI-STORM 100 System are described in Section 2.2. The HI-STORM 100 System may include use of ancillary or support equipment for ISFSI implementation. Ancillary equipment and structures utilized outside of the reactor facility's 10CFR Part 50 structures may be broken down into two broad categories, namely Important to Safety (ITS) ancillary equipment and Not Important to Safety (NITS) ancillary equipment. NUREG/CR-6407, "Classification of Transportation Packaging and Dry Spent Fuel Storage System Components According to Importance to Safety", provides guidance for the determination of a component's safety classification. Certain ancillary equipment (such as trailers, rail cars, skids, portable cranes, transporters, or air pads) are not required to be designated as ITS for most ISFSI implementations, if the HI-STORM 100 is designed to withstand the failure of these components.

The listing and ITS designation of ancillary equipment in Table 8.1.6 follows NUREG/CR-6407. Ancillary equipment is classified as the highest ITS classification of any of its constituent parts/components. The ITS classification of the ancillary equipment constituent parts/components are determined and documented in the quality program documents such as purchase specifications. ITS ancillary equipment utilized in activities that occur outside the 10CFR Part 50 structure shall be engineered to meet all functional, strength, service life, and operational safety requirements to ensure

that the design and operation of the ancillary equipment is consistent with the intent of this Safety Analysis Report. The design for these components shall consider the following information, as applicable:

1. Functions and boundaries of the ancillary equipment
2. The environmental conditions of the ISFSI site, including tornado-borne missile, tornado wind, seismic, fire, lightning, explosion, ambient humidity limits, flood, tsunami and any other environmental hazards unique to the site.
3. Material requirements including impact testing requirements
4. Applicable codes and standards
5. Acceptance testing requirements
6. Quality assurance requirements
7. Foundation type and permissible loading
8. Applicable loads and load combinations
9. Pre-service examination requirements
10. In-use inspection and maintenance requirements
11. Number and magnitude of repetitive loading significant to fatigue
12. Insulation and enclosure requirements (on electrical motors and machinery)
13. Applicable Reg. Guides and NUREGs.
14. Welding requirements
15. Painting, marking, and identification requirements
16. Design Report documentation requirements
17. Operational and Maintenance (O&M) Manual information requirements

All design documentation shall be subject to a review, evaluation, and safety assessment process in accordance with the provisions of the QA program described in Chapter 13.

Users may effectuate the inter-cask transfer of the MPC between the HI-TRAC transfer cask and either the HI-STORM 100 or the HI-STAR 100 overpack in a location of their choice, depending upon site-specific needs and capabilities. For those users choosing to perform the MPC inter-cask transfer using devices not integral to structures governed by the regulations of 10 CFR Part 50 (e.g., fuel handling or reactor building), a Cask Transfer Facility (CTF) is required. The CTF may be any of the following types to effectuate the cask manipulations and MPC transfers:

1. Stand-alone, aboveground
2. Underground, combined with a mobile lifting device
3. Underground, combined with a cask transporter (e.g., crawler)

The detailed design criteria which must be followed for the design and operation of the CTF are set down in Paragraphs A through R below.

The inter-cask transfer operations consist of the following potential scenarios of MPC transfer:

- Transfer between a HI-TRAC transfer cask and a HI-STORM overpack
- Transfer between a HI-TRAC transfer cask and a HI-STAR 100 overpack

In both scenarios, the standard design HI-TRAC is mounted on top of the overpack (HI-STAR 100, HI-STORM 100, HI-STORM 100S) and the MPC transfer is carried out by opening the transfer lid doors located at the bottom of the HI-TRAC transfer cask and by moving the MPC vertically to the cylindrical cavity of the recipient cask. For the HI-TRAC 100D, 125D, and 100G designs, the MPC transfer is carried out in a similar fashion, except that there is no transfer lid involved - the pool lid is removed while the transfer cask is mounted atop the HI-STORM overpack with the HI-STORM mating device located between the two casks (see Figure 1.2.18). However, the devices utilized to lift the HI-TRAC cask to place it on the overpack and to vertically transfer the MPC may be of stationary or mobile type.

The specific requirements for the CTF employing stationary and mobile lifting devices are somewhat different. The requirements provided in the following specification for the CTF apply to both types of lifting devices, unless explicitly differentiated in the text. The numbers in brackets {} after each design criterion indicate which of the 3 types of CTF design they apply to.

A General Specifications:

- i. The cask handling functions which may be required of the Cask Transfer Facility include:
 - a. Upending and downending of a HI-STAR 100 overpack on a flatbed rail car or other transporter (see Figure 2.3.1 for an example). {1, 2}
 - b. Upending and downending of a HI-TRAC transfer cask on a heavy-haul transfer trailer or other transporter (see Figure 2.3.2 for an example). {1, 2}
 - c. Raising and placement of a HI-TRAC transfer cask on top of a HI-STORM 100 overpack for MPC transfer operations (see Figure 2.3.3 for an example of the cask arrangement with the standard design HI-TRAC transfer cask. The HI-TRAC 100D, 125D, and 100G designs would include the mating device and no transfer lid). {1, 2, 3}
 - d. Raising and placement of a HI-TRAC transfer cask on top of a HI-STAR 100 overpack for MPC transfer operations (see Figure 2.3.4 for an example of the cask arrangement with the standard design HI-TRAC transfer cask. The HI-TRAC 100D, 125D, and 100G designs would include the mating device and no transfer lid). {1, 2, 3}
 - e. MPC transfer between the HI-TRAC transfer cask and the HI-STORM overpack. {1, 2, 3}
 - f. MPC transfer between the HI-TRAC transfer cask and the HI-STAR 100 overpack. {1, 2, 3}

ii. Other Functional Requirements:

The CTF should possess facilities and capabilities, as applicable, to support cask operations such as:

- a. Devices and areas to support installation and removal of the HI-STORM overpack lid. {1, 2, 3}
- b. Devices and areas to support installation and removal of the HI-STORM 100 overpack vent shield block inserts. {1, 2, 3}
- c. Devices and areas to support installation and removal of the HI-STAR 100 closure plate. {1, 2, 3}
- d. Devices and areas to support installation and removal of the HI-STAR 100 transfer collar. {1, 2, 3}
- e. Features to support positioning and alignment of the HI-STORM overpack and the HI-TRAC transfer cask. {1, 2, 3}
- f. Features to support positioning and alignment of the HI-STAR 100 overpack and the HI-TRAC transfer cask. {1, 2, 3}
- g. Areas to support jacking of a loaded HI-STORM overpack for insertion of a translocation device underneath. {1, 2, 3}
- h. Devices and areas to support placement of an empty MPC in the HI-TRAC transfer cask or HI-STAR 100 overpack. {1, 2, 3}
- i. Devices and areas to support receipt inspection of the MPC, HI-TRAC transfer cask, HI-STORM overpack, and HI-STAR overpack. {1, 2, 3}
- j. Devices and areas to support installation and removal of the HI-STORM mating device (HI-TRAC 100D, 125D, and 100G only). {1, 2, 3}

iii. Definitions:

The components of the CTF covered by this specification consist of all structural members, lifting devices, and foundations which bear all or a significant portion of the dead load of the transfer cask or the multi-purpose canister during MPC transfer operations. The definitions of typical terms not defined elsewhere in this FSAR and used in this specification are provided

below. Not all parts defined in this paragraph apply to all CTF designs.

- Connector Brackets: The mechanical part used in the load path which connects to the cask trunnions. A fabricated weldment, slings, and turnbuckles are typical examples of connector brackets. {1, 2, 3}
- CTF structure: The CTF structure is the stationary, anchored portion of the CTF which provides the required structural function to support MPC transfer operations, including lateral stabilization of the HI-TRAC transfer cask and, if required, the overpack, to protect against seismic events. The MPC lifter, if used in the CTF design, is integrated into the CTF structure (see Lifter Mount). {1}
- HI-TRAC lifter(s): The HI-TRAC lifter is the mechanical lifting device, typically consisting of jacks or hoists, that is utilized to lift a loaded or unloaded HI-TRAC to the required elevation in the CTF so that it can be mounted on the overpack.[†] {1, 2, 3}
- Lifter Mount: A beam-like structure (part of the CTF structure) that supports the HI-TRAC and MPC lifter(s). {1}
- Lift Platform: The lift platform is the intermediate structure that transfers the vertical load of the HI-TRAC transfer cask to the HI-TRAC lifters. {1}
- Mobile lifting devices: A mobile lifting device is a device defined in ASME B30.5-1994, Mobile and Locomotive Cranes. A mobile lifting device may be used in lieu of the HI-TRAC lifter and/or an MPC lifter provided all requirements set forth in this subsection are satisfied. {2}
- MPC lifter: The MPC lifter is a mechanical lifting device, typically consisting of jacks or hoists, that is utilized to vertically transfer the MPC between the HI-TRAC transfer cask and the overpack. {1}
- Pier: The portion of the reinforced concrete foundation which projects above the concrete floor of the CTF. {1}
- Single-Failure-Proof (SFP): A single-failure-proof handling device is

[†] The term overpack is used in this specification as a generic term for the HI-STAR 100 and the various HI-STORM overpacks.

one wherein all directly loaded tension and compression members are engineered to satisfy the enhanced safety criteria given in of NUREG-0612 and/or is designed in accordance with ANSI N14.6 and employs redundant drop protection features. {1, 2, 3}

- Translocation Device: A low vertical profile device used to laterally position an overpack such that the bottom surface of the overpack is fully supported by the top surface of the device. Typical translocation devices are air pads and Hillman rollers. {1,2}
- Vertical Cask Transporter: A device which is capable of performing the CTF functions as well as transporting the transfer cask and overpack to and from the CTF. A vertical cask transporter may be used in lieu of the CTF structure, HI-TRAC lifter, and/or an MPC lifter provided all requirements set forth in this subsection are satisfied. {3}

iv. Important to Safety Designation:

All components and structures which comprise the CTF shall be given an ITS category designation in accordance with a written procedure which is consistent with NUREG/CR-6407 and the Holtec quality assurance program. {1,2,3}

B. Environmental and Design Conditions

- i. Lowest Service Temperature (LST): Unless otherwise specified, the LST for the CTF is 0°F (consistent with the specification for the HI-TRAC transfer cask in Subsection 3.1.2.3). Based on its local meteorological data, a host nuclear site may use a higher LST value for the Cask Transfer Facility. {1, 2, 3}
- ii. Snow and Ice Load, S: The CTF structure shall be designed to withstand the dead weight of snow and ice for unheated structures as set forth in ASCE 7-88 [2.2.2] for the specific ISFSI site. {1}
- iii. Tornado Missile, M, and Tornado Wind, W': The tornado wind and tornado-generated missile data applicable to the HI-STORM 100 System (Tables 2.2.4 and 2.2.5) will be used in the design of the CTF unless existing site design basis data or a probabilistic risk assessment (PRA) for the CTF site with due consideration of short operation durations indicates that a less severe tornado missile impact or wind loading on the CTF can be postulated. The PRA analysis can be performed in the manner of the EPRI Report NP-

2005, “Tornado Missile Simulation and Design Methodology Computer Code Manual”. USNRC Reg. Guide 1.117 and Section 2.2.3 of NUREG-800 may be used for guidance in establishing the appropriate tornado missile and wind loading for the CTF.

The following additional clarifications apply to the large tornado missile (4,000 lb. automobile) in Tables 2.2.4 and 2.2.5 in the CTF analysis:

- The missile has a planform area of 20 sq. ft. and impact force characteristics consistent with the HI-TRAC missile impact analysis.
- The large missile can strike the CTF in any orientation up to an elevation of 15 feet.

If the site tornado missile data developed by the ISFSI owner suggests that tornado missiles of greater kinetic energies than that postulated in this FSAR (Table 2.2.4 and 2.2.5) should be postulated for CTF during its use, then the integrity analysis of the CTF shall be carried out under the site-specific tornado missiles. This situation would also require the HI-TRAC transfer cask and the overpack to be re-evaluated under the provisions of 10CFR72.212 and 72.48.

The wind speed specified in this FSAR (Tables 2.2.4 and 2.2.5), likewise, shall be evaluated for their applicability to the site. Lower or higher site-specific wind velocity, compared to the design basis values cited in this FSAR shall be used if justified by appropriate analysis, which may include PRA.

Intermediate penetrant missile and small missiles postulated in this FSAR are not considered to be a credible threat to the functional integrity of the CTF and, therefore, need not be considered. {1, 2, 3}

- iv. Flood: The CTF will be assumed to be flooded to the highest elevation for the CTF facility determined from the local meteorological data. The flood velocity shall be taken as the largest value defined for the ISFSI site. {1, 2, 3}
- v. Lightning: Meteorological data for the region surrounding the ISFSI site shall be used to specify the applicable lightning input to the CTF for personnel safety evaluation purposes. {1, 2, 3}
- vi. Water Waves (Tsunami, Y): Certain coastal CTF sites may be subject to

sudden, short duration waves of water, denoted in the literature by various terms, such as tsunami. If the applicable meteorological data for the CTF site indicates the potential of such water-borne loadings on the CTF, then such a loading, with due consideration of the short duration of CTF operations, shall be defined for the CTF. {1, 2, 3}

- vii. Design Basis Earthquake (DBE), E: The DBE event applicable to the CTF facility pursuant to 10CFR100, Appendix A, shall be specified. The DBE should be specified as a set of response spectra or acceleration time-histories for use in the CTF structural and impact consequence analyses. {1, 2, 3}
- viii. Design Temperature: Unless a lower value can be justified for a specific site, all material properties used in the stress analysis of the CTF structure shall utilize a reference design temperature of 150°F. {1, 2, 3}

C. Heavy Load Handling:

- i. Apparent dead load, D*: The dead load of all components being lifted shall be increased in the manner set forth in Subsection 3.4.3 to define the Apparent Dead Load, D*. {1, 2, 3}
- ii. NUREG-0612 Conformance:

The Connector Bracket, HI-TRAC lifter, and MPC lifter shall comply with the guidance provided in NUREG-0612 (1980) for single failure proof devices. Where the geometry of the lifting device is different from the configurations contemplated by NUREG-0612, the following exceptions apply:

- a. Mobile lifting devices at the CTF shall conform to the guidelines of Section 5.1.1 of NUREG-0612 with the exception that mobile lifting devices shall meet the requirements of ANSI B30.5, "Mobile and Locomotive Cranes", in lieu of the requirements of ANSI B30.2, "Overhead and Gantry Cranes". The mobile lifting device used shall have a minimum safety factor of two over the allowable load table for the lifting device in accordance with Section 5.1.6(1)(a) of NUREG-0612, and shall be capable of stopping and holding the load during a DBE event. {2}
- b. Section 5.1.6(2) of NUREG-0612 specifies that new cranes should be designed to meet the requirements of NUREG-0554. For mobile lifting devices, the guidance of Section 5.1.6(2) of NUREG-0612 does not apply. {2}

- c. Vertical cask transporters shall be designed in accordance with ANSI N14.6 and shall employ redundant drop protection features. {3}

iii. Defense-in-Depth Measures:

- a. The lift platform and the lifter mount shall be designed to ensure that the stresses produced under the apparent dead load, D^* , are less than the Level A (normal condition) stress limits for ASME Section III, Subsection NF, Class 3, linear structures. {1}
- b. The CTF structure shall be designed to ensure that the stresses produced in it under the apparent dead load, D^* , are less than the Level A (normal condition) stress limits for ASME Section III, Subsection NF, Class 3, linear structures. {1}
- c. Maximum deflection of the lift platform and the lifter mount under the apparent dead load shall comply with the limits set forth in CMAA-70. {1}
- d. When the HI-TRAC transfer cask is stacked on the overpack, HI-TRAC shall be either held by the lifting device or laterally restrained by the CTF structure. Furthermore, when the HI-TRAC transfer cask is placed atop the overpack, the overpack shall be laterally restrained from uncontrolled movement, if required by the analysis specified in Subsection 2.3.3.1.N. {1}
- e. The design of the lifting system shall ensure that the lift platform (or lift frame) is held essentially horizontal at all times and that the symmetrically situated axial members are symmetrically loaded. {1,3}
- f. In order to minimize occupational radiation exposure to ISFSI personnel, design of the MPC lifting attachment (viz., sling) should not require any human activity inside the HI-TRAC cylindrical space. {1, 2, 3}
- g. The HI-TRAC lifter and MPC lifter shall possess design features to avoid excessive side-sway of the payload during lifting operations. {1, 2, 3}
- h. The lifter (HI-TRAC and MPC) design shall ensure that any electrical malfunction in the motor or the power supply will not lead to an uncontrolled lowering of the load. {1, 2, 3}

- i. The kinematic stability of HI-TRAC or HI-STORM standing upright in an unrestrained configuration (if such a condition exists during the use of the CTF) shall be analytically evaluated and ensured under all postulated extreme environmental phenomena loadings for the CTF facility. {1, 2, 3}

iv. Shielding Surety:

The design of the HI-TRAC and MPC lifters shall preclude the potential for the MPC to be removed, completely or partially, from the cylindrical space formed by the HI-TRAC and the underlying overpack. {1, 2, 3}

v. Specific Requirements for Mobile Lifting Devices and Vertical Cask Transporters:

A mobile lifting device, if used in the CTF in the role of the HI-TRAC lifter or MPC lifter is governed in part by ANSI/ASME N45.2.15 with technical requirements specified in ANSI B30.5 (1994). {2}

When lifting the MPC from an overpack to the HI-TRAC transfer cask, limit switches or load limiters shall be set to ensure that the lifted load does not exceed 110% of the loaded MPC weight. {2,3}

An analysis of the consequences of a potential MPC vertical drop which conforms to the guidelines of Appendix A to NUREG-0612 shall be performed. The analysis shall demonstrate that a postulated drop would not result in the MPC developing a thru-wall breach resulting in loss of confinement or experiencing a deceleration in excess of its design basis deceleration specified in this FSAR. {2}

vi. Lift Height Limitation: The HI-TRAC lift heights shall be governed by the Technical Specifications. {1,2,3}

vii. Control of Side Sway: Procedures shall provide provisions to ensure that the load is lifted essentially vertically with positive control of the load. Key cask lifting and transfer procedures, as determined by the user, should be reviewed by the Certificate Holder before their use. {1, 2, 3}

D. Loads and Load Combinations for the CTF Structure

The applicable loadings for the CTF have been summarized in paragraph B in the preceding. A stress analysis of the CTF structure shall be performed to demonstrate compliance with the Subsection NF stress limits for Class 3 linear structures for the

service condition germane to each load combination. Table 2.3.2 provides the load combinations (the symbols in Table 2.3.2 are defined in the preceding text and in Table 2.2.13). {1}

E. Materials and Failure Modes

- i. Acceptable Materials and Material Properties: All materials used in the design of the CTF shall be ASME or ASTM approved or equal, consistent with the ITS category of the part (see discussion in subsection 2.I.0). Reinforced concrete, if used, shall comply with the provisions of ACI 318 (89). The material property and allowable stress values for all steel structures shall be taken from the ASME and B&PV Code, Section II, wherever such data is available; otherwise, the data provided in the ASTM standards shall be used. {1, 2, 3}
- ii. Brittle Fracture: All materials used for structural components of the CTF structure and the lift platform, designated as primary load bearing, shall meet the fracture toughness requirements for ASME Section III, Subsection NF, and Class 3 structures (NF-2300). If required, Charpy impact test temperature shall be equal to the designated LST or lower. {1, 2, 3}
- iii. Fatigue: Fatigue failure modes of primary structural members in the CTF structure whose failure may result in uncontrolled lowering of the HI-TRAC transfer cask or the MPC (critical members) shall be evaluated. A minimum factor of safety of 2 on the number of permissible loading cycles on the critical members shall apply. {1, 2, 3}
- iv. Buckling: For all critical members in the CTF structure (defined above), potential failure modes through buckling under axial compression shall be considered. The margin of safety against buckling shall comply with the provisions of ASME Section III, Subsection NF, for Class 3 linear structures. {1, 2, 3}

F. CTF Pad

A reinforced concrete pad in conformance with the specification for the ISFSI pad set forth in this FSAR (see Table 2.2.9) may be used in the region of the CTF where the overpack and HI-TRAC are stacked for MPC transfer. Alternatively, the pad may be designed using the guidelines of ACI-318(89). {1, 2, 3}

G. Miscellaneous Components

Hoist rings, turnbuckles, slings, and other appurtenances which are in the load path

during heavy load handling at the CTF shall have enhanced margin of safety per ANSI N14.6 or be single-failure-proof. {1, 2, 3}

H. Structural Welds

All primary structural welds in the CTF structure shall comply with the specifications of ASME Section III for Class 3 NF linear structures. {1}

I. Foundation

The design of the CTF structure foundation and piers, including load combinations, shall be in accordance with ACI-318(89). {1}

J. Rail Access

The rail lines that enter the Cask Transfer Facility shall be set at grade level with no exposed rail ties or hardware other than the rail itself. {1,2}

K. Vertical Cask Crawler/Translocation Device Access (If Required)

- i. The cask handling bay in the CTF shall allow access of a vertical cask crawler or translocation device carrying a transfer cask or overpack. The building floor shall be equipped with a smooth transition to the cask travel route such that the vertical cask crawler tracks do not have to negotiate sharp lips or slope transitions and the translocation devices have a smooth transition. Grading of exterior aprons shall be no more than necessary to allow water drainage. {1}
- ii. If roll-up doors are used, the roll up doors shall have no raised threshold that could damage the vertical cask crawler tracks (if a crawler is used). {1}
- iii. Exterior aprons shall be of a material that will not be damaged by the vertical cask crawler tracks, if a crawler is used. {1}

L. Facility Floor

- i. The facility floor shall be sufficiently flat to allow optimum handling of casks with a translocation device. {1}
- ii. Any floor penetrations, in areas where translocation device operations may occur, shall be equipped with flush inserts. {1}

- iii. The rails, in areas where translocation device operations may occur shall be below the finish level of the floor. Flush inserts, if necessary, shall be sized for installation by hand. {1}

M. Cask Connector Brackets

- i. Primary lifting attachments between the cask and the lifting platform are the cask connector brackets. The cask connector brackets may be lengthened or shortened to allow for differences in the vehicle deck height of the cask delivery vehicle and the various lifting operations. The connector brackets shall be designed to perform cask lifting, upending and downending functions. The brackets shall be designed in accordance with ANSI N14.6 [Reference 2.2.3] and load tested at 300% of the load applied to them during normal handling. {1, 2, 3}
- ii. The connector brackets shall be equipped with a positive engagement to ensure that the cask lifting attachments do not become inadvertently disconnected during a seismic event and during normal cask handling operations. {1, 2, 3}
- iii. The design of the connector brackets shall ensure that the HI-TRAC transfer cask is fully secured against slippage during MPC transfer operations. {1, 2, 3}

N. Cask Restraint System

A time-history analysis of the stacked overpack/HI-TRAC transfer cask assemblage under the postulated ISFSI Level D events in Table 2.3.2 shall be performed to demonstrate that a minimum margin of safety of 1.1 against overturning or kinematic instability exists and that the CTF structure complies with the applicable stress limits (Table 2.3.2) and that the maximum permissible deceleration loading specified in the FSAR is not exceeded. If required to meet the minimum margin of safety of 1.1, a cask restraining system shall be incorporated into the design of the Cask Transfer Facility to provide lateral restraint to the overpack (HI-STORM or HI-STAR 100). If the HI-STORM/HI-TRAC stack is laterally supported such that the fundamental natural frequency of the beam mode vibration of the stack is in the rigid range of the horizontal acceleration time histories (or the corresponding response spectra), then the dynamic time history solution converges to the static solution using the ZPA (see Glossary) of the corresponding time history. In such a case, a time history analysis or a static analysis may be performed since the maximum predicted responses from both solutions are identical. {1, 2, 3}

O. Design Life

The Cask Transfer Facility shall be constructed to have a minimum design life of 40 years. {1}

P. Testing Requirements

In addition to testing recommended in NUREG-0612 (1980), a structural adequacy test of the CTF structure at 125% of its operating load prior to its first use in a cask loading campaign shall be performed. This test should be performed in accordance with the guidance provided in the CMAA Specification 70 [2.2.16]. {1}

Q. Quality Assurance Requirements

All components of the CTF shall be manufactured in full compliance with the quality assurance requirements applicable to the ITS category of the component as set forth in the Holtec QA program. {1, 2, 3}

R. Documentation Requirements

- i. O&M Manual: An Operations and Maintenance Manual shall be prepared which contains, at minimum, the following items of information: {1, 2, 3}
 - Maintenance Drawings
 - Operating Procedures
- ii. Design Report: if required by the safety classification, a QA-validated design report documenting full compliance with the provisions of this specification shall be prepared and archived for future reference in accordance with the provisions of the Holtec QA program. {1, 2, 3}

2.3.3.2 Instrumentation

As a consequence of the passive nature of the HI-STORM 100 System, instrumentation which is important to safety is not necessary. No instrumentation is required or provided for HI-STORM 100 storage operations, other than normal security service instruments and TLDs.

However, in lieu of performing the periodic inspection of the HI-STORM overpack vent screens, temperature elements may be installed in two of the overpack exit vents to continuously monitor the air temperature. If the temperature elements and associated temperature monitoring instrumentation are used, they shall be designated important to safety as specified in Table 2.2.6.

The temperature elements and associated temperature monitoring instrumentation provided to monitor the air outlet temperature shall be suitable for a temperature range of -40°F to 500°F. At a

minimum, the temperature elements and associated temperature monitoring instrumentation shall be calibrated and tested at 3 temperature points with an accuracy of $\pm 4^{\circ}\text{F}$ across the suitable temperature range.

2.3.4 Nuclear Criticality Safety

The criticality safety criteria stipulates that the effective neutron multiplication factor, k_{eff} , including statistical uncertainties and biases, is less than 0.95 for all postulated arrangements of fuel within the cask under all credible conditions.

2.3.4.1 Control Methods for Prevention of Criticality

The control methods and design features used to prevent criticality for all MPC configurations are the following:

- a. Incorporation of permanent neutron absorbing material in the MPC fuel basket walls.
- b. Favorable geometry provided by the MPC fuel basket

Additional control methods used to prevent criticality for the MPC-24, MPC-24E, and MPC-24EF (all with higher enriched fuel), and the MPC-32 and MPC-32F are the following:

- a. Loading of PWR fuel assemblies must be performed in water with a minimum boron content as specified in Table 2.1.14 or 2.1.16, as applicable.
- b. Prevention of fresh water entering the MPC internals.

Administrative controls shall be used to ensure that fuel placed in the HI-STORM 100 System meets the requirements described in Chapters 2 and 6. All appropriate criticality analyses are presented in Chapter 6.

2.3.4.2 Error Contingency Criteria

Provision for error contingency is built into the criticality analyses performed in Chapter 6. Because biases and uncertainties are explicitly evaluated in the analysis, it is not necessary to introduce additional contingency for error.

2.3.4.3 Verification Analyses

In Chapter 6, critical experiments are selected which reflect the design configurations. These critical experiments are evaluated using the same calculation methods, and a suitable bias is incorporated in the reactivity calculation.

2.3.5 Radiological Protection

2.3.5.1 Access Control

As required by 10CFR72, uncontrolled access to the ISFSI is prevented through physical protection means. A peripheral fence with an appropriate locking and monitoring system is a standard approach to limit access. The details of the access control systems and procedures, including division of the site into radiation protection areas, will be developed by the licensee (user) of the ISFSI utilizing the HI-STORM 100 System.

2.3.5.2 Shielding

The shielding design is governed by 10CFR72.104 and 10CFR72.106 which provide radiation dose limits for any real individual located at or beyond the nearest boundary of the controlled area. The individual must not receive doses in excess of the limits given in Table 2.3.1 for normal, off-normal, and accident conditions.

The objective of shielding is to assure that radiation dose rates at key locations are as low as practical in order to maintain occupational doses to operating personnel As Low As Reasonably Achievable (ALARA) and to meet the requirements of 10 CFR 72.104 and 10 CFR 72.106 for dose at the controlled area boundary. Three locations are of particular interest in the storage mode:

- immediate vicinity of the cask
- restricted area boundary
- controlled area (site) boundary

Dose rates in the immediate vicinity of the loaded overpack are important in consideration of occupational exposure. Conservative evaluations of dose rate have been performed and are described in Chapter 5 based on the contents of the BWR and PWR MPCs permitted for storage as described in Section 2.1.9. Actual dose rates in operation will be lower than those reported in Chapter 5 for the following reasons:

- The shielding evaluation model has a number of conservatisms, as discussed in Chapter 5.
- No single cask will likely contain design basis fuel in each fuel storage location and the full compliment of non-fuel hardware allowed by Section 2.1.9.
- No single cask will contain fuel and non-fuel hardware at the limiting burnups and cooling times allowed by Section 2.1.9.

Consistent with 10 CFR 72, there is no single dose rate limit established for the HI-STORM 100 System. Compliance with the regulatory limits on occupational and controlled area doses is performance-based, as demonstrated by dose monitoring performed by each cask. A design objective for the maximum average radial surface dose rate has been established as 300 mrem/hr. Areas adjacent to the inlet and exit vents which pass through the radial shield are limited to 175 mrem/hr.

The average dose rate at the top of the overpack is limited to below 60 mrem/hr. Chapter 5 of this FSAR presents the analyses and evaluations to establish HI-STORM 100 compliance with these design objectives.

Because of the passive nature of the HI-STORM 100 System, human activity related to the system is infrequent and of short duration. Personnel exposures due to operational and maintenance activities are discussed in Chapter 10. Chapter 10 also provides information concerning temporary shielding which may be utilized to reduce the personnel dose during loading, unloading, transfer, and handling operations. The estimated occupational doses for personnel comply with the requirements of 10CFR20.

For the loading and unloading of the HI-STORM overpack with the MPC, several transfer cask designs are provided (i.e., HI-TRAC 125, HI-TRAC 100, HI-TRAC 100D, HI-TRAC 125D, and HI-TRAC 100G). The two 125 ton HI-TRAC provide better shielding than the HI-TRAC 100, 100D, and 100G due to the increased shielding thickness and corresponding greater weight. Provided the licensee is capable of utilizing the 125 ton HI-TRAC, ALARA considerations would normally dictate that the 125 ton HI-TRAC should be used. However, sites may not be capable of utilizing the 125 ton HI-TRAC due to crane capacity limitations, floor loading limitations, or other site-specific considerations. As with other dose reduction-based plant activities, individual users who cannot accommodate the 125 ton HI-TRAC should perform a cost-benefit analysis of the actions (e.g., plant modifications) that would be necessary to use the 125 ton HI-TRAC. The cost of the action(s) would be weighed against the value of the projected reduction in radiation exposure and a decision made based on each plant's particular ALARA implementation philosophy.

Dose rates at the restricted area and site boundaries shall be in accordance with applicable regulations. Licensees shall demonstrate compliance with 10CFR72.104 and 10CFR72.106 for the actual fuel being stored, the ISFSI storage array, and the controlled area boundary distances.

The analyses presented in Chapters 5, 10, and 11 demonstrate that the HI-STORM 100 System is capable of meeting the above radiation dose limits.

2.3.5.3 Radiological Alarm System

There are no credible events that could result in release of radioactive materials or increases in direct radiation above the requirements of 10CFR72.106.

2.3.6 Fire and Explosion Protection

There are no combustible or explosive materials associated with the HI-STORM 100 System. No such materials would be stored within an ISFSI. However, for conservatism we have analyzed a hypothetical fire accident as a bounding condition for HI-STORM 100. An evaluation of the HI-STORM 100 System in a fire accident is discussed in Chapter 11.

Small overpressures may result from accidents involving explosive materials which are stored or transported near the site. Explosion is an accident loading condition considered in Chapter 11.

Table 2.3.1

RADIOLOGICAL SITE BOUNDARY REQUIREMENTS

BOUNDARY OF CONTROLLED AREA (m) (minimum)	100
NORMAL AND OFF-NORMAL CONDITIONS:	
Whole Body (mrem/yr)	25
Thyroid (mrem/yr)	75
Any Other Critical Organ (mrem/yr)	25
DESIGN BASIS ACCIDENT:	
TEDE (rem)	5
DDE + CDE to any individual organ or tissue (other than lens of the eye) (rem)	50
Lens dose equivalent (rem)	15
Shallow dose equivalent to skin or any extremity (rem)	50

Table 2.3.2

Load Combinations[†] and Service Condition Definitions for the CTF Structure

Load Combination	Service Condition for Section III of the ASME Code for Definition of Allowable Stress	Comment
D*	Level A	All primary load bearing members must satisfy Level A stress limits.
D+S	Level A	
D+M ^{††} +W' D+F D+E or D+Y	Level D	Factor of safety against overturning shall be ≥ 1.1

[†] The reinforced concrete portion of the CTF structure shall also meet factored combinations of the above loads set forth in ACI-318(89).

^{††} This load may be reduced or eliminated based on a PRA for the CTF site.

FIGURE 2.3.3: HI-TRAC PLACEMENT ON HI-STORM 100 FOR MPC TRANSFER OPERATIONS

FIGURE 2.3.4: HI-TRAC PLACEMENT ON HI-STAR 100 FOR MPC TRANSFER OPERATIONS

2.4 DECOMMISSIONING CONSIDERATIONS

Efficient decommissioning of the ISFSI is a paramount objective of the HI-STORM 100 System. The HI-STORM 100 System is ideally configured to facilitate rapid, safe, and economical decommissioning of the storage site.

The MPC is being licensed for transport off-site in the HI-STAR 100 dual-purpose cask system (Reference Docket No. 71-9261). No further handling of the SNF stored in the MPC is required prior to transport to a licensed centralized storage facility or licensed repository.

The MPC which holds the SNF assemblies is engineered to be suitable as a waste package for permanent internment in a deep Mined Geological Disposal System (MGDS). The materials of construction permitted for the MPC are known to be highly resistant to severe environmental conditions. No carbon steel, paint, or coatings are used or permitted in the MPC in areas where they could be exposed to spent fuel pool water or the ambient environment. Therefore, the SNF assemblies stored in the MPC should not need to be removed. However, to ensure a practical, feasible method to defuel the MPC, the top of the MPC is equipped with sufficient gamma shielding and markings locating the drain and vent locations to enable semiautomatic (or remotely actuated) boring of the MPC lid to provide access to the MPC vent and drain. The circumferential welds of the MPC lid closure ring can be removed by semiautomatic or remotely actuated means, providing access to the SNF.

Likewise, the overpack consists of steel and concrete rendering it suitable for permanent burial. Alternatively, the MPC can be removed from the overpack, and the latter reused for storage of other MPCs.

In either case, the overpack would be expected to have no interior or exterior radioactive surface contamination. Any neutron activation of the steel and concrete is expected to be extremely small, and the assembly would qualify as Class A waste in a stable form based on definitions and requirements in 10CFR61.55. As such, the material would be suitable for burial in a near-surface disposal site as Low Specific Activity (LSA) material.

If the MPC needs to be opened and separated from the SNF before the fuel is placed into the MGDS, the MPC interior metal surfaces will be decontaminated using existing mechanical or chemical methods. This will be facilitated by the MPC fuel basket and interior structures' smooth metal surfaces designed to minimize crud traps. After the surface contamination is removed, the MPC radioactivity will be diminished significantly, allowing near-surface burial or secondary applications at the licensee's facility.

It is also likely that both the overpack and MPC, or extensive portions of both, can be further decontaminated to allow recycle or reuse options. After decontamination, the only radiological hazard the HI-STORM 100 System may pose is slight activation of the HI-STORM 100 materials caused by irradiation over a 40-year storage period.

Due to the design of the HI-STORM 100 System, no residual contamination is expected to be left behind on the concrete ISFSI pad. The base pad, fence, and peripheral utility structures will require no decontamination or special handling after the last overpack is removed.

To evaluate the effects on the MPC and HI-STORM overpack caused by irradiation over a 40-year storage period, the following analysis is provided. Table 2.4.1 provides the conservatively determined quantities of the major nuclides after 40 years of irradiation. The calculation of the material activation is based on the following:

- Beyond design basis fuel assemblies (B&W 15x15, 4.8% enrichment, 70,000 MWD/MTU, and five-year cooling time) stored for 40 years. A constant source term for 40 years was used with no decrease in the neutron source term. This bounds the source term associated with the limiting PWR burnup of 68,200 MWD/MTU.
- Material quantities based on the drawings in Section 1.5.
- A constant flux equal to the initial loading condition is conservatively assumed for the full 40 years.
- Material activation is based on MCNP-4A calculations.

As can be seen from the material activation results presented in Table 2.4.1, the MPC and HI-STORM overpack activation is very low, even including the very conservative assumption of a constant flux for 40 years. The results for the concrete in the HI-STORM overpack can be conservatively applied to the ISFSI pad. This is extremely conservative because the overpack shields most of the flux from the fuel and, therefore, the ISFSI pad will experience a minimal flux.

In any case, the HI-STORM 100 System would not impose any additional decommissioning requirements on the licensee of the ISFSI facility per 10CFR72.30, since the HI-STORM 100 System could eventually be shipped from the site.

Table 2.4.1
MPC ACTIVATION

Nuclide	Activity After 40-Year Storage (Ci/m ³)
⁵⁴ Mn	2.20e-3
⁵⁵ Fe	3.53e-3
⁵⁹ Ni	2.91e-6
⁶⁰ Co	3.11e-4
⁶³ Ni	9.87e-5
Total	6.15e-3

HI-STORM OVERPACK ACTIVATION

Nuclide	Activity After 40-Year Storage (Ci/m ³)
Overpack Steel	
⁵⁴ Mn	3.62e-4
⁵⁵ Fe	6.82e-3
Total	7.18e-3
Overpack Concrete	
³⁹ Ar	3.02e-6
⁴¹ Ca	2.44e-7
⁵⁴ Mn	1.59e-7
⁵⁵ Fe	2.95e-5
Total	3.43e-5

2.5 REGULATORY COMPLIANCE

Chapter 2 provides the principal design criteria related to structures, systems, and components important to safety. These criteria include specifications regarding the fuel, as well as, external conditions that may exist in the operating environment during normal and off-normal operations, accident conditions, and natural phenomena events. The chapter has been written to provide sufficient information to allow verification of compliance with 10CFR72, NUREG-1536, and Regulatory Guide 3.61. A more detailed evaluation of the design criteria and an assessment of compliance with those criteria is provided in Chapters 3 through 13.

APPENDIX 2.A

GENERAL DESIGN AND CONSTRUCTION REQUIREMENTS FOR THE ISFSI PAD FOR HI-STORM 100A

2.A.1 General Comments

As stated in Section 2.0.4, an ISFSI slab that anchors a spent fuel storage cask should be classified as "important to safety." This classification of the slab follows from the provisions of 10CFR72, which require that the cask system retain its capacity to store spent nuclear fuel in a safe configuration subsequent to a seismic or other environmental event. Since the slab for anchored HI-STORM deployment is designated as ITS, the licensee is required to determine whether the reactor site parameters, including earthquake intensity and large missiles, are enveloped by the cask design bases. The intent of the regulatory criteria is to ensure that the slab meets all interface requirements of the cask design and the geotechnical characteristics of the ISFSI site.

This appendix provides general requirements for design and construction of the ISFSI concrete pad as an ITS structure, and also establishes the framework for ensuring that the ISFSI design bases are clearly articulated. The detailed design of the ISFSI pad for anchored HI-STORM deployment shall comply with the technical provisions set forth in this appendix.

2.A.2 General Requirements for ISFSI Pad

- Consistent with the provisions of NUREG-1567 [2.0.6], all concrete work shall comply with the requirements of ACI-349-85 [2.0.2].
- All reinforcing steel shall be manufactured from high strength billet steel conforming to ASTM designation A615 Grade 60.
- The ISFSI owner shall develop appropriate mixing, pouring, reinforcing steel placement, curing, testing, and documentation procedures to ensure that all provisions of ACI 349-85 [2.0.2] are met.
- The placement, depth, and design and construction of the slab shall take into account the depth of the frost line at the ISFSI location. The casks transmit a very small amount of heat into the cask pad through conduction. The American Concrete Institute guidelines on reinforced concrete design of ground level slabs to minimize thermal and shrinkage induced cracking shall be followed.

5. General Requirements for Steel Embedment: The steel embedment, excluding the pre-tensioned anchorage studs, is required to follow the provisions stipulated in ACI 349-85 [2.0.2], Appendix B "Steel Embedment" and the associated Commentary on Appendix B, as applicable. Later editions of this Code may be used provided a written reconciliation is performed. An example of one acceptable embedment configuration is provided in Figure 2.A.1. Site-specific embedment designs may vary from this example, depending on the geotechnical characteristics of the site-specific foundation. The embedment designer shall consider any current, relevant test data in designing the pad embedment for HI-STORM 100A and HI-STORM 100SA.
6. The ISFSI owner shall ensure that pad design analyses, using interface loads provided in this report, demonstrate that all structural requirements of NUREG-1567 and ACI-349-85 are satisfied.
7. Unless the load handling device is designed in accordance with ANSI N14.6 and incorporates redundant drop protection features, the ISFSI owner shall ensure that a permissible cask carry height is computed for the site-specific pad/foundation configuration such that the design basis deceleration set forth in this FSAR are not exceeded in the event of a handling accident involving a vertical drop.
8. The ISFSI owner shall ensure that the pad/foundation configuration provides sufficient safety margins for overall kinematic stability of the cask/pad/foundation assemblage.
9. The ISFSI owner shall ensure that the site-specific seismic inputs, established at the top surface of the ISFSI pad, are bounded by the seismic inputs used as the design basis for the attachment components. If required, the ISFSI owner shall perform additional analyses to ensure that the site-specific seismic event or durations greater than the design basis event duration analyzed in this report, do not produce a system response leading to structural safety factors (defined as allowable stress (load) divided by calculated stress (load)) less than 1.0. Table 2.0.5 and Table 2.2.8 provide the limiting values of ZPAs in the three orthogonal directions that must not be exceeded at an ISFSI site (on the pad top surface) to comply with the general CoC for the HI-STORM 100A (and 100SA) System.
10. An ISFSI pad used to support anchored HI-STORM overpacks, unlike the case of free standing overpacks, may experience tensile (vertically upward) anchorage forces in addition to compression loads. The reinforcing steel (pattern and quantity) must be selected to meet the demands of the anchorage forces under seismic and other environmental conditions that involve destabilizing loadings (such as the large tornado missile defined in this FSAR).

2.A.3 Steel Embedment for Anchored Casks

Figure 2.A.1 shows a typical fastening arrangement for the HI-STORM 100A System. The details of the rebars in the pad (which are influenced by the geotechnical characteristics of the foundation and its connection to the underlying continuum) are not shown in Figure 2.A.1. Representative dimensions of the embedment and anchorage system are provided in Table 2.A.1.

The embedment detail illustrated in Figure 2.A.1 is designed to resist a load equal to the ASME Code, Section III Appendix F Level D load capacity of the cask anchor studs. The figure does not show the additional reinforcement required to ensure that tensile cracking of concrete is inhibited (see Figure B-4 in the Commentary ACI-349R-97) as this depends on the depth chosen for the ITS ISFSI pad concrete. The ACI Code contemplates ductile failure of the embedment steel and requires that the ultimate load capacity of the steel embedment be less than the limit pullout strength of the concrete surrounding the embedment that resists the load transferred from the cask anchor stud. If this criterion cannot be assured, then additional reinforcement must be added to inhibit concrete cracking (per Subsection B.4.4 of Appendix B of ACI-349-97).

The anchor stud receptacle described in Figure 2.A.1 is configured so that the cask anchor studs (which interface with the overpack baseplate as well as the pad embedment per Table 2.0.5 and are designed in accordance with ASME Section III, Subsection NF stress limits), sits flush with the ISFSI top surface while the cask is being positioned. Thus, a translocation device such as an “air pad” (that requires a flat surface) can be used to position the HI-STORM overpack at the designated location. Subsequent to positioning of the cask, the cask anchor stud is raised, the anchor stud nut installed, and the anchor stud preload applied. The transfer of load from the cask anchor stud to the embedment is through the bearing surface of the lower head of the cask anchor stud and the upper part of the anchor stud receptacle shown in the figure. The members of the anchoring system illustrated in Figure 2.A.1, as well as other geometries developed by the ISFSI designer, must meet the following criteria:

- i. The weakest structural link in the system shall be in the ductile member. In other words, the tension capacity of the anchor stud/anchor receptacle group (based on the material ultimate strengths) shall be less than the concrete pull-out strength (computed with due recognition of the rebars installed in the pad).
- ii. The maximum ratio of embedment plus cask anchor stud effective tensile stiffness to the effective compressive stiffness of the embedment plus concrete shall not exceed 0.25 in order to ensure the effectiveness of the pre-load.
- iii. The maximum axial stress in the cask anchor studs under normal and seismic conditions shall be governed by the provisions of ASME Section III Subsection NF (1995).

- iv. The load-bearing members of the HI-STORM 100A anchorage system shall be considered important-to-safety. This includes the following components shown in Figure 2.A.1: anchor stud and nut, top ring, upper collar, anchor receptacle, and anchor ring.

For sites with lower ZPA DBE events, compared to the limiting ZPAs set down in this FSAR, the size of the anchor studs and their number can be appropriately reduced. However, the above three criteria must be satisfied in all cases.

Table 2.A.1

Typical Embedment and Anchoring Data*

Nominal diameter of the anchor stud, (inch)	2
Thickness of the embedment ring, (inch)	2
I.D. of the embedment ring, (inch)	130
Anchor receptacle: Upper Position O.D. and I.D. (inch) Lower portion O.D. and I.D. (inch)	O.D.: 2.5 / I.D.: 2.125 (min.) O.D.: 4.875 / I.D.: 3.625 (min.)
Depth of anchor receptacle collar, d, (inch)	2.5
Free fall height of the anchor stud, h_e , (inch)	8
Representative Materials of Construction are as follows:[†]	
Anchor Studs:	Per Table 2.0.4
Anchor Receptacle:	Low carbon steel such as A-36, A-105
Top Ring, Upper Collar, Anchor Ring:	Low carbon steel such as A-36, SA-516-Gr. 70

* Refer to Figure 2.A.1

[†] The ISFSI designer shall ensure that all permanently affixed embedment parts (such as the anchor receptacle) made from materials vulnerable to deleterious environmental effects (e.g. low carbon steel) are protected through the use of suitably engineered corrosion barrier. Alternatively, the selected material of construction must be innately capable of withstanding the long term environmental conditions at the ISFSI site.

Note: Rebars in the ISFSI pad and sub-surface soil/rock continuum not shown.

Appendix 2.B The Forced Helium Dehydration (FHD) System

2.B.1 System Overview

The Forced Helium Dehydration (FHD) system is used to remove the remaining moisture in the MPC cavity after all of the water that can practically be removed through the drain line using a hydraulic pump or an inert gas has been expelled in the water blowdown operation. The FHD system may be used as an optional drying method for all MPCs to be stored.

Expelling the water from the MPC using a conventional pump or a water displacement method using inert gas would remove practically all of the contained water except for the small quantity remaining on the MPC baseplate below the bottom of the drain line and an even smaller adherent amount wetting the internal surfaces. A skid-mounted, closed loop dehydration system will be used to remove the residual water from the MPC such that the partial pressure of the trace quantity of water vapor in the MPC cavity gas is brought down to ≤ 3 torr. The FHD system, engineered for this purpose, shall utilize helium gas as the working substance.

The FHD system, schematically illustrated in Figure 2.B.1, can be viewed as an assemblage of four thermal modules, namely, (i) the condensing module, (ii) the demister module, (iii) the helium circulator module and (iv) the pre-heater module. The condensing module serves to cool the helium/vapor mixture exiting the MPC to a temperature well below its dew point such that water may be extracted from the helium stream. The condensing module is equipped with suitable instrumentation to provide a direct assessment of the extent of condensation that takes place in the module during the operation of the FHD system. The demister module, engineered to receive partially cooled helium exiting the condensing module, progressively chills the recirculating helium gas to a temperature that is well below the temperature corresponding to the partial pressure of water vapor at 3 torr.

The motive energy to circulate helium is provided by the helium circulator module, which is sized to provide the pressure rise necessary to circulate helium at the requisite rate. The last item, labeled the pre-heater module, serves to pre-heat the flowing helium to the desired temperature such that it is sufficiently warm to boil off any water present in the MPC cavity.

The pre-heater module, in essence, serves to add supplemental heat energy to the helium gas (in addition to the heat generated by the stored SNF in the MPC) so as to facilitate rapid conversion of water into vapor form. The heat input from the pre-heater module can be adjusted in the manner of a conventional electric heater so that the recirculating helium entering the MPC is sufficiently dry and hot to evaporate water, but not unduly hot to place unnecessary thermal burden on the condensing module.

The FHD system described in the foregoing performs its intended function by continuously removing water entrained in the MPC through successive cooling, moisture removal and reheating of the working substance in a closed loop. In a classical system of the FHD genre, the moisture removal operation occurs in two discrete phases. In the beginning of the FHD system's operation (Phase 1), the helium exiting the MPC is laden with water vapor produced by boiling of the entrained bulk

water. The condensing module serves as the principal device to condense out the water vapor from the helium stream in Phase 1. Phase 1 ends when all of the bulk water in the MPC cavity is vaporized. At this point, the operation of the FHD system moves on to steadily lowering the relative humidity and bulk temperature of the circulating helium gas (Phase 2). The demister module, equipped with the facility to chill flowing helium, plays the principal role in the dehydration process in Phase 2.

2.B.2 Design Criteria

The design criteria set forth below are intended to ensure that design and operation of the FHD system will drive the partial pressure of the residual vapor in the MPC cavity to ≤ 3 torr if the gas has met the specified temperature or dew point value and duration criteria. The FHD system shall be designed to ensure that during normal operation (i.e., excluding startup and shutdown ramps) the following criteria are met:

- i. The temperature of helium gas in the MPC shall be at least 15°F higher than the saturation temperature at coincident pressure.
- ii. The pressure in the MPC cavity space shall be less than or equal to 60.3 psig (75 psia).
- iii. The recirculation rate of helium shall be sufficiently high (minimum hourly throughput equal to ten times the nominal helium mass backfilled into the MPC for fuel storage operations) so as to produce a turbulent flow regime in the MPC cavity.
- iv. The partial pressure of the water vapor in the MPC cavity will not exceed 3 torr. The limit will be met if the gas temperature at the demister outlet is verified by measurement to remain $\leq 21^\circ\text{F}$ for ≥ 30 minutes or if the dew point of the gas exiting the MPC is verified by measurement to remain $\leq 22.9^\circ\text{F}$ for ≥ 30 minutes.

In addition to the above system design criteria, the individual modules shall be designed in accordance with the following criteria:

- i. The condensing module shall be designed to de-vaporize the recirculating helium gas to a dew point of 120°F or less.
- ii. The demister module shall be configured to be introduced into its helium conditioning function after the condensing module has been operated for the required length of time to assure that the bulk moisture vaporization in the MPC (defined as Phase 1 in Section 2.B.1) has been completed.
- iii. The helium circulator shall be sized to effect the minimum flow rate of circulation required by the system design criteria described above.
- iv. The pre-heater module shall be engineered to ensure that the temperature of the helium gas in the MPC meets the system design criteria described above.

2.B.3 Analysis Requirements

The design of the FHD system shall be subject to the confirmatory analyses listed below to ensure that the system will accomplish the performance objectives set forth in this FSAR.

- i. System thermal analysis in Phase 1: Characterize the rate of condensation in the condensing module and helium temperature variation under Phase 1 operation (i.e., the scenario where there is some unevaporated water in the MPC) using a classical thermal-hydraulic model wherein the incoming helium is assumed to fully mix with the moist helium inside the MPC.
- ii. System thermal analysis in Phase 2: Characterize the thermal performance of the closed loop system in Phase 2 (no unvaporized moisture in the MPC) to predict the rate of condensation and temperature of the helium gas exiting the condensing and the demister modules. Establish that the system design is capable to ensure that partial pressure of water vapor in the MPC will reach ≤ 3 torr if the temperature of the helium gas exiting the demister is predicted to be at a maximum of 21°F for 30 minutes.
- iii. Fuel Cladding Temperature Analysis: A steady-state thermal analysis of the MPC under the forced helium flow scenario shall be performed using the methodology described in HI-STORM 100 FSAR Subsection 4.5.3 with due recognition of the forced convection process during FHD system operation. This analysis shall demonstrate that the peak temperature of the fuel cladding under the most adverse condition of FHD system operation (design maximum heat load, no moisture, and maximum helium inlet temperature), is below the peak cladding temperature limit for normal conditions of storage for the applicable fuel type (PWR or BWR) and cooling time at the start of dry storage.

2.B.4 Acceptance Testing

The first FHD system designed and built for the MPC drying function required by HI-STORM's technical specifications shall be subject to confirmatory testing as follows:

- a. A representative quantity of water shall be placed in a manufactured MPC (or equivalent mock-up) and the closure lid and RVOAs installed and secured to create a hermetically sealed container.
- b. The MPC cavity drying test shall be conducted for the worst case scenario (no heat generation within the MPC available to vaporize water).
- c. The drain and vent line RVOAs on the MPC lid shall be connected to the terminals located in the pre-heater and condensing modules of the FHD system.

- d. The FHD system shall be operated through the moisture vaporization (Phase 1) and subsequent dehydration (Phase 2). The FHD system operation will be stopped after the temperature of helium exiting the demister module has been at or below 21°F for thirty minutes (nominal). Thereafter, a sample of the helium gas from the MPC will be extracted and tested to determine the partial pressure of the residual water vapor in it. The FHD system will be deemed to have passed the acceptance testing if the partial pressure in the extracted helium sample is less than or equal to 3 torr.

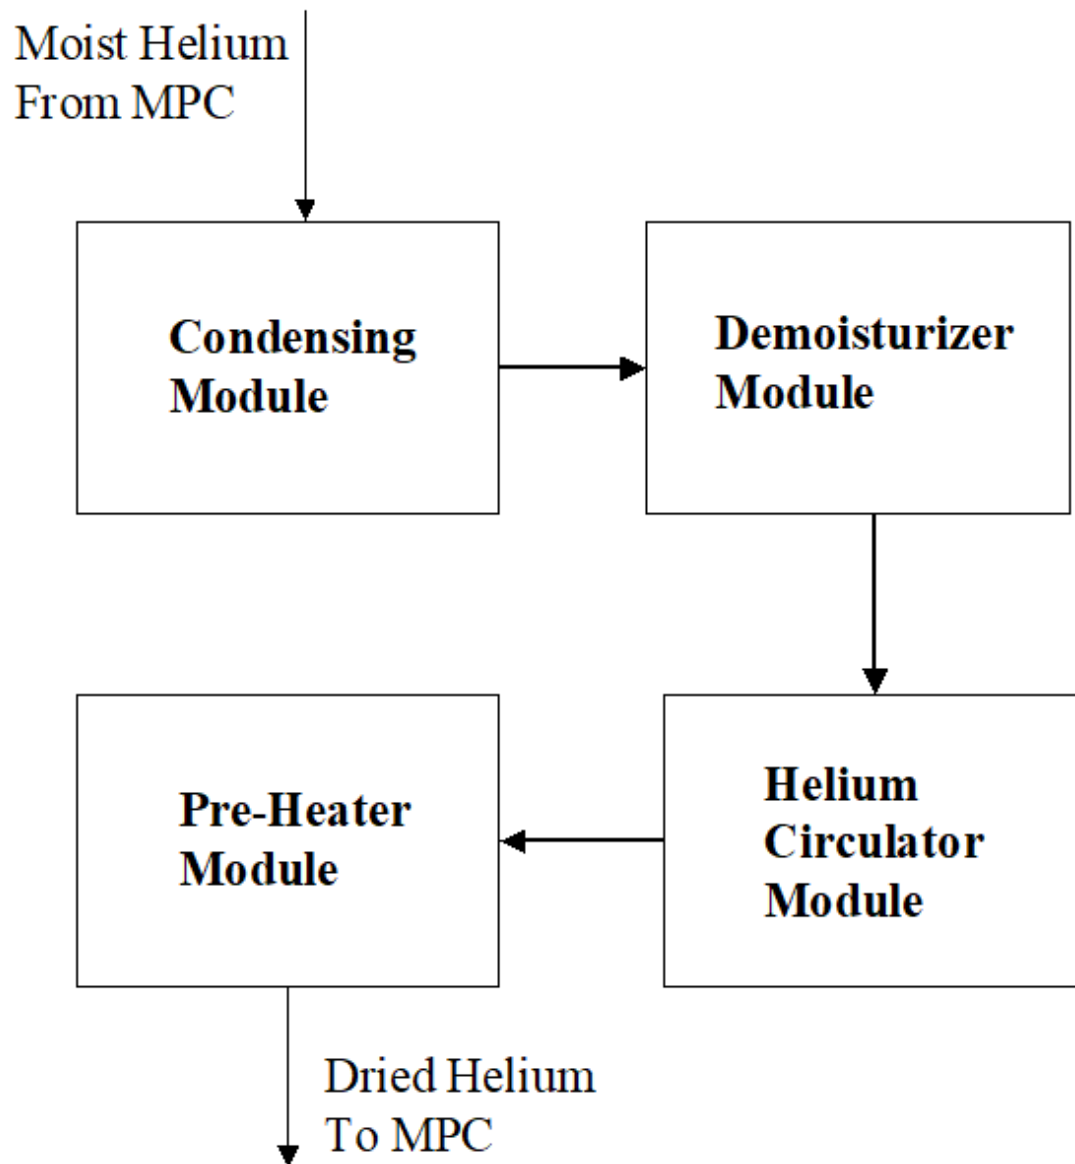

FIGURE 2.B.1: Schematic of the Forced Helium Dehydration System

Appendix 2.C

The Supplemental Cooling System

2.C.1 Purpose

The Supplemental Cooling System (SCS) will be utilized, as necessary, to maintain the peak fuel cladding temperature below the limit set forth in Chapter 2 of the FSAR during normal short-term operations (as defined in Section 2.2).

2.C.2 General Description and Requirements

The SCS is a system for cooling the MPC inside the HI-TRAC transfer cask during on-site transport. During normal SCS operation, heat is removed by a coolant from the HI-TRAC annulus and rejected to the heat sink (ambient air). The SCS shall be designed to meet the following criteria:

- (i) If the system uses water as the coolant, the system is sized to limit the coolant temperature to below 180°F under steady-state conditions for the design basis heat load at an ambient air temperature of 110°F. Active components (i.e., pump or air-cooler fan) are powered by electric motors with a backup power supply for uninterrupted operation.
- (ii) The system will utilize a contamination-free fluid medium in contact with the external surfaces of the MPC and inside surfaces of the HI -TRAC transfer cask to minimize corrosion. Figure 2.C.1 shows a typical P&ID for a SCS.
- (iii) The number of active components in the SCS will be minimized.
- (iv) All passive components such as tubular heat exchangers, manually operated valves and fittings shall be designed to applicable standards (TEMA, ANSI).

2.C.3 Thermal/Hydraulic Design Criteria

- (i) The heat dissipation capacity of the SCS shall be equal to or greater than the minimum necessary to ensure that the peak cladding temperature of High-Burnup fuel assemblies is below the ISG-11, Rev. 3 limit of 400°C (752°F). All heat transfer surfaces in any heat exchangers shall be assumed to be fouled to the maximum limits specified in a widely used heat exchange equipment standard such as the Standards of Tubular Exchanger Manufacturers Association.
- (ii) The coolant utilized to extract heat from the MPC shall be either high purity water or air. Anti-freeze may be used to prevent water from freezing if warranted by operating conditions.

2.C.4 Mechanical Requirements

- (i) All pressure boundaries (as defined in the ASME Boiler and Pressure Vessel Code, Section VIII Division 1) shall have pressure ratings that are greater than the maximum system operating pressure by at least 15 psi.
- (ii) All ASME Code components shall comply with Section VIII Division 1 of the ASME Boiler and Pressure Vessel Code.
- (iii) Prohibited Materials

The following materials will not be in contact with the system coolant in the SCS.

- Lead
- Mercury
- Sulfur
- Saran
- Silastic L8-53
- Cadmium
- Tin
- Antimony
- Bismuth
- Mischmetal
- Neoprene or similar gasket materials made of halogen containing elastomers
- Phosphorus
- Zinc
- Copper and Copper Alloys
- Rubber-bonded asbestos
- Nylon
- Magnesium oxide (e.g., insulation)
- Materials that contain halogens in amounts exceeding 75 ppm

- (iv) Not Used.
- (v) The SCS skid shall be equipped with appropriate lifting lugs to permit its handling by the plant's lifting devices in full compliance with NUREG-0612 provisions.

2.C.5 Regulatory Requirements

The SCS is classified as Important-to-Safety Category B.

FIGURE 2.C.1: SUPPLEMENTAL COOLING SYSTEM EXAMPLE P&I DIAGRAM

SUPPLEMENT 2.I

PRINCIPAL DESIGN CRITERIA FOR THE HI-STORM 100U SYSTEM

2.I.0 OVERVIEW OF THE PRINCIPAL DESIGN CRITERIA

General

A description of the HI-STORM 100U VVM is provided in Supplement 1.I. Because the HI-STORM 100U System uses the same MPCs, transfer cask, and ancillary equipment as the aboveground systems, the design criteria presented in Table 2.0.1 for the MPC, and Table 2.0.3 for the HI-TRAC transfer cask provide the basis for setting down the applicable criteria in this supplement with due recognition of the advances in the analysis methodologies over the past decade. The applicable loads, the affected parts under each loading condition, and the applicable structural acceptance criteria are compiled in this supplement to provide a complete framework for the required qualifying analyses in Supplement 3.I. Information consistent with the regulatory requirements related to shielding, thermal performance, confinement, radiological, and operational considerations is also provided. The licensing drawing of the HI-STORM 100 System 100U VVM, provided in Section 1.I.5, along with Table 2.I.2 herein provide information on all necessary critical characteristics to define the “100U” storage system. The constituents of the HI-STORM 100U ISFSI fall into two broad categories, namely:

- i. VVM components
- ii. ISFSI structures

The safety analyses documented in Supplement 3.I address both the VVM components and the ISFSI Structures. The ISFSI Structures consist of:

- i. The Support Foundation Pad (SFP)
- ii. The Top Surface Pad (TSP),
- iii. The VVM Interface Pad (VIP), and
- iv. The Retaining Wall, if used at the site.

Figure 2.I.5 depicts the subgrade and undergrade nomenclature for the ISFSI. The density and shear wave velocities of these are given in Table 2.I.2. The following are a description of the areas shown in Figure 2.I.5 which contribute to the analysis of the ISFSI.

- i. Space A is the lateral subgrade space, in and around the VVMs, which may be excavated and refilled with engineered fill.
- ii. Space B is the lateral subgrade that extends by the amount W around the ISFSI where W is the characteristic dimension of the ISFSI.
- iii. Space C is the undergrade below the SFP extending 100 feet below the bottom of the SFP.
- iv. Space D is the undergrade surrounding Space C extending 100 feet below the bottom of the SFP.

Structural

All required information on the design bases and criteria for the VVM are compiled in this supplement to fulfill the requirements of 10CFR72.24(c)(3) and 72.44(d). Table 2.I.1 contains a detailed listing of the information and its location in this FSAR corresponding to each relevant requirement in 10CFR72 with reference to the VVM. The VVM structure described in Supplement 1.I is designed for all applicable normal, off-normal, extreme environmental phenomena, and accident condition loadings pursuant to 10CFR72.24(c), 72.122(b) and 72.122(c).

The subgrade surrounding the VVM, the SFP on which the VVM is founded, and the VIP are categorized as “interfacing SSCs”, while the TSP and the retaining wall (if used) are categorized as “proximate structures”. All of these structures are classified as important-to-safety (ITS) (see Table 2.I.8) and are included in the analyses in Supplement 3.I, and in other supplements as applicable. Table 2.I.2 defines the essential design requirements for these structures. ACI-318 (2005) [2.I.5] is specified as the governing code for the design qualification of the SFP, the VIP, the TSP, and the retaining wall (if used) using the load combinations specified in Table 2.I.11. The seismic qualification of the storage system is performed in Supplement 3.I using the design data of the ISFSI.

In addition to defining the design details of the ISFSI components and structures, the material types used in the VVM are also identified in Table 2.I.8. Material designations used by ASTM and ASME for various product forms are, however, subject to change as these material certifying organizations publish periodic updates of their standards. Material designations adopted by the International Standards Organization (ISO) also affect the type of steels and steel alloys available from suppliers around the world. Therefore, it is necessary to provide for the ability in this FSAR to substitute materials with equivalent materials in the manufacture of the equipment governed by this FSAR.

As defined in this FSAR, the term “Equivalent Material” has a specific meaning: Equivalent materials are those that can be substituted for each other without adversely affecting the safety function of the SSC (system, structure, and component) in which the substitution is made. Substitution by an equivalent material can be made after the equivalence in accordance with the provisions of this FSAR has been established.

The concept of material equivalence explained above has been previously used in this FSAR to qualify four different austenitic stainless steel alloys (ASME SA240 Types 304, 304LN, 316, and 316LN) to serve as candidate MPC basket materials.

The equivalence of materials is directly tied to the notion of *critical characteristics*. A critical characteristic of a material is a material property whose value must be specified and controlled to ensure an SSC will render its intended function. The numerical value of the critical characteristic invariably enters in the safety evaluation of an SSC and therefore its range must be guaranteed. To ensure that the safety calculation is not adversely affected, material properties such as Yield Strength, Ultimate Strength and Elongation must be specified as *minimum* guaranteed values in VVM Components. However, there are certain properties where both minimum and maximum acceptable values are required. In this category lie VVM Component properties such as specific

gravity and thermal expansion coefficient.

Table 2.I.10 lists the array of material properties typically required in safety evaluation of an SSC in dry storage and transport applications. The required value of each applicable property, guided by the safety evaluation defines the critical characteristics of the material. The subset of applicable properties for a material depends on the role played by the material. The role of a material in the SSC is divided into three categories:

Type	Technical Area of Applicability
S	Those needed to ensure <u>structural</u> compliance
T	Those needed to ensure compliance with <u>thermal</u> (temperature limits)
R	Those needed to ensure <u>radiation</u> (criticality and shielding) compliance

The material properties listed in Table 2.I.10 are the ones that may apply in a dry storage or transport application.

To summarize, the following procedure shall be used to establish acceptable equivalent materials for a particular application.

Criterion i: Functional Adequacy:
Evaluate the guaranteed critical characteristics of the equivalent material against the values required to be used in safety evaluations. The required values of each critical characteristic must be met by the minimum (or maximum) guaranteed values (MGVs of the selected material).

Criterion ii: Chemical and Environmental Compliance:
Perform the necessary evaluations and analyses to ensure the candidate material will not excessively corrode or otherwise degrade in the operating environment.

A material from another designation regime that meets Criteria (i) and (ii) above is deemed to be an acceptable material, and hence, equivalent to the candidate material.

Equivalent materials as an alternative to the U.S. national standards materials (e.g., ASME, ASTM, ANSI) shall not be used for the Confinement Boundary materials. For other ITS materials, recourse to equivalent materials shall be made only in the extenuating circumstances where the designated material in this FSAR is not readily available.

As can be ascertained from its definition in the glossary, the *critical characteristics* of the material used in a subcomponent depend on its function. The Closure Lid, for example, serves as a shielding device and as a physical barrier to protect the MPC against loadings under all service conditions, including the Extreme Environmental phenomena. Therefore, the critical characteristics of steel used in the lid are its strength (yield and ultimate), ductility, and fracture resistance.

The appropriate critical characteristics for structural components of the VVM, therefore, are:

- i. Material yield strength, σ_y
- ii. Material ultimate strength, σ_u
- iii. Elongation, ϵ
- iv. Charpy impact strength at the lowest service temperature for the part, C_i

Thus, the carbon steel specified in the drawing package can be substituted with different steel so long as each of the four above properties in the replacement material is equal to or greater than the minimum values used in the qualifying analyses in this FSAR. The above *critical characteristics* apply to all materials used in the structural parts of the CEC. Table 2.I.9 provides guidance for the critical characteristics associated with the steels used in the VVM.

In the event that one or more of the *critical characteristics* of the replacement material is slightly lower than the original material, then the use of the §72.48 process is necessary to ensure that all regulatory predicates for the material substitution are fully satisfied.

In addition to the design configuration, the maximum magnitude of Design Basis Earthquake for the “100U” ISFSI is also specified in this FSAR. A three-dimensional non-linear time-history solution procedure implemented on LS-DYNA is used in Supplement 3.I to qualify the ISFSI including the storage system. This same three-dimensional non-linear time-history solution procedure may be used to perform safety evaluation under 10CFR72.212 at a host site, as indicated in Paragraph 2.I.6(v). Likewise, the loadings from the extreme environmental phenomena, defined in the main body of Chapter 2, are considered in Supplement 3.I. Site specific loadings that deviate from those analyzed in Supplement 3.I are subject to 72.212 safety evaluations in the manner of all HI-STORM models.

To serve their intended functions, the CEC and Closure Lid shall ensure physical protection, biological shielding, and allow the retrieval of the MPC under all conditions of storage (10 CFR 72.122(l)). Because the VVM is an in-ground structure, drops and tip-over of the VVM are not credible events and, therefore, do not warrant analysis. The load cases germane to establishing the structural adequacy of the VVM pursuant to 10 CFR 72.24(c) are compiled in Table 2.I.5. The physical characteristics of the MPCs intended for storage in the VVMs are presented in the main body of Chapter 1.

The design bases and criteria provided in this supplement are intended to quantify the safety margins in the VVM design with respect to all applicable loadings that follow from the provisions of 10CFR72.24(c)(3), §72.122(b) and §72.122(c).

Thermal

The engineered thermal performance of the HI-STORM 100U system is essentially equivalent to its aboveground counterparts under quiescent conditions. Ambient air enters from a circumferential opening provided in the Closure Lid. The intake air flows downward through an annular passage or intake plenum formed between the CEC and the Divider Shell. At the bottom of the intake plenum the air turns inwards through openings or cutouts provided in the Divider Shell bottom and rises up through an annular gap formed between the MPC and the Divider Shell. Heat is dissipated from the MPC to this upward rising column of air. The rising air column enters the curved flow passages

engineered in the Closure Lid and exhausts from the top through a large central opening (see Figure 1.I.4). To minimize the heating of the downward flowing inlet air and the upward column of heated air, the divider shell is insulated on its outside surface. The *critical characteristic* of the insulation is specified in Table 2.I.1. This thermal insulation material is required to meet the service conditions (temperature and humidity) for the design life of the VVM. Because the thermal performance of the HI-STORM 100U relies on buoyancy-driven convection of air and because of the relative proximity of the inlet and outlet vents to each other, the effect of wind on its thermal performance is also considered.

The allowable long-term and short term section-average temperature limits for concrete (used in the Closure Lid) are established in Appendix 1.D. Section-average temperature limits for structural steel in the VVM are provided in Table 2.I.8.

The VVM is designed for extreme cold conditions, as discussed in Subsection 2.2.2.2. The safety of structural steel material used for the VVM from brittle fracture is discussed in Subsection 3.1.2.3.

The VVM is designed to reject the maximum allowable heat load as defined below in a reliable and testable manner consistent with its important-to-safety designation (10CFR72.128(a)(4)).

The maximum permissible HI-STORM 100U heat load $Q(X)$ is a function of the parameter “X” defined as the ratio of the maximum permissible inner region assembly heat load q_1 , and outer region assembly heat load q_2 . The inner and outer fuel storage regions are defined in Table 2.1.27. The functional relationship $Q(X)$ is presented below:

$$Q(X) = 2 \cdot \alpha \cdot Q_d / (1 + X^y) \text{ where } y = 0.23/X^{0.1}$$

Q_d is the maximum heat load where $X=1$ (34kW) and α is a penalty factor for underground storage discussed in Supplement 4.I.

Shielding

The off-site dose for normal operating conditions to any real individual beyond the controlled area boundary is limited by 10CFR72.104(a) to a maximum of 25 mrem/year whole body, 75 mrem/year thyroid, and 25 mrem/year for other critical organs, including contributions from all nuclear fuel cycle operations. Since these limits are dependent on plant operations as well as on site-specific conditions (e.g., the ISFSI design and proximity to the controlled area boundary, and the number and arrangement of loaded storage casks at the ISFSI), the determination and comparison of ISFSI doses to these limits are necessarily site-specific. Dose rates from the HI-STORM 100U System are provided in Supplement 5.I. The determination of site-specific ISFSI dose rates at the site boundary and demonstration of compliance with regulatory limits is to be performed by the licensee for the specific VVM array in accordance with 10CFR72.212.

The VVM is designed to limit the dose rates for all MPCs to ALARA values. The VVM is also designed to maintain occupational exposures ALARA during MPC transfer operations, in accordance with 10CFR20. The underground location of the VVM significantly reduces the radiation

from the ISFSI at the site boundary compared to an aboveground cask. The calculated VVM dose rates are discussed in Supplement 5.I, which also discusses dose rates during site construction next to an operating ISFSI.

The dose rate calculations presented in Supplement 5.I conservatively use a lower density for the subgrade than is specified in Table 2.I.2. For dose rate calculation at a particular ISFSI, the spatial average of the actual subgrade density shall be used.

Criticality

The VVM does not perform any criticality control function. The MPCs provide criticality control for all design basis normal, off-normal and postulated accident conditions, as discussed in Chapter 6.

Confinement

The VVM does not perform any confinement function. Confinement during storage is provided by the MPC and is addressed in Chapter 7. The CEC provides physical protection and biological shielding for the MPC confinement boundary during MPC dry storage operations.

Operations

MPC preparation for storage and onsite transport of the MPC in the HI-TRAC transfer cask is the same for the VVM as for the aboveground overpack designs. The cask transporter is used to move the loaded transfer cask to the ISFSI and to transfer the MPC into the VVM. Generic operating instructions for the use of the HI-STORM 100U System that parallel those for the aboveground overpack are provided in Supplement 8.I.

Acceptance Tests and Maintenance

The fabrication acceptance bases and maintenance program to be applied to the VVM are described in Supplement 9.I. Application of these requirements will assure that the VVM is fabricated and maintained in a manner that satisfies the design criteria defined in this FSAR.

Decommissioning

Decommissioning considerations for the HI-STORM 100U System, including the VVM, are addressed in Section 2.I.11.

2.I.1 SPENT FUEL TO BE STORED

There is no difference in the authorized contents of the HI-STORM 100U VVM and the aboveground HI-STORM systems. The information in Section 2.1 is applicable.

2.I.2 HI-STORM 100U VVM COMPONENTS, ISFSI STRUCTURES, AND CORROSION MITIGATION MEASURES

The VVM is engineered for below-grade storage for the duration of its design life, and is designed to withstand normal, off-normal, and extreme environmental phenomena as well as accident conditions of storage with appropriate margins of safety.

As discussed in Supplement 1.I, the VVM Components are (see Figure 1.I.2):

1. The MPC Cavity Enclosure Container (CEC), and
2. The Closure Lid

The CEC is comprised of the following subcomponents:

1. Container Shell (a cylindrical enclosure shell)
2. Bottom Plate
3. Container Flange (a top ring flange)
4. Divider Shell with insulation and MPC Guides
5. MPC bearing pads

The Closure Lid consists of:

1. The integral steel weldment (filled with shielding concrete), and
2. The removable vent screen assemblies (inlet and outlet).

The structural limit criteria imposed on the VVM Components are selected to comply with the provisions of 10CFR72, with an embedded large margin of safety. Table 2.I.1 provides the principal design criteria applicable to the VVM Components. The specifications of the materials of construction for the load bearing and non-load bearing parts are provided in Table 2.I.8 along with their maximum permissible temperature for different conditions of storage.

The interfacing SSCs, the proximate structures, and corrosion mitigation measures germane to the design of a HI-STORM 100U ISFSI are:

- i) The SFP that supports the weight of the loaded VVMs.
- ii) The ISFSI pad consisting of the VIP which provides a water seepage barrier against rainwater and melting snow and also acts as a missile barrier, and the TSP which serves as a water seepage barrier as well as the riding surface for the transporter.
- iii) The lateral subgrade (natural or engineered fill) surrounding the CEC (Space “A” in Figure 2.I.5).
- iv) The impressed current cathodic protection system (ICCPS) that may be used as a corrosion mitigation measure for the CEC in accordance with the Technical Specifications.

v) The concrete encasement that may be used as a corrosion mitigation measure for the CEC in accordance with Technical Specifications. Reference is made to Figure 2.I.3 for typical concrete encasement of the CEC.

vi) The retaining wall used to protect the soil column in the Radiation Protection Space from excavation activities adjacent to the ISFSI.

Each of these is discussed below:

i. The Support Foundation Pad (SFP) (Interfacing Structure)

The structural requirements on the SFP are focused on providing a robust support to the CEC structure (for shear and compression), and to limit the long-term settlement of the SFP. The minimum structural design requirements on the SFP are provided in Table 2.I.2 and the licensing drawing in 1.I.5.

ACI-318(2005) is the prescribed Code for SFP design. As specified in ACI-318(2005), the applicable loads on the SFP are:

1. Dead load (from the TSP, the VIP, the loaded VVM, and the mass of soil above the SFP).
2. Live load (from the loaded vertical cask transporter bearing on the TSP).
3. Seismic load (the additional inertia load, in excess of the dead weight, live load transmitted to the SFP from the loaded VVM and the transporter under the ISFSI's DBE event).
4. Long-term differential settlement.

The load combinations for the structural analysis of the SFP pursuant to ACI-318(2005) are provided in Table 2.I.11.

Of the above loads, the effect of long-term settlement on the SFP is treated together with the Dead load. The standard approach to compute the long-term settlement is provided in [2.I.6]. This methodology, which is based on classical soil mechanics and is utilized in the structural analysis in Supplement 3.I, is summarized below.

1. Compute the total long-term settlement, "d", of the subgrade under the SFP (Space C) over the Design Life assuming that the total load "P" (modeled as a uniform pressure at the top of the subgrade) is equivalent to that produced by the SFP fully populated with loaded VVMs for the entire life using the methodology in [2.I.6].
2. Determine an "effective" elastic spring constant "K" of Space C that emulates the cumulative settlement:

$$K = P/d.$$
3. Using the spring constant computed above, which accounts for the effect of long-term settlement under static loading, an appropriate elastic modulus is defined for the soil column

under the SFP. The degraded soil modulus so defined is used in the finite element model of the SFP to evaluate the pad flexure under the factored dead load.

The maximum permitted settlement of the SFP is limited to the value specified in Table 2.I.2. Remedial measures such as pilings must be used if the Table 2.I.2 limit cannot be met.

In the structural qualification of the SFP, the loading from the seismic event is computed using the dynamic elastic modulus corresponding to the minimum strain wave velocity of the subgrades specified in Table 2.I.2.

ii. VVM Interface Pad (VIP) (Interfacing Structure) and Top Surface Pad (TSP) (Proximate Structure)

The VIP portion of the ISFSI Pad serves no structural function in supporting the VVM. However, it girdles the Container Shell and underlies the Container Flange to form a leak tight interface, and directs water away from the CEC. The principal functions of the TSP are to provide the riding surface for the loaded transporter and also to enable rainwater to be channeled away from the storage arrays and into the site's storm drain system. The TSP is isolated from the VIP by appropriately located expansion joints to isolate the CEC from any unbalanced loads imparted by the transporter. Similarly, an expansion joint between the CEC and the VIP is incorporated to permit differential movement between the two. The licensing drawing in Section 1.I.5 provides details for the expansion joint and typical drainage and sealing details. Because the sealing is visible and accessible, re-sealing, when and if necessary, is easily accomplished. Thus, continued sealing is assured. A specific brand of sealant is noted on the expansion joint detail, but there are several equivalent* proven sealant materials commercially available that are ideal for this application and the expected ambient conditions.

In summary, the design objectives for the VIP and the TSP are: to provide a leak tight interface and to provide a sufficiently inflexible travel surface for the loaded transporter, respectively. The top surface of the VIP, as shown in the 100U licensing drawing package, also serves to keep rain water away from the VVM. The minimum structural design requirements on the VIP and TSP are provided in Table 2.I.2 and the licensing drawing in 1.I.5. The applicable loads on the TSP and VIP are:

1. Dead load (Self weight including settlement effects) (TSP and VIP)
2. Live load (Weight of a loaded cask transporter) (TSP only)
3. Seismic Load (Inertia load from the concrete pad and the transporter under the ISFSI's DBE event) (TSP only).

The applicable load combinations for the structural analysis of the VIP and TSP pursuant to ACI-318(2005) are provided in Table 2.I.11.

* The definition of the term "equivalent" is provided in the Glossary.

The effect of settlement is incorporated in the stress analysis of the TSP using the same procedure as the SFP discussed above. As in the case of the SFP stress analysis, the settlement of the TSP from Dead load (self-weight) relative to the SFP over their Design Life is computed and incorporated in the stress analysis. The maximum permissible settlement of the TSP with respect to the SFP is required to be limited to the value in Table 2.I.2.

The design of the TSP together with the lateral subgrade must also satisfy the allowable bearing capacity requirement of ACI 360R-06 [2.I.8] for slabs on grade. In particular, the total load imparted by the TSP on the lateral subgrade, including the live load and seismic load from the transporter, shall be less than 50 percent of the allowable bearing capacity thereof when the load is applied uniformly.

iii. Lateral Subgrade (Interfacing SSC)

The physical characteristics of the subgrade surrounding the VVM vary from site-to-site. Further, an ISFSI owner may elect to excavate the natural subgrade and replace it with an engineered fill of an appropriate density and composition to fulfill shielding demand. While the surrounding subgrade may not provide a structural support function to the CEC structure, as an interfacing SSC, it plays a role in the loading applied to the CEC under certain scenarios, namely:

- a. during an earthquake event;
- b. during movement of the cask transporter along the Top Surface Pad;
- c. normal storage condition from the natural overburden or under the state of maximum soil saturation (hydraulic buoyancy).

During a seismic event, the subgrade surrounding the VVM may exert a time-varying lateral pressure loading on the Container Shell, which, in principle, may ovalize the Container Shell and possibly bend it like a beam.

During the movement of the cask transporter, which is loaded with the transfer cask (see Supplement 8.I for operational details), the vertical load of the cask transporter results in a lateral pressure on the Container Shell. Although the lateral pressure is apt to be quite small due to the physical restriction on how close to the Container Shell the transporter can ride, mandatory limits on the lateral separation and subgrade properties are necessary to ensure a design with adequate safety margins. Accordingly, the minimum average density and the minimum shear wave velocity in the lateral subgrade surrounding the VVMs have been specified in Table 2.I.2.

The soil overburden pressure on the Container Shell is the third loading category which must be evaluated. Also, the condition of maximum soil saturation applies a hydrostatic pressure on the CEC. The maximum value depends on the depth of the MPC storage cavity and the effective density of the saturated soil.

iv. Impressed Current Cathodic Protection System (ICCPs) (Corrosion Mitigation Measure)

If an ICCPS is required by the technical specifications, it shall be implemented in accordance with

the requirements in Supplement 3.I, Subsection 3.I.4.1 and appropriate references. The following general design procedure may be followed:

1. Select the current density to be applied.
2. Compute the total current required to achieve the selected current density.
3. Design the ground bed system or distributed anode system.
4. Select a rectifier of proper voltage and current output.
5. Design all electrical circuits, fittings, and switchgear in accordance with good electrical practice.
6. Locate the cathodic protection test stations.
7. Prepare the necessary drawings and specifications for the project.

An example design is provided in this subsection for illustrative purposes and should not be interpreted as implying to present the best design or the only possible design. Because there are a multitude of ISFSI variables that will bear upon the design of the ICCPS for a particular site including differing ISFSI layouts, certain simplifying assumptions are made throughout the example. The example provides the user with insight on the types of design decisions that will need to be made. For example, because of possible shielding effects between CECs, as well as other SSC obstructions, the design implements a layout with closely distributed anodes to provide more uniform current distribution. Also, the example design implements closed loop electrical connections such that if the wire/cable is severed at any one place, electrical continuity is maintained to all anodes. Another item to be considered during the design phase is whether or not a test station is needed for each and every CEC.

Figure 2.I.1 presents an example ICCPS design layout for a 2x6 Array of VVMs. The ICCPS consists of the following four main subsystems/components:

- 1) Rectifier
- 2) Anodes
- 3) Test Stations
- 4) Wires and Cables

Figure 2.I.2 presents an example ICCPS test station.

The following is an example computation for determining the required current (approximate dimensions and quantities are used) as applicable to Figure 2.I.1:

Assume a CEC length (determined from “top of grade” to bottom of CEC bottom plate): 219.5 in.
 CEC outside diameter: 86 in.
 CEC condition: exterior is coated
 Coating efficiency: 91.5% (i.e. 8.5% of the coated CEC surface is considered bare metal)
 Cathodic Protection: Rectifier and distributed Natural Graphite Anodes with carbonaceous backfill
 Soil resistivity: 4,000 ohm/cm²
 Current density: 1 mA/ft² exposed metal
 Outside area of each CEC: 59,300 in² (412 ft²)

Total area for an array of twelve CECs: 4,944 ft²
 Bare CEC metal exposed: 4,944 ft² x 0.085 or 420 ft²
 Current required: 420 ft² x 1 mA/ft² or 420 mA

The following is additional data applicable to Figure 2.I.1.

Approximate Anode quantity: 11
 Approximate Anode size: 5 in dia. x 120 in. long
 Approximate Backfill quantity: 6,000 lbs of carbonaceous backfill

The total number of anodes required is determined primarily by the total current requirements of the CEC metal to be protected and the optimum current density of the anode material selected.

Graphite is a semi-consumable anode. Graphite typically has experienced corrosion rates of 1.5 to 2.16 lbs /amp year [2.I.3] or as determined by experiment, 0.08 grams per square meter of anode per amp-hour of current (at 30 C, 40 mA/cm² anode current density) [2.I.4]. A computed anode life of less than 40 years is acceptable as long as appropriate measures are taken to facilitate the replacement of anodes during the design phase and appropriate maintenance planning measures are implemented. Use of carbonaceous backfill should be considered since it can substantially lengthen the anode life. Inert (non-consumable) platinized anodes may also be considered.

v. Concrete Encasement (Corrosion Mitigation Measure)

If concrete encasement is used, it shall be implemented in accordance with the requirements in Supplement 3.I, Subsection 3.I.4.1 and appropriate references.

The following points shall also be taken into consideration:

- The effect of the concrete encasement on the ICCPS, if an ICCPS is also implemented.
- The concrete encasement should not interfere with the settlement of the TSP (which provides the transporter support surface) without appropriate evaluation.

vi. Retaining Wall

Because the subgrade within and around an operating 100U ISFSI serves a principal shielding function, it is essential that any excavation activity adjacent to the ISFSI (e.g., to build an extension of the ISFSI), must not disturb the soil in the Radiation Protection Space (RPS) shown in the licensing drawings (Section 1.I.5).

The extent of the RPS is set down to ensure, with sufficient margin of safety, that the ISFSI will continue to meet all relevant safety criteria under all applicable conditions of storage including normal, off-normal, extreme environmental phenomena and accident conditions. For example, the RPS must provide sufficient buffer so that design basis projectiles (large, medium, and penetrant missiles) will not access an MPC stored in a VVM cavity. In this case, as explained in Supplement 3.I, the incident missile is assumed to act when a deep cavity has been excavated contiguous to the

RPS and the direction of action of the missile is oriented to achieve maximum penetration of the sub-grade towards the CEC shell.

A retaining wall at the edge of or beyond the RPS is recommended if an excavation activity is planned adjacent to the RPS boundary while the ISFSI is in active service. The retaining wall, as shown in the licensing drawing, shall be keyed to the TSP and connected using dowels to the SFP so that it is laterally restrained from movement but does not transmit any bending moment to the SFP or the TSP. The minimum structural design requirements on the retaining wall are provided in Table 2.I.2 and the licensing drawing in 1.I.5. The applicable load combinations for the structural analysis of the retaining wall pursuant to ACI-318(2005) are provided in Table 2.I.11.

When a retaining wall is installed on one or more sides of the 100U ISFSI, excavation activities associated with the construction of a new underground ISFSI can be performed directly adjacent to the retaining wall(s) at depths above the bottom surface of the existing SFP. Soil excavations below the bottom surface of the existing SFP shall be treated as though no retaining walls are installed and, therefore, are subject to the limitations of the following paragraph.

For the case where a retaining wall is not installed, no excavation activities associated with the construction of a new underground ISFSI shall take place within a distance from the RPS equal to ten times the planned excavation depth. Alternatively, the Excavation Exclusion Zone (EEZ), defined as the minimum distance from the centerline of a VVM located on the periphery of the ISFSI to where the effect of DBE is sufficiently attenuated such that a full depth excavation will not cause collapse of the lateral sub-grade at the RPS boundary during an earthquake, can be determined by a site specific seismic analysis. If a retaining wall is installed at or beyond the RPS then the wall becomes the EEZ boundary, but only for excavation depths above the bottom surface of the existing SFP.

2.I.3 Service Conditions and Applicable Loads

The categories of loads on the HI-STORM 100U VVM are identified below. They parallel those for the aboveground systems.

- Normal Condition: dead weight, handling of the Closure Lid, soil overburden pressure from subgrade, live load due to cask transporter movement, snow loads, and buoyancy effect of water saturation of surrounding subgrade and foundation. Most normal condition loadings occur at an ambient temperature denoted as the “normal storage condition temperature”; however, for calculations involving the Closure Lid, a higher temperature is assumed when the VVM carries a loaded MPC since the Closure Lid outlet ducts will be subject to heated air.
- Off-Normal Condition: elevated ambient temperature and partial blockage of air inlets.
- Extreme Environmental Phenomena and Accident Condition: handling accidents, fire, tornado, flood, earthquake, explosion, lightning, burial under debris, 100% blockage of air

inlets, extreme environmental temperature, 100% fuel rod rupture, and an accident during construction in the vicinity of a loaded ISFSI.

The design basis magnitudes of the above loads, as applicable, are provided in Tables 2.I.1 and 2.I.5, and are discussed further in the following subsections. Applicable loads for an MPC contained in a VVM or for a HI-TRAC that services a VVM are identical to those already identified in the main body of Chapter 2 and, therefore, are not repeated or discussed within this supplement. However, recognizing that the support of an MPC in a VVM is different from the support provided in an above ground HI-STORM, the design basis dynamic analysis model includes the fuel assemblies, the fuel basket, and the enclosure vessel so that the loads described above are properly distributed within the VVM.

2.I.4 Normal Condition Operating Parameters and Loads

i. Dead Load

The HI-STORM 100U System must withstand the static loads due to the weight of each of its components. As the support provided by the subgrade and the VVM Interface Pad from lateral friction is apt to be negligible, the weight of the Closure Lid is assumed to bear on the Container Flange and the Container Shell; the load to the VVM Support Foundation is transferred through direct bearing action.

ii. Handling Loads

The only instance of a handling load occurs during emplacement or removal of the Closure Lid while the CEC contains a loaded MPC. To provide defense-in-depth, Closure Lid lifting attachments are conservatively designed to meet the design requirements of ANSI N14.6 [2.2.3].

Lift locations for the CEC and the Divider Shell are used for lifting only during construction, and possibly during maintenance and decommissioning of the VVM with no loaded MPC present; therefore, these lifting locations are not subject to the defense-in-depth measures of NUREG-0612. They are therefore considered as a part of the site construction safety plan, site-specific maintenance program, or site decommissioning plan, as applicable, and as such are treated as being outside the scope of this FSAR.

iii. Live Loads

a. Subgrade Pressure Due to Transporter Movement

The properties of the surrounding subgrade and the presence of a loaded cask transporter affect the state of stress in the subgrade continuum. This stress field may produce a lateral compressive load on the Container Shell, which acts together with the effect from soil overburden.

b. MPC Transfer Operation

The VVM must withstand the weight of the loaded HI-TRAC transfer cask and the mating device during MPC transfer operations. Bounding weights for these components are used in the qualifying analysis.

iv. Ambient Temperature

The HI-STORM 100U System is analyzed for the same maximum yearly average ambient air temperature as that used for the aboveground overpacks. This normal operating condition temperature bounds all locations in the continental United States.

v. Snow

An appropriately conservative snow load on the Closure Lid is considered as a potential bounding case (see Table 2.I.1).

vi. Long-Term Settlement

There is no mechanism for an appreciable long-term settlement of Support Foundation Pad from loaded VVMs because the equivalent density of the loaded VVM is nearly equal to the density of the removed subgrade. Therefore, at an ISFSI site, depending on the density of the subgrade, there may be a small mismatch between the mass of the subgrade displaced by the loaded VVM leading to a minor amount of long-term settlement.

The TSP and the VIP are founded on well conditioned subgrade that is typically installed after the CECs are emplaced on the SFP. In addition to its own weight, the sole long-term load is the dead weight of the pads (TSP and VIP) which is evidently insufficient to cause appreciable long-term settlement in a subgrade continuum installed to meet or exceed a specific shear wave velocity and density criterion (see Table 2.I.2). Therefore, the long-term settlement of the TSP and the VIP relative to the SFP is expected to be small. Limiting allowable values of settlement for the SFP and the TSP have been specified in Table 2.I.2 for a conservative stress analysis of the TSP and SFP under the load combinations including the generic Design Basis Earthquake .

The effect of long-term settlement on the SFP and TSP shall be considered as a concurrent load with Dead load in all load combinations in the manner described in Section 2.I.2.

2.I.5 Off-Normal Condition Design Criteria

i. Elevated Ambient Air Temperature

The HI-STORM 100U System must be able to reject the design basis heat load under short-term conditions of elevated ambient air temperature.

ii. Partial Blockage of Inlet Air Ducts

The HI-STORM 100U System must withstand 50% blockage of the inlet air flow area without exceeding allowable temperature and pressure limits.

2.I.6 Environmental Phenomena and Accident Condition Criteria

The extreme environmental phenomena and accident conditions applicable to the HI-STORM 100U System are listed below. The loadings apply to either or both the VVM components and ISFSI structures.

i. Handling Accidents (Drops and Tipover)

Because the VVM is situated underground and cannot be moved, drop and tipover events are not credible accidents for this design. The Closure Lid, as discussed in Supplement 1.I, cannot strike the MPC lid due to geometry constraints if it were to undergo a free fall. Further, because the load handling device and lifting equipment are required to meet the defense-in-depth criteria set down in this FSAR, the drop of the Closure Lid or transfer cask during handling operation is termed non-credible (as is the case for the aboveground HI-STORM system MPC transfer operations at the ISFSI).

ii. Fire

The VVM must withstand the effects of a fire that consumes the maximum volume of fuel permitted to be in the fuel tank of the cask transporter. The duration of the fire for the VVM is conservatively assumed to be the same as that used for the aboveground overpacks. As is the case for aboveground overpacks, the fuel is assumed to spill, surround one storage system and burn until it is depleted. Because the VVM is configured to have a surrounding built-in step or spill barrier (see Figure 1.I.3), the spilled fuel will collect and burn over the Top Surface Pad, also referred to as Top-of-Grade (see Figure 1.I.2). Therefore, the location of fuel combustion will be somewhat removed from the CEC. Also, the natural grade in the TSP surface, engineered to direct the rainwater away from the VVMs, will do the same to the spilled fuel, further ameliorating the thermal consequence of the fire to the stored SNF.

The closed-end geometry of the MPC storage cavity ensures that a sustained combustion of the fuel, even if it were to be hypothesized to enter the VVM cavity, is not possible.

The loss of shielding effectiveness due to heat up of the concrete and the surrounding SSCs is primarily due to vaporization of the small amount of volatiles, including the contained moisture present in the concrete. This reduction in shielding is small and is permitted under the regulations. Therefore, the fire analysis of the VVM is focused on determining safety against a structural collapse due to elevation in the structure's metal temperature.

The sole effect of fire on the VVM structure is to raise the metal temperature of the structural members surrounding the shielding concrete in the Closure Lid. The analysis for the fire

event accordingly seeks to establish that the load bearing structure will not be weakened by the rise in its metal temperature (and a consequent reduction in the yield and ultimate strength) and result in its structural collapse.

iii. Tornado

The HI-STORM 100U System is protected from the effects of a tornado and accompanying missiles by virtue of its underground configuration. The only VVM component that warrants evaluation for the effects of a tornado-induced missile strike is the Closure Lid, which is made of a steel weldment with encased concrete.

The HI-STORM 100U System is inherently stable under tornado missile impact. The impact of a large missile (1800kg Automobile) is evaluated to determine whether the Closure Lid continues to maintain its required shielding function. Penetration and perforation issues associated with the Closure Lid due to intermediate missiles that constitute the Extreme Environmental Phenomena loads for the HI-STORM 100U system are also addressed. The Closure Lid is analyzed for penetration of a solid steel cylinder traveling at a high speed consistent with the characteristics of the intermediate missile listed in Table 2.2.5. As there is no direct line of sight to the MPC, small missiles are not considered. Also, since a tornado is a short duration event, the effect of extremely high tornado winds on the thermal performance of the VVM would be negligible due to the system's thermal inertia. Therefore, the effect of tornado wind on the thermal performance of the HI-STORM 100U system is not analyzed.

iv. Flood

As discussed in Subsection 1.I.2, the HI-STORM 100U System is engineered to be flood resistant. However, even though the potential water ingress passages are elevated in the HI-STORM 100U (in contrast to the pad level inlet ducts in typical ventilated overpacks), submersion flooding that fills all or a portion of the ducts could occur at certain ISFSI sites located in flood zones. The MPC is designed to withstand 125 feet of water submergence. The VVM will clearly withstand this static head of water above the surface of the ISFSI because all structural members either are not subject to any pressure differential from the flood or are backed by the subgrade, which resists the flood water directly. Full or partial submergence of the MPC is not a concern from a thermal perspective, as discussed in Supplement 1.I, because heat removal is enhanced by the floodwater.

The most severe flooding event from a thermal perspective would be the partial filling of the intake plenum such that airflow is blocked but the MPC is not submerged in water. To mitigate the consequences of this event, the height of the Divider Shell cutouts is purposely located well above the bottom elevation of the MPC. Therefore, if the flood level is just high enough to block air flow, the lower portion of the MPC will be submerged in water. The wetted MPC bottom region serves as an efficient means of heat rejection to the floodwater. This accident event is described in Supplement 11.I.

v. Earthquake

As explained herein and in Subsection 3.I.4.7, the generic seismic loading for the HI-STORM 100U system is established using the combination of an earthquake and soil subgrade properties that maximize the severity of the inertia forces on the ISFSI structures and components.

As required by 10CFR72.102(f), the Design Basis Earthquake for the ISFSI must be specified. For the HI-STORM 100U system, a generic Design Basis Earthquake is specified with horizontal and vertical ZPAs intended to envelope the site-specific DBEs at all U.S. plant sites (See Table 2.I.2). For purposes of the generic seismic analysis in this FSAR, the Design Basis Earthquake for the HI-STORM 100U system is defined by two sets of response spectra specified at the SFP bottom surface elevation and at the TSP top surface elevation, as shown in Figure 2.I.4. These two spectra sets together exhibit the severity of the earthquake experienced by the ISFSI structures and VVM Components and are henceforth referred to as the governing spectra. The two sets of response spectra are obtained from the two-step SHAKE/LS-DYNA seismic response analyses performed using a lower-bound soil shear wave velocity profile (see Figure 2.I.6). This lower bound profile was established in [2.I.10] based on the geotechnical data of typical U.S. nuclear power plant sites. To develop the governing spectra, the input seismic acceleration time history for the SHAKE analysis is derived from the Regulatory Guide 1.60 seismic response spectrum and designated as the rock outcrop motion. The synthetic time history complies with the response spectrum and power density enveloping criteria in SRP 3.7.1 in NUREG-0800, Rev 2. The input acceleration time history is scaled to yield ground surface ZPAs (at the top of grade elevation) specified in Table 2.I.2. The average strain-compatible shear wave velocities of the soil column obtained from the SHAKE analysis are used to specify the minimum shear wave velocity values in Table 2.I.2. The ZPAs of the rock outcropping acceleration that yielded the governing spectra are 0.538 g's for the horizontal direction and 0.483 g's for the vertical direction.

The soil model for the subsequent LS-DYNA seismic response analysis uses the average strain-compatible wave velocities obtained from the SHAKE analysis (i.e., minimum shear wave velocity values in Table 2.I.2) to define the structural characteristics of the soil layers above and below the SFP elevation (see Figure 2.I.5 for sub-grade and under-grade space nomenclature). The acceleration time history at the soil column bottom surface, also obtained from the above-mentioned SHAKE analysis, is used as the input seismic motion for the LS-DYNA seismic response analysis performed in Supplement 3.I. The response spectrum plots shown in Figure 2.I.4 are the results of the LS-DYNA seismic response analysis (in the absence of the ISFSI). The same soil model and input seismic motion used in the LS-DYNA seismic response analysis is used for the LS-DYNA Soil-Structure Interaction (SSI) analysis (with the ISFSI included in the model) in Supplement 3.I.

The combination of weak soil properties and strong earthquake, as specified in Table 2.I.2 and Figure 2.I.4 for the structural evaluation of the underground ISFSI, has been selected to ensure that the Design Basis Earthquake response spectra at the ISFSI location will

uniformly envelope those at most U.S. nuclear plants and that the Design Basis structural evaluation for the “100U” system is performed conservatively based on the lower bound support from the sub-grade and the under-grade. Thus, the HI-STORM 100U system can be deployed in most U.S. nuclear power plant sites without the need for a site-specific analysis to satisfy the requirements of 72.212. Specifically, a candidate 100U ISFSI site will be exempt from a detailed SSI analysis if the seismic response analysis for the site (using SHAKE or similar program) can demonstrate that the following two criteria are met:

1. The site’s response spectra at both TSP and SFP elevations are enveloped by the Design Basis Earthquake response spectra shown in Figures 2.I.4-A and 2.I.4-B, respectively;
2. The soil properties of the candidate site are greater than the minimum values specified in Table 2.I.2.

In order to satisfy the first criterion, the site must consider multiple time history sets as input to the seismic response analysis based on the guidelines set forth in SRP 3.7.1 [2.I.12] and ASCE 4-98 [2.I.11]. The site’s response spectra at both the TSP and SFP elevations must be bounded by the Design Basis Earthquake response spectra in Figure 2.I.4 for all acceleration time histories sets used as input.

For the case where only one of the above two criteria is not satisfied, a site-specific evaluation under 10CFR72.212 is permitted. Typical scenarios that warrant a site specific evaluation are discussed below:

Scenario A: The site’s response spectra are not completely enveloped by the Design Basis Earthquake response spectra in Figure 2.I.4. However, the site’s overall earthquake strength, represented by the resultant ZPA (see Table 2.I.2 for definition) is bounded by that of the Design Basis Earthquake at both TSP and SFP elevations.

While the ZPA represents the strength of the earthquake (in terms of the maximum value of the seismic acceleration time history), the shape of the seismic response spectrum is affected by many factors such as the overall stiffness of the site and the stiffness profile of soil layers. Therefore, for the same input seismic time history at the base of the soil column, a stiffer site could have a peak response that is not enveloped by the Design Basis Earthquake response spectrum (as demonstrated in the SHAKE parametric study results presented in Table 2.I.4, where the only difference between the two analyzed cases is the stiffness (i.e., shear wave velocity) of the soil column). Although it is expected that the 100U system would exhibit a greater safety margin against the earthquake loading at the stiffer subgrade/undergrade site, a site-specific evaluation under 10CFR72.212 is the appropriate vehicle to confirm the structural integrity in this situation.

Scenario B: The strain compatible wave velocity of the soil in Space B and/or Space D of the ISFSI site (see Figure 2.I.5) is less than the required minimum value specified in Table 2.I.2.

Typically, Spaces B and D (in Figure 2.I.5) contain native soils whose properties are not affected by the ISFSI construction. More importantly, the loaded VVMs are not directly supported by the soil in the two spaces. Therefore, it is reasonable to assume that a small reduction of soil stiffness in these two spaces would not significantly modify the structural response of the VVM system. Structural compliance through a site specific analysis is assured if the ZPA of the DBE is well below the Design Basis value set down in this FSAR (Figure 2.I.4).

The site-specific safety analysis, if performed, shall follow the methodology set down in Supplement 3.I. In addition, since the soil and rock configuration varies from site to site, the total depth of the soil model for site-specific analysis shall be determined following the guideline in Section 3.3.3.2 of ASCE 4-98 [2.I.11]. Uncertainties in SSI analysis for a candidate 100U ISFSI site shall be accounted for by varying the best estimate low strain shear modulus of the substrates between the best estimate values times $(1+c)$ and the best estimate value divided by $(1+c)$. If sufficient, adequate soil investigation data is available, the mean and standard deviation of the low strain shear modulus shall be established for every soil layer. The value of c may be established so that it will cover the mean plus or minus one standard deviation for every layer; however, the minimum value for c shall be no less than 0.5. If sufficient data is not available to determine a statistically meaningful mean and standard deviation, then the value for c shall be no less than 1.0.

The qualification of the ISFSI under the system's DBE event involves the following safety determinations:

1. Compliance of the VVM components (Divider shell, CEC shell, etc.) to the applicable stress/deformation limits specified in Table 2.I.6.
2. Strength compliance of the ISFSI reinforced concrete structures under ACI -318(2005) load combinations listed in Table 2.I.11.

A candidate 100U ISFSI site that does not meet the requirement discussed above for seismic qualification shall not be allowed for the consideration of a 100U general license.

vi. Explosion

The HI-STORM 100U System must withstand the pressure pulse due to a design basis explosion event. The effect of overpressure due to an explosion near the VVM is evaluated. The overpressure design value applied to the Closure Lid outer shell surface is intended to bound all credible explosion events because no combustible material is permitted to be stored near the VVM, and all materials of construction are engineered to be compatible with the operating environment. However, site-specific explosion scenarios that are not evidently bounded by the design basis explosion load considered herein (see Table 2.I.1) shall be evaluated under the provisions of 10CFR72.212.

vii. Lightning

The HI-STORM 100U System must withstand a lightning strike without a significant loss in its shielding capability. The effect of a lightning strike on the VVM is the same as that described for the aboveground overpack design, even though the likelihood of a lightning strike on the VVM is lower due to its low height above grade. Lightning is treated as an Extreme Environmental Phenomena event in Supplement 11.I. Because of its non-significant structural effect on the VVM, it is not considered as a load that warrants analysis in Supplement 3.I.

viii. Burial Under Debris

The burial under debris event for the HI-STORM 100U System is bounded by the evaluation performed for the aboveground overpacks, as discussed in Supplement 4.I.

ix. 100% Blockage of Air Inlets

The blockage of the entire inlet air flow area is analyzed as an accident event and is described in Supplement 11.I and analyzed in Supplement 4.I.

x. Extreme Environmental Temperature

An extremely high ambient air temperature is analyzed as an extreme environmental event and is described in Supplement 11.I and analyzed in Supplement 4.I.

xi. 100% Fuel Rod Rupture

This loading condition is specific to the MPC thermal evaluation and treated in Supplement 11.I.

2.I.7 Codes, Standards, and Practices to Ensure Regulatory Compliance

There is no U.S. or international code that is sufficiently comprehensive to provide a completely prescriptive set of requirements for the design, manufacturing, and structural qualification of the VVM. The various sections of the ASME Codes, however, contain a broad range of specifications that can be assembled to provide a complete set of requirements for the design, analysis, shop manufacturing, and field erection of the VVM. The portions of the ASME Codes that are invoked for the various elements of the VVM design, analysis, and manufacturing activities are summarized in Table 2.I.3.

The ASME Boiler and Pressure Vessel Code (ASME Code) Section III, Subsection NF Class 3, 1995 Edition, with Addenda through 1997 [2.2.1], is the applicable code to determine stress limits for the metallic structural components of the VVM when required by the acceptance criteria listed in Table 2.I.5. Table 2.I.3 summarizes considerations for design, fabrication, materials, and inspection. The permitted material types and their permissible temperature limits for long-term use are listed in Table 2.I.8. Manufacturing requirements are set down in licensing and design drawings.

ACI-318(2005) [2.I.5] is the applicable reference code to establish applicable limits on unreinforced concrete (in the Closure Lid), which is subject to secondary structural loadings. Appendix 1.D contains the design, construction, and testing criteria applicable to the plain concrete in the VVM's Closure Lid. The load combinations applicable to the TSP, SFP, and the retaining wall, pursuant to ACI-318(2005) are summarized in Table 2.I.11. Since the VIP carries no load except for the self-weight and is thicker than the TSP, the structural evaluation of the VIP is not necessary. Applicable sections of ACI-318(2005) should be used in the design of the interfacing SSCs and proximate structures.

The selection of the ISFSI site shall be made with due consideration of the potential of liquefaction. The host plant's criteria with respect to liquefaction for siting the Part 50 structures shall be used.

As mandated by 10CFR72.24(c)(3) and §72.44(d), Holtec International's quality assurance program requires all constituent parts of an SSC subject to NRC's certification under 10CFR72 to be assigned an ITS category appropriate to its function in the control and confinement of radiation. The ITS designations for the constituent parts of the HI-STORM 100U VVM, using the guidelines of NUREG-CR/6407 [2.0.5], are provided in Table 2.I.8.

The aggregate of the citations from the codes, standards, and generally recognized industry publications invoked in this FSAR, supplemented by the commitments in Holtec's quality assurance procedures, provide the necessary technical framework to ensure that the as-installed VVM would meet the intent of §72.24(c), §72.120(a) and §72.236(b). As required by Holtec's QA Program (discussed in Chapter 13), all operations on ITS components must be performed under QA validated written procedures and specifications that are in compliance with the governing citations of codes, standards, and practices set down in this FSAR. For activities that may be performed by others, such as site construction work to install the VVM, Holtec International requires that all activities be formalized in procedures and subject to the CoC holder's as well as the ISFSI owner's review and approval.

An ITS designation is also applied to the interfacing SSCs (such as the Support Foundation), which requires that all quality assurance measures set down in Holtec's Quality Assurance Procedure Manual be complied with by the entity performing the site construction work. In this manner, the compliance of the as-built VVMs with its engineered safety margins under all design basis scenarios of loading is assured.

2.I.8 Service Limits

No new service limits are defined for the HI-STORM 100U System beyond those described in Subsection 2.2.5.

2.I.9 Loads and Acceptance Criteria

Subsections 2.I.4, 2.I.5, and 2.I.6 describe the loadings for normal, off-normal, and extreme environmental phenomena and accident conditions, respectively, for the HI-STORM 100U System.

Tables 2.I.1 and 2.I.2, respectively, provide the design loads and seismic load parameters in terms of ZPA values for a bounding analysis using the methodology of Subsection 3.I.4.7.

Bounding load cases that are significant to the structural performance of the VVM and require evaluation are compiled in Table 2.I.5 using information provided in Sections 2.I.4, 2.I.5, and 2.I.6. Supplement 3.I contains a description of the evaluations, establishes the evaluation methodology, and provides evaluation results that demonstrate compliance of the VVM to the applicable load cases and acceptance criteria described below. The load cases and acceptance criteria are explained in subsequent paragraphs and summarized in Table 2.I.5. Table 2.I.6 summarizes the acceptance criteria for the CEC and internals under extreme environmental events.

Each loading case in Table 2.I.5 is distinct in respect of the sub-component of the VVM that it affects most significantly. The acceptance criteria consist of demonstrating that (i) radiation shielding does not degrade under normal and off-normal conditions of storage loadings, (ii) the system does not deform under credible loading conditions in a manner that would jeopardize the subcritical condition or retrievability of the MPC, and (iii) the MPC maintains confinement. For accident condition loadings, any permissible degradation in shielding must be shown to result in dose rates sufficiently low to permit recovery of the MPC from the damaged cask, including unloading if necessary, and loss of function must be readily visible, apparent or detectable.

The above set of criteria, extracted from NUREG-1536, is further particularized in a more conservative form for each applicable loading case in this subsection.

Load Case 01: Buoyant Force

This loading case pertains to the scenario wherein a VVM has been built, but the Closure Lid and MPC are not yet installed. Strictly speaking, this condition is not important to storage safety because the MPC is not present. However, considerations of long-term service life warrant that a minimum weight CEC, subject to the maximum buoyant force of water under an assumed hypothetical condition of submergence in water with a head equal to the length of the CEC, does not float. This evaluation sets a minimum additional weight (usually on a temporary cover) that will be set in place during construction to protect the CEC from construction debris, to provide for construction worker safety, and to insure that the CEC does not suffer uplift from buoyant forces. In addition, the Bottom Plate of the CEC must have sufficient flexural strength such that under a buoyant uplift pressure, its primary bending stress intensity remains below the ASME Level D allowable stress intensity at the reference metal temperature (assumed to be same as the extreme environmental condition temperature specified in Table 2.I.1 of this FSAR).

Load Case 02: Dead Load plus Design Basis Explosion Pressure

The dead weight loading, explained in Paragraph 2.I.4(i) is accentuated by the design basis explosion loading defined in Paragraph 2.I.6(vi). The explosion load is stated in terms of an equivalent static pressure. The affected sub-components are:

- a. The Container Shell, subjected to a compressive state of stress under the combined effect of dead weight of the Closure Lid and surface pressure on the Closure Lid under the explosion event.
- b. The Closure Lid, subject to self-weight and the Closure Lid surface pressure under the explosion event.

Other VVM components are not in the direct path of this loading. The explosion pressure envelops other mechanical loads such as snow and flood. Load Case 02, therefore, is a bounding load combination that conservatively subsumes a number of normal and extreme environmental phenomena loads. As this load case is intended to bound any normal condition, Level A stress limits are applicable to this case based on reference metal temperatures that bound all mechanical loading scenarios.

Load Case 03: Tornado Missile Impact

The Closure Lid is the only exposed portion of the VVM. Therefore, the tornado-borne missile strikes must be postulated to occur on the lid. The only other affected VVM part is the Container Flange, which prevents lateral sliding of the lid.

When subject to a tornado missile strike, the Closure Lid must not be dislodged, resulting in a direct line of sight from the top of the MPC to the outside. For the intermediate missile, the Closure Lid must resist full penetration. Finally, any CEC deformation from the compressive axial impulse due to the missile strike must not prevent MPC retrievability.

Load Case 04: Design Basis Seismic Event

The Design Basis Seismic Event is classified as an extreme environmental phenomenon. As such the Level D service condition limits are applicable to the Code components, such as the MPC Enclosure Vessel. The MPC Enclosure Vessel and fuel basket have been qualified to a 60g deceleration limit in the HI-STAR 100 (Docket Nos. 72-1008, 71-9261); this deceleration exceeds the expected deceleration from a seismic event. However, to ensure an accurate structural evaluation of the VVM, the evaluation of the response of the VVM to the design basis seismic event shall include a detailed model of the MPC, the fuel basket, and the contained fuel; this model, referred to as the Design Basis Seismic Model, should capture impacts between the fuel and the fuel basket, between the fuel basket and the MPC, and between the MPC and applicable components of the VVM.

The CEC shell is subject to performance-based limits, which require that the deformation of the CEC does not prevent MPC retrievability, does not cause loss of MPC confinement, and that the system remains subcritical. This is accomplished by demonstrating that after the seismic event, permanent ovalization of the Container Shell and/or Divider Shell does not result in a geometry that precludes retrievability of the MPC and that the impact loadings on the MPC due to its rattling inside the CEC do not cause a breach of the MPC confinement boundary.

The Divider Shell's sole function is to direct the airflow inside the CEC cavity and to hold MPC

Guides that serve to restrain the MPC from excessive rattling motion during an earthquake event. The MPC guides welded to the Divider Shell are subject to compressive impacts from the “hard points” on the MPC (the approximately 2.5-inch thick baseplate at the bottom and the 9.5-inch thick lid at the top). The MPC tubular guides are engineered to serve as “impact limiters” to minimize the local plastic strains in the MPC Confinement Boundary.

Finally, because the MPC Enclosure Vessel is designed to meet ASME Section III, Subsection “NB” (Class 1) stress intensity limits, and the earthquake is categorized as a “Level D” event, the primary stress intensities in the MPC Enclosure Vessel must meet Level D limits. The primary stress intensity in the MPC shell is the maximum longitudinal flexural stress intensity, which is compared against the primary membrane stress intensity limit for the material (Alloy X) at the applicable service temperature. The fuel basket is a multi-flange 3-D beam structure, designed to meet the stress limits of Subsection “NG” of the Code. The maximum longitudinal primary stress intensity in the basket, calculated from the 3-D fuel basket/fuel assembly model, must be less than the corresponding Level D condition limit at the service temperature. In addition to the primary stress based limits it is also necessary to demonstrate that the transverse bending stress in any panel normalized over the length of the fuel basket is less than the Level D primary stress limit.

The limits on the primary stresses in the MPC components for the DBE condition are also applicable to other Level D (faulted) events. Dynamic analysis using a 3-D detailed model of the MPC (which includes the Confinement Boundary, the internal fuel basket, and the fuel assemblies inside the basket) is the vehicle for performing the structural qualification. In addition to the primary stress limits, the local strain in the Confinement Boundary due to the impact between the MPC and the MPC guides under the Design Basis Earthquake requires evaluation.

Table 2.I.5 summarizes the above discussion in tabular form.

Load Case 05: Closure Lid Handling

The Closure Lid lifting attachments are conservatively designed to meet the strength limits of ANSI N14.6 for heavy load handling. The metal load bearing parts shall satisfy the requirements of Reg. Guide 3.61 for primary stresses near the lifting locations and shall satisfy ASME NF Level A limits away from the lifting locations.

Yield and ultimate strength values used in the stress compliance demonstration per ANSI N14.6 shall utilize confirmed material test data through either independent coupon testing or material suppliers’ CMTR or COC, as appropriate.

Load Case 06: Design Basis Fire Event

The exposed portion of the VVM, namely the Closure Lid, will experience the heat input and temperature rise under the fire event. The balance of the VVM, because of its underground location, will be subject to only a secondary temperature increase.

It is required to demonstrate that the structural collapse of the Closure Lid cannot occur due to the reduction of its structural material's (low carbon steel) strength at the elevated temperatures from the fire.

Load Case 07: CEC Loading From Surrounding Subgrade

The CEC is subject to a lateral pressure from the soil in the non-seismic condition. This pressure is affected by the presence of a loaded cask transporter adjacent to the CEC. The CEC must be shown to provide adequate resistance to this loading.

This load case tends to ovalize the CEC; the maximum primary membrane plus bending stress is limited to the material yield strength under normal conditions of storage.

In evaluating the structural safety margins in Supplement 3.I for the load cases described above, design data for the interfacing SSCs presented in Table 2.I.2 is used as applicable.

2.I.10 Safety Protection Systems

The HI-STORM 100U System, featuring the VVM with the stored MPC, provides for confinement, criticality control, and heat removal for the stored spent nuclear fuel in the manner of the aboveground overpacks. The VVM provides better shielding and protection from environmental events, such as tornado missiles, because of its underground configuration. The information in Section 2.3 also applies to the HI-STORM 100U System, with the recognition that the air ventilation system is modified. Instead of the ambient air entering through inlet ducts at the bottom, the cooling air enters the circumferentially symmetric passage at the top of the VVM and is directed to the bottom of the VVM cavity along a radially symmetric annulus (Figure 1.I.4). However, the mechanism of heat transfer from the MPC to the cooling air is identical to the aboveground overpack designs.

The HI-STORM 100U System is completely passive requiring no active components or instrumentation to perform its design functions. Temperature monitoring or scheduled visual verification of the integrity of the air passages is used to verify continued operability of the VVM heat removal system, as set down in the system's Technical Specification.

2.I.11 Decommissioning Considerations

The HI-STORM 100U VVM is specifically engineered to facilitate convenient decommissioning. As discussed in Supplement 1.I, the component most proximate to the active fuel and, hence, likely to be the most activated, is the Divider Shell. The Divider Shell is not welded to the CEC structure; therefore, it can be conveniently removed for decommissioning. The CEC structure can be removed by excavating the surrounding subgrade. Alternatively, the cavity can be filled with suitable fill materials and the CEC left in place. While the above discussion is unique to the VVM design, the information in Section 2.4 pertaining to decommissioning of other HI-STORM models is also applicable to the VVM. Even if the decision is made to dispose of all activated material, the VVM, due to differences in its geometry and construction (particularly, use of the native soil as the

biological shield to the extent possible) will result in less steel and concrete to be disposed of. In the aggregate, it is estimated that less material will need to be disposed of to decommission a VVM ISFSI in comparison to an ISFSI containing aboveground overpacks.

Finally, the activation estimate in Table 2.4.1 for the aboveground overpack inner shell is conservatively applicable to the VVM steel shell enclosure.

2.I.12 Regulatory Compliance

Pursuant to the guidance provided in NUREG-1536, the foregoing material in this supplement provides:

- i. a complete set of principal design criteria for the VVM as mandated by 10CFR72.24I(1), §72.24(c)(2), §72.120(a) and §72.236(b);
- ii. a clear identification of VVM structural parts subject to a fully articulated design subject to certification under 10CFR72 and of interfacing SSCs;
- iii. the required set of limiting critical characteristics of the interfacing SSCs to ensure that the VVM will render its intended function under all design basis scenarios of operation;
- iv. a complete set of requirements premised on well-recognized codes and standards to govern the design and analysis (to establish safety margins) and manufacturing of the VVM; and
- v. a table containing cross-reference between the applicable 10CFR72 requirements and the location in this FSAR where the fulfillment of each specific requirement is demonstrated.

It is noted that the requirements of 10CFR72 do not preclude the use of an underground storage system such as the HI-STORM 100U. The VVM concept, while not specifically mentioned in the regulatory guidance literature associated with implementing the requirements in 10CFR72 (i.e., NUREG-1536), meets and exceeds the intent of the guidance in that it provides an enhanced protection of the stored spent nuclear fuel and a significantly reduced site boundary dose, enables a more convenient handling operation, and presents a much smaller target for missiles/projectiles compared to an aboveground storage system.

DESIGN DATA FOR HI-STORM 100U ISFSI

	Item	Value	Comment
9.	Lower bound, strain compatible effective shear wave velocity in Space D, V ft/sec (see Notes 1 and 2)	485	This space will typically contain native soil.
10.	Design Basis Earthquake	<p>Ground surface spectra per Figure 2.I.4-A with horizontal ZPA, a_H and vertical ZPA, a_V as:</p> <p style="text-align: center;">$a_H = 1.0g$ $a_V = 0.75g$</p> <p>and foundation surface spectra per Figure 2.I.4-B.</p>	<p>Horizontal and vertical spectra shown in Figures 2.I.4-A and 2.I.4-B are based on 5% damping.</p> <p>Following the Newmark 100-40-40 response combination technique [2.I.13] endorsed by the Regulatory Guide 1.92 [2.I.14], the <i>resultant ZPA</i> for a 3-D earthquake site is defined as: $a_R = a_1 + 0.4a_2 + 0.4a_3$, where a_1, a_2 and a_3 are the site's ZPAs in three orthogonal directions and $a_1 \geq a_2 \geq a_3$.</p> <p>Hence, the DBE <i>resultant ZPAs</i> at ground surface and foundation surface elevations are $1.3 \text{ g's } (=1.0 \times 1.0 \text{ g's } + 0.4 \times 0.75 \text{ g's})$ and $1.228 \text{ g's } (=1.0 \times 0.94 \text{ g's } + 0.4 \times 0.72 \text{ g's})$, respectively.</p>
11.	Maximum permissible long-term settlement of the SFP	0.2 inches	
12.	Maximum permissible long-term settlement of the TSP with respect to the SFP	0.4 inches	

TABLE 2.I.2 (continued)
DESIGN DATA FOR HI-STORM 100U ISFSI

Note 1:

Strain compatible shear wave velocities in each space at an ISFSI site (see Figure 2.I.5) shall be computed using the guidance provided in Section 16 of the International Building Code, 2009 Edition [2.I.9]. The equivalent wave velocity is defined so that the wave transit time for an equivalent homogeneous material of the same total depth is the same as the actual layered substrate.

$$V = \frac{d}{\sum \frac{d_i}{v_i}}$$

d_i = thickness of i^{th} layer within the region (ft.);

v_i = strain compatible shear wave velocity of i^{th} layer within the region (ft./sec.);

d = total thickness of substrate region (e.g. 20', 80')

V = Equivalent Strain Compatible Shear Wave Velocity for substrate thickness "d".

Note 2:

The lower bound, strain compatible effective shear wave velocities at a particular site must account for the potential variability (i.e., uncertainty) in the site soil properties in accordance with Section 3.7.2 of NUREG-0800. This means that a site must demonstrate that, when the lower bound values for shear wave velocity (based on the site soil investigation data) are used as input, the free-field site response analysis yields a strain compatible effective shear wave velocity greater than the minimum value provided in this table for each space. The lower bound shear wave velocities used as input to the free-field site response analysis shall be determined using the following formula:

$$V_{LB} = \frac{V_{BE}}{\sqrt{1 + COV}}$$

where V_{BE} is the best estimate shear wave velocity for a given soil layer based on the soil investigation data, and COV is the coefficient of variation for the site soil properties. For well-investigated sites, the COV should be no less than 0.5. For sites that are not well investigated, the COV shall be set equal to 1.0.

Note: The figure shows a 5 by 5 array with a slice through the centerline of the first row of VVMs facing the reader. Space A is the lateral subgrade space in and around the VVMs which may be excavated and refilled with engineered fill. Space B is the lateral subgrade that extends by the amount W around the ISFSI where W is the characteristic dimension of the ISFSI. Space C is the undergrade below the SFP. Space D is the undergrade surrounding Space C. P is the distance to the Retaining wall.

FIGURE 2.I.6 TYPICAL SHEAR WAVE VELOCITY PROFILES FOR NUCLEAR POWER PLANT SITES (REPRODUCED FROM FIGURE I-1 OF [2.I.10])

SUPPLEMENT 2.II: PRINCIPAL DESIGN CRITERIA

2.II.0 Scope and Introduction

The principal design criteria for the HI-STORM 100 storage system are derived from 10CFR72 [2.II.1]. This supplement applies to Chapter 2 of the HI-STORM 100 FSAR appropriately updated using latest NRC-approved FSAR (HI-STORM FW) [2.II.2]. This supplement supports the HI-STORM 100 system containing the HI-STORM Version E overpack (including the HI-STORM Version E1 overpack), HI-TRAC Version MS transfer cask, MPC-32M multi-purpose canister, including the MPC-32MCBS variant, and Version 1 of MPC-32 and MPC-68 (Alloy X canisters). The design criteria for HI-TRAC MS transfer cask allow the alternative of using a ventilation feature that provides a significantly better heat dissipation ability and ALARA characteristics compared to HI-TRAC 100 and HI-TRAC 125 casks that are presently certified for this purpose.

A principal objective of this revision to the FSAR is to update the licensing-basis analysis models which are in some cases, over two decades old and essentially obsolete in comparison to more recent FSARs such as HI-STORM FW (Docket # 72-1032). This issue of the FSAR will therefore serve as reference of the authoritative state-of-art safety analysis models which will help harmonize the analysis procedures for HI-STORM 100 and “FW” systems unifying the approach for future site-specific safety evaluations and §72.48 changes. This licensing submittal contains all actively used MPC models.

2.II.0.1 Summary of MPC Design Criteria

The design data common to the MPC models introduced in this supplement is provided in Table 1.II.2.3. The Design Criteria for the MPCs provided in Table 2.0.1 in the main body of this FSAR remain applicable for the MPCs introduced in this Supplement II with the following clarifications:

- a. Forced Helium Dehydration (FHD) and Vacuum drying are two distinct methods available for drying the Canister. The FHD may be used without limitation for drying the confinement space of the Canister containing both high burn-up and moderate burn-up fuel.

The Vacuum drying method may be used provided the restrictions on fuel cladding temperature limits and number of thermal cycles set forth in ISG-11 Rev 3 are met for the applicable burn-up class of the fuel (moderate or high burn-up).

- b. For Fuel Baskets made of Metamic HT, the deflection based structural criterion applies as set forth in Supplement III (wherein MPC-68M, presently certified and widely deployed, made of Metamic HT has been qualified) as well as in the HI-STORM FW FSAR [1.II.1]. Fuel Baskets made of Alloy X listed in the ASME Codes (various types of stainless steels listed in Appendix 1.A) namely Version 1 of MPC-32 and MPC-68, continue to be subject to the same stress limits as their forerunners treated in the main body of this FSAR.
- c. The MPC confinement boundary is qualified to ASME Section III Class 1 requirements with respect to all critical aspects including procurement, examination, testing, stress intensity compliance, quality assurance, and satisfaction of all service condition loads. For example, all MPC Enclosure Vessel material is subject to 100% volumetric examination (viz., UT); all butt-welds in the fabricated Enclosure Vessel weldment are also subject to 100% radiography or UT examination.

- d. The MPC shall meet the acceptance criteria per Table 2.II.2.3b under all Design Basis Loads (DBLs) under all applicable service conditions.
- e. The Threaded Anchor Locations (TAL) in the Top Lid shall meet the safety margins set down in NUREG-0612 with 15% dynamic amplifier factor applied to the dead load.

The above criteria and applicable loads for the MPCs are further considered in Section 2.II.2 in this supplement.

2.II.0.2 Summary of Design Criteria for HI-STORM Version E Overpack (including the HI-STORM Version E1)

The Design Criteria for the HI-STORM overpack listed in Table 2.0.2 (in the main body of this FSAR) remain applicable with the following clarifications:

- a. While the HI-STORM Overpack's steel structure is non-Code, the primary bending and in-plane stresses in the steel components shall meet the stress limits of ASME Section III Subsection NF Class 3 structures under all applicable normal loading events except for the impact loading. For impact loading the following criteria shall be met.
- b. The Overpack's principal function, namely protecting its stored MPC and prevention of radiation streaming under impactive and impulsive loadings during its interim storage at the ISFSI must be demonstrated.
- c. The Threaded Anchor Locations (TAL) in the Top Lid shall meet the safety margins set down in NUREG-0612 with 15% dynamic amplifier factor applied to the dead load.

The above criteria and applicable loads for "Version E" are further considered in Section 2.II.2 in this supplement.

2.II.0.3 Summary of HI-TRAC MS Design Criteria

The HI-TRAC MS is a ventilated overpack with a multi-buttressed steel shell structure. The HI-TRAC MS design includes a detachable Neutron Shield Cylinder (NSC) feature that can be removed for movements of the MPC and HI-TRAC into and out of the pool such that the amount of gamma shielding is maximized relative to the crane capacity while the water in the MPC provides neutron shielding. The HI-TRAC is then placed inside of and connected to the NSC such that it provides neutron shielding after the water is drained from the MPC. To meet the diverse needs of different users (nuclear plants), the HI-TRAC MS is available with or without lifting trunnions as shown in the licensing drawing. The shielding in the HI-TRAC MS is maximized within the constraint of the allowable weight at a plant site. Its Design Criteria mirror those of the earlier transfer cask models treated in the main body of this FSAR and in Table 2.0.3 with clarifications/updates as follows:

- a. The ID and height of the MS transfer cask, as shown in the Licensing drawing, are fixed for an MPC of a given height. The Licensing drawing provides the nominal weight of the empty transfer cask which is used in licensing basis analyses. However, the OD of the cask can be customized to enable it to be staged in the host Plant's cask pit and other locations in the Fuel Building. The weight of the loaded cask is governed by the capacity of the Cask Crane. The thickness of the lead shielding and size of the water jacket can be adjusted to maximize the

cask's shielding capacity within the constraint of the Plant's crane and the Part 50 staging area limitations using the authorized change process in 10CFR72.48.

- b. While the HI-TRAC overpack's steel structure is not an ASME Code structure, it is required to meet the stress limits of ASME Section III Subsection NF Class 3 structures under applicable mechanical loading conditions except for the impact loading. For impact loading the following criteria shall be met.
- c. The transfer overpack's principal safety function, namely protecting the enclosed MPC and prevention of radiation streaming under impactive and impulsive loadings during its on-site operations, must be demonstrated.

The above criteria and applicable loads for HI-TRAC MS are further considered in Section 2.II.2 in this supplement.

2.II.0.4 Principal Design Criteria for the ISFSI Pad

2.II.0.4.1 Design and Construction Criteria

Free standing HI-STORMSs: In compliance with 10CFR72, Subpart F, "General Design Criteria", the HI-STORM 100 cask system is classified as "important-to-safety" (ITS). This FSAR explicitly recognizes the HI-STORM 100 System as an assemblage of equipment containing numerous ITS components. The reinforced concrete pad, on which the cask is situated in a freestanding configuration; however, is designated as a "not important to safety" (NITS) structure because of a lack of a physical connection between the cask and the pad.

Because the geological conditions vary widely across the United States, it is not possible *a priori*, to define the detailed design of the ISFSI pad. Accordingly, in this FSAR, the limiting requirements on the design and installation of the pad are provided. The user of the HI-STORM 100 System bears the responsibility to ensure that all requirements on the pad set forth in this FSAR are fulfilled by the pad design. Specifically, the ISFSI owner must ensure that:

- The pad design complies with the structural provisions of this FSAR.
- The material of construction of the pad (viz., the additives used in the pad concrete) are compatible with the ambient environment at the ISFSI site.
- Appropriate structural evaluations must be performed pursuant to 10CFR72.212 to demonstrate that the pad is structurally competent to permit the cask to withstand the seismic and other credible inertial loadings at the site.

4.

2.II.0.4.2 Load Combinations and Applicable Codes

Factored load combinations for ISFSI pad design are provided in NUREG-1536 [2.1.5]. The factored loads applicable to the pad design consist of dead weight of the cask, thermal gradient loads, impact loads arising from handling and accident events, external missiles, and bounding environmental phenomena (such as earthquakes, wind, tornado, and flood).

The factored load combinations presented in Table 3-1 of NUREG 1536 are reduced in number by eliminating loading types that are not germane or controlling in a HI-STORM ISFSI pad design. The applicable factored load combinations are as follows:

- a. Definitions

D = Dead load plus effect of long-term settlement; L = Live load; T = Thermal load; E = DBE seismic load; U_c = Reinforced concrete available strength

5. b. Load Combinations for the Concrete Pad

Normal Events: $U_c > 1.4 D + 1.7 L$

Off-Normal Events: $U_c > 1.05 D + 1.275 (L+T)$

Accident Events: $U_c > D + L + T + E$

As an interfacing structure, the ISFSI pad and its underlying substrate must possess the structural strength to satisfy the above inequalities. As discussed in the main body of this FSAR, thermal gradient loads are generally small; therefore, the Off-Normal Event does not generally provide a governing load combination.

Table 2.II.0.1 provides a reference set of parameters for the ISFSI pad and its foundation that are used solely as input to the non-mechanistic tip-over analysis. Analyses in Chapter 3 show that this reference pad design does not violate the design criterion applicable to the *non-mechanistic tip-over* of the HI-STORM 100 storage system. The pad design may be customized to meet the requirements of a particular site without performing a site-specific tip-over analysis, provided that all ISFSI pad strength properties are less than or equal to the values in Table 2.II.0.1.

Applicable sections of industry codes such as ACI 318-05, “Building Code Requirements for Structural Concrete”; ACI 360R-92, “Design of Slabs on Grade”; ACI 302.1R, “Guide for Concrete Floor and Slab Construction”; and ACI 224R-90, “Control of Cracking in Concrete Structures” may be used in the design, structural evaluation, and construction of the concrete pad. However, load combinations in ACI 318-05 are not applicable to the ISFSI pad structural evaluation and are replaced by the load combinations stated in this subsection.

2.II.0.4.3 Anchored Installation

Because the HI-STORM 100 overpack has a thick outer shell welded to a thick Bottom Plate, it is straightforward to weld attachment lugs to the cask that serve to anchor it to ISFSI pad. The safety category for the ISFSI pad used to anchor the cask is raised to ITS-C if the cask is anchored to the pad.

Both the HI-STORM body and the anchor bolts (studs) are required to meet the stress limits of Section III, Subsection NF and Appendix F [2.II.9]. The applicable load combinations and allowable stress limits for the attachment bolts and the primary stresses in the attachment lugs and Cask body are provided in Table 2.II.0.2.

2.II.0.5 Important -To Safety (ITS) Classification

The ITS category of each part for each component (Version E overpack, Version E1 overpack, HI-STORM 100S Common Lid, MPC-32M, MPC-32MCBS, Version 1 of MPC-32 and MPC-68, and HI-TRAC MS transfer cask) is provided in the respective component’s Licensing Drawing in Section 1.II.5.

The ITS classification of a part serves to define the quality rigor applied to the part and its welds throughout the manufacturing life cycle of the SSC. A set of Holtec Standard Procedures (HSPs) provide the specific guidance on implementing quality requirements in all phases of the SSC’s manufacturing process beginning with material procurement, fabrication operations (rolling, forming, welding, machining, etc.) and inspection operations (VT, MT, PT, RT, etc.) ending with final acceptance testing (FAT) prior to shipment.

Table 2.II.0.1**Reference ISFSI Pad Data for Non-Mechanistic Tip-Over Analysis**

Item	Minimum Permitted Value
Thickness (inch)	36
Concrete Pad Compressive Strength (psi)	6,000
Modulus of elasticity of the subgrade (psi)	28,000

Table 2.II.0.2**ASME Code Stress Limits for the Cask Body, attachments Lugs and Anchor Bolts**

Loading Condition	ASME Code paragraph applicable to Anchor bolts	ASME Code paragraph applicable to Cask body and attachment lugs
Level A Service Condition (Normal Condition of Storage)	NF-3322.1, 3324.6	NF-3221.1, NF-3321.2
Level B Service Condition (Off-Normal condition of storage)	NF-3322.1, 3324.6 with all stress limits increased by 1.33	NF-3221.1, NF-3321.2 with all stress limits increased by 1.33
Level D Service Condition (Accident Condition)	Appendix F, Section F-1334, 1335	Appendix F, Section F-1334, 1335

2.II.1 Summary of Authorized Contents

The heat generation rate, axial burnup distribution, and all other bounding radiological, thermal, and criticality parameters specified in Chapter 2 of this FSAR are used to ensure the adequacy of the performance of the HI-STORM System.

2.II.1.1 MPC 24/24E/24EF, MPC-32/32F, MPC-68/68F/68FF

Same as Section 2.1. in the main report.

2.II.1.2 MPC-32 Version 1

Same as MPC-32 in Section 2.1 of the main report.

Table 2.1.24 and associated referenced tables provides the acceptable fuel characteristics for the fuel array/class authorized for storage in MPC-32. All PWR fuel assembly array/classes which are authorized for the MPC-32 are authorized in the MPC-32 Version 1. The regions for the MPC-32 Version 1 are the same as for MPC-32 and are presented in Table 2.1.27.

2.II.1.3 MPC-68 Version 1

Same as MPC-68 in Section 2.1 of the main report.

Table 2.1.22 and associated referenced tables provides the acceptable fuel characteristics for the fuel array/class authorized for storage in MPC-68. All BWR fuel assembly array/classes which are authorized for the MPC-68 are authorized in the MPC-68 Version 1. The regions for the MPC-68 Version 1 are the same as for MPC-68 and are presented in Table 2.1.27.

2.II.1.4 MPC-68M

Same as Section 2.III.1 in Supplement 2.III.

2.II.1.5 MPC-32M (including MPC-32MCBS)

Table 2.II.1.1 provides the acceptable fuel characteristics for the fuel array/class authorized for storage in MPC-32M. All PWR fuel assembly array/classes which are authorized for the MPC-32 are authorized in the MPC-32M. Maximum allowable initial enrichment for fuel assemblies are consistent with the criticality analysis described in Supplement 6.II.

Fuel classified as damaged fuel assemblies will be loaded into damaged fuel containers (DFCs) (Figure 2.II.1-4) or basket cell locations with damaged fuel isolators (DFIs) (Figure 2.II.1-5) installed at the upper and lower ends. Fuel debris will be loaded into DFCs for storage in the MPCs. Damaged fuel assemblies stored with DFIs may contain missing or partial fuel rods and/or fuel rods with known or suspected cladding defects greater than hairline cracks or pinhole leaks as long as the fuel assembly can be handled by normal means and whose structural integrity is such that geometric rearrangement of fuel is not expected. Damaged fuel that does not meet these conditions must be stored in a DFC. The appropriate thermal and criticality analyses have been performed to account for damaged fuel and fuel debris and are described in Supplements 4.II and 6.II, respectively. Non-fuel hardware is applicable to all the PWR fuel classes/arrays.

2.II.1.5.1 Design Heat Load

MPC-32M is designed for the uniform and regionalized fuel loading strategies as described in Subsection 2.0.1 and 2.1.9. The design basis uniform heat load defined in Section 2.1.9, Q_d , for MPC-32M is provided in Table 2.II.1.5. The regions for the MPC-32M are presented in Table 2.II.1.3. Additionally, two *discrete* heat load patterns have been defined for MPC-32M as shown in Figures 2.II.1.2 and 2.II.1.3. The quadrants for the MPC-32M are defined in Table 2.II.1.4 and the maximum quadrant decay heat loads are given in Table 2.II.1.5. The same fuel cladding temperature limits as those for the regionalized loading configuration apply to these heat load patterns.

The MPC-32M is designed to accommodate variable fuel heights. For fuel with a longer active fuel length than the reference fuel (144in), the total heat load, quadrant heat load limits and specific heat load limit in each cell may be increased by the ratio $\text{SQRT}(L/144)$, where L is the active length of the fuel in inches. For fuel with a shorter active fuel length than the reference fuel (144in), the total heat load, quadrant heat load limits and specific heat load limit in each cell shall be reduced by the ratio $L/144$, where L is the active length of the fuel in inches.

2.II.1.5.2 Radiological Parameters for Spent Fuel and Non-Fuel Hardware

MPC-32M is authorized to store fuel and non-fuel hardware with burnup - cooling time combinations as given in Tables 2.II.1.2 and 2.II.1.6.

The burnup and cooling time for every fuel assembly loaded into the MPC-32M must satisfy the following equation:

$$Ct = A \cdot Bu^3 + B \cdot Bu^2 + C \cdot Bu + D$$

where,

Ct = Minimum cooling time (years),

Bu = Assembly-average burnup (MWd/mtU),

A, B, C, D = Polynomial coefficients listed in Table 2.II.1.6

The coefficients for above equation for the assembly in an individual cell depend on the heat load limit in that cell, Table 2.II.1.6 lists the coefficients for several heat load limit ranges. Note that the heat load limits are only used for the lookup of the coefficients in that table, and do not imply any equivalency. Specifically, meeting heat load limits is not a substitute for meeting burnup and cooling time limits, and vice versa.

2.II.1.5.3 Criticality Paramters

Table 2.II.1.7 contains the soluble boron requirements for wet loading and unloading operations for the MPC-32M.

Table 2.II.1.1
Limits for Material to be Stored in MPC-32M

PARAMETER	VALUE (Note 1)	
Fuel Type	Uranium oxide, PWR undamaged fuel assemblies meeting the limits in Table 2.II.1.8 for the applicable fuel assembly array/class	Uranium oxide, PWR damaged fuel assemblies and fuel debris in DFCs meeting the limits in Table 2.II.1.8 for the applicable fuel assembly array/class
Cladding Type	ZR for all fuel assembly array/class except Stainless Steel (SS) for 14x14D and 15x15G fuel assembly array/class.	ZR for all fuel assembly array/class except Stainless Steel (SS) for 14x14D and 15x15G fuel assembly array/class.
Maximum Initial Enrichment per Assembly	5.0 wt. % U-235	5.0 wt. % U-235
Post-irradiation Cooling Time and Average Burnup per Assembly	<p>ZR clad: Cooling time ≥ 1 year and average burnup $\leq 68,200$ MWD/MTU</p> <p>SS clad: Cooling time ≥ 9 years and $\leq 30,000$ MWD/MTU or ≥ 20 years and $\leq 40,000$ MWD/MTU</p>	<p>Zr clad: Cooling time ≥ 1 year and average burnup $\leq 68,200$ MWD/MTU</p> <p>SS clad: Cooling time ≥ 9 years and $\leq 30,000$ MWD/MTU or ≥ 20 years and $\leq 40,000$ MWD/MTU</p>
Decay Heat Per Fuel Storage Location	<p>ZR clad: As specified in Section 2.II.1.5.</p> <p>SS clad: ≤ 500 Watts</p>	<p>ZR clad: As specified in Section 2.II.1.5.</p> <p>SS clad: ≤ 500 Watts</p>
Non-fuel hardware post-irradiation Cooling Time and Burnup	As specified in Table 2.II.1.2	As specified in Table 2.II.1.2
Fuel Assembly Length	≤ 176.8 in. (nominal design)	≤ 176.8 in. (nominal design)
Fuel Assembly Width	≤ 8.54 in. (nominal design)	≤ 8.54 in. (nominal design)
Fuel Assembly Weight	$\leq 2,050$ lbs (including non-fuel hardware)	$\leq 2,050$ lbs (including DFC/DFI and non-fuel hardware)

Table 2.II.1.1 (cont'd)
Limits for Material to be Stored in MPC-32M

PARAMETER	VALUE
<i>Other Limitations</i>	<ul style="list-style-type: none"> ▪ Quantity is limited to up to 32 PWR undamaged fuel assemblies and/or up to sixteen (16) damaged fuel assemblies in DFIs/DFCs and/or fuel classified as fuel debris in DFCs in fuel cell locations indicated in Table 2.II.1.7. The remaining basket cell locations may contain undamaged fuel assemblies up to a total of 32 or may be left empty. ▪ One NSA is permitted for loading with a fuel assembly in fuel storage location 13, 14, 19, or 20 ▪ BPRAs, TPDs, WABAs, water displacement guide tube plugs, orifice rod assemblies, and/or vibration suppressor inserts, with or without ITTRs, may be stored with fuel assemblies in any fuel cell location. ▪ CRAs, RCCSs, CEAs, or APSRs may only be loaded with fuel assemblies in fuel cell locations 7, 8, 12-15, 18-21, 25 and/or 26 ▪ Soluble boron requirements during wet loading and unloading are specified in Table 2.II.1.7.

NOTES:

1. A fuel assembly must meet the requirements of any one column and the other limitations to be authorized for storage.

Table 2.II.1.2
Non-Fuel Hardware Burnup and Cooling Time Limits (Notes 1, 2)

Post-irradiation Cooling Time (years)	Inserts (Note 3) Burnup (MWD/MTU)	TPD Burnup (Note 4) (MWD/MTU)	Control Component (Note 5), NSA Burnup (MWD/MTU)
≥ 1	$\leq 60,000$	$\leq 225,000$	NA (Note 6)
≥ 2	-	-	$\leq 630,000$

- Notes:
1. Burnups for non-fuel hardware are to be determined based on the burnup and uranium mass of the fuel assemblies in which the component was inserted during reactor operation.
 2. Non-fuel hardware burnup and cooling times are not applicable to ITTRs since they are installed post irradiation.
 3. Includes Burnable Poison Rod Assemblies (BPRAs), Wet Annular Burnable Absorbers (WABAs), and vibration suppressor inserts.
 4. Includes Thimble Plug Devices (TPDs), water displacement guide tube plugs and orifice rod assemblies.
 5. Includes Axial Power Shaping Rods (APSRs), Control Rod Assemblies (CRAs), Control Element Assemblies (CEAs) and Rod Cluster Control Assemblies (RCCAs).
 6. NA means not authorized for loading at this cooling time.

2.II.2 Principal Design Criteria

2.II.2.1 Significant Loadings Applicable to HI-STORM, HI-TRAC and MPC

Section 2.2 of this FSAR provides a complete list of the loadings germane to the safety analysis of the HI-STORM 100 system. The determination of non-governing loadings (such as lightning, high wind, and snow) because of the design characteristics of the system (such as a large metal mass, heavy weight, and a thick structural Top Lid) has been made in the FSAR and therefore, such loadings do not require continued consideration.

Similarly, safety analysis is not required for certain conditions because of their passive features or redundancy, as follows:

- Leakage of one seal (See paragraph 2.2.2.4): The scenario of leakage from the MPC has been ruled out as non-credible in every HI-STORM/HI-STAR FSAR and accordingly do not require further evaluation.
- FHD malfunction (See paragraph 2.2.2.7): Initiating events of FHD malfunction are: (i) a loss of external power to the FHD System and (ii) an active component trip. In both cases a stoppage of forced helium circulation occurs and heat dissipation in the MPC transitions to natural convection cooling. The natural convection process, however, keeps the fuel below the normal condition ISG-11 Rev 3 limit. Malfunction of the FHD, therefore, does not qualify as a safety significant event.
- Auxiliary MPC Cooling Device: Heat extraction from the MPC during “Part 50 Short Term Operations” using a gravity actuated, single failure proof water spray device does not require safety analysis because it does not involve any active components.
- Supplemental Cooling System: Supplemental cooling of the MPC by active means using air or water or any other cooling medium must be provided in the form of two redundant and independent systems to preclude the need for a safety consequence analysis.

The qualification of the MPC under loadings that act on the loaded HI-STORM overpack or the HI-TRAC overpack is considered along with its host overpack.

The categories of loadings applicable to the loaded HI-STORM and HI-TRAC can be subdivided into four categories:

- a. Mechanical Loadings: The mechanical loadings that remain in contention to merit safety analysis are listed in Table 2.II.2.1 for both the HI-STORM 100 and HI-TRAC MS cask systems. Acceptance criteria for each loading type are set down in the next sub-section.
- b. Thermal Conditions: Table 2.II.2.9 provides a listing of the normal, off-normal and accident conditions for which the compliance of the fuel cladding to ISG-11 Rev 3 limits and other constituent parts of the system to their respective limits must be demonstrated.
- c. Dose Compliance: Compliance of the storage system with the site boundary dose limits of 72.104 and 72.106, elaborated in Section 2.2 in the main report, must be demonstrated.

Specific limits on the HI-TRAC's accreted dose is not in the regulatory literature; however, hard limits in the spirit of ALARA are specified herein.

- d. Criticality Compliance: Supplement 6.II contains the results of the criticality analyses and demonstrates compliance with the sub-criticality margin specified in Section 2.2 of the FSAR for the MPCs introduced in this Supplement II.

2.II.2.2 Detailed Acceptance Criteria for Mechanical Loadings

Articulated acceptance criteria for each mechanical loading listed in Table 2.II.2.1 are provided below.

- a. High Wind and Design Basis Missile (DBM) [Load ID M-1]: The wind and tornadic missile loadings apply to both HI-STORM in storage and the HI-TRAC transfer cask during "part 72 short term operations". The applicable acceptance criteria are itemized below:
 - 1) The deformation of the cask body from the missile's impact must be sufficiently small to preserve the Canister's retrievability.
 - 2) The bolted lid of the cask will not separate from the body resulting in excessive personnel dose.
 - 3) The loss of bulk shielding, if any, shall not be significant.
 - 4) The missile shall not impact the cylindrical surface of the stored MPC.
 - 5) A dose streaming path will not be created by the missile impact.
- b. Non-Mechanistic Tip-Over [Load ID: M-4]
 - 1) The MPC will remain in the HI-STORM overpack after the tip-over event and the overpack will not suffer any ovalization which would preclude the removal of the MPC.
 - 2) The maximum plastic deformation for the Metamic baskets (MPC 32M basket) sustained by the fuel basket panels is limited to the value given in Table 2.II.2.4.
 - 3) The HI-STORM overpack will not suffer a significant loss of shielding.
 - 4) The confinement boundary will not be breached.

It shall be noted that the handling drops (Load Cases M2 and M3) for the HI-STORM and HI-TRAC casks are precluded by virtue of meeting the redundant load path requirements from NUREG-0612.

In case the handling drops are credible due to the use of non-redundant lifting devices for a specific site, the above acceptance criteria shall be applied for the postulated drops of the HI-STORM and the HI-TRAC. The site-specific conditions will be evaluated as part of the 10CFR72.212 process.

- c. Design Basis Earthquake

The acceptance criteria for the storage system under the site's Design Basis Earthquake (DBE) are as follows:

- i. The loaded overpacks will not impact each other during the DBE event.

- ii. The loaded overpack will not slide off the ISFSI.
- iii. The loaded overpack will not tip over.
- iv. The confinement boundary will not be breached.

The first step in the earthquake qualification of the cask array involves computing the *on-the-pad acceleration time history* with appropriate consideration of the soil-structure interaction effects. The detailed methodology described in Docket # 72-1040 (HI-STORM UMAX) shall be used for this purpose. The zero-period accelerations computed for a site are used to classify a site as (i) low intensity and (ii) high intensity. A low intensity earthquake must satisfy two criteria based on static equilibrium:

- 1) The loaded cask will not slide under the earthquake.
- 2) The loaded cask will not tip-over under the earthquake.

A high intensity earthquake is one that cannot pass the “static equilibrium test” adopted in this docket and in docket # 72-1032, summarized below:

The criterion for static equilibrium is derived from elementary statics with the simplifying assumption that the cask and its contents are fixed and emulate a rigid body with six degrees-of-freedom. The earthquake is represented by its on-the pad ZPA in horizontal (the vector sum of the two horizontal ZPAs for a 3-D earthquake site) and vertical directions. The limits on a_H and a_v for HI-STORM FW are readily derived as follows:

- i. Prevention of sliding: Assuming the vertical ZPA to be acting to reduce the weight of the cask, horizontal force equilibrium yields:

$$W \cdot a_H \leq f \cdot W \cdot (1 - a_v)$$

$$\text{Or} \quad a_H \leq (1 - a_v) \cdot f$$

- ii. Prevention against “edging” of the cask:

Balancing the moment about the cask’s pivot point for edging yields:

$$W \cdot a_H \cdot h \leq W \cdot (1 - a_v) \cdot r$$

$$\text{Or} \quad a_H \leq (1 - a_v) \cdot \frac{r}{h}$$

Where:

- r: radius of the footprint of the cask’s base
- h: height of the CG of the cask
- f: Static friction coefficient between the cask and the ISFSI pad.

The above two inequalities define the limits on a_H and a_v for a site if the earthquake is to be considered of “low intensity.” For low intensity earthquake sites, additional analysis to demonstrate integrity of the confinement boundary is not required.

However, if the earthquake’s ZPAs do not satisfy either of the above inequalities, then a time history dynamic analysis shall be performed as a part of the §72.212 safety evaluation.

d. Explosion & moving flood waters

The pressure exerted by moving flood waters can be obtained from classical hydrodynamics with 0.6 set as the drag factor for cylindrical bodies. Likewise, the pressure from explosion depends on the strength of the explosive force and its distance. The values applicable to an ISFSI must be conservatively established by the ISFSI owner by an appropriate environmental evaluation.

The allowable pressure from explosion or moving flood waters, p_e , can be computed from static equilibrium to prevent sliding or tipping of the cask. A simplified inequality to ensure that the cask will not slide is given by

$$p_e D L \leq \mu W$$

where:

- D: diameter of the cask
- L: height of the cask above the ISFSI pad
- μ : limiting value of the interface friction coefficient
- W: weight of the cask (lower bound weight, assuming minimum MPC weight)

$$p_e \leq \frac{\mu W}{DL} \quad (A)$$

The inequality for protection against tipping is obtained by moment equilibrium.

$$p_e D \frac{L^2}{2} \leq \frac{W D}{2}$$

$$\text{or} \quad p_e \leq \frac{W}{L^2} \quad (B)$$

The allowable value of p_e must be lesser of the two values given by inequalities (A) and (B) above.

In contrast to the overpack, the MPC is a closed pressure vessel. Because of the enveloping overpack around it, the explosive pressure wave would manifest as an external pressure on the external surface of the MPC.

The maximum overpressure on the MPC resulting from an explosion is limited by the accident condition design external pressure specified in Table 1.II.2.3.

2.II.2.3 Detailed Acceptance Criteria for Thermal Conditions Listed

a. Normal Condition of Storage (T-1): The reference ambient conditions corresponding to the normal, off-normal and accident conditions of storage are provided in Table 1.II.2.3. These environmental conditions have been determined to bound their respective meteorological data for the entire continental United States. Unsheltered condition of storage requires inclusion of insolation to the storage system as external heat input.

The fuel cladding temperature limits pursuant to ISG 11 Rev 3 are provided in Table 1.II.2.3. The temperature limits on other ITS parts of the HI-STORM 100 system are provided in Table 2.2.3.

b. Accident Condition of Storage: This condition is characterized by an elevated ambient temperature (Table 1.II.2.4) and 100% rod rupture.

For conservatism, 100% of the fuel rods are assumed to rupture with 100% of the fill gas and 30% of the significant radioactive gases (e.g., H^3 , Kr, and Xe) released in accordance with NUREG-1536. All of the fill gas contained in non-fuel hardware, such as burnable poison rod assemblies (BPRAs), is also assumed to be released concomitantly. Because of the relatively high fuel cladding temperature limit for this condition (Table 1.II.2.3 and Table 2.2.3), the accident condition of storage has not been found to challenge the temperature limits in HI-STORM systems.

b. Design Basis Fire:

The accident condition design temperatures for the HI-STORM 100 System are specified in Table 2.2.3. The specified fuel cladding temperature limits are based on the temperature limits specified in ISG-11, Rev. 3 reproduced in Table 1.II.2.3.

2.II.2.4 Applicability of Governing Documents

Section III Subsection NB of the ASME Boiler and Pressure Vessel Code (ASME Code), [2.II.8], is the governing code for the structural design of the MPC. The alternatives to the ASME Code, Section III Subsection NB, applicable to the MPC are listed in Table 2.II.2.6. Table 2.II.2.8 provides the ASME Code, Section and Subsection for manufacturing requirements.

The stress limits of ASME Section III Subsection NF [2.II.9] are applied to the HI-STORM overpack and HI-TRAC MS structural parts where the applicable loading is designated as a code service condition.

The fuel basket, made of Metamic-HT, is subject to the requirements in Supplement II to this FSAR. Structural limits on the Metamic HT panel is specified as a (lateral) deformation limit of its walls under accident conditions of loading (credible and non-mechanistic) (see Table 2. II. 2.4). The basis for the lateral deflection limit in the active fuel region, θ , is provided in [2.II.11]].

The Version1 Alloy X fuel baskets are subject to the requirements of Section III, Subsection NG of the ASME Code, identical to their predecessor designs viz. MPC 32 and MPC 68 baskets. The acceptance criteria for these baskets is summarized in Table 2.II.2.3a.

ACI 318 [2.II.7] is the reference code for the plain concrete in the HI-STORM Overpack. ACI 318.1-85(05) is the applicable code utilized to determine the allowable compressive strength of the plain concrete credited in strength analysis.

Each structure, system and component (SSC) of the storage system that is identified as important-to-safety is shown on the licensing drawings in Section 1.II.5.

Table 2.2.15 provides the information on the applicable Codes and Standards for material procurement, design, fabrication and inspection of the components of the HI-STORM 100 System. In particular, the ASME Code is relied on to define allowable stresses for structural analyses of primary load bearing parts.

To maintain continuity, the allowable stress tables from the originally referenced Section III of the ASME Code (1995 with all addenda including 1997) continue to be used in this Supplement. However, material specifications, NDE specifications, welding specifications are updated to the 2016 edition of the Code to conform to the industry practice (viz., materials to non-current codes are scarce to procure).

2.II.2.5 Service Limits

In the ASME Code, plant and system operating conditions are commonly referred to as normal, upset, emergency, and faulted. Consistent with the terminology in NRC documents, this FSAR utilizes the terms normal, off-normal, and accident conditions.

The ASME Code defines four service conditions in addition to the Design Limits for nuclear components. They are referred to as Level A, Level B, Level C, and Level D service limits, respectively. Their definitions are provided in Paragraph NCA-2142.4 of the ASME Code. The four levels are used in this FSAR as follows:

- i. Level A Service Limits are used to establish allowables for normal condition load combinations.
- ii. Level B Service Limits are used to establish allowables for off-normal conditions.
- iii. Level C Service Limits are not used.
- iv. Level D Service Limits are used to establish allowables for certain accident conditions.

The ASME Code service limits are used in the structural analyses for definition of allowable stresses and allowable stress intensities, as applicable. Allowable stresses and stress intensities for structural analyses are tabulated in Chapter 3. These service limits are matched with normal, off-normal, and accident condition loads combinations in the following subsections.

2.II.2.6 Allowable Stress/Deflection Limits

- (i) MPC Confinement Boundary: The stress intensity limits for the MPC confinement boundary for the design condition and the service conditions are provided in Table 2.II.2.3b. The MPC confinement boundary stress intensity limits are obtained from ASME Code, Section III, Subsection NB.
- (ii) Metamic HT Baskets (MPC-32M, including MPC-32MCBS): As in the case of MPC-68M analyzed in Supplement III and certified previously, the displacement limit for the MPC fuel basket is expressed as a dimensionless parameter θ defined as [2.2.11]

$$\theta = \frac{\delta}{w}$$

where δ is defined as the maximum total deflection sustained by the basket panels under the loading event and w is the nominal inside (width) dimension of the storage cell. The limiting value of θ is provided in Table 2.II.2.4.

- (iii) Alloy X Baskets (Version 1 of MPC-32 and MPC-68): The stress limits defined in Table 2.II.2.3a, are the same as those applicable to the predecessors of these baskets. The numerical values of stress limits are presented in Tables 3.1.15 and 3.1.16.

- (iv) Overpacks: The steel structure of the HI-STORM Version E overpack, HI-STORM Version E1 overpack and the HI-TRAC MS transfer cask must meet the stress limits of Subsection NF of ASME Code, Section III for the applicable service conditions except for the impact loadings. The impact loading shall use the acceptance criteria from section 2.II.2.2b.

Table 2.II.2.5 provides the location of mechanical properties for the MPC, and the storage and transfer overpacks for convenience of reference.

The following definitions of terms apply to the tables on stress intensity limits; these definitions are the same as those used throughout the ASME Code:

- S_m : Value of Design Stress Intensity listed in ASME Code Section II, Part D, Tables 2A, 2B and 4
- S_y : Minimum yield strength at temperature
- S_u : Minimum ultimate strength at temperature

2.II.2.7 Lifting and Handling Safety

All lifting devices whether custom engineered or commercially procured are subject to stringent structural margin requirements as spelled out in the following in this sub-section. All new lifting and handling equipment shall meet the enhanced safety margin criteria which render them exempt from a postulated drop consequence analysis. Such devices are referred to as “drop-postulate exempt (DPE)” which is synonymous with the term “Single Failure Proof” used in NUREG-0612 and Regulatory Guide 1.13. Single Failure Proof lifting and handling devices are designed such that a single failure will not result in the lifting or handling device losing the capability to perform its safety function. [2.II.14]. Additional conservative provisions to ensure heightened safety margins are also set down in paragraph 2.II.2.7.4 in this sub-section. Table 2.II.2.7 provides the reference ASME codes for the load bearing parts of the overpack and transfer cask.

2.II.2.7.1 "Lifting Devices" and "Special Lifting Devices"

The lifting and handling systems used in Holtec’s used fuel management program are made up of individual components or devices. These components can be further classified as either “*lifting devices*” or “*special lifting devices*.”

The term *lifting device* refers to components of a lifting and handling system that are not classified as *special lifting devices*. ANSI N14.6 is not applicable to these *lifting devices*. These include non-active structural components (components that bear the primary load but are not a constituent of a moving part, e.g., gear train, hydraulic cylinder) of the system. Examples of *lifting devices* are a VCT overhead beam or the main girder of a gantry crane.

The term *special lifting device* refers to components to which ANSI N14.6 applies. As stated in ANSI N14.6 (both 1978 and 1993 versions), “This standard shall apply to *special lifting devices* that transmit the load from lifting attachments, which are structural parts of a container to the hook(s) of an overhead hoisting system.” Examples of *special lifting devices* are MPC lift cleats, lift brackets, and lift yokes used to lift and handle transfer and storage overpacks.

In order for a *lifting device* or *special lifting device* to be considered *single failure proof*, the design must also follow the guidance in NUREG-0612, which requires that a single failure proof device have twice the

normal safety margin. This designation can be achieved by either providing redundant devices or providing twice the design safety factor as required by the applicable code. Therefore, for a *lifting device* to be considered single failure proof, the applicable code requirements should be doubled, or a redundant *lifting device* should be provided. Similarly, for a *special lifting device* to be considered single failure proof, the design safety factors in ANSI N14.6 should be doubled, or a redundant *special lifting device* should be provided.

2.II.2.7.2 Stress compliance criteria applicable to *Lifting Devices* (LDs)

The stress compliance criteria for *lifting devices* are taken from the code applicable to the specific component. For example, slings are required to meet the guidelines of ANSI B30.9, and overhead beams are required to meet the guidelines of an applicable consensus national standard selected by the designer, such as AISC, CMAA, or ASME Code (Subsection NF).

2.II.2.7.3 Stress compliance criteria for *Special lifting devices* (SLDs)

ANSI N14.6 Special Lifting Devices for Shipping Containers Weighing 10,000 Pounds or More (1993) in Section 7 (special lifting devices for critical loads) defines two distinct system features to be used when handling a critical load. A system with *increased stress design factors* has “Load bearing members with increased stress design factors for handling the critical load.” A system with a *dual-load path* has “a design such that while handling the critical loads a single component failure or malfunction shall not result in uncontrolled lowering of the load.” Specifically, a *dual-load path hoisting system* is defined as “a system providing two distinct paths of support from the crane through the special lifting device to the container. Each path is capable of supporting the container in such a manner that no uncontrolled movement of the container will result from the failure or malfunction of a single part.” A SLD, therefore, can be designed with *increased stress factors* or *dual load path*.

(a) Increased Stress factor approach: The increased stress factor criterion is interpreted and implemented in the following manner:

- i. Define the magnitude of the dead load, D , to be lifted. D is also referred to as the “rated load”.
- ii. Apply a magnification factor, α , to the dead load to establish the Apparent Dead Load, D^* .

$$D^* = \alpha D$$
- iii. In Holtec dry storage systems, α will be set equal to 1.15.
- iv. The *primary* stress in the lifting device under D^* must be less than $1/6^{\text{th}}$ of the material yield strength σ_y and less than $1/10^{\text{th}}$ of the material ultimate strength, σ_u .

σ_y and σ_u can be taken from the applicable material mill test reports; or from a relevant publication such as ASTM, ASM, SAE, etc.
- v. Pursuant to NUREG-0612, no explicit limits on local membrane, secondary, or peak stresses are imposed.

In Holtec FSARs, the preferred terminology for special lifting devices designed to meet NUREG-0612 is “NUREG-0612 compliant”. In general, “NUREG-0612 compliant” for a Holtec special lifting device means that it is engineered to meet the procedure described in the foregoing.

(b) Dual Load Path option: The following requirements are applicable to special lifting devices with a *dual-load path*:

- (i) The *primary* stress in the lifting device under D* must be less than $1/3^{\text{th}}$ of the material yield strength σ_y and less than $1/5^{\text{th}}$ of the material ultimate strength, σ_u .

σ_y and σ_u can be taken from the applicable material mill test reports; or from a relevant publication such as ASTM, ASME, SAE, etc.

Pursuant to NUREG-0612 and ANSI N-14.6, no explicit limits on local membrane, secondary, or peak stresses are imposed.

- (ii) dual-load path attachment points on the special lifting device shall be so designed that each load path will be able to support a static load $3W$ (“W” being the weight of the critical load, including intervening components of the lifting device) plus the impact load due to any weight transfer that occurs due to failure of one load path, without exceeding the yield point of the material.

- (iii) In the event of a failure of one of the dual-load paths, the weight of the container is transferred from one load path to the other. Any expected increase in stress level shall be within design limits of all components, including those of the crane hoisting system. Provision should be made to minimize the time and distance for load transfer.

- (c) Exemption from NUREG-0612 compliance

Both NUREG-0612 and ANSI N14.6 allow for a load drop analysis to be performed. The increased safety factors are not required if the consequences of the drop predicted by the analysis are below the applicable safety metrics (viz., dose rate and criticality limits).

This approach (latitude) shall not be used in the design and qualification of any new lifting equipment for a Holtec dry storage system. However, if the lifting device is pre-existing and designed to this paragraph, then it may be used provided the host Plant’s operating procedures permit its use.

In the event that the load drop analysis indicates exceedance of the basket stress (for Alloy X baskets) or dimensionless deflection limit for the Metamic HT basket, then a suitably sized impact limiters can be deployed to ensure structural compliance.

2.II.2.7.4 Stress limits in integral appurtenances

The stress limit in the cask’s or canister’s appurtenances used in lifting/handling operations (such as *Threaded Anchor Locations* and *Trunnions*) shall meet the stress limits in NUREG-0612 with due consideration of the coincident metal temperature of the part. The reference temperature for allowable stresses for these appurtenances shall be equal to or greater than the bulk metal temperature of the part during the handling evolution. This is conservative because the ambient temperature is the default value for compliance with ANSI N-14.6 and NUREG-0612.

2.II.2.7.5 Lifting under off-normal conditions

An Off-normal load handling condition corresponds to lifting under an elevated off-normal ambient temperature and/or an unbalanced load which causes a significant load shift to one lifting location. The applicable stress criterion for off-normal lift scenarios is Reg Guide 3.61 with the allowable stresses referred to the coincident metal temperature of the lift location.

Table 2.II.2.1

Governing Mechanical Loadings Applicable to the Safety Analysis of the Loaded HI-STORM 100 System with Version E (including the Version E1) Overpack and Loaded HI-TRAC MS Transfer Cask

Mech. Loading #	Description of loading	FSAR Paragraph here the loading is discussed	Applicable to HI-STORM /HI-TRAC	Comment
M-1	Tornadic wind and tornado-borne missile acting synergistically	2.II.2.2	Both	Defined in Table 2.2.4 and 2.2.5. Applies to the HI-STORM systems in interim storage at the ISFSI & to HI-TRAC during travel on the haul path
M-2	Vertical Free fall of loaded cask during handling (non-single failure proof handling device)	2.II.2.2	Both	Uncontrolled lowering of HI-STORM is not credible if the handling device is drop-postulate-exempt; ie, is single failure proof by virtue of meeting the criteria in 2.II.2.7
M-3	Free fall of cask in the horizontal configuration	2.II.2.2	HI-TRAC	Uncontrolled lowering of HI-TRAC is not credible if the handling device is drop-postulate-exempt; ie, is single failure proof by virtue of meeting the criteria in 2.II.2.7
M-4	Non-mechanistic tip-over	2.II.2.2	HI-STORM	Applies if the cask is stored in a free-standing configuration
M-5	Design Basis Earthquake (DBE)	2.II.2.2	HI-STORM	Qualifying the storage system under the DBE can be by a simple static equilibrium model or by a dynamic time history analysis

Table 2.II.2.2**Governing Thermal Loading Conditions**

Thermal Loading ID	Caption of Loading	FSAR paragraph where the loading is discussed	Applicable to HI-STORM /HI-TRAC?	Comments
T- 1	Normal Condition of Storage	2.2.1	HI-STORM	The ISG-Rev 3 peak cladding temperature limits reproduced in Table 1.II.2.2 must be met. In addition, the temperature of proximate safety significant materials must meet the temperature limit in Table 2.2.3 in the main body of the FSAR
T-2	Design Basis Fire	2.2.3.3	Both	
T-3	Two inlet ducts blocked	2.2.3.4	HI-STORM	
T-4	Burial- under- debris	2.2.3.12	HI-STORM	
T-5	All inlet ducts blocked	2.2.3.13	HI-STORM	
T-6	Short Term Operations	2.2	HI-TRAC	

Table 2.II.2.3a**MPC Basket Stress Intensity Limits per NG-3220 for Different Conditions**

STRESS CATEGORY	DESIGN	LEVELS A & B	LEVEL D[†]
Primary Membrane, P_m	S_m	S_m	$AMIN(2.4S_m, .7S_u)^{††}$
Primary Membrane plus Primary Bending	$1.5S_m$	$1.5S_m$	150% of P_m Limit
Primary Membrane plus Primary Bending plus Secondary	$N/A^{†††}$	$3S_m$	N/A

[†] Governed by Appendix F, Paragraph F-1331 of the ASME Code, Section III.

^{††} Governed by NB-3227.2 or F-1331.1(d).

^{†††} No specific stress intensity limit applicable.

Table 2.II.2.3b
MPC Confinement Boundary Stress Intensity Limits for Different Loading Conditions

STRESS CATEGORY	DESIGN	LEVELS A & B	LEVEL D ^{††}
Primary Membrane, P_m	S_m	N/A ^{†††}	AMIN ($2.4S_m$, $.7S_u$)
Local Membrane, P_L	$1.5S_m$	N/A	150% of P_m Limit
Membrane plus Primary Bending	$1.5S_m$	N/A	150% of P_m Limit
Primary Membrane plus Primary Bending	$1.5S_m$	N/A	150% of P_m Limit
Membrane plus Primary Bending plus Secondary	N/A	$3S_m$	N/A
Average Shear Stress ^{††††}	$0.6S_m$	$0.6S_m$	$0.42S_u$

[†] Stress combinations including F (peak stress) apply to fatigue evaluations only.

^{††} Governed by Appendix F, Paragraph F-1331 of the ASME Code, Section III.

^{†††} No Specific stress limit applicable.

^{††††} Governed by NB-3227.2 or F-1331.1(d).

^{††} Governed by Appendix F, Paragraph F-1331 of the ASME Code, Section III.

^{†††} No Specific stress limit applicable.

^{††††} Governed by NB-3227.2 or F-1331.1(d).

Table 2.II.2.4**Structural Design Criteria for the Fuel Basket**

PARAMETER	VALUE
Minimum service temperature	-40°F
Maximum total (lateral) deflection in the active fuel region - dimensionless	0.005

Table 2.II.2.5**Location of Stress Limits and Mechanical Properties Tables**

ITEM	Reference Table in the FSAR	COMMENT
Permissible Stress intensity limits for the MPC Enclosure Vessel.	2.2.10	MPC Confinement boundary stress analysis performed in the main body of the FSAR remains applicable. Therefore, this table is not used.
Stress limits for the primary load bearing structures in the storage and transfer overpack	2.2.12	ASME Section III Subsection NF limits [2.II.9] are used
Allowable maximum temperatures of HI-STORM system parts under normal, off-normal, accident and fire conditions	2.2.3	Temperatures are used in both the HI-STORM 100 and HI-STORM FW [2.II.2] FSARs
Properties of Metamic HT	1.III.2, 1.III.3	Can be found in Supplement III of this FSAR
Deflection and temperature limit for the Metamic HT Fuel Basket	2.II.2.4	Reproduced from Table 2.2.11 of “FW” FSAR [2.II.2].

Table 2.II.2.6
List of ASME Code Alternatives for HI-STORM Multi-Purpose Canisters (MPCs)

MPC Enclosure Vessel	Subsection NCA	General Requirements. Requires preparation of a Design Specification, Design Report, Overpressure Protection Report, Certification of Construction Report, Data Report, and other administrative controls for an ASME Code stamped vessel.	<p>Because the MPC is not an ASME Code stamped vessel, none of the specifications, reports, certificates, or other general requirements specified by NCA are required. In lieu of a Design Specification and Design Report, the HI-STORM FSAR includes the design criteria, service conditions, and load combinations for the design and operation of the MPCs as well as the results of the stress analyses to demonstrate that applicable Code stress limits are met. Additionally, the fabricator is not required to have an ASME-certified QA program. All important-to-safety activities are governed by the NRC-approved Holtec QA program.</p> <p>Because the cask components are not certified to the Code, the terms “Certificate Holder” and “Inspector” are not germane to the manufacturing of NRC-certified cask components. To eliminate ambiguity, the responsibilities assigned to the Certificate Holder in the Code, as applicable, shall be interpreted to apply to the NRC Certificate of Compliance (CoC) holder (and by extension, to the component fabricator) if the requirement must be fulfilled. The Code term “Inspector” means the QA/QC personnel of the CoC holder and its vendors assigned to oversee and inspect the manufacturing process.</p>
MPC Enclosure Vessel	NB-1100	Statement of requirements for Code stamping of components.	MPC Enclosure Vessel is designed and will be fabricated in accordance with ASME Code, Section III, Subsection NB to the maximum practical extent, but Code stamping is not required.

Table 2.II.2.6
List of ASME Code Alternatives for HI-STORM Multi-Purpose Canisters (MPCs)

MPC lift lugs	NB-1130	<p>NB-1132.2(d) requires that the first connecting weld of a non-pressure retaining structural attachment to a component shall be considered part of the component unless the weld is more than $2t$ from the pressure retaining portion of the component, where t is the nominal thickness of the pressure retaining material.</p> <p>NB-1132.2(e) requires that the first connecting weld of a welded nonstructural attachment to a component shall conform to NB-4430 if the connecting weld is within $2t$ from the pressure retaining portion of the component.</p>	The lugs that are used exclusively for lifting an empty MPC are welded to the inside of the pressure-retaining MPC shell, but are not designed in accordance with Subsection NB. The lug-to-Enclosure Vessel Weld is required to meet the stress limits of Reg. Guide 3.61 in lieu of Subsection NB of the Code.
MPC Enclosure Vessel	NB-2000	Requires materials to be supplied by ASME-approved material supplier.	Materials will be supplied by Holtec approved suppliers with Certified Material Test Reports (CMTRs) in accordance with NB-2000 requirements.
MPC Enclosure Vessel	NB-2121	Provides permitted material specification for pressure-retaining material, which must conform to Section II, Part D, Tables 2A and 2B.	Certain duplex stainless steels are not included in Section II, Part D, Tables 2A and 2B. UNS S31803 duplex stainless-steel alloy is evaluated in the HI-STORM FW FSAR and meet the required design criteria for use in the HI-STORM 100 system per ASME Code Case N-635-1. Appendix 1.A provides the required property data for the necessary safety analysis.
MPC Enclosure Vessel	NB-3100 NF-3100	Provides requirements for determining design loading conditions, such as pressure, temperature, and mechanical loads.	100 system FSAR, serving as the Design Specification, which establishes the service conditions and load combinations for the storage system. FSAR, serving as the Design Specification, which establishes the service conditions and load combinations for the storage system.
MPC Enclosure Vessel	NB-4120	NB-4121.2 and NF-4121.2 provide requirements for repetition of tensile or impact tests for material subjected to heat treatment during fabrication or installation.	In-shop operations of short duration that apply heat to a component, such as plasma cutting of plate stock, welding, machining, and coating are not, unless explicitly stated by the Code, defined as heat treatment operations.

Table 2.II.2.6
List of ASME Code Alternatives for HI-STORM Multi-Purpose Canisters (MPCs)

MPC Enclosure Vessel	NB-4220	Requires certain forming tolerances to be met for cylindrical, conical, or spherical shells of a vessel.	The cylindricity measurements on the rolled shells are not specifically recorded in the shop travelers, as would be the case for a Code-stamped pressure vessel. Rather, the requirements on inter-component clearances (such as the MPC-to-transfer cask) are guaranteed through fixture-controlled manufacturing. The fabrication specification and shop procedures ensure that all dimensional design objectives, including inter-component annular clearances are satisfied. The dimensions required to be met in fabrication are chosen to meet the functional requirements of the dry storage components. Thus, although the post-forming Code cylindricity requirements are not evaluated for compliance directly, they are indirectly satisfied (actually exceeded) in the final manufactured components.
MPC Enclosure Vessel	NB-4122	Implies that with the exception of studs, bolts, nuts and heat exchanger tubes, CMTRs must be traceable to a specific piece of material in a component.	MPCs are built in lots. Material traceability on raw materials to a heat number and corresponding CMTR is maintained by Holtec through markings on the raw material. Where material is cut or processed, markings are transferred accordingly to assure traceability. As materials are assembled into the lot of MPCs being manufactured, documentation is maintained to identify the heat numbers of materials being used for that item in the multiple MPCs being manufactured under that lot. A specific item within a specific MPC will have a number of heat numbers identified as possibly being used for the item in that particular MPC of which one or more of those heat numbers (and corresponding CMTRS) will have actually been used. All of the heat numbers identified will comply with the requirements for the particular item.
MPC Lid and Closure Ring Welds	NB-4243	Full penetration welds required for Category C Joints (flat head to main shell per NB-3352.3)	MPC lid and closure ring are not full penetration welds. They are welded independently to provide a redundant seal.

Table 2.II.2.6 List of ASME Code Alternatives for HI-STORM Multi-Purpose Canisters (MPCs)			
MPC Closure Ring, Vent and Drain Cover Plate Welds	NB-5230	Radiographic (RT) or ultrasonic (UT) examination required.	Root (if more than one weld pass is required) and final liquid penetrant examination to be performed in accordance with NB-5245. The closure ring provides independent redundant closure for vent and drain cover plates. Vent and drain port cover plate welds are helium leakage tested.
MPC Lid to Shell Weld	NB-5230	Radiographic (RT) or ultrasonic (UT) examination required.	<ul style="list-style-type: none"> Only progressive liquid penetrant (PT) examination is permitted. PT examination will include the root and final weld layers and each approx. 3/8" of weld depth.

Table 2.II.2.6
List of ASME Code Alternatives for HI-STORM Multi-Purpose Canisters (MPCs)

MPC Enclosure Vessel and Lid	NB-6111	All completed pressure retaining systems shall be pressure tested.	<ul style="list-style-type: none"> The MPC vessel is strength welded in the field following fuel assembly loading. Pressure tests (Hydrostatic or pneumatic) will not be performed because lack of accessibility for leakage inspections precludes a meaningful pressure retention capability test. The different models of MPCs available in the industry are not subject to pressure tests because of the dose to the crew, the proven ineffectiveness of the pressure tests to reveal any leaks and the far more effective tests performed on the MPC confinement boundary, such as: All MPC enclosure vessel welds (except closure ring and vent/drain cover plate) are inspected by volumetric examination. All MPC shell and baseplate materials are UT tested. Finally, the MPC lid-to-shell weld shall be verified by progressive PT examination. PT must include the root and final layers and each approximately 3/8 inch of weld depth. The inspection results, including relevant findings (indications) shall be made a permanent part of the user's records by video, photographic, or other means which provide an equivalent record of weld integrity. The video or photographic records should be taken during the final interpretation period described in ASME Section V, Article 6, T-676. The vent/drain cover plate and the closure ring welds are confirmed by liquid penetrant examination. The inspection of the weld must be performed by qualified personnel and shall meet the acceptance requirements of ASME Code Section III, NB-5350.

Table 2.II.2.9**Temperature Limits**

Material	Long Term, Normal Condition Design Temperature Limits (Long-Term Events) (°F)	Short-Term Events (°F)	Off-Normal and Accident Condition* (°F)	30-Day Accident Condition† (°F)
Alloy X‡	800	800	800	572
MPC basket (Alloy X or Metamic-HT)	752	1058	1058	752
Neutron Absorber (Metamic)	752	1058	1058	752
Aluminum Alloy	752	1000	1000	752
Carbon Steel and Variants	800	800	800	450
Neutron Shielding (Water)	N/A	307	307	N/A
Neutron Shielding (Holtite)	N/A	350	350	N/A
Gamma Shielding (Lead)	N/A	600	600	N/A
Concrete (Appendix 1.D)	300	572 (local temperature)	572 (local temperature)	450 (local temperature)

* For the ISFSI fire event, the local temperature limit of HI-STORM concrete is 1100°F (Appendix 1.D), and the steel structure is required to remain physically stable (i.e., so there will be no risk of structural instability such as gross buckling, the maximum temperature shall be less than approximately 50% of the component's melting temperature and the specific temperature limits in this table do not apply). Concrete that exceeds 1100°F shall be considered unavailable for shielding of the overpack.

† 30-day accident event is defined as a 100% blocked vent condition at threshold heat loads defined in Section 4.6.

‡ Temperature limits in Table 1.A.6 shall take precedence if duplex stainless steels are used for the fabrication of confinement boundary components as described in Appendix 1.A

Table 2.II.2.10**MATERIALS AND COMPONENTS OF THE HI-STORM 100 SYSTEM****MPC Version 1** ^[1,2]

Primary Function	Component^[3]	Safety Class^[4]	Codes/Standards (as applicable to component)	Material	Strength (ksi)	Special Surface Finish/Coating	Contact Matl.(if dissimilar)

- Notes:
- 1) There are no known residuals on finished component surfaces
 - 2) All welding processes used in welding the components shall be qualified in accordance with the requirements of ASME Section IX. All welds shall be made using welders qualified in accordance with ASME Section IX. Weld material shall meet the requirements of ASME Section II and the applicable Subsection of ASME Section III.
 - 3) Component nomenclature taken from Bill of Materials in Chapter 1.
 - 4) A, B, and C denote important to safety classifications as described in the Holtec QA Program. NITS stands for Not Important to Safety.

2.II.3 Safety Protection Systems

Same as Section 2.3 in the main report except as noted below.

2.II.3.5.2 Shielding

Consistent with 10 CFR 72, there is no single dose rate limit established for the HI-STORM 100 Version E and Version E1 Systems. Compliance with the regulatory limits on occupational and controlled area doses is performance-based, as demonstrated by dose monitoring performed by each cask user.

Design objective dose rates for the HI-STORM 100 Version E (including the Version E1) overpack surfaces are presented in Table 2.II.3.1.

Table 2.II.3.1**Design Objective Dose Rate for HI-STORM 100 Version E (including the Version E1) Overpack Surfaces**

Area of Interest	Dose Rate (mrem/hr)
Radial Surface Excluding Vents	150
Inlet and Outlet Vents	600
Top of the Lid (Horizontal Surface at approximate center)	15

2.II.4 Decommissioning Considerations

Same as Section 2.4 in the main report.

2.II.5 Regulatory Compliance

In this supplement, the principal design criteria and applicable loading related to the HI-STORM 100 system containing the Version E (including the Version E1) VVM and the MPC-32M Canister and successor versions of MPC-32 and MPC-68 (referred to as Version 1) as well as the HI-TRAC MS transfer cask and the associated structures, systems, and components (SSCs) have been compiled. These criteria include requirements on the Canister contents as well as external environmental conditions that are classified as normal and off-normal and accident conditions, and during short term operations. In particular, the governing environmental loads, referred to as Design Basis Loadings (DBLs) that have a direct bearing on the system's performance and operational safety have been identified and their acceptance criteria fully articulated for use in the subsequent sister supplements of this FSAR. This supplement serves to add and update the existing information in Chapter 2 to ensure rigorous compliance with 10CFR72 regulations. Conformance to the pertinent regulatory guidance documents such as ISGs, Reg Guides, NUREG-1536 and Regulatory Guide 3.61 is also ensured. A detailed evaluation of the transport overpack, the transfer cask and the MPCs under the design criteria set down in this supplement, and an assessment of compliance with those criteria are provided in the series of supplements labelled 3.II thru 12. II.

SUPPLEMENT 2.III

PRINCIPAL DESIGN CRITERIA FOR THE MPC-68M

2.III.0 OVERVIEW OF THE PRINCIPAL DESIGN CRITERIA

A general description of the MPC-68M is provided in Supplement 1.III. This supplement specifies the loading conditions and associated design criteria applicable to the MPC-68M fuel basket. The loads, loading conditions, and design criteria presented in Chapter 2 are applicable to the HI-STORM 100 System using the MPC-68M unless otherwise specified in this supplement. The drawing package for the MPC-68M fuel basket is provided in Section 1.5. The safety classifications of Metamic-HT basket and basket shims are ITS-A and NITS, respectively.

The design criteria pertaining to the HI-STORM overpack and the HI-TRAC transfer cask are completely unaffected by the incorporation of the MPC-68M. Likewise, the structural demands on the MPC Enclosure Vessel (whose design remains unchanged) are also unaffected. The design criteria in this supplement pertain to the loading conditions that bear upon the fuel basket's function and performance.

2.III.0.1 MPC-68M (Including MPC-68MCBS) Design Criteria

i. Structural

The fuel basket is designed to meet a more stringent displacement limit under mechanical loadings than those implicit in the stress limits of the ASME code (see Section 2.III.2). The basket shims are designed to remain below the yield limit of the selected aluminum alloy. If used, fuel basket welds are designed and fabricated in accordance with Supplement 9.III and the drawing package in Section 1.5. Fuel basket structural welds are designed to the minimum weld strength specified in the drawing package in Section 1.5. Fuel basket welds are not used the CBS design variant of the MPC-68M. Metamic-HT is a Holtec proprietary (non-ASME code) material. The *critical characteristics* and the attainment of the required critical characteristics through a comprehensive qualification process and production testing are discussed in Supplement 1.III with acceptance criteria established in Supplement 9.III.

All normal and off-normal conditions (including pressures) for the MPC-68M are the same as those described in Section 2.2. All loads on the HI-STORM 100 overpack and HI-TRAC transfer cask described in Section 2.2 remain applicable when using the MPC-68M.

The main acceptance criterion for the evaluation of accident conditions on the MPC-68M fuel basket is for the basket structure to maintain the fuel contents in a subcritical configuration. The structural design criteria for the MPC-68M basket are provided in Table 2.III.4.

The fuel basket material is subject to the requirements in Supplement 1.III and is designed to a specific (lateral) deformation limit of its walls under accident conditions of loading (credible and

non-mechanistic). The basis for the lateral deflection limit in the active fuel region, θ , is provided in [2.III.6.1] as

$$\theta = \frac{\delta}{w}$$

where δ is defined as the maximum total deflection sustained by the basket panels under the loading event and w is the nominal inside (width) dimension of the storage cell. The limiting value of θ is provided in Table 2.III.4. The above deflection-based criterion has been used previously in the HI-STAR 180 Transportation Package [2.III.6.2] to qualify similar Metamic-HT fuel baskets.

ii. Thermal

The design and operation of the HI-STORM 100 System with the MPC-68M must meet the intent of the review guidance contained in ISG-11, Revision 3 [2.0.8] as described in Subsection 2.0.1.

All applicable material design temperature limits in Section 2.2 and 4.3 continue to apply to the MPC-68M. Temperature limits of MPC-68M fuel basket and basket shim materials are specified in Table 4.III.2.

The MPC-68M is designed for both uniform and regionalized fuel loading strategies as described in Subsection 2.0.1. The regions for the MPC-68M are given in Table 2.III.1. Additionally, four quarter-symmetric heat load patterns have been defined for MPC-68M as shown in Figures 2.III.1 through 2.III.4. The same temperature limits apply to these configurations.

iii. Shielding

Same as Subsection 2.0.1.

iv. Criticality

Same as Subsection 2.0.1 with the clarifications herein.

Criticality control is maintained by the geometric spacing of the fuel assemblies and spatially distributed B-10 isotope in the Metamic-HT. No soluble boron is required in the MPC-68M water. The minimum specified boron concentration in the Metamic-HT purchasing specification must be met in every lot of the material manufactured. No credit is taken for burnup. Enrichment limits are delineated in Table 2.III.2.

v. Confinement

Same as Subsection 2.0.1

vi. Operations

Same as Subsection 2.0.1. Generic operating procedures for the HI-STORM 100 System with MPC-68M are provided in Chapter 8 with certain limitations and clarifications provide in Supplement 8.III.

vii. Acceptance Tests and Maintenance

Same as Subsection 2.0.1. The acceptance criteria for the HI-STORM 100 System with MPC-68M are provided in Chapter 9 and Supplement 9.III.

vi. Decommissioning

The MPC is designed to be transportable in a HI-STAR overpack and is not required to be unloaded prior to shipment off-site. Decommissioning of the HI-STORM 100 System is addressed in Section 2.III.4.

2.III.1 SPENT FUEL TO BE STORED

Table 2.1.22 and the limitations/clarification in this supplement provide the limits for material to be stored in the MPC-68M. All BWR fuel assembly array/classes which are authorized for the MPC-68 are authorized in the MPC-68M except fuel assembly array/classes 6x6A, 6x6B, 6x6C, 7x7A, 8x8A, 10x10D, and 10x10E. Table 2.1.4 in Chapter 2 provides the acceptable fuel characteristics for the fuel array/class authorized for storage in the MPC-68M, however fuel with planar-average initial enrichments up to 4.8 wt.% U-235 are authorized in the MPC-68M. The maximum planar-average initial enrichments acceptable for loading in the MPC-68M, for each fuel assembly array/class given in Table 2.1.4, are provided in Table 2.III.2. Table 2.III.3 provides the description of five additional fuel assembly array/classes which are added as acceptable contents to the MPC-68M only, 10x10F, 10x10G, 10x10I, 10x10J, and 11x11A. The maximum allowable initial enrichment for fuel assemblies are consistent with the criticality analysis described in Supplement 6.III.

Fuel classified as damaged fuel assemblies or fuel debris will be loaded into damaged fuel containers (DFCs) or basket cell locations with DFIs installed at the upper and lower ends. Fuel debris will be loaded into DFCs for storage in the MPC-68M. Damaged fuel assemblies stored with DFIs may contain missing or partial fuel rods and/or fuel rods with known or suspected cladding defects greater than hairline cracks or pinhole leaks as long as the fuel assembly can be handled by normal means and whose structural integrity is such that geometric rearrangement of fuel is not expected. Damaged fuel that does not meet these conditions must be stored in a DFC. The appropriate thermal and criticality analyses have been performed to account for damaged fuel and fuel debris and are described in Supplements 4.III and 6.III, respectively. Figures 2.III.1 through 2.III.4 contain loading patterns for storage of fuel in the MPC-68M. The loading pattern in Figure 2.III.4, allows damaged fuel to be stored in inner locations. Non-fuel hardware is not applicable to all the BWR fuel classes/arrays.

The heat generation rate, axial burnup distribution, and all other bounding radiological, thermal, and criticality parameters specified for MPC-68 are used to ensure the performance of the HI-STORM SYSTEM with the MPC-68M.

2.III.2 MPC-68M DESIGN LOADINGS

Design loadings in Section 2.2 apply to the HI-STORM 100 System using the MPC-68M.

2.III.3 SAFETY PROTECTION SYSTEMS

Same as Section 2.3.

2.III.4 DECOMMISSIONING CONSIDERATION

Same as Section 2.4.

2.III.5 REGULATORY COMPLIANCE

Same as Section 2.5.

10x10 B	4.8	5.0
10x10 C	4.8	5.0

Notes:

1. All other fuel assembly array/class specifications from Table 2.1.4 apply.
2. Fuel assemblies classified as damaged fuel assemblies are limited to 4.0 wt.% U-235 except when loaded in the pattern as shown in Figure 2.III.4. Fuel assemblies classified as damaged fuel assemblies are limited to 4.5 wt.% U-235 when loaded in the pattern as shown in Figure 2.III.4.
3. For MPC-68M loaded with both undamaged fuel assemblies and damaged fuel assemblies or fuel debris, the maximum planar average initial enrichment for the undamaged fuel assemblies is limited to the enrichment of the damaged assembly.
4. In accordance with the definition of undamaged fuel assembly, certain fuel assemblies may be limited to 3.3 wt.% U-235. When loading these fuel assemblies, all fuel assemblies in the MPC are limited to 3.3 wt.% U-235.
5. The restrictions in Table 2.III.5 apply. Fuel assemblies classified as damage fuel assemblies are limited to 5.0 wt% U-235.

Table 2.III.3 (continued)
BWR FUEL ASSEMBLY CHARACTERISTICS

NOTES:

1. All dimensions are design nominal values. Maximum and minimum dimensions are specified to bound variations in design nominal values among fuel assemblies within a given array/class.
2. See Table glossary for the definition of “ZR.”
3. Design initial uranium weight is the nominal uranium weight specified for each assembly by the fuel manufacturer or reactor user. For each BWR fuel assembly, the total uranium weight limit specified in this table may be increased up to 1.5 percent for comparison with users’ fuel records to account for manufacturer tolerances.
4. This assembly contains 92 total fuel rods; 78 full length rods and 14 partial length rods.
5. One diamond-shaped water rod replacing the four center fuel rods and four rectangular water rods dividing the assembly into four quadrants.
6. These rods may also be sealed at both ends and contain ZR material in lieu of water.
7. Fuel assemblies classified as damaged fuel assemblies are limited to 4.6 wt.% U-235 for the 10x10F and 10x10G arrays/classes.
8. For MPC-68M loaded with both undamaged fuel assemblies and damaged fuel assemblies or fuel debris, the maximum planar average initial enrichment for the undamaged fuel assemblies is limited to the enrichment of the damaged assembly.
9. In accordance with the definition of UNDAMAGED FUEL ASSEMBLY, certain assemblies may be limited to up to 3.3 wt.% U-235. When loading these fuel assemblies, all other undamaged fuel assemblies in the MPC are limited to enrichments specified in this table and Table 2.III.2.
10. Fuel assemblies classified as damaged fuel assemblies are limited to 4.6 wt.% U-235 for the 10x10G array/class except when loaded to Figures 2.III.4. Fuel assemblies classified as damaged fuel assemblies are limited to 4.5 wt.% U-235 for the 10x10G array/class when loaded to Figure 2.III.4
11. The restrictions in Table 2.III.5 apply. Fuel assemblies classified as damaged fuel assemblies are limited to 5.0 wt.% U-235.
12. Contains in total 91 fuel rods; 79 full length rods, 12 partial length rods, and one square water rod, replacing nine fuel rods.

13. Contains in total 96 fuel rods; 80 full length rods, 8 long partial length rods, 8 short partial length rods and one water rod replacing 4 fuel rods.
14. Contains in total 112 fuel rods; 92 full length rods, 8 long partial length rods, 12 short partial length rods, and one square water rod, replacing nine fuel rods.

CHAPTER 3: STRUCTURAL EVALUATION[†]

3.0 OVERVIEW

In this chapter, the structural components of the HI-STORM 100 System that are important to safety (ITS) are identified and described. The objective of the structural analyses is to ensure that the integrity of the HI-STORM 100 System is maintained under all credible loads for normal, off-normal, and design basis accident/natural phenomena. The chapter results support the conclusion that the confinement, criticality control, radiation shielding, and retrievability criteria set forth by 10CFR72.236(l), 10CFR72.124(a), 10CFR72.104, 10CFR72.106, and 10CFR72.122(l) are met. In particular, the design basis information contained in the previous two chapters and in this chapter provides sufficient data to permit structural evaluations to demonstrate compliance with the requirements of 10CFR72.24. To facilitate regulatory review, the assumptions and conservatisms inherent in the analyses are identified along with a complete description of the analytical methods, models, and acceptance criteria. A summary of other material considerations, such as corrosion and material fracture toughness is also provided. Design calculations for the HI-TRAC transfer cask are included where appropriate to comply with the guidelines of NUREG-1536.

The organization of technical information in this chapter follows the format and content guidelines of USNRC Regulatory Guide 3.61 (February 1989). The FSAR ensures that the responses to the review requirements listed in NUREG-1536 (January 1997) are complete and comprehensive. The areas of NRC staff technical inquiries, with respect to structural evaluation in NUREG-1536, span a wide array of technical topics within and beyond the material in this chapter. To facilitate the staff's review to ascertain compliance with the stipulations of NUREG-1536, Table 3.0.1 "Matrix of NUREG-1536 Compliance - Structural Evaluation", is included in this chapter. A comprehensive cross-reference of the topical areas set forth in NUREG-1536, and the location of the required compliance information is contained in Table 3.0.1.

Section 3.7 describes in detail HI-STORM 100 System's compliance to NUREG-1536 Structural Evaluation Requirements.

The HI-STORM 100 System matrix of compliance table given in this section is developed with the supposition that the storage overpack is designated as a steel structure that falls within the purview of subsection 3.V.3 "Other Systems Components Important to Safety" (page 3-28 of NUREG-1536), and therefore, does not compel the use of reinforced concrete. (Refer to Table 1.0.2 for an explicit statement of exception on this matter). The concrete mass installed in the HI-STORM 100 overpack is accordingly equipped with "plain concrete" for which the sole applicable industry code is ACI 318.1 (92). Plain concrete, in contrast to reinforced concrete, is the preferred shielding material HI-STORM 100 because of three key considerations:

[†] This chapter has been prepared in the format and section organization set forth in Regulatory Guide 3.61. However, the material content of this chapter also fulfills the requirements of NUREG-1536. Pagination and numbering of sections, figures, and tables are consistent with the convention set down in Chapter 1, Section 1.0, herein. Finally, all terms-of-art used in this chapter are consistent with the terminology of the glossary and component nomenclature of the drawings (Section 1.5).

- (i) Plain concrete is more amenable to a void free pour than reinforced concrete in narrow annular spaces typical of ventilated vertical storage casks.
- (ii) The tensile strength bearing capacity of reinforced concrete is not required to buttress the steel weldment of the HI-STORM 100 overpack.
- (iii) The compression and bearing strength capacity of plain concrete is unaffected by the absence of rebars. A penalty factor, on the compression strength, pursuant to the provisions of ACI-318.1 is, nevertheless, applied to insure conservatism. However, while plain concrete is the chosen shielding embodiment for the HI-STORM 100 storage overpack, all necessary technical, procedural Q.C., and Q.A. provisions to insure nuclear grade quality will be implemented by utilizing the relevant sections from ACI-349 (85) as specified in Appendix 1.D.

In other words, guidelines of NUREG 1536 pertaining to reinforced concrete are considered to insure that the material specification, construction quality control and quality assurance of the shielding concrete comply with the provisions of ACI 349 (85). These specific compliance items are listed in the compliance matrix.

3.1 STRUCTURAL DESIGN

3.1.1 Discussion

The HI-STORM 100 System consists of three principal components: the Multi-Purpose Canister (MPC), the storage overpack, and the transfer cask. The MPC is a hermetically sealed, welded structure of cylindrical profile with flat ends and a honeycomb fuel basket. A complete description is provided in Subsection 1.2.1.1 wherein the anatomy of the MPC and its fabrication details are presented with the aid of figures. The MPCs utilized in the HI-STORM 100 System are identical to those for the HI-STAR 100 System submitted under Dockets 72-1008 and 71-9261. The evaluation of the MPCs presented herein draws upon the work described in those earlier submittals. In this section, the discussion is confined to characterizing and establishing the structural features of the MPC, the storage overpack, and the HI-TRAC transfer cask. Since a detailed discussion of the HI-STORM 100 Overpack and HI-TRAC transfer cask geometries is presented in Section 1.2, attention is focused here on structural capabilities and their inherent margins of safety for housing the MPC. Detailed design drawings for the HI-STORM 100 System are provided in Section 1.5.

The design of the MPC seeks to attain three objectives that are central to its functional adequacy, namely:

- **Ability to Dissipate Heat:** The thermal energy produced by the stored spent fuel must be transported to the outside surface of the MPC such that the prescribed temperature limits for the fuel cladding and for the fuel basket metal walls are not exceeded.
- **Ability to Withstand Large Impact Loads:** The MPC, with its payload of nuclear fuel, must be sufficiently robust to withstand large impact loads associated with the postulated handling accident events. Furthermore, the strength of the MPC must be sufficiently isotropic to meet structural requirements under a variety of handling and tip-over accidents.
- **Restraint of Free End Expansion:** The membrane and bending stresses produced by restraint of free-end expansion of the fuel basket are categorized as primary stresses. In view of the concentration of heat generation in the fuel basket, it is necessary to ensure that structural constraints to its external expansion do not exist.

Where the first two criteria call for extensive inter-cell connections, the last criterion requires the opposite. The design of the MPC seeks to realize all of the above three criteria in an optimal manner.

From the description presented in Chapter 1, the MPC enclosure vessel is the confinement vessel designed to meet ASME Code, Section III, Subsection NB stress limits. The enveloping canister shell, the baseplate, and the lid system form a complete confinement boundary for the stored fuel that is referred to as the "enclosure vessel". Within this cylindrical shell confinement vessel is an integrally welded assemblage of cells of square cross sectional openings for fuel storage, referred to herein as the fuel basket. The fuel basket is analyzed under the provisions of Subsection NG of Section III of the ASME Code. All multi-purpose canisters designed for deployment in the HI-

STORM 100 and HI-STAR 100 systems are exactly alike in their external dimensions. The essential difference between the MPCs lies in the fuel baskets. Each fuel storage MPC is designed to house fuel assemblies with different characteristics. Although all fuel baskets are configured to maximize structural ruggedness through extensive inter-cell connectivity, they are sufficiently dissimilar in structural details to warrant separate evaluations. Therefore, analyses for each of the MPC types were carried out to ensure structural compliance. Inasmuch as no new MPC designs are introduced in this application, and all MPC designs were previously reviewed by the USNRC under Docket 72-1008, the MPC analyses submitted under Docket Numbers 72-1008 and 71-9261 for the HI-STAR 100 System are not reproduced herein unless they need to be modified by HI-STORM 100 conditions or geometry differences. Analyses provided in the HI-STAR 100 System safety analysis reports that are applicable to the HI-STORM 100 System are referenced in this FSAR by docket number and subsection or appendix.

Components of the HI-STORM 100 System that are important to safety and their applicable design codes are defined in Chapter 2.

Some of the key structural functions of the MPC in the storage mode are:

1. To position the fuel in a subcritical configuration, and
2. To provide a confinement boundary.

Some of the key structural functions of the overpack in the storage mode are:

1. To serve as a missile barrier for the MPC,
2. To provide flow paths for natural convection,
3. To ensure stability of the HI-STORM 100 System, and
4. To maintain the position of the radiation shielding.
5. To allow movement of the overpack with a loaded MPC inside.

Some structural features of the MPCs that allow the system to perform these functions are summarized below:

- There are no gasketed ports or openings in the MPC. The MPC does not rely on any sealing arrangement except welding. The absence of any gasketed or flanged joints makes the MPC structure immune from joint leaks. The confinement boundary contains no valves or other pressure relief devices.

- The closure system for the MPCs consists of two components, namely, the MPC lid and the closure ring. The MPC lid can be either a single thick circular plate continuously welded to the MPC shell along its circumference or two dual lids welded around their common periphery. The MPC closure system is shown in the design drawings in Section 1.5. The MPC lid is equipped with vent and drain ports which are utilized for evacuating moisture and air from the MPC following fuel loading, and subsequent backfilling with an inert gas (helium) at a specified mass. The vent and drain ports are covered by a cover plate and welded before the closure ring is installed. The closure ring is a circular annular plate edge-welded to the MPC lid and shell. The two closure members are interconnected by welding around the inner diameter of the ring. Lift points for the MPC are provided in the MPC lid.
- The MPC fuel baskets consist of an array of interconnecting plates. The number of storage cells formed by this interconnection process varies depending on the type of fuel being stored. Basket designs containing cell configurations for PWR and BWR fuel have been designed and are explained in detail in Section 1.2. All baskets are designed to fit into the same MPC shell. Welding of the basket plates along their edges essentially renders the fuel basket into a multiframe beam. Figure 3.1.1 provides an isometric illustration of a fuel basket for the MPC-68 design.
- The MPC basket is separated from its basket supports by a gap. The gap size decreases as a result of thermal expansion (depending on the magnitude of internal heat generation from the stored spent fuel). The provision of a small gap between the basket and the basket support structure is consistent with the natural thermal characteristics of the MPC. For MPCs that contain basket shims welded to the MPC basket, the MPC shell wall is separated from the basket shims by a gap. The planar temperature distribution across the basket, as shown in Section 4.4, approximates a shallow parabolic profile. This profile will create high thermal stresses unless structural constraints at the interface between the basket and the basket support structure (or between the MPC shell wall and the basket shims) are removed.
- The MPCs will be loaded with fuel with widely varying heat generation rates. The basket/basket support structure (or MPC shell/basket shim or MPC shell/Extruded Shim/basket) gap tends to be reduced for higher heat generation rates due to increased thermal expansion rates. These aforementioned gaps are specified to be sufficiently large such that a gap exists around the periphery after any thermal expansion but are not excessively large so as to hinder the performance of the design functions of the MPC.
- In some early vintage MPCs, a small number of flexible thermal conduction elements (thin aluminum tubes) are interposed between the basket and the MPC shell. The elements are designed to be resilient. They do not provide structural support for the basket, and thus their resistance to thermal growth is negligible.

It is quite evident from the geometry of the MPC that a critical loading event pertains to the drop condition when the MPC is postulated to undergo a handling side drop (the longitudinal axis of the MPC is horizontal) or tip-over. Under the side drop or tip-over condition the flat panels of the fuel basket are subject to an equivalent pressure loading that simulates the deceleration-magnified inertia load from the stored fuel and the MPC's own metal mass.

The MPC fuel basket maintains the spent nuclear fuel in a subcritical arrangement. Its safe operation is assured by maintaining the physical configuration of the storage cell cavities intact in the aftermath of a drop event. This requirement is considered to be satisfied if the MPC fuel basket meets the stress intensity criteria set forth in the ASME Code, Section III, Subsection NG. Therefore, the demonstration that the fuel basket meets Subsection NG limits ensures that there is no impairment of ready retrievability (as required by NUREG-1536), and that there is no unacceptable effect on the subcritical arrangement.

The MPC confinement boundary contains no valves or other pressure relief devices. The MPC enclosure vessel is shown to meet the stress intensity criteria of the ASME Code, Section III, Subsection NB for design and all service conditions. Therefore, the demonstration that the enclosure vessel meets Subsection NB limits ensures that there is no unacceptable release of radioactive materials.

The HI-STORM 100 storage overpack is a steel cylindrical structure consisting of inner and outer low carbon steel shells, a lid, and a baseplate. Between the two shells is a thick cylinder of unreinforced (plain) concrete. Additional regions of fully confined (by enveloping steel structure) unreinforced concrete are attached to the lid and to the baseplate depending on the specific configuration (see applicable figures in previous chapters). The storage overpack serves as a missile and radiation barrier, provides flow paths for natural convection, provides kinematic stability to the system, and acts as a cushion for the MPC in the event of a tip-over accident. The storage overpack is not a pressure vessel since it contains cooling vents that do not allow for a differential pressure to develop across the overpack wall. The structural steel components of the HI-STORM 100 Overpack are designed to meet the stress limits of the ASME Code, Section III, Subsection NF, Class 3. Short versions of the HI-STORM 100 overpack, designated as the HI-STORM 100S, the HI-STORM 100S Version B and the HI-STORM 100S Version B Type IS, are included in this revision. To accommodate nuclear plants with limited height access, the HI-STORM 100S has a re-configured lid and a lower overall height. There are minor weight redistributions but the overall bounding weight of the system is unchanged. The HI-STORM 100S Version B incorporates other improvements and modifications designed to improve fabricability and enhance some margins. Structural analyses are revisited if and only if the modified configuration cannot be demonstrated to be bounded by the original calculation. New or modified calculations focused on the HI-STORM 100S and the HI-STORM 100S Version B are clearly identified within the text of this chapter. Unless otherwise designated, general statements using the terminology "HI-STORM 100" also apply to the HI-STORM 100S, to the HI-STORM 100S Version B and to the HI-STORM 100S Version B Type IS. The HI-STORM 100S overpacks can carry all MPCs and transfer casks that can be carried in the HI-STORM 100.

As discussed in Chapters 1 and 2, and Section 3.0, the principal shielding material utilized in the HI-STORM 100 Overpack is plain concrete. Plain concrete was selected for the HI-STORM 100 Overpack in lieu of reinforced concrete, because there is no structural imperative for incorporating tensile load bearing strength into the contained concrete. From a purely practical standpoint, the absence of rebars facilitate pouring and curing of concrete with minimal voids, which is an important consideration in light of its shielding function in the HI-STORM 100 Overpack. Plain concrete, however, acts essentially identical to reinforced concrete under compressive and bearing loads, even though ACI standards apply a penalty factor on the compressive and bearing strength of concrete in the absence of rebars (vide ACI 318.1).

Accordingly, the plain concrete in the HI-STORM 100 is considered as a structural material only to the extent that it may participate in supporting direct compressive loads. The allowable compression/bearing resistance is defined and quantified in the ACI 318.1-89(92) Building Code for Structural Plain Concrete.

In general, strength analysis of the HI-STORM 100 Overpack and its confined concrete is carried out only to demonstrate that the concrete is able to perform its radiation protection function and that retrievability of the MPC subsequent to any postulated accident condition of storage or handling is maintained.

A discrete ITS component in the HI-STORM 100 System is the HI-TRAC transfer cask. The HI-TRAC serves to provide a missile and radiation barrier during transport of the MPC from the fuel pool to the HI-STORM 100 Overpack. The HI-TRAC body is a double-walled steel cylinder that constitutes its structural system. Contained between the two steel shells is an intermediate lead cylinder. Attached to the exterior of the HI-TRAC body outer shell is a water jacket that acts as a radiation barrier. The HI-TRAC is not a pressure vessel since it contains a penetration in the HI-TRAC top lid that does not allow for a differential pressure to develop across the HI-TRAC wall. Nevertheless, in the interest of conservatism, structural steel components of the HI-TRAC are subject to the stress limits of the ASME Code, Section III, Subsection NF, Class 3.

Since both the HI-STORM 100 and HI-TRAC may serve as an MPC carrier, their lifting attachments are designed to meet the design safety factor requirements of NUREG-0612 [3.1.1] and Regulatory Guide 3.61 [1.0.2].

Table 2.2.6 provides a listing of the applicable design codes for all structures, systems, and components which are designated as ITS. Since no structural credit is required for the weld between the adjustable basket support pieces (i.e., shims and basket support flat plates), the adjustable basket supports are classified as NITS. In addition, for MPCs using basket shims welded to the MPC fuel basket, the basket supports are classified as NITS.

3.1.2 Design Criteria

Principal design criteria for normal, off-normal, and accident/environmental events are discussed in Section 2.2. In this section, the loads, load combinations, and allowable stresses used in the structural evaluation of the HI-STORM 100 System are presented in more detail.

Consistent with the provisions of NUREG-1536, the central objective of the structural analysis presented in this chapter is to ensure that the HI-STORM 100 System possesses sufficient structural capability to withstand normal and off-normal loads and the worst case loads under natural phenomenon or accident events. Withstanding such loadings enables the HI-STORM 100 System to successfully preclude the following negative consequences:

- unacceptable risk of criticality
- unacceptable release of radioactive materials
- unacceptable radiation levels
- impairment of ready retrievability of the SNF

The above design objectives for the HI-STORM 100 System can be particularized for individual components as follows:

- The objectives of the structural analysis of the MPC are to demonstrate that:
 1. Confinement of radioactive material is maintained under normal, off-normal, accident conditions, and natural phenomenon events.
 2. The MPC basket does not deform under credible loading conditions such that the subcriticality or retrievability of the SNF is jeopardized.
- The objectives of the structural analysis of the storage overpack are to demonstrate that:
 1. Tornado-generated missiles do not compromise the integrity of the MPC confinement boundary.
 2. The overpack can safely provide for on-site transfer of the loaded MPC and ensure adequate support to the HI-TRAC transfer cask during loading and unloading of the MPC.
 3. The radiation shielding remains properly positioned in the case of any normal, off-normal, or natural phenomenon or accident event.
 4. The flow path for the cooling airflow shall remain available under normal and off-normal conditions of storage and after a natural phenomenon or accident event.
 5. The loads arising from normal, off-normal, and accident level conditions exerted on the contained MPC do not exceed the structural design criteria of the MPC.
 6. No geometry changes occur under any normal, off-normal, and accident level conditions of storage that may preclude ready retrievability of the contained MPC.
 7. A freestanding storage overpack can safely withstand a non-mechanistic

tip-over event with a loaded MPC within the overpack. The HI-STORM 100A is specifically engineered to be permanently attached to the ISFSI pad. The ISFSI pad engineered for the anchored cask is designated as “Important to Safety”. Therefore, the non-mechanistic tipover is not applicable to the HI-STORM 100A.

8. The inter-cask transfer of a loaded MPC can be carried out without exceeding the structural capacity of the HI-STORM 100 Overpack, provided all required auxiliary equipment and components specific to an ISFSI site comply with their design criteria set forth in this FSAR and the handling operations are in full compliance with operational limits and controls prescribed in this FSAR.
- The objective of the structural analysis of the HI-TRAC transfer cask is to demonstrate that:
 1. Tornado generated missiles do not compromise the integrity of the MPC confinement boundary while the MPC is contained within HI-TRAC.
 2. No geometry changes occur under any postulated handling or storage conditions that may preclude ready retrievability of the contained MPC.
 3. The structural components perform their intended function during lifting and handling with the loaded MPC.
 4. The radiation shielding remains properly positioned under all applicable handling service conditions for HI-TRAC.
 5. The lead shielding, top lid, and transfer lid doors remain properly positioned during postulated handling accidents.

The aforementioned objectives are deemed to be satisfied for the MPC, the overpack, and the HI-TRAC, if stresses (or stress intensities, as applicable) calculated by the appropriate structural analyses are less than the allowables defined in Subsection 3.1.2.2, and if the diametral change in the storage overpack (or HI-TRAC), if any, after any event of structural consequence to the overpack (or transfer cask), does not preclude ready retrievability of the contained MPC.

Stresses arise in the components of the HI-STORM 100 System due to various loads that originate under normal, off-normal, or accident conditions. These individual loads are combined to form load combinations. Stresses and stress intensities resulting from the load combinations are compared to their respective allowable stresses and stress intensities. The following subsections present loads, load combinations, and the allowable limits germane to them for use in the structural analyses of the MPC, the overpack, and the HI-TRAC transfer cask.

3.1.2.1 Loads and Load Combinations

The individual loads applicable to the HI-STORM 100 System and the HI-TRAC cask are defined in Section 2.2 of this report (Table 2.2.13). Load combinations are developed by assembling the individual loads that may act concurrently, and possibly, synergistically (Table 2.2.14). In this subsection, the individual loads are further clarified as appropriate and the required load combinations are identified. Table 3.1.1 contains the load combinations for the storage overpack where kinematic stability is of primary importance. The load combinations where stress or load level is of primary importance are set forth in Table 3.1.3 for the MPC fuel basket, in Table 3.1.4 for the MPC confinement boundary, and in Table 3.1.5 for the storage overpack and the HI-TRAC transfer cask. Load combinations are applied to the mathematical models of the MPCs, the overpack, and the HI-TRAC. Results of the analyses carried out under bounding load combinations are compared with their respective allowable stresses (or stress intensities, as applicable). The analysis results from the bounding load combinations are also assessed, where warranted, to ensure satisfaction of the functional performance criteria discussed in the preceding subsection.

3.1.2.1.1 Individual Load Cases

The individual loads that address each design criterion applicable to the structural design of the HI-STORM 100 System are catalogued in Table 2.2.13. Each load is given a symbol for subsequent use in the load combination listed in Table 2.2.14.

Accident condition and natural phenomena-induced events, collectively referred to as the "Level D" condition in Section III of the ASME Boiler & Pressure Vessel Codes, in general, do not have a universally prescribed limit. For example, the impact load from a tornado-borne missile, or the overturning load under flood or tsunami, cannot be prescribed as design basis values with absolute certainty that all ISFSI sites will be covered. Therefore, as applicable, allowable magnitudes of such loadings are postulated for the HI-STORM 100 System. The allowable values are drawn from regulatory and industry documents (such as for tornado missiles and wind) or from an intrinsic limitation in the system (such as the permissible "drop height" under a postulated handling accident). In the following, the essential characteristic of each "Level D" type loading is explained.

3.1.2.1.1.1 Tip-Over

It is required to demonstrate that the free-standing HI-STORM 100 storage overpack, containing a loaded MPC, will not tip over as a result of a postulated natural phenomenon event, including tornado wind, a tornado-generated missile, a seismic or a hydrological event (flood). However, to demonstrate the defense-in-depth features of the design, a non-mechanistic tip-over scenario per NUREG-1536 is analyzed. Since the HI-STORM 100S, the HI-STORM 100S Version B and the HI-STORM 100S Version B Type IS have an overall length that is less than the regular HI-STORM 100, the maximum impact velocity of the overpack will be reduced. Therefore, the results of the tipover analysis for the HI-STORM 100 (reported in Appendix 3.A) are bounding for the HI-STORM 100S, the HI-STORM 100S Version B and the HI-STORM 100S Version B Type IS. The potential of the HI-STORM 100 Overpack tipping over during the lowering (or raising) of the loaded MPC into (or out of) it with the HI-TRAC cask mounted on it is ruled out because of the

safeguards and devices mandated by this FSAR for such operations (Subsection 2.3.3.1 and Technical Specification 4.9). The physical and procedural barriers under the MPC handling operations have been set down in the FSAR to preclude overturning of the HI-STORM/HI-TRAC assemblage with an extremely high level of certainty. Much of the ancillary equipment needed for the MPC transfer operations must be custom engineered to best accord with the structural and architectural exigencies of the ISFSI site. Therefore, with the exception of the HI-TRAC cask, their design cannot be prescribed, a priori, in this FSAR. However, carefully drafted Design Criteria and conditions of use set forth in this FSAR eliminate the potential of weakening of the safety measures contemplated herein to preclude an overturning event during MPC transfer operations. Subsection 2.3.3.1 contains a comprehensive set of design criteria for the ancillary equipment and components required for MPC transfer operations to ensure that the design objective of precluding a kinematic instability event during MPC transfer operations is met. Further information on the steps taken to preclude system overturning during MPC transfer operations may be found in Chapter 8, Section 8.0.

In the HI-STORM 100A configuration, wherein the overpack is physically anchored to the ISFSI pad, the potential for a tip-over is a priori precluded. Therefore, the ISFSI pad need not be engineered to be sufficiently compliant to limit the peak MPC deceleration to Table 2.2.8 values. The stiffness of the pad, however, may be controlled by the ISFSI structural design and, therefore, may result in a reduced “carry height” from that specified for a freestanding cask. If a non-single failure proof lifting device is employed to carry the cask over the pad, determination of maximum carry height must be performed by the ISFSI owner once the ISFSI pad design is formalized.

3.1.2.1.1.2 Handling Accident

A handling accident during transport of a loaded HI-STORM 100 storage overpack is assumed to result in a vertical drop. The HI-STORM 100 storage overpack will not be handled in a horizontal position while containing a loaded MPC. Therefore, a side drop is not considered a credible event.

HI-TRAC can be carried in a horizontal orientation while housing a loaded MPC. Therefore, a handling accident during transport of a loaded HI-TRAC in a horizontal orientation is considered to be a credible accident event. A handling accident of a loaded HI-TRAC 100G is not credible as the HI-TRAC 100G will always be handled by a single failure-proof lifting equipment.

As discussed in the foregoing, the vertical drop of the HI-TRAC and the tip-over of the assemblage of a loaded HI-TRAC on the top of the HI-STORM 100 storage overpack during MPC transfer operations do not need to be considered.

3.1.2.1.1.3 Flood

The postulated flood event results into two discrete scenarios which must be considered; namely,

1. stability of the HI-STORM 100 System due to flood water velocity, and
2. structural effects of hydrostatic pressure and water velocity induced lateral pressure.

The maximum hydrostatic pressure on the cask in a flood where the water level is conservatively set at 125 feet is calculated as follows:

Using

p = the maximum hydrostatic pressure on the system (psi),

γ = weight density of water = 62.4 lb/ft³

h = the height of the water level = 125 ft;

The maximum hydrostatic pressure is

$$p = \gamma h = (62.4 \text{ lb/ft}^3)(125 \text{ ft})(1 \text{ ft}^2/144 \text{ in}^2) = 54.2 \text{ psi}$$

The accident condition design external pressure for the MPC (Table 2.2.1) bounds the maximum hydrostatic pressure exerted by the flood.

3.1.2.1.1.4 Explosion

The potential for explosive materials shall be evaluated based on site specific conditions as required in the HI-STORM 100 Technical Specification.

Pressure waves from an explosive blast in a property near the ISFSI site result in an impulsive aerodynamic loading on the stored HI-STORM 100 Overpacks. Depending on the rapidity of the pressure build-up, the inside and outside pressures on the HI-STORM METCON™ shell may not equalize, leading to a net lateral loading on the upright overpack as the pressure wave traverses the overpack. The magnitude of the dynamic pressure wave is conservatively set to a value below the magnitude of the pressure differential that would cause a tip-over of the cask if the pulse duration were set at one second. With the maximum design basis pressure pulse established (by setting the design basis pressure differential sufficiently low that cask tip-over is not credible due to the travelling pressure wave), the stress state under this condition requires analysis. The lateral pressure difference, applied over the overpack full height, causes axial and circumferential stresses and strains to develop. Level D stress limits must not be exceeded under this state of stress. It must also be demonstrated that no permanent ovalization of the cross section occurs that leads to loss of clearance to remove the MPC after the explosion.

Once the pressure wave traverses the cask body, then an elastic stability evaluation is warranted. An all-enveloping pressure from the explosion may threaten safety by buckling the overpack outer shell.

In contrast to the overpack, the MPC is a closed pressure vessel. Because of the enveloping overpack around it, the explosive pressure wave would manifest as an external pressure on the external surface of the MPC.

The maximum overpressure on the MPC resulting from an explosion is limited to the accident

condition design external pressure specified in Table 2.2.1. The maximum external pressure differential on the overpack is limited to the accident condition design pressure differential specified in Table 2.2.1.

3.1.2.1.1.5 Tornado

The three components of a tornado load are:

1. pressure changes,
2. wind loads, and
3. tornado-generated missiles.

Wind speeds and tornado-induced pressure drop are specified in Table 2.2.4. Tornado missiles are listed in Table 2.2.5. A central functional objective of a storage overpack is to maintain the integrity of the “confinement boundary”, namely, the multi-purpose canister stored inside it. This operational imperative requires that the mechanical loadings associated with a tornado at the ISFSI do not jeopardize the physical integrity of the loaded MPC. Potential consequences of a tornado on the cask system are:

- Instability (tip-over) due to tornado missile impact plus either steady wind or impulse from the pressure drop (only applicable for free-standing cask).
- Stress in the overpack induced by the lateral force caused by the steady wind or missile impact.
- Loadings applied on the MPC transmitted to the inside of the overpack through its openings or as a secondary effect of loading on the enveloping overpack structure.
- Excessive storage overpack permanent deformation that may prevent ready retrievability of the MPC.
- Excessive storage overpack permanent deformation that may significantly reduce the shielding effectiveness of the storage overpack.

Analyses must be performed to ensure that, due to the tornado-induced loadings:

- The loaded overpack does not become kinematically unstable (only applicable for free-standing cask).
- The overpack does not deform plastically such that the retrievability of the stored MPC is threatened.
- The MPC does not sustain an impact from an incident missile.
- The MPC is not subjected to inertia loads (acceleration or deceleration) in

excess of its design basis limit set forth in Chapter 2 herein.

- The overpack does not deform sufficiently due to tornado-borne missiles such that the shielding effectiveness of the overpack is significantly affected.

The results obtained for the HI-STORM 100 bound the corresponding results for the HI-STORM 100S versions because of the reduced height. In the anchored configuration (HI-STORM 100A), the kinematic stability requirement stated above is replaced with the requirement that the stresses in the anchor studs do not exceed level D stress limits for ASME Section III, Class 3, Subsection NF components.

3.1.2.1.1.6 Earthquake

Subsections 2.2.3.7 and 3.4.7 contain the detailed specification of the seismic inputs applied to the HI-STORM 100 System. The design basis earthquake is assumed to be at the top of the ISFSI pad. Potential consequences of a seismic event are sliding/overturning of a free-standing cask, overstress of the sector lugs and anchor studs for the anchored HI-STORM 100A, and lateral force on the overpack causing excessive stress and deformation of the storage overpack.

In the anchored configuration (HI-STORM 100A), a seismic event results in a fluctuation in the state of stress in the anchor bolts and a local bending action on the sector lugs.

Analyses must be performed to ensure that:

- The maximum axial stress in the anchor bolts remains below the Level D stress limits for Section III Class 3 Subsection NF components.
- The maximum primary membrane plus bending stress intensity in the sector lugs during the DBE event satisfies Level D stress limits of the ASME Code, Subsection NF.
- The anchor bolts will not sustain fatigue failure due to pulsation in their axial stress during the DBE event.
- The stress in the weld line joining the sector lugs to the HI-STORM 100 weldment is within Subsection NF limits for Level D condition.

3.1.2.1.1.7 Lightning

The HI-STORM 100 Overpack contains over 25,000 lb of highly conductive carbon steel with over 700 square feet of external surface area. Such a large surface area and metal mass is adequate to dissipate any lightning that may strike the HI-STORM 100 System. There are no combustible materials on the HI-STORM 100 surface. Therefore, lightning will not impair the structural performance of components of the HI-STORM 100 System that are important to safety.

3.1.2.1.1.8 Fire

The potential structural consequences of a fire are: the possibility of an interference developing between the storage overpack and the loaded MPC due to free thermal expansion; and, the degradation of material properties to the extent that their structural performance is affected during a subsequent recovery action. The fire condition is addressed to the extent necessary to demonstrate that these adverse structural consequences do not materialize.

3.1.2.1.1.9 100% Fuel Rod Rupture

The effect on structural performance by 100% fuel rod rupture is felt as an increase in internal pressure. The accident internal pressure limit set in Chapter 2 bounds the pressure from 100% fuel rod rupture. Therefore, no new load condition has been identified.

3.1.2.1.2 Load Combinations

Load combinations are created by summing the effects of several individual loads. The load combinations are selected for the normal, off-normal, and accident conditions. The loadings appropriate for HI-STORM 100 under the various conditions are presented in Table 2.2.14. These loadings are combined into meaningful combinations for the various HI-STORM 100 System components in Tables 3.1.1, and 3.1.3-3.1.5. Table 3.1.1 lists the load combinations that address overpack stability. Tables 3.1.3 through 3.1.5 list the applicable load combinations for the fuel basket, the enclosure vessel, and the overpack and HI-TRAC, respectively.

As discussed in Subsection 2.2.7, the number of discrete load combinations for each situational condition (i.e., normal, off-normal, etc.) is consolidated by defining bounding loads for certain groups of loadings. Thus, the accident condition pressure P_o^* bounds the surface loadings arising from accident and extreme natural phenomenon events, namely, tornado wind W' , flood F , and explosion E^* .

As noted previously, certain loads, namely earthquake E , flowing water under flood condition F , force from an explosion pressure pulse F^* , and tornado missile M , act to destabilize a cask. Additionally, these loads act on the overpack and produce essentially localized stresses at the HI-STORM 100 System to ISFSI interface. Table 3.1.1 provides the load combinations that are relevant to the stability analyses of freestanding casks. The site ISFSI DBE zero period acceleration (ZPA) must be bounded by the design basis seismic ZPA defined by the Load Combination C of Table 3.1.1 to demonstrate that the margin against tip-over during a seismic event is maintained.

The major constituents in the HI-STORM 100 System are: (i) the fuel basket, (ii) the enclosure vessel, (iii) the HI-STORM 100 (or HI-STORM 100S versions) Overpack, and (iv) the HI-TRAC transfer cask. The fuel basket and the enclosure vessel (EV) together constitute the multi-purpose canister. The multi-purpose canister (MPC) is common to HI-STORM 100 and HI-STAR 100, and as such, has been extensively analyzed in the storage FSAR and transport SAR (Dockets 72-1008 and 71-9261) for HI-STAR 100. Many of the loadings on the MPC (fuel basket and enclosure vessel) are equal to or bounded by loadings already considered in the HI-STAR 100 SAR

documents. Where such analyses have been performed, their location in the HI-STAR 100 SAR documents is indicated in this HI-STORM 100 SAR for continuity in narration. A complete account of analyses and results for all load combinations for all four constituents parts is provided in Section 3.4 as required by Regulatory Guide 3.61.

In the following, the loadings listed as applicable for each situational condition in Table 2.2.14 are addressed in meaningful load combinations for the fuel basket, enclosure vessel, and the overpack. Each component is considered separately.

Fuel Basket

Table 3.1.3 summarizes all loading cases (derived from Table 2.2.14) that are germane to demonstrating compliance of the fuel baskets to Subsection NG when these baskets are housed within HI-STORM 100 or HI-TRAC.

The fuel basket is not a pressure vessel; therefore, the pressure loadings are not meaningful loads for the basket. Further, the basket is structurally decoupled from the enclosure vessel. The gap between the basket and the enclosure vessel is sized to ensure that no constraint of free-end thermal expansion of the basket occurs. The demonstration of the adequacy of the basket-to -enclosure vessel (EV) gap to ensure absence of interference is a physical problem that must be analyzed.

The normal handling loads on the fuel basket in an MPC within the HI-STORM 100 System or the HI-TRAC transfer cask are identical to or bounded by the normal handling loads analyzed in the HI-STAR 100 FSAR Docket Number 72-1008.

Three accident condition scenarios must be considered: (i) drop with the storage overpack axis vertical; (ii) drop with the HI-TRAC axis horizontal (not applicable for the HI-TRAC 100G); and (iii) storage overpack tipover. The vertical drop scenario is considered in the HI-STAR 100 FSAR.

The horizontal drop and tip-over must consider multiple orientation of the fuel basket, as the fuel basket is not radially symmetric. Therefore, two horizontal drop orientations are considered which are referred to as the 0 degree drop and 45 degree drop, respectively. In the 0 degree drop, the basket drops with its panels oriented parallel and normal to the vertical (see Figure 3.1.2). The 45-degree drop implies that the basket's honeycomb section is rotated meridionally by 45 degrees (Figure 3.1.3).

Enclosure Vessel

Table 3.1.4 summarizes all load cases that are applicable to structural analysis of the enclosure vessel to ensure integrity of the confinement boundary.

The enclosure vessel is a pressure vessel consisting of a cylindrical shell, a thick circular baseplate at the bottom, and a thick circular lid at the top. This pressure vessel must be shown to meet the primary stress intensity limits for ASME Section III Class 1 at the design temperature and primary plus secondary stress intensity limits under the combined action of pressure plus thermal loads.

Normal handling of the enclosure vessel is considered in Docket 72-1008; the handling loads are independent of whether the enclosure vessel is within HI-STAR 100, HI-STORM 100, or HI-TRAC.

The off-normal condition handling loads are identical to the normal condition and, therefore, a separate analysis is not required.

Analyses presented in this chapter are intended to demonstrate that the maximum decelerations in drop and tip-over accident events are limited by the bounding values in Table 3.1.2. The vertical drop event is considered in the HI-STAR 100 FSAR Docket 72-1008.

The deceleration loadings developed in the enclosure vessel during a horizontal drop event are combined with those due to P_i (internal pressure) acting alone. The accident condition pressure is bounded by P_i^* . The design basis deceleration for the MPC in the HI-STAR 100 System is 60g's, whereas the design basis deceleration for the MPC in the HI-STORM 100 System is 45g's. The design pressures are identical. The fire event (T^* loading) is considered for ensuring absence of interference between the enclosure vessel and the fuel basket and between the enclosure vessel and the overpack.

It is noted that the MPC basket-enclosure vessel thermal expansion and stress analyses are reconsidered in this submittal to reflect the different MPC-to-overpack gaps that exist in the HI-STORM 100 Overpack versus the HI-STAR 100 overpack, coupled with the different design basis decelerations.

Storage Overpack

Table 3.1.5 identifies the load cases to be considered for the overpack. These are in addition to the kinematic criteria listed in Table 3.1.1. Within these load cases and kinematic criteria, the following items must be addressed:

Normal Conditions

- The dead load of the HI-TRAC with the heaviest loaded MPC (dry) on top of the HI-STORM 100 Overpack must be shown to be able to be supported by the metal-concrete (METCON™) structure consisting of the two concentric steel shells and the radial ribs.
- The dead load of the HI-STORM 100 Overpack itself must be supportable by the steel structure with no credit for concrete strength other than self-support in compression.
- Normal handling loads must be accommodated without taking any strength credit from the contained concrete other than self-support in compression.

Accident Conditions

- Maximum flood water velocity for the overpack with an empty MPC must be specified to ensure that no sliding or tip-over occurs.
- Tornado missile plus wind on an overpack with an empty MPC must be specified to demonstrate that no cask tip-over occurs.
- Tornado missile penetration analysis must demonstrate that the postulated large and penetrant missiles cannot contact the MPC. The small missile must be shown not to penetrate the MPC pressure vessel boundary, since it can enter the overpack cavity through the vent ducts.
- Under seismic conditions, a fully loaded, free-standing HI-STORM 100 overpack must be demonstrated to not tip over under the maximum ZPA event. The maximum sliding of the overpack must demonstrate that casks will not impact each other.
- Under a non-mechanistic postulated tip-over of a fully loaded, freestanding HI-STORM 100 overpack, the overpack lid must not dislodge.
- Accident condition stress levels must not be exceeded in the steel and compressive stress levels in the concrete must remain within allowable limits.
- Accident condition induced gross general deformations of the storage overpack must be limited to values that do not preclude ready retrievability of the MPC.

As noted earlier, analyses performed using the HI-STORM 100 generally provide results that are identical to or bound results for the shorter HI-STORM 100S versions; therefore, analyses are not repeated specifically for the HI-STORM 100S unless the specific geometry changes significantly influence the safety factors.

HI-TRAC Transfer Cask

Table 3.1.5 identifies load cases applicable to the HI-TRAC transfer cask.

The HI-TRAC transfer cask must provide radiation protection, must act as a handling cask when carrying a loaded MPC, and in the event of a postulated accident must not suffer permanent deformation to the extent that ready retrievability of the MPC is compromised. This submittal includes five types of transfer casks: a 125-ton HI-TRAC (referred to as the HI-TRAC 125), a modified version of the HI-TRAC 125 called the HI-TRAC 125D, a 100-ton HI-TRAC (referred to as the HI-TRAC 100), a modified version of the HI-TRAC 100 called the HI-TRAC 100D, and a modified version of the HI-TRAC 100 called the HI-TRAC 100G. The details of these five transfer casks are provided in the design drawings in Section 1.5. The same steel structures (i.e., shell thicknesses, lid thicknesses, etc.) are maintained with the only major differences being in the amount of lead shielding, the water jacket configuration, the bottom flange, and the lower dead weight loading. Therefore, all structural analyses performed for the HI-TRAC 125 are repeated for the HI-TRAC 125D, the HI-TRAC 100, the HI-TRAC 100D, and the HI-TRAC 100G only if it

cannot be clearly demonstrated that the HI-TRAC 125 calculation is bounding.

3.1.2.2 Allowables

The important to safety components of the HI-STORM 100 System are listed in Table 2.2.6. Allowable stresses, as appropriate, are tabulated for these components for all service conditions.

In Subsection 2.2.5, the applicable service level from the ASME Code for determination of allowables is listed. Table 2.2.14 provides a tabulation of normal, off-normal, and accident conditions and the service levels defined in the ASME Code, along with the applicable loadings for each service condition.

Allowable stresses and stress intensities are calculated using the data provided in the ASME Code and Tables 2.2.10 through 2.2.12. Tables 3.1.6 through 3.1.16 contain numerical values of the stresses/stress intensities for all MPC, overpack, and HI-TRAC load bearing materials as a function of temperature.

In all tables the terms S , S_m , S_y , and S_u , respectively, denote the design stress, design stress intensity, minimum yield strength, and the ultimate strength. Property values at intermediate temperatures that are not reported in the ASME Code are obtained by linear interpolation. Property values are not extrapolated beyond the limits of the Code in any structural calculation.

Additional terms relevant to the analyses are extracted from the ASME Code (Figure NB-3222-1, for example) as follows:

Symbol	Description	Notes
P_m	Average primary stress across a solid section	Excludes effects of discontinuities and concentrations. Produced by pressure and mechanical loads.
P_L	Average stress across any solid section	Considers effects of discontinuities but not concentrations. Produced by pressure and mechanical loads, including earthquake inertial effects.
P_b	Primary bending stress	Component of primary stress proportional to the distance from the centroid of a solid section. Excludes the effects of discontinuities and concentrations. Produced by pressure and mechanical loads, including earthquake inertial effects.
P_e	Secondary expansion stress	Stresses that result from the constraint of free-end displacement. Considers effects of discontinuities but not local stress concentration. (Not applicable to vessels.)
Q	Secondary membrane plus bending stress	Self-equilibrating stress necessary to satisfy continuity of structure. Occurs at structural discontinuities. Can be caused by pressure, mechanical loads, or differential thermal expansion.

Symbol	Description	Notes
F	Peak stress	Increment added to primary or secondary stress by a concentration (notch), or, certain thermal stresses that may cause fatigue but not distortion. This value is not used in the tables.

It is shown that there is no interference between component parts due to free thermal expansion. Therefore, P_e does not develop within any HI-STORM 100 component.

It is recognized that the planar temperature distribution in the fuel basket and the overpack under the maximum heat load condition is the highest at the cask center and drops monotonically, reaching its lowest value at the outside surface. Strictly speaking, the allowable stresses/stress intensities at any location in the basket, the enclosure vessel, or the overpack should be based on the coincident metal temperature under the specific operating condition. However, in the interest of conservatism, reference temperatures are established for each component, which are upper bounds on the metal temperature for each situational condition. Table 3.1.17 provides the reference temperatures for the fuel basket and the MPC canister utilizing Tables 3.1.6 through 3.1.16, and provides conservative numerical limits for the stresses and stress intensities for all loading cases. Reference temperatures for the MPC baseplate and the MPC lid are 400 degrees F and 550 degrees F, respectively, as specified in Table 2.2.3.

Finally, the lifting attachments or the interfacing lift points in the HI-STORM 100 and HI-TRAC casks and the multi-purpose canisters must meet the requirements of NUREG- 0612 and/or Regulatory Guide 3.61 as described in Subsection 3.4.3 and Tables 2.0.1, 2.0.2 and 2.0.3 under a normal handling condition (Load Case 01 in Table 3.1.5). The load combination D+H in Table 3.1.5 is equivalent to 1.15D. This is further explained in Subsection 3.4.3.

The region around the trunnions is part of the NF structure in HI-STORM 100 and HI-TRAC and NB pressure boundary in the MPC, and as such, must satisfy the applicable stress (or stress intensity) limits for the load combination. In addition to meeting the applicable Code limits, it is further required that the primary stress required to maintain equilibrium at the defined trunnion/mother structure interface must not exceed the material yield stress at three times the handling condition load (1.15D). This criterion, mandated by Regulatory Guide 3.61, Section 3.4.3, insures that a large safety factor exists on non-local section yielding at the trunnion/mother structure interface that would lead to unacceptable section displacement and rotation.

3.1.2.3 Brittle Fracture

The MPC canister and basket are constructed from a series of stainless steels termed Alloy X. These stainless steel materials do not undergo a ductile-to-brittle transition (DBT) in the operating temperature range of the HI-STORM 100 System. Therefore, brittle fracture is not a concern for the MPC components fabricated using austenitic stainless steel. Such an assertion cannot be made a' priori for the MPC confinement boundary components fabricated using duplex stainless steel grade of Alloy X, or for the HI-STORM storage overpack and the HI-TRAC transfer cask that contain ferritic steel parts.

The use of duplex stainless steel grade of Alloy X material is limited to the MPC confinement boundary components and shall be restricted to the maximum temperatures specified in Table 1.A.6 as the material may suffer from precipitation of brittle micro-constituents above 600°F.

The duplex stainless steel material undergoes DBT below the temperature of -40°F/-40°C [3.1.4] (which is equal to the Lowest Service Temperature (LST) of MPC). In addition, Holtec Position Paper DS-213 [9.1.6] demonstrates that crack propagation in MPC lid-to-shell weld is not credible for austenitic and duplex stainless steel grades of Alloy X. Therefore, brittle fracture is not a concern for the MPC confinement boundary components fabricated using duplex stainless steel grade of Alloy X as well.

In general, the impact testing requirements for the HI-STORM overpack and the HI-TRAC transfer cask are a function of two parameters: the LST and the normal stress level. The significance of these two parameters, as they relate to impact testing of the overpack and the transfer cask, is discussed below.

In normal storage mode, the LST of the HI-STORM storage overpack structural members may reach -40°F in the limiting condition wherein the spent nuclear fuel (SNF) in the contained MPCs emits no (or negligible) heat and the ambient temperature is at -40°F (design minimum per Chapter 2: Principal Design Criteria). During the HI-STORM handling operations, the applicable lowest service temperature is 0°F (which is the threshold ambient temperature below which lifting and handling of the HI-STORM 100 Overpack or the HI-TRAC cask is not permitted by the Technical Specification). Therefore, two distinct LSTs are applicable to load bearing metal parts within the HI-STORM 100 Overpack and the HI-TRAC cask; namely,

LST = 0°F for the HI-STORM overpack during handling operations and for the HI-TRAC transfer cask during all normal operating conditions.

LST = -40°F for the HI-STORM overpack during all non-handling operations (i.e., normal storage mode).

Parts used to lift the overpack or the transfer cask, which include the anchor block in the HI-STORM 100 overpack, the lifting trunnion, and the lifting trunnion block in HI-TRAC, will henceforth be referred to as “significant-to-handling” (STH) parts. The applicable design codes for these elements of the structure are NUREG-0612 and Regulatory Guide 3.61. All other parts of the overpack and the transfer cask will be referred to as “NF” components. It is important to ensure that all materials designated as “NF” or “STH” parts possess sufficient fracture toughness to preclude brittle fracture. For the STH parts, the necessary level of protection against brittle fracture is deemed to exist if the NDT (nil ductility transition) temperature of the part is at least 40° below the LST. Therefore, the required NDT temperature for all STH parts is -40°F.

It is well known that the NDT temperature of steel is a strong function of its composition, manufacturing process (viz., fine grain vs. coarse grain practice), thickness, and heat treatment. For example, according to Burgreen [3.1.3], increasing the carbon content in carbon steels from

0.1% to 0.8% leads to the change in NDT from -50°F to approximately 120°F. Likewise, lowering of the normalizing temperature in the ferritic steels from 1200°C to 900°C lowers the NDT from 10°C to -50°C [3.1.3]. It, therefore, follows that the fracture toughness of steels can be varied significantly within the confines of the ASME Code material specification set forth in Section II of the Code. For example, SA516 Gr. 70 (which is a principal NF material in the HI-STORM 100 Overpack) can have a maximum carbon content of up to 0.3% in plates up to four inches thick. Section II further permits normalizing or quenching followed by tempering to enhance fracture toughness. Manufacturing processes which have a profound effect on fracture toughness, but little effect on tensile or yield strength of the material, are also not specified with the degree of specificity in the ASME Code to guarantee a well defined fracture toughness. In fact, the Code relies on actual coupon testing of the part to ensure the desired level of protection against brittle fracture. For Section III, Subsection NF Class 3 parts, the desired level of protection is considered to exist if the lowest service temperature is equal to or greater than the NDT temperature (per NF 2311(b)(10)). Accordingly, the required NDT temperature for all load bearing metal parts in the HI-STORM 100 Overpack (NF and STH) is -40°F. Likewise, the NDT temperature for all NF parts in HI-TRAC (except for STH parts) is set equal to 0°F.

The STH components (HI-STORM bolt anchor block, HI-TRAC lifting trunnion, HI-TRAC lifting trunnion block, and HI-TRAC pocket trunnion) have thicknesses greater than 2". SA350-LF3 has been selected as the material for these items (except for the lifting trunnions) due to its capability to maintain acceptable fracture toughness at low temperatures (see Table 5 in SA350 of ASME Section IIA). Additionally, material for the HI-TRAC top flange, pool lid (100 ton) and pool lid outer ring (125 ton) has been defined as SA350-LF3, SA350-LF2, or SA203E (see Table A1.15 of ASME Section IIA) in order to achieve low temperature fracture toughness. The HI-TRAC lifting trunnion is fabricated from SB-637 Grade N07718, a high strength nickel alloy material. This material has a high resistance to fracture at low temperatures. For the HI-TRAC 100G, the lifting trunnions are fabricated from SA-182 F60, forged ferritic stainless steel material. All other steel structural materials in the HI-STORM 100 overpack and HI-TRAC cask are made of SA516 Gr. 70, SA515 Gr. 70, or SA36 (with some components having an option for SA203E or SA350-LF3 depending on material availability).

Either as-rolled or normalized SA516 Gr. 70 plate can be used to fabricate the overpack and the transfer cask. If the SA516 Gr. 70 plate is normalized, then it is exempt from impact testing per NF-2311(b). The specific reasons are:

1. The LST for handling operations is above the Minimum Design Temperature of SA516 Gr. 70 normalized plate (for thickness less than 2-1/2") per Figure NF-2311(b)-1, and;
2. During non-handling operations (i.e., normal storage mode), the maximum tensile stress in the HI-STORM overpack is less than the threshold limit of 6,000 psi specified in NF-2311(b)(7).

If the SA516 Gr. 70 plate is as-rolled (i.e., not normalized), then impact testing is required, except when the material is used for the following HI-STORM components: inner and outer shells, top

plate, lid shear ring, lid shield ring, lid outer ring (for 100S Version B), and lid cover plate (for 100S Version B) and Base-Bottom Plate (for 100S Version B). The material for these components is exempt from impact testing per NF-2311(b)(7) since the maximum stress under normal conditions, including handling operations, does not exceed 6,000 psi tension or is compressive.

Even though SA516 Gr. 70 normalized plate is exempt from impact testing per the above, certain components of the HI-STORM 100A overpack, namely the lug support ring, the gussets, and the baseplate, are impact tested, as a defense-in-depth measure, because they are potentially subject to high tensile stress levels (i.e., greater than 6,000 psi) during an earthquake.

Table 3.1.18 provides a summary of impact testing requirements to satisfy the requirements for prevention of brittle fracture.

3.1.2.4 Fatigue

In storage, the HI-STORM 100 System is not subject to significant cyclic loads. Failure due to fatigue is not a concern for the HI-STORM 100 System.

In an anchored installation, however, the anchor studs sustain a pulsation in the axial load during the seismic event. The amplitude of axial stress variation under the DBE event is computed in this chapter and a significant margin of safety against fatigue failure during the DBE event is demonstrated.

The system is subject to cyclic temperature fluctuations. These fluctuations result in small changes of thermal expansions and pressures in the MPC. The loads resulting from these changes are small and do not significantly contribute to the "usage factor" of the cask.

Inspection of the HI-TRAC trunnions specified in Chapter 9 will preclude use of a trunnion that exhibits visual damage.

3.1.2.5 Buckling

Certain load combinations subject structural sections with relatively large slenderness ratios (such as the enclosure vessel shell) to compressive stresses that may actuate buckling instability before the allowable stress is reached. Tables 3.1.4 and 3.1.5 list load combinations for the enclosure vessel and the HI-STORM 100/HI-TRAC structures; the cases which warrant stability (buckling) check are listed therein (note that a potential buckling load has already been identified as a consequence of a postulated explosion).

TABLE 3.1.1

**LOAD COMBINATIONS SIGNIFICANT TO HI-STORM 100 OVERPACK
KINEMATIC STABILITY ANALYSIS**

Loading Case	Combinations[†]	Comment	Analysis of this Load Case Presented in:
A	D + F	This case establishes flood water flow velocity with a minimum safety factor of 1.1 against overturning and sliding.	Subsection 3.4.6
B	D + M + W'	Demonstrate that the HI-STORM 100 Overpack with minimum SNF stored (minimum D) will not tip over.	Subsection 3.4.8
C	D + E	Establish the value of ZPA ^{††} that will not cause the overpack to tip over.	Subsection 3.4.7

[†] Loading symbols are defined in Table 2.2.13

^{††} ZPA is zero period acceleration

TABLE 3.1.2**DESIGN BASIS DECELERATIONS FOR THE DROP EVENTS**

Case	Value[†] (in multiples of acceleration due to gravity)
Vertical axis drop (HI-STORM 100 Overpack only)	45
Horizontal axis (side) drop (HI-TRAC only) (not applicable for HI-TRAC 100G)	45

[†] The design basis value is set from the requirements of the HI-STORM 100 System, as its components are operated as a storage system. The MPC is designed to higher loadings (60g's vertical and horizontal) when in a HI-STAR 100 overpack. Analysis of the MPC in a HI-STAR 100 overpack under a 60g loading is provided in HI-STAR 100 Docket Numbers 71-9261 and 72-1008.

TABLE 3.1.3
LOADING CASES FOR THE FUEL BASKET

Load Case I.D.	Loading [†]	Notes	Location Where this Case is Evaluated
F1	T, T'	Demonstrate that the most adverse of the temperature distributions in the basket will not cause fuel basket to expand and contact the enclosure vessel wall. Compute the secondary stress intensity and show that it is small.	Subsection 3.4.4.2
F2 (Note 1)	D + H	Conservatively add the stresses in the basket due to vertical and horizontal orientation handling to form a bounding stress intensity.	Table 3.4.9 of HI-STAR FSAR (Docket 72-1008)
F3 F3.a (Note 2)	D + H'	Vertical axis drop event	HI-STAR FSAR, Subsection 3.4.4.3.1.3
F3.b (Note 3)	D + H'	Side Drop, 0 degree orientation (Figure 3.1.2)	Table 3.4.6
F3.c (Note 3)	D + H'	Side Drop, 45 degree orientation (Figure 3.1.3)	Table 3.4.6

Notes:

1. Load Case F2 for the HI-STORM 100 System is identical to Load Case F2 for the HI-STAR 100 System in Docket Number 72-1008, Table 3.1.3.
2. Load Case F3.a is bounded by the 60g deceleration analysis performed for the HI-STAR 100 System in Docket Number 72-1008, Subsection 3.4.4.3.1.3. The HI-STORM 100 vertical deceleration loading is limited to 45g.
3. Load Cases F3.b and F3.c are analyzed here for a 45g deceleration, while the MPC is housed within a HI-STORM 100 Overpack or a HI-TRAC transfer cask. The initial clearance at the interface between the MPC shell and the HI-STORM 100 Overpack or HI-TRAC transfer cask is greater than or equal to the initial clearance between the MPC shell and the HI-STAR 100 overpack. This difference in clearance directly affects the stress field. The side drop analysis for the MPC in the HI-STAR 100 overpack under 60g's bounds the corresponding analysis of the MPC in HI-TRAC for 45 g's.

[†] The symbols used for the loadings are defined in Table 2.2.13.

TABLE 3.1.4**LOADING CASES FOR THE ENCLOSURE VESSEL (CONFINEMENT BOUNDARY)**

TABLE 3.1.4 (CONTINUED)**LOADING CASES FOR THE ENCLOSURE VESSEL (CONFINEMENT BOUNDARY)**

Load Case I.D.	Load Combination[†]	Notes	Comments and Location Where this Case is Analyzed	
E5	P_i^* or $P_o^* + D + T^*$	Demonstrate compliance with Level D stress limits – buckling stability.	Lid	3.4.4.3.1.10
			Baseplate	3.4.4.3.1.10
			Shell	Docket 72-1008 Buckling methodology in 3.H
				3.4.4.3.1.2 (stress)
			Supports	N/A

Notes:

1. Load Cases E1.a and E1.b are identical to the load cases presented in Docket Number 72-1008, Table 3.1.4. Design pressures and MPC weights are identical.
2. Load Case E3.a is bounded by the 60g deceleration analysis performed for the HI-STAR 100 System in Docket Number 72-1008. The HI-STORM 100 vertical deceleration loading is limited to 45g.
3. Load Cases E3.b and E3.c are analyzed in this HI-STORM 100 SAR for a 45g deceleration, while the MPC is housed within the HI-STORM 100 storage overpack. The interface between the MPC shell and storage overpack is not identical to the MPC shell and HI-STAR 100 overpack. The analysis for an MPC housed in HI-TRAC is not performed since results are bounded by those reported in the HI-STAR 100 TSAR for a 60g deceleration.

[†] The symbols used for the loadings are defined in Table 2.2.13.

TABLE 3.1.5**LOAD CASES FOR THE HI-STORM 100 OVERPACK/HI-TRAC TRANSFER CASK**

Load Case I.D.	Loading[†]	Notes	Location in FSAR
01	D + H + T + (P _o ,P _i)	Vertical load handling of HI-STORM 100 Overpack/HI-TRAC.	Overpack 3.4.3.5 HI-TRAC Shell 3.4.3.3, 3.4.3.4 Pool lid 3.4.3.8 Transfer lid 3.4.3.9
02			
02.a	D + H' + (P _o ,P _i)	Storage Overpack: End drop; primary stress intensities must meet level D stress limits.	Overpack 3.4.4.3.2.3
02.b	D + H' + (P _o ,P _i)	HI-TRAC: Horizontal (side) drop; meet level D stress limits for NF Class 3 components away from the impacted zone; show lids stay in-place. Show primary and secondary impact decelerations are within design basis. (This case is only applicable to HI-TRAC.) (Not applicable to HI-TRAC 100G)	HI-TRAC Shell 3.4.9.1 Transfer Lid 3.4.4.3.3.3 Slapdown 3.4.9.2
02.c	D + H'	Storage Overpack: Tip-over; any permanent deformations must not preclude ready retrieval of the MPC.	Overpack 3.4.10, 3.A

[†] The symbols used for the loadings are defined in Table 2.2.13

TABLE 3.1.5 (CONTINUED)**LOAD CASES FOR THE HI-STORM 100 OVERPACK/HI-TRAC TRANSFER CASK**

Load Case I.D.	Loading[†]	Notes	Location in FSAR
03	D (water jacket)	Satisfy primary membrane plus bending stress limits for water jacket (This case is only applicable to HI-TRAC).	3.4.4.3.3.4
04	M (penetrant missiles)	Demonstrate that no thru-wall breach of the HI-STORM overpack or HI-TRAC transfer cask occurs, and the primary stress levels are not exceeded. Small and intermediate missiles are examined for HI-STORM and HI-TRAC. Large missile penetration is also examined for HI-TRAC.	Overpack 3.4.8.1 HI-TRAC 3.4.8.2.1, 3.4.8.2.2
05	P _o	Explosion: must not produce buckling or exceed primary stress levels in the overpack structure.	3.4.4.5.2, 3.4.7.2

Notes:

- Under each of these load cases, different regions of the structure are analyzed to demonstrate compliance.

[†] The symbols used for the loadings are defined in Table 2.2.13

TABLE 3.1.6**DESIGN, LEVELS A AND B: STRESS INTENSITY**

Code: ASME NB
Material: SA203-E
Service Conditions: Design, Levels A and B
Item: Stress Intensity

Temp. (Deg. F)	Classification and Value (ksi)					
	S_m	P_m^\dagger	P_L^\dagger	$P_L + P_b^\dagger$	$P_L + P_b + Q^{\dagger\dagger}$	$P_e^{\dagger\dagger}$
-20 to 100	23.3	23.3	35.0	35.0	69.9	69.9

E2	Alloy X	500	17.5	26.3	52.5
E3	Alloy X	500	42.0	63.0	NL ^{††}
E4	Alloy X	500	17.5	26.3	52.5
E5	Alloy X	775	36.15	54.25	NL

Notes:

1. Q, P_m, P_L, and P_b are defined in Table 3.1.6.
2. Reference temperatures for Load Cases E1-E4 are for MPC shell; for MPC lid and MPC baseplate, reference temperatures are 550 deg. F and 400 deg. F, respectively (per Table 2.2.3) and stress intensity allowables should be adjusted accordingly.

[†] Values for reference temperatures are chosen to bound the thermal results in Chapter 4. Lower temperature values may be used provided that they are at least equal to the calculated temperature for the specific component and location or otherwise justified.

^{††} NL: No specified limit in the Code

TABLE 3.1.17 (CONTINUED)**REFERENCE TEMPERATURES AND STRESS LIMITS FOR THE VARIOUS LOAD CASES**

Load Case I.D.	Material	Reference Temperature, ^{†,††} ° F	Stress Intensity Allowables, ksi		
			P _m	P _L + P _b	P _L + P _b + Q
O1	SA203-E	400	17.5	26.3	NL ^{†††}
	SA350-LF3	400	17.5	26.3	NL
	SA516 Gr. 70 SA515 Gr. 70	400	17.5	26.3	NL
O2	SA203-E	400	41.2	61.7	NL
	SA350-LF3	400	38.6	58.0	NL
	SA516 Gr. 70 SA515 Gr. 70	400	39.1	58.7	NL
O3	SA203-E	400	17.5	26.3	NL
	SA350-LF3	400	17.5	26.3	NL
	SA516 Gr. 70 SA515 Gr. 70	400	17.5	26.3	NL
O4	SA203-E	400	41.2	61.7	NL
	SA350-LF3	400	38.6	58.0	NL
	SA516 Gr. 70 SA515 Gr. 70	400	39.1	58.7	NL

Note:

1. P_m, P_L, P_b, and Q are defined in Table 3.1.6.
2. Load Cases O1 and O3 are for Normal Conditions; therefore the values listed refer to allowable stress, not allowable stress intensity

[†] Values for reference temperatures are chosen to bound the thermal results in Chapter 4. Lower temperature values may be used provided that they are at least equal to the calculated temperature for the specific component and location or otherwise justified.

^{††} For storage fire analysis, temperatures are defined by thermal solution

^{†††} NL: No specified limit in the Code

TABLE 3.1.18
FRACTURE TOUGHNESS TEST REQUIREMENTS

Material	Test Requirement	Test Temperature	Acceptance Criterion
Bolting (SA193 B7)	Not required (per NF-2311(b)(13) and Note (e) to Figure NF-2311(b)-1)	-	-
Ferritic steel with nominal section thickness of 5/8" or less	Not required per NF-2311(b)(1)	-	-
SA36 (thickness greater than 5/8")	Not required per NF-2311(b)(7)	-	-
Normalized SA516 Gr. 70 (thickness greater than 5/8", but less than or equal to 2-1/2"), except when used for HI-STORM 100A baseplate, lug support ring, and gussets	Not required per NF-2311(b)(7), NF-2311(b)(13), and curve D in Figure NF-2311(b)-1	-	-
HI-STORM 100A baseplate, lug support ring, and gussets (See Note 2)	Per NF-2331	See Note 1. (Also must meet ASME Section IIA requirements)	Table NF-2331(a)-3 or Figure NF-2331(a)-2 (Also must meet ASME Section IIA requirements)
As-rolled SA516 Gr. 70, except when used for HI-STORM inner and outer shells, top plate, lid shear ring, lid shield ring, lid outer ring (for 100S Version B), and lid cover plate (for 100S Version B)	Per NF-2331	See Note 1. (Also must meet ASME Section IIA requirements)	Table NF-2331(a)-3 or Figure NF-2331(a)-2 (Also must meet ASME Section IIA requirements)
As-rolled SA516 Gr. 70 used for HI-STORM inner and outer shells, top plate, lid shear ring, lid shield ring, lid outer ring (for 100S Version B), and lid cover plate (for 100S Version B) and Base- Bottom Plate (for 100S Version B)	Not required per NF-2311(b)(7)	-	-
SA203, SA515 Gr. 70, SA350-LF2, SA350-LF3 (thickness greater than	Per NF-2331	See Note 1. (Also must meet ASME Section IIA requirements)	Table NF-2331(a)-3 or Figure NF-2331(a)-2

5/8")			(Also must meet ASME Section IIA requirements)
Weld material	Test per NF-2430 if: 1) either of the base materials of the production weld requires impact testing, or; 2) either of the base materials is SA516 Gr. 70 with nominal section thickness greater than 5/8".	See Note 1	Per NF-2330

Notes:

1. Required NDT temperature = -40 deg. F for all materials in the HI-STORM 100 Overpack, -40 deg. F for HI-TRAC "STH" materials, and 0 deg. F for HI-TRAC "NF" materials.
2. In accordance with ASME Code Subsection NF, impact testing is not required for these components; specified testing is performed strictly for defense-in-depth.

TABLE 3.1.19**DESIGN AND LEVEL A: STRESS**

Code: ASME NF
Material: SA36
Service Conditions: Design and Level A
Item: Stress

Temp. (Deg. F)	Classification and Value (ksi)		
	S	Membrane Stress	Membrane plus Bending Stress
-20 to 650	14.5	14.5	21.8
700	13.9	13.9	20.9

Notes:

1. S = Maximum allowable stress values from Table 1A of ASME Code, Section II, Part D.
2. Stress classification per Paragraph NF-3260.
3. Limits on values are presented in Table 2.2.12.

TABLE 3.1.20**LEVEL B: STRESS**

Code: ASME NF
Material: SA36
Service Conditions: Level B
Item: Stress

Temp. (Deg. F)	Classification and Value (ksi)	
	Membrane Stress	Membrane plus Bending Stress
-20 to 650	19.3	28.9
700	18.5	27.7

Notes:

1. Limits on values are presented in Table 2.2.12 with allowables from Table 3.1.19.

TABLE 3.1.21**LEVEL D: STRESS INTENSITY**

Code: ASME NF
Material: SA36
Service Conditions: Level D
Item: Stress Intensity

Temp. (Deg. F)	Classification and Value (ksi)		
	S_m	P_m	P_m + P_b
-20 to 100	19.3	43.2	64.8
200	19.3	37.0	55.5
300	19.3	36.0	54.0
400	19.3	34.7	52.1
500	19.3	32.8	49.2
600	17.7	30.0	45.0
650	17.4	29.5	44.3
700	17.3	29.2	43.8

Notes:

1. Level D allowable stress intensities per Appendix F, Paragraph F-1332.
2. S_m = Stress intensity values per Table 2A of ASME, Section II, Part D.
3. Limits on values are presented in Table 2.2.12.
4. P_m and P_b are defined in Table 3.1.6.

FIGURE 3.1.1: MPC-68 AND MPC-32 FUEL BASKET GEOMETRY

FIGURE 3.1.2: 0^0 DROP ORIENTATIONS FOR THE MPCs

FIGURE 3.1.3: 45° DROP ORIENTATIONS FOR THE MPCs

3.2 WEIGHTS AND CENTERS OF GRAVITY

Tables 3.2.1 and 3.2.2 provide the calculated weights of the individual HI-STORM 100 components as well as the total system weights. The actual weights will vary within a narrow range of the calculated values due to the tolerances in metal manufacturing and fabrication permitted by the ASME Codes. Contained water mass during fuel loading is not included in this table.

The locations of the calculated centers of gravity (CGs) are presented in Table 3.2.3. All centers of gravity are located on the cask centerline since the non-axisymmetric effects of the cask system plus contents are negligible.

Table 3.2.4 provides the lift weight when the HI-TRAC transfer cask with the heaviest fully loaded MPC is being lifted from the fuel pool. The effect of buoyancy is neglected, and the weight of rigging is set at a conservative value.

In all weight tables, bounding values are also listed where necessary for use in structural calculations where their use will provide a conservative result.

TABLE 3.2.1
HI-STORM OVERPACK WEIGHT DATA

Item	Bounding Weight (lb)
MPC-24 <ul style="list-style-type: none"> Without SNF Fully loaded with SNF and Fuel Spacers 	42,000 90,000 ^{††}

HI-STORM OVERPACK WEIGHT DATA

Item	Bounding Weight (lb)
HI-STORM 100S(243) Overpack [†] <ul style="list-style-type: none"> Overpack top lid Overpack w/ lid (empty) Overpack w/ fully loaded MPC-24 Overpack w/ fully loaded MPC-32 Overpack w/ fully loaded MPC-68/68F/68FF Overpack w/ fully loaded MPC-24E/EF 	25,500 ^{††} 270,000 360,000 360,000 360,000 360,000
HI-STORM 100A Overpack [†]	Same as above
HI-STORM 100S Version B(218) Overpack (values in parentheses use high density concrete in overpack body) <ul style="list-style-type: none"> Overpack top lid Overpack w/ lid (empty) Overpack w/ fully loaded MPC-24 Overpack w/ fully loaded MPC-32 Overpack w/ fully loaded MPC-68/68F/68FF Overpack w/ fully loaded MPC-24E/EF 	29,000 ^{††††} 270,000 (305,000) 360,000 (395,000) 360,000 (395,000) 360,000 (395,000) 360,000 (395,000)
HI-STORM 100S Version B(229) Overpack (values in parentheses use high density concrete in overpack body) <ul style="list-style-type: none"> Overpack top lid Overpack w/ lid (empty) Overpack w/ fully loaded MPC-24 Overpack w/ fully loaded MPC-32 Overpack w/ fully loaded MPC-68/68F/68FF Overpack w/ fully loaded MPC-24E/EF 	29,000 ^{††††} 270,000 (320,000) 360,000 (410,000) 360,000 (410,000) 360,000 (410,000) 360,000 (410,000)
HI-STORM 100S Version B Type IS (218) Overpack (values in parentheses use high density concrete in overpack body) ^{†††††} <ul style="list-style-type: none"> Overpack top lid Overpack w/ lid (empty) 	25,500 (28,300) 263,500 (298,100)
HI-STORM 100S Version B Type IS (229) Overpack (values in parentheses use high density concrete in overpack body) ^{†††††} <ul style="list-style-type: none"> Overpack top lid Overpack w/ lid (empty) 	25,500 (28,300) 276,100 (312,500)

- † The bounding weights for the HI-STORM 100S(232) and 100S(243) overpacks listed in the above table are based on a maximum concrete (dry) density of 160.8 pcf. For improved shielding effectiveness, higher density concrete (up to 200 pcf dry) may be poured in the radial cavity of each of the HI-STORM 100S overpacks. At 200 pcf, the bounding weights of an empty overpack and a fully loaded overpack increase to 320,000 lb and 410,000 lb, respectively. Higher density concrete cannot be used in the HI-STORM 100 or 100A overpacks.
- †† Based on a maximum concrete (dry) density of 155 pcf. Higher density concrete (up to 200 pcf dry) may be poured in the HI-STORM 100S lids. At 200 pcf, the bounding weight of the lid increases to 28,000 lb.
- ††† Based on the following maximum fuel assembly weights (as applicable):
 1,680 lb per assembly (including non-fuel hardware) for PWR fuel that requires fuel spacers
 1,720 lb per assembly (including non-fuel hardware) for PWR fuel that does not require fuel spacers
 830 per assembly (including channels and DFCs) for BWR fuel
- †††† Based on a maximum concrete (dry) density of 155 pcf. Higher density concrete (up to 185 pcf dry) may be poured in the HI-STORM 100S Version B lids. At 185 pcf, the bounding weight of the lid increases to 32,000 lbs. Maximum weight limits specified in Table 2.0.2 are still required to be met.
- ††††† The bounding weights for the HI-STORM 100S Version B Type IS (218) and 100S Version B Type IS (229) overpacks (including overpack lids) listed in the above table are based on a minimum concrete (dry) density of 170 pcf. Higher density concrete (up to 200 pcf dry) may be poured in the HI-STORM 100S Version B Type IS. The bounding weights of empty overpack and the overpack lid at 200 pcf are also listed in the above table in parentheses.

HI-TRAC 100D Transfer Cask w/ Top Lid, Pool Lid, and fully loaded MPC-24 (water jacket filled)	99.2
HI-TRAC 100D Transfer Cask w/ Top Lid, Pool Lid, and fully loaded MPC-32 (water jacket filled)	101.2
HI-TRAC 100D Transfer Cask w/ Top Lid, Pool Lid, and fully loaded MPC-68/68F/68FF (water jacket filled)	100.4
HI-TRAC 100D Transfer Cask w/ Top Lid, Pool Lid, and fully loaded MPC-24E/EF (water jacket filled)	99.1
HI-TRAC 100G Transfer Cask w/ Top Lid and Pool Lid (water jacket filled)	94.0
HI-TRAC 100G Transfer Cask w/ Top Lid, Pool Lid, and fully loaded MPC-24 (water jacket filled)	105.0
HI-TRAC 100G Transfer Cask w/ Top Lid, Pool Lid, and fully loaded MPC-32 (water jacket filled)	107.0
HI-TRAC 100G Transfer Cask w/ Top Lid, Pool Lid, and fully loaded MPC-68/68F/68FF (water jacket filled)	106.2
HI-TRAC 100G Transfer Cask w/ Top Lid, Pool Lid, and fully loaded MPC-24E/EF (water jacket filled)	105.0

Notes:

1. The datum used for calculations involving the HI-STORM is the bottom of the overpack baseplate. The datum used for calculations involving the HI-TRAC is the bottom of the pool lid or transfer lid, as appropriate.

2. The datum used for calculations involving only the MPC is the bottom of the MPC baseplate.
3. The CG heights of the HI-STORM overpacks are calculated based on standard density concrete (i.e., 150 pcf dry). At higher densities, the CG heights are slightly lower, which makes the HI-STORM overpacks less prone to tipping.
4. The CG heights of an empty or a fully loaded HI-STORM Version B Type IS overpack (with top lid) are at or below the mid-height of the overpack with all MPC types. Therefore, mid-height CG values can be used in safety evaluations.

TABLE 3.2.4
LIFT WEIGHT ABOVE POOL WITH HI-TRAC 125

Item	Estimated Weight (lb)	Bounding Weight (lb)
HI-TRAC 125 w/ Top Lid and Pool Lid (water jacket filled)	142,976	
MPC-32 fully loaded with SNF and fuel spacers	89,765 [†]	
HI-TRAC 125 Top Lid	-2,730 ^{††}	
Water in MPC and HI-TRAC 125 Annulus	16,570	
Water in Water Jacket	-9,757 ^{†††}	
Lift yoke	4,200	
Inflatable annulus seal	50	
TOTAL	241,074	250,000

[†] Includes MPC closure ring.

^{††} HI-TRAC top lid weight is included in transfer cask weight. However, the top lid is not installed during in-pool operations.

^{†††} Total weight of HI-TRAC 125 includes water in water jacket. However, during removal from the fuel pool no water is in the water jacket since the water within the MPC cavity provides sufficient shielding.

TABLE 3.2.4 (CONTINUED)
LIFT WEIGHT ABOVE POOL WITH HI-TRAC 100

Item	Estimated Weight (lb)	Maximum Weight (lb)
HI-TRAC 100 w/ Top Lid and Pool Lid (water jacket filled)	100,194

^{††} HI-TRAC top lid weight is included in transfer cask weight. However, the top lid is not installed during in-pool operations.

^{†††} Under worst case conditions, removal of a portion of water from the MPC and the water jacket, and use of in-plant built lift yoke may be required to reduce the in-pool lift weight.

3.3 MECHANICAL PROPERTIES OF MATERIALS

Table 2.2.6 provides a comprehensive listing of materials of construction, applicable code, and ITS designation for all functional parts in the HI-STORM 100 System. This section provides the mechanical properties used in the structural evaluation. The properties include yield stress, ultimate stress, modulus of elasticity, Poisson's ratio, weight density, and coefficient of thermal expansion. Values are presented for a range of temperatures which envelopes the maximum and minimum temperatures under all service conditions discussed in the preceding section where structural analysis is performed.

The materials selected for use in the MPC, HI-STORM 100 Overpack, and HI-TRAC transfer cask are presented in the Bills-of-Material in Section 1.5. In this chapter, the materials are divided into two categories, structural and nonstructural. Structural materials are materials that act as load bearing members and are, therefore, significant in the stress evaluations. Materials that do not support mechanical loads are considered nonstructural. For example, the HI-TRAC inner shell is a structural material, while the lead between the inner and outer shell is a nonstructural material. For nonstructural materials, the only property that is used in the structural analysis is weight density. In local deformation analysis, however, such as the study of penetration from a tornado-borne missile, the properties of lead in HI-TRAC and plain concrete in HI-STORM 100 are included.

3.3.1 Structural Materials

3.3.1.1 Alloy X

A hypothetical material termed Alloy X is defined for all MPC structural components. The material properties of Alloy X are the least favorable values from the set of candidate alloys. The purpose of a least favorable material definition is to ensure that all structural analyses are conservative, regardless of the actual MPC material. For example, when evaluating the stresses in the MPC, it is conservative to work with the minimum values for yield strength and ultimate strength. This guarantees that the material used for fabrication of the MPC will be of equal or greater strength than the hypothetical material used in the analysis. In the structural evaluation, the only property for which it is not always conservative to use the set of minimum values is the coefficient of thermal expansion. Two sets of values for the coefficient of thermal expansion are specified, a minimum set and a maximum set. For each analysis, the set of coefficients, minimum or maximum that causes the more severe load on the cask system is used.

Table 3.3.1 lists the numerical values for the material properties of Alloy X versus temperature. These values, taken from the ASME Code, Section II, Part D [3.3.1] and Appendix 1.A, are used in all structural analyses. A minimum requirement on yield strength is set for MPC Lids in Table 3.3.1, to ensure that the lid internal threads have enough capacity under the lifted load as mandated by NUREG-0612. The maximum temperatures in some MPC components may exceed the long term normal allowable temperature limits during short term loading operations, off-normal events, or storage accident events. However, it is ensured that the maximum temperature of austenitic stainless steel grades of Alloy X used for or within the confinement boundary does not

exceed 1000°F under any condition and the maximum temperature of duplex stainless steel (UNS S31803) grade of Alloy X used for the confinement boundary does not exceed 600°F under any condition. As shown in ASME Code Case N-47-33 (Class 1 Components in Elevated Temperature Service, 1995 Code Cases, Nuclear Components), the strength properties of austenitic stainless steels do not change due to exposure to 1000°F temperature for up to 10,000 hours. In addition, per ASME Code Case N-635-1 (Use of 22Cr-5Ni-3Mo-N (Alloy UNS S31803) Forgings, Plate, Bar, Welded and Seamless Pipe, and/or Tube, Fittings, and Fusion Welded Pipe with Additional of Filler Metal, Classes 1, 2, and 3, Section III, Division 1), the maximum permissible temperature for duplex stainless steel grade of Alloy X is 600°F. Therefore, there is no significant effect on mechanical properties of the confinement or basket material during the short time duration loading. It is noted that duplex stainless steel material shall not be used for the fabrication of MPC baskets and MPC internal components. A further description of Alloy X, including the materials from which it is derived, is provided in Appendix 1.A.

Two properties of Alloy X that are not included in Table 3.3.1 are weight density and Poisson's ratio. These properties are assumed constant for all structural analyses, regardless of temperature. The values used are shown in the table below.

PROPERTY	VALUE
Weight Density (lb/in ³)	0.290
Poisson's Ratio	0.30

3.3.1.2 Carbon Steel, Low-Alloy and Nickel Alloy Steel

The carbon steels used in the structural qualification of the HI-STORM 100 System are SA516 Grade 70, SA515 Grade 70, and SA36. The nickel alloy and low alloy steels are SA203-E and SA350-LF3, respectively. These steels are not constituents of Alloy X. The material properties of SA516 Grade 70 and SA515 Grade 70 are shown in Tables 3.3.2. The material properties of SA203-E and SA350-LF3 are given in Table 3.3.3. The material properties of SA36 are shown in Table 3.3.6.

Two properties of these steels that are not included in Tables 3.3.2, 3.3.3 and 3.3.6 are weight density and Poisson's ratio. These properties are assumed constant for all structural analyses. The values used are shown in the table below.

PROPERTY	VALUE
Weight Density (lb/in ³)	0.283
Poisson's Ratio	0.30

3.3.1.3 Bolting Materials

Material properties of the bolting materials used in the HI-STORM 100 System and HI-TRAC lifting trunnions are given in Table 3.3.4. Material properties of HI-TRAC 100G trunnions are given in Table 3.3.7. The properties of representative anchor studs used to fasten HI-STORM 100A are listed in Table 1.2.7.

3.3.1.4 Weld Material

All weld materials utilized in the welding of the Code components comply with the provisions of the appropriate ASME subsection (e.g., Subsection NB for the MPC enclosure vessel) and Section IX. All non-code welds will be made using weld procedures that meet the requirements specified in the licensing drawings. The minimum tensile strength of the weld wire and filler material (where applicable) will be equal to or greater than the tensile strength of the base metal listed in the ASME Code.

3.3.2 Nonstructural Materials

3.3.2.1 Solid Neutron Shield

The solid neutron shielding material in the HI-TRAC top lid and transfer lid doors is not considered as a structural member of the HI-STORM 100 System. Its load carrying capacity is neglected in all structural analyses except where such omission would be non-conservative. The only material property of the solid neutron shield that is important to the structural evaluation is weight density (1.63g/cm^3).

3.3.2.2 Solid Neutron Absorber

The fuel basket solid neutron absorber is not a structural member of the HI-STORM 100 System. Its load carrying capacity is neglected in all structural analyses. The only material property of the solid neutron absorber that is important to the structural evaluation is weight density. As the MPC fuel baskets can be constructed with neutron absorber panels of variable areal density, the weight that produces the most severe cask load is assumed in each analysis (density 2.644 g/cm^3).

3.3.2.3 Concrete

The primary function of the plain concrete in the HI-STORM storage overpack is shielding. Concrete in the HI-STORM 100 Overpack is not considered as a structural member, except to withstand compressive, bearing, and penetrant loads. While concrete is not considered a structural member, its mechanical behavior must be quantified to determine the stresses in the structural members (steel shells surrounding it) under accident conditions. Table 3.3.5 provides the concrete mechanical properties. Allowable, bearing strength in concrete for normal loading conditions is calculated in accordance with ACI 318.1 -89 (92) [3.3.2]. The procedure specified in ASTM C-39 is utilized to verify that the assumed compressive strength will be realized in the actual in-situ pours. In addition, although the concrete is not reinforced (since the absence of reinforcement does

not degrade the compressive strength), the requirements of ACI-349-85 [3.3.3] are imposed to insure the suitability of the concrete mix. Appendix 1.D provides additional information on the requirements on plain concrete for use in HI-STORM 100 storage overpack.

To enhance the shielding performance of the HI-STORM storage overpack, high density concrete can be used during fabrication. The permissible range of concrete densities is specified in Table 1.D.1. The structural calculations consider the most conservative density value (i.e., maximum or minimum weight), as appropriate.

3.3.2.4 Lead

Lead is not considered as a structural member of the HI-STORM 100 System. Its load carrying capacity is neglected in all structural analysis, except in the analysis of a tornado missile strike where it acts as a missile barrier. Applicable mechanical properties of lead are provided in Table 3.3.5.

3.3.2.5 Aluminum Heat Conduction Elements

In early vintage MPCs, aluminum heat conduction elements may be located between the fuel basket and MPC vessel. They are optional thin flexible elements whose sole function is to transmit heat as described in Chapter 4. They are not credited with any structural load capacity and are shaped to provide negligible resistance to basket thermal expansion. The total weight of the aluminum inserts is less than 1,000 lb. per MPC.

3.3.2.6 Extruded Aluminum Shims

The extruded aluminum shims, as presented on the drawings in Section 1.5, are made of an aluminum alloy (ASTM B221 2219). Representative mechanical properties for the fuel basket shims are tabulated in Table 3.III.3.

The extruded aluminum shim does not withstand any tensile loads and is located in a confined space which would prevent its uncontrolled deformation under load. The evaluation of the extruded shim utilizes its mechanical properties, of which only Yield Strength has a meaningful role. Accordingly, in this FSAR, the nominal value of the Yield Strength specified in Table 3.III.3 is set down as a “critical characteristic” for the shim material. The minimum value of the Yield Strength reported in the material supplier’s CoC must be at least 90% of the nominal value in the above referenced table to ensure that its performance in the non-mechanistic tip-over analysis will not have to be revisited.

TABLE 3.3.1
ALLOY X MATERIAL PROPERTIES

Temp. (Deg. F)	Alloy X				
	S_y^{\ddagger}	S_u^{\dagger}	α_{\min}	α_{\max}	E

800	16.6 (18.26)	61.7 (57.6)	9.82	9.90	24.1

Definitions:

 S_y = Yield Stress (ksi) α = Mean Coefficient of thermal expansion (in./in. per degree F x 10^{-6}) S_u = Ultimate Stress (ksi)E = Young's Modulus (psi x 10^6)

Notes:

- Source for S_y values is Table Y-1 of [3.3.1] for austenitic stainless steels of Alloy X and Appendix 1.A for duplex stainless steel of Alloy X.
- Source for S_u values is Table U of [3.3.1] for austenitic stainless steels of Alloy X and Appendix 1.A for duplex stainless steel of Alloy X.

\ddagger Values in the parentheses correspond to yield stress of MPC Lids which are 10% greater than the minimum yield stress values tabulated in Table 1.A.3. These higher values are only credited for the stress analysis of the MPC Lid lifting holes.

\dagger The ultimate stress of Alloy X is dependent on the product form of the material (i.e., forging vs. plate). Values in parentheses are based on SA-336 forged materials (type F304, F304LN, F316, and F316LN), which are used solely for the one-piece construction MPC lids. All other values correspond to SA-240 plate material.

3. Source for α_{\min} and α_{\max} values is Table TE-1 of [3.3.1] for austenitic stainless steels of Alloy X. Values of α for duplex stainless steel grade of Alloy X can be obtained from Appendix 1.A.
4. Source for E values is material group G in Table TM-1 of [3.3.1] for austenitic stainless steels of Alloy X and Appendix 1.A for duplex stainless steel of Alloy X.
5. Minimum values of S_y , S_u and E from all candidate Alloy X materials are listed.
6. Duplex stainless steel grade of Alloy X is only used in fabrication of MPC confinement boundary components and its use is limited to 600 °F per Appendix 1.A.

3.4 GENERAL STANDARDS FOR CASKS

3.4.1 Chemical and Galvanic Reactions

In this section, it is shown that there is no credible mechanism for significant chemical or galvanic reactions in the HI-STORM 100 System during long-term storage operations (including HI-STORM 100S and HI-STORM 100A).

The MPC, which is filled with helium, provides a nonaqueous and inert environment. Insofar as corrosion is a long-term time-dependent phenomenon, the inert gas environment in the MPC precludes the incidence of corrosion during storage on the ISFSI. Furthermore, the only dissimilar material groups in the MPC are: (1) the neutron absorber material and stainless steel and (2) aluminum (found in some early vintage MPCs) and stainless steel. Neutron absorber materials and stainless steel have been used in close proximity in wet storage for over 30 years. Many spent fuel pools at nuclear plants contain fuel racks, which are fabricated from neutron absorber materials and stainless steel materials, with geometries similar to the MPC. Not one case of chemical or galvanic degradation has been found in fuel racks built by Holtec. This experience provides a sound basis to conclude that corrosion will not occur in these materials. Additionally, the aluminum conduction inserts, as well as extruded aluminum shims, and stainless steel basket are very close on the galvanic series chart. Aluminum, like other metals of its genre (e.g., titanium and magnesium) rapidly passivates in an aqueous environment, leading to a thin ceramic (Al_2O_3) barrier, which renders the material essentially inert and corrosion-free over long periods of application. The physical properties of the material, e.g., thermal expansion coefficient, diffusivity, and thermal conductivity, are essentially unaltered by the exposure of the aluminum metal stock to an aqueous environment.

The aluminum in the optional heat conduction elements (found in some early vintage MPCs) will quickly passivate in air and in water to form a protective oxide layer that prevents any significant hydrogen production during MPC cask loading and unloading operations. The aluminum in the neutron absorber material, as well as in the extruded aluminum shims, may also react with the water to generate hydrogen gas. The exact rate of generation and total amount of hydrogen generated is a function of a number of variables (see Section 1.2.1.3.1) and cannot be predicted with any certainty. Therefore, to preclude the potential for hydrogen ignition during lid welding or cutting, the operating procedures in Chapter 8 require monitoring for combustible gas and purging the space beneath the MPC lid with an inert gas during these activities. Once the MPC cavity is drained, dried, and backfilled with helium, the source of the hydrogen gas (the aluminum-water reaction) is eliminated.

The HI-STORM 100 storage overpack and the HI-TRAC transfer cask each combine low alloy and nickel alloy steels, carbon steels, neutron and gamma shielding materials, and bolting materials. All of these materials have a long history of non-galvanic behavior within close proximity of each other. The internal and external steel surfaces of each of the storage overpacks are sandblasted and coated to preclude surface oxidation. The HI-TRAC coating does not chemically react with borated water. Therefore, chemical or galvanic reactions involving the storage overpack materials are highly unlikely and are not expected.

In accordance with NRC Bulletin 96-04 [3.4.7], a review of the potential for chemical, galvanic, or other reactions among the materials of the HI-STORM 100 System, its contents and the operating environments, which may produce adverse reactions, has been performed. Table 3.4.2 provides a listing of the materials of fabrication for the HI-STORM 100 System and evaluates the performance of the material in the expected operating environments during short-term loading/unloading operations and long-term storage operations. As a result of this review, no operations were identified which could produce adverse reactions beyond those conditions already analyzed in this FSAR.

3.4.2 Positive Closure

There are no quick-connect/disconnect ports in the confinement boundary of the HI-STORM 100 System. The only access to the MPC is through the storage overpack lid, which weighs over 23,000 pounds (see Table 3.2.1). The lid is fastened to the storage overpack with large bolts. Inadvertent opening of the storage overpack is not feasible; opening a storage overpack requires mobilization of special tools and heavy-load lifting equipment.

3.4.3 Lifting Devices

As required by Reg. Guide 3.61, in this subsection, analyses for all lifting operations applicable to the deployment of a member of the HI-STORM 100 family are presented to demonstrate compliance with applicable codes and standards.

The HI-STORM 100 System has the following components and devices participating in lifting operations: lifting trunnions located at the top of the HI-TRAC transfer cask, lid lifting connections for the HI-STORM 100 lid and for other lids in the HI-TRAC transfer cask, connections for lifting and carrying a loaded HI-STORM 100 vertically, and lifting connections for the loaded MPC.

Analyses of HI-STORM 100 storage overpack and HI-TRAC transfer cask lifting devices are reported in this submittal. Analyses of MPC lifting operations are presented in the HI-STAR 100 FSAR (Docket Number 72-1008, Subsection 3.4.3) and are also applicable here.

The evaluation of the adequacy of the lifting devices entails careful consideration of the applied loading and associated stress limits. The load combination $D+H$, where H is the “handling load”, is the generic case for all lifting adequacy assessments. The term D denotes the dead load. Quite obviously, D must be taken as the bounding value of the dead load of the component being lifted. In all lifting analyses considered in this document, the handling load H is assumed to be $0.15D$. In other words, the inertia amplifier during the lifting operation is assumed to be equal to $0.15g$. This value is consistent with the guidelines of the Crane Manufacturer’s Association of America (CMAA), Specification No. 70, 1988, Section 3.3, which stipulates a dynamic factor equal to 0.15 for slowly executed lifts. Thus, the “apparent dead load” of the component for stress analysis purposes is $D^* = 1.15D$. Unless otherwise stated, all lifting analyses in this report use the “apparent dead load”, D^* , as the lifted load.

Analysis methodology to evaluate the adequacy of the lifting device may be analytical or numerical. For the analysis of the trunnion, an accepted conservative technique for computing the

bending stress is to assume that the lifting force is applied at the tip of the trunnion “cantilever” and that the stress state is fully developed at the base of the cantilever. This conservative technique, recommended in NUREG-1536, is applied to all trunnion analyses presented in this FSAR and has also been applied to the trunnions analyzed in the HI-STAR 100 FSAR.

In general, the stress analysis to establish safety pursuant to NUREG-0612, Regulatory Guide 3.61, and the ASME Code, requires evaluation of three discrete zones which may be referred to as (i) the trunnion, (ii) the trunnion/component interface, hereinafter referred to as Region A, and (iii) the rest of the component, specifically the stressed metal zone adjacent to Region A, herein referred to as Region B. During this discussion, the term “trunnion” applies to any device used for lifting (i.e., trunnions, lift bolts, etc.)

Stress limits germane to each of the above three areas are discussed below:

- i. Trunnion: NUREG-0612 and Reg. Guide 3.61 require that under the “apparent dead load”, D^* , the maximum primary stress in the trunnion be less than $1/10^{\text{th}}$ of the trunnion material ultimate strength and less than $1/3^{\text{rd}}$ of the trunnion material yield strength, respectively. Because of the materials of construction selected for trunnions in all HI-STORM 100 System components, the ultimate strength-based limit is more restrictive in every case. Therefore, all trunnion safety factors reported in this document pertain to the ultimate strength-based limit.
- ii. Region A: Trunnion/Component Interface: Stresses in Region A must meet ASME Code Level A limits under applied load D^* . Additionally, Regulatory Guide 3.61 requires that the primary stress under $3D^*$, associated with the cross-section, be less than the yield strength of the applicable material. In cases involving section bending, the developed section moment may be compared against the plastic moment at yield. The circumferential extent of the characteristic cross-section at the trunnion/component interface is calculated based on definitions from ASME Section III, Subsection NB and is defined in terms of the shell thickness and radius of curvature at the connection to the trunnion block. By virtue of the construction geometry, only the mean shell stress is categorized as “primary” for this evaluation.
- iii. Region B: Typically, the stresses in the component in the vicinity of the trunnion/component interface are higher than elsewhere. However, exceptional situations exist. For example, when lifting a loaded MPC, the MPC baseplate, which supports the entire weight of the fuel and the fuel basket, is a candidate location for high stress even though it is far removed from the lifting location (which is located in the top lid).

Even though the baseplate in the MPC would normally belong to the Region B category, for conservatism it was considered as Region A in the HI-STAR 100 SAR. The pool lid and the transfer lid of the HI-TRAC transfer cask also fall into this dual category. In general, however, all locations of high stress in the component under D^* must also be checked for compliance with ASME Code Level A stress limits.

The acceptance criteria for lifting operations summarized above are consistent with those used in the HI-STORM FW FSAR, which has been approved by the NRC.

Unless explicitly stated otherwise, all analyses of lifting operations presented in this report follow the load definition and allowable stress provisions of the foregoing. Consistent with the practice adopted throughout this chapter, results are presented in dimensionless form, as safety factors, defined as

$$\text{Safety Factor, } \beta = \frac{\text{Allowable Stress in the Region Considered}}{\text{Computed Maximum Stress in the Region}}$$

The safety factor, defined in the manner of the above, is the added margin over what is mandated by the applicable code (NUREG-0612 or Regulatory Guide 3.61).

In the following subsections, we briefly describe each of the lifting analyses performed to demonstrate compliance with regulations. Summary results are presented for each of the analyses.

It is recognized that stresses in Region A are subject to two distinct criteria, namely Level A stress limits under D* and yield strength at 3D*. We will identify the applicable criteria in the summary tables, under the column heading “Item”, using the “3D*” identifier.

All of the lifting analyses reported on in this Subsection are designated as Load Case 01 in Table 3.1.5.

3.4.3.1 125 Ton HI-TRAC Lifting Analysis – Trunnions

The lifting device in the HI-TRAC 125 cask is presented in Holtec Drawing 1880 (Section 1.5 herein). The two lifting trunnions for HI-TRAC are spaced at 180 degrees. The trunnions are designed for a two-point lift in accordance with the aforementioned NUREG-0612 criteria. Figure 3.4.21 shows the overall lifting configuration. The lifting analysis demonstrates that the stresses in the trunnions, computed using the conservative methodology described previously, comply with NUREG-0612 provisions.

Specifically, the following results are obtained:

HI-TRAC 125 Lifting Trunnions[†]		
	Value (ksi)	Safety Factor
Bending stress	16.09	1.13
Shear stress	7.26	1.50
[†] The lifted load is 245,800 lb.(a value that bounds the actual lifted weight from the pool after the lift yoke weight is eliminated per Table 3.2.4).		

Note that the safety factor presented in the previous table represents the additional margin beyond the mandated limit of 3 on yield strength and 10 on tensile strength.

Similar calculations have been performed for the HI-TRAC 125D cask, which differs from the HI-TRAC 125 with respect to the material options for the lifting trunnions. The lifting trunnions for the HI-TRAC 125 are fabricated from SB637-N07718; the lifting trunnions for the HI-TRAC 125D can be fabricated from either SB637-N07718 or SA564-630. The bounding results for the HI-TRAC 125D are:

HI-TRAC 125D Lifting Trunnions[†]		
	Value (ksi)	Safety Factor
Bending stress	13.57	1.03
Shear stress	7.26	1.16
[†] The lifted load is 245,800 lb. (a value that bounds the actual lifted weight from the pool after the lift yoke weight is eliminated per Table 3.2.4).		

3.4.3.2 125 Ton HI-TRAC Lifting – Trunnion Lifting Block Welds, Bearing, and Thread Shear Stress (Region A)

As part of the Region A evaluation, the weld group connecting the lifting trunnion block to the inner and outer shells, and to the HI-TRAC top flange, is analyzed. Conservative analyses are also performed to determine safety factors for bearing stress and for thread shear stress at the interface between the trunnion and the trunnion block. The following results are obtained for the HI-TRAC 125 and 125D transfer casks:

125 Ton HI-TRAC Lifting Trunnion Block (Region A Evaluation)			
Item	Value (ksi)	Allowable (ksi)	Safety Factor
Trunnion Block Bearing Stress	5.95	11.4	1.91
Trunnion Block Thread Shear Stress	5.05	6.84	1.35
Weld Shear Stress (3D*)	4.35 [†]	11.4	2.62

[†] No quality factor has been applied to the weld group. (Subsection NF or NUREG-0612 do not apply penalty factors to the structural welds).

3.4.3.3 125 Ton HI-TRAC Lifting – Structure near Trunnion (Region B/Region A)

A three-dimensional elastic model of the HI-TRAC 125 metal components is analyzed using the ANSYS finite element code. The structural model includes, in addition to the trunnion and the trunnion block, a portion of the inner and outer HI-TRAC shells and the HI-TRAC top flange. Stress results over the characteristic interface section are summarized and compared with allowable strength limits per ASME Section III, Subsection NF, and per Regulatory Guide 3.61. The results show that the primary stresses in the HI-TRAC 125 structure comply with the level A stress limits for Subsection NF structures.

The results from the analysis are summarized below:

HI-TRAC 125 Trunnion Region (Regions A and B)			
Item	Value (ksi)	Allowable (ksi)	Safety Factor
Membrane Stress	6.50	17.5	2.69
Membrane plus Bending Stress	8.71	26.25	3.01
Membrane Stress (3D*)	19.5	34.6	1.77

The results above are also valid for the HI-TRAC 125D since the dimensions and the configuration of the inner shell, outer shell, top flange, and the trunnion block are the same in both the HI-TRAC 125 and 125D transfer casks, and the dimension used in the finite element model for the trunnion length conservatively bounds both transfer casks.

3.4.3.4 100 Ton HI-TRAC Lifting Analysis

The lifting trunnions and the trunnion blocks for the 100 Ton HI-TRAC are identical to the trunnions analyzed for the 125 Ton HI-TRAC. However, the outer shell geometry (outer diameter) is different. A calculation performed in the spirit of strength-of-materials provides justification that, despite the difference in local structure at the attachment points, the stresses in the body of the HI-TRAC 100 Ton unit meet the allowables set forth in Subsection 3.1.2.2.

Figure 3.4.10 illustrates the differences in geometry, loads, and trunnion moment arms between the body of the 125-Ton HI-TRAC and the body of the 100-Ton HI-TRAC. It is reasonable to assume that the level of stress in the 100 Ton HI-TRAC body, in the immediate vicinity of the interface (Section X-X in Figure 3.4.10), is proportional to the applied force and the bending moment applied. In the figure, the subscripts 1 and 0 refer to 100 Ton and 125 Ton casks, respectively. Figure 3.4.10 shows the location of the area centroid (with respect to the outer surface) and the loads and moment arms associated with each construction. Conservatively, neglecting all other interfaces between the top of the trunnion block and the top flange and between the sides of the trunnion block and the shells, equilibrium is maintained by developing a force and a moment in the section comprised of the two shell segments interfacing with the base of the

trunnion block.

The most limiting stress state is in the outer shell at the trunnion block base interface. The stress level in the outer shell at Section X-X is proportional to $P/A + Mc/I$. Evaluating the stress for a unit width of section permits an estimate of the stress state in the HI-TRAC 100 outer shell if the corresponding stress state in the HI-TRAC 125 is known (the only changes are the applied load, the moment arm and the geometry). Using the geometry shown in Figure 3.4.10 gives the result as:

$$\text{Stress (HI-TRAC 100 outer shell)} = 1.242 \times \text{Stress (HI-TRAC 125 outer shell)}$$

The tabular results in the previous subsection can be adjusted accordingly and are reported below:

100 Ton HI-TRAC Near Trunnion (Region A and Region B)	
Item	Safety Factor
Membrane Stress	2.17
Membrane plus Bending Stress	2.42
Membrane Stress (3D*)	1.43

The lifting trunnions and the shell geometry surrounding lifting trunnions are different for the HI-TRAC 100G compared to the HI-TRAC 100 or 100D. The HI-TRAC 100G differs from the HI-TRAC 100 with respect to the material options for the lifting trunnions, where the lifting trunnions for the HI-TRAC 100G are fabricated from SA 182 F60. The bounding results for the HI-TRAC 100G are:

HI-TRAC 100G Lifting Trunnions[†]		
	Value (ksi)	Safety Factor
Bending stress	5.92	1.47
Shear stress	3.20	1.63
[†] The lifted load is 210,000 lb. (a value that bounds the actual lifted weight from the pool per Table 3.2.4).		

3.4.3.5 HI-STORM 100 Lifting Analyses

There are two vertical lifting scenarios for the HI-STORM 100 storage overpack carrying a fully loaded MPC. Figure 3.4.17 shows a schematic of these lifting scenarios. Both lifting scenarios are examined using finite element models that focus on the local regions near the lift points. The analysis is based on the geometry of the HI-STORM 100; the alterations to the lid and to the length of the overpack barrel to configure the HI-STORM 100S have no effect on the conclusions reached in the area of the baseplate. Therefore, there is no separate analysis for the baseplate, inboard of

the inner shell, for the HI-STORM 100S as the results are identical to or bounded by the results presented here. Since the upper portion of the HI-STORM 100S, the HI-STORM 100S lid, and the radial ribs and anchor block have a different configuration than the HI-STORM 100, separate calculations have been performed for these areas of the HI-STORM 100S. Similarly, where differences in construction between the HI-STORM 100 and the HI-STORM 100S Version B exist, separate calculations have been performed and the results summarized here.

Scenario #1 considers a “bottom lift” where the fully loaded HI-STORM 100 storage overpack is lifted vertically by four synchronized hydraulic jacks each positioned at one of the four inlet air vents. This lift allows for installation and removal of “air pads” which may be used for horizontal positioning of HI-STORM 100 at the ISFSI pad.

Scenario #2, labeled the “top lift scenario” considers the lifting of a fully loaded HI-STORM 100 vertically through the four lifting lugs located at the top end.

No structural credit is assumed for the HI-STORM concrete in either of the two lifting scenarios except as a vehicle to transfer compressive loads.

For the bottom lift, a three-dimensional one-quarter symmetry finite element model of the bottom region of the HI-STORM 100 storage overpack is constructed. The model includes the inner shell, the outer shell, the baseplate, the inlet vent side and top plates, and the radial plates connecting the inner and outer shells.

In the finite element analysis, the concrete is modeled as an equivalent pressure load applied over the baseplate as well as the four horizontal inlet vent plates. In reality, the concrete is supported only at the four inlet vents, directly above the hydraulic jacks. In other words, the concrete has sufficient strength to carry its own weight between these four support locations. The average shear stress in the concrete on a vertical cross section at the edge of an inlet vent is calculated as:

$$\tau_{concrete} = \frac{\rho V}{2A}$$

where:

- ρ equals the weight density of concrete;
- V equals the volume of unsupported concrete between two adjacent inlet vents;
- A cross-sectional area of concrete at location of maximum shear stress;

For $\rho = 160.8 \text{ lb/ft}^3$, $V = 231 \text{ ft}^3$, and $A = 5,665 \text{ in}^2 (= 27.5 \text{ in} \times 206 \text{ in})$, the average shear stress is only 3.28 psi, which is negligible compared to the allowable shear stress of 126.5 psi for 4,000 psi compressive strength concrete. If the density of concrete is increased to 200 lb/ft^3 , the shear stress increases by roughly 0.8 psi. Clearly, the concrete can support this load. Moreover, the positive effect that the concrete strength has on the results outweighs any adverse impact due to high density concrete. Therefore, the safety factors reported in this subsection (where the concrete is treated like water) for the bottom lift remain conservative for concrete densities up to 200 lb/ft^3 .

For the analysis of the “top lift” scenario, a three-dimensional 1/8-symmetry finite element model of the top segment of HI-STORM 100 storage overpack is constructed. The metal HI-STORM 100 material is modeled (shells, radial plates, lifting block, ribs, vent plates, etc.) using shell or solid elements. Lumped weights are used to ensure that portions of the structure not modeled are, in fact, properly represented as part of a lifted load. The model is supported vertically at the lifting lug. The results are reported in tabular form at the end of this subsection.

The finite element results for the HI-STORM 100, as well as the results of similar analyses for the HI-STORM 100S, are based on inner and outer shell thicknesses of 1-1/4” and 3/4”, respectively. Per Bill of Material 1575 and Drawing 3669, the thickness of both shells may be changed to 1” as an option for the HI-STORM 100 and 100S overpacks. With respect to the lifting analyses, the 1” thick inner and outer shells would have a negligible effect on the maximum calculated stress in the inlet vent horizontal plate, the HI-STORM baseplate, and the radial ribs. Therefore, the safety factors reported below for the HI-STORM 100 and 100S are valid for either thickness option.

To provide an alternate calculation to demonstrate that the bolt anchor blocks are adequate, we compute the average normal stress in the net metal area of the block under three times the lifted load. Further conservatism is introduced by including an additional 15% for dynamic amplification, i.e., the total load is equal to 3D*.

The average normal load in one bolt anchor block is

$$\text{Load} = 3 \times 1.15 \times 360,000 \text{ lb.}/4 = 310,500 \text{ lb.} \quad (\text{Weight comes from Table 3.2.1})$$

The net area of the bolt anchor block is

$$\text{Area} = (3.14159)/4 \times (5'' \times 5'' - 3.25'' \times 3.25'') = 11.34 \text{ sq. inch} \quad (\text{Dimensions from BM-1575})$$

Therefore, the safety factor (yield strength at 350 degrees F/calculated stress from Table 3.3.3) is

$$\text{SF} = 31,400 \text{ psi}/ (\text{Load}/\text{Area}) = 1.14$$

The shear stress in the threads of the lifting block is also examined. This analysis considers a cylindrical area of material under an axial load resisting the load by shearing action. The diameter of the area is the basic pitch diameter of the threads, and the length of the cylinder is the thread engagement length.

The analysis also examines the capacity of major welds in the load path and the compression capacity of the pedestal shield and pedestal shield shell.

The table below summarizes key results obtained from the analyses described above for the HI-STORM 100.

HI-STORM 100 Top and Bottom Lifting Analyses^{†‡}			
Item	Value (ksi)	Allowable (ksi)	Safety Factor
Primary Membrane plus Bending – Bottom Lift – Inlet Vent Plates –	8.0	26.3	3.28

HI-STORM 100 Top and Bottom Lifting Analyses^{†‡}			
Item	Value (ksi)	Allowable (ksi)	Safety Factor
Region B			
Primary Membrane – Top Lift – Radial Rib Under Lifting Block – Region B	6.67	17.5	2.63
Primary Membrane plus Bending – Top Lift – Baseplate – Region B	7.0	26.3	3.75
Primary Membrane Region A (3D*)	19.97	33.15	1.66
Primary Membrane plus Bending Region A (3D*)	24.02	33.15	1.38
Lifting Block Threads – Top Lift – Region A (3D*)	10.67	18.84	1.76
Lifting Stud – Top Lift – Region A (3D*)	43.733	108.8	2.49
Welds – Anchor Block-to-Radial Rib Region B	5.74	19.695	3.43
Welds – Anchor Block-to-Radial Rib Region A (3D*)	17.21	19.62	1.14
Welds – Radial Rib-to-Inner and Outer Shells Region B	5.83	21.00	3.60
Welds – Radial Rib-to-Inner and Outer Shells Region A (3D*)	17.49	19.89	1.13
Weld – Baseplate-to Inner Shell Region A (3D*)	1.59	19.89	12.48
Weld – Baseplate-to-Inlet Vent Region A (3D*)	14.89	19.89	1.33
Pedestal Shield Concrete (3D*)	0.096	1.266	13.19
Pedestal Shell (3D*)	3.269	33.15	10.14

[†] Regions A and B are defined at beginning of Subsection 3.4.3

[‡] The lifted load is 360000 lb. and an inertia amplification of 15% is included.

It is concluded that all structural integrity requirements are met during a lift of the HI-STORM 100 storage overpack under either the top lift or the bottom lift scenario. All factors of safety are greater than 1.0 using criteria from the ASME Code Section III, Subsection NF for Class 3 plate and shell supports and from USNRC Regulatory Guide 3.61.

Similar calculations have been performed for the HI-STORM 100S where differences in configuration warrant. The results are summarized in the table below:

HI-STORM 100S Top and Bottom Lifting Analyses^{†‡}			
Item	Value (ksi)	Allowable (ksi)	Safety Factor
Primary Membrane plus Bending – Bottom Lift – Inlet Vent Plates – Region A (3D*)	9.824	33.15	3.374
Lifting Block Threads – Top Lift – Region A (3D*)	7.950	18.840	2.37
Lifting Stud – Top Lift – Region A (3D*)	49.806	83.7	1.68
Welds – Anchor Block-to-Radial Rib Region B	5.556	21.0	3.78
Welds – Anchor Block-to-Radial Rib Region A (3D*)	16.670	18.84	1.13
Welds – Radial Rib-to-Inner and Outer Shells Region B	5.631*	21.00	3.73*
Welds – Radial Rib-to-Inner and Outer Shells Region A (3D*)	16.895*	19.89	1.18*
Weld – Baseplate-to Inner Shell Region A (3D*)	3.188	19.89	6.24
Weld – Baseplate-to-Inlet Vent Region A (3D*)	13.47	19.89	1.476
Radial Rib Membrane Stress – Bottom Lift Region A (3D*)	10.58	33.15	3.132
Pedestal Shield Concrete (3D*)	0.095	1.535	16.17
Pedestal Shell (3D*)	3.235	33.15	10.24

[†] Regions A and B are defined at beginning of Subsection 3.4.3

[‡] The lifted load is 410,000 lb and an inertia amplification of 15% is included. The increased weight (over the longer HI-STORM 100) comes from conservatively assuming an increase in concrete weight density in the HI-STORM 100S overpack and lid to provide additional safety margin.

* Result is specific to HI-STORM 100S overpacks fabricated with full height radial plates. For HI-STORM 100S overpacks fabricated with shorter top and bottom radial plates (i.e., two-piece configuration), the results tabulated below for the HI-STORM 100S Version B overpack, for the radial rib to inner and outer shell welds, are bounding.

Similar calculations have been performed for the HI-STORM 100S, Version B where differences in configuration warrant. The results are summarized in the table below for the heaviest HI-STORM 100S Version B (using high density concrete and with SA 564-630 stud material):

HI-STORM 100S Version B Top and Bottom Lifting Analyses			
Item	Value (ksi)	Allowable (ksi)	Safety Factor
Primary Membrane – Bottom Lift – Inlet Vent Plates – Region A (3D*)	27.06	33.15	1.22
Primary Membrane + Bending – Bottom Lift –	20.455	33.15	1.62

Inlet Vent Plates – Region A (3D*)			
Lifting Block Threads – Top Lift –Region A (3D*)	9.315	19.620	2.11
Lifting Stud – Top Lift –Region A (3D*)	49.369	108.8	2.20
Welds – Anchor Block-to-Radial Rib Region B	5.507	19.695	3.58
Welds – Anchor Block-to-Radial Rib Region A (3D*)	16.523	19.620	1.19
Welds – Radial Rib-to-Inner and Outer Shells Region B	6.120	21.00	3.43
Welds – Radial Rib-to-Inner and Outer Shells Region A (3D*)	18.36	19.89	1.08
Weld – Baseplate-to Inner Shell Region A (3D*)	2.724	19.89	7.302
Radial Rib to Inner and Outer Shell – Bottom Lift Region A (3D*)	18.360	19.89	1.08

For the longest HI-STORM 100S, Version B, with high-density concrete, the lifted load is 406,400 lb.

Similar calculations have been performed for the HI-STORM 100S Version B Type IS. The results are summarized in Supplement 37 of [3.4.17].

It is concluded that all structural integrity requirements are met during a lift of the HI-STORM 100, HI-STORM 100S, and HI-STORM 100S, Version B and Version B Type IS storage overpacks under either the top lift or the bottom lift scenario. All factors of safety are greater than 1.0 using criteria from the ASME Code Section III, Subsection NF for Class 3 plate and shell supports and from USNRC Regulatory Guide 3.61.

3.4.3.6 MPC Lifting Analysis

The MPC can be inserted or removed from an overpack by lifting cleats that are designed for installation into threaded holes in the top lid. The attachment bolts are considered a part of a special lifting device and are evaluated against the requirements of ANSI N14.6. The threaded holes in the top lid are considered interfacing lift points and are examined based on the strength requirements of NUREG 0612 and Regulatory Guide 3.61. Sufficiency of thread engagement length and bolt pre-load are also considered. The MPC top closure is examined considering the top lid as “Region B”, where satisfaction of ASME Code Level A requirements is demonstrated. The analysis also considers highly stressed regions of the top closure as “region A” where applied load is 3D*. The MPC baseplate is analyzed under normal handling and subject to the allowable strengths appropriate to a component considered in “Region B”. Finally, the baseplate region is further analyzed where loading is “3D*” consistent with the MPC baseplate being considered as “Region A”. The definitions of “Region A”, “Region B”, and “3D*” as they apply to lifting analyses have been introduced at the beginning of this subsection.

The following table summarizes the minimum safety factors from these analyses. As stated earlier, safety factors tabulated below represent margins that are over and beyond those implied by the loading magnification mandated in NUREG 0612 or Regulatory Guide 3.61, as appropriate.

Summary of MPC Lifting Analyses			
Item	MPC Lid Internal Threads Safety Factor (NUREG- 0612/Reg. Guide 3.61)	Region A Safety Factor (Note 1)	Region B Safety Factor (Note 1)
MPC	1.67	1.54	1.08

Notes:

1. Safety factor is for MPC baseplate.

When dual lids are used on the MPC, the outer lid transfers the entire lifted load to the peripheral weld. The maximum bending stress in the outer lid from the lifted load can be conservatively computed by strength of materials theory using the solution for a simply supported circular plate under a central concentrated load equal to 115% of the bounding MPC load. The calculation and result are presented below using tabular results from Timoshenko, Strength of Materials, Vol. II, 3rd Edition.

$$P = 90,000 \text{ lb.} \times 1.15$$

$$\text{Outer Diameter } a = 67.375''$$

$$\text{Effective Central Diameter where load is applied } b = 13.675'' \text{ (conservative assumption)}$$

$$a/b = 5$$

$$\text{Lid thickness} = 4.75'' \text{ (Dual lids)}$$

From the reference, $k=1.745$ and the maximum bending stress under the amplified lifted load is

$$\sigma = kP/h^2 = 8005 \text{ psi}$$

Supplement 38 of [3.4.6] provides results for the stress in the lid under maximum normal condition internal pressure. For the case with dual lids, the stress must be doubled. Therefore, the maximum primary stress is

$$S = 2 \times 1,795 \text{ psi}$$

Therefore, the combined bending stress at the center of the dual lid is 11,595. Using the allowable strength from Table 3.4.7, the safety factor is

$$SF = 25,450 \text{ psi} / 11,595 \text{ psi} = 2.195$$

3.4.3.7 Miscellaneous Lid Lifting Analyses

The HI-STORM 100 lid lifting analysis is performed to ensure that the threaded connections provided in the lid are adequately sized. The lifting analysis of the top lid is based on a vertical orientation of loading from an attached lifting device. The top lid of the HI-STORM 100 storage overpack is lifted using four lugs that are threaded into holes in the top plate of the lid (Holtec Drawing 1495, Section 1.5). It is noted that failure of the lid attachment would not result in any event of safety consequence because a free-falling HI-STORM 100 lid cannot strike a stored MPC

(due to its size and orientation). Operational limits on the carry height of the HI-STORM 100 lid above the top of the storage overpack containing a loaded MPC preclude any significant lid rotation out of the horizontal plane in the event of a handling accident. Therefore, contact between the top of the MPC and the edge of a dropped lid due to uncontrolled lowering of the lid during the lid placement operation is judged to be a non-credible scenario. Except for location of the lift points, the lifting device for the HI-STORM 100S and for the HI-STORM 100S Version B and Version B Type IS lid is the same as for the regular HI-STORM 100 lid. Since the lid weight for the HI-STORM 100S, Version B bounds the HI-STORM 100 and the HI-STORM 100S, the calculated safety factors for the lifting of the HI-STORM 100S lid are reduced and are also reported in the summary table below. Lifting calculations for the HI-STORM 100S Version B Type IS lid are performed in Supplement 36 of [3.4.17] and it is noted that all factors of safety are greater than 1.0.

In addition to the HI-STORM 100 top lid lifting analysis, the strength qualification of the lid lifting holes, and associated lid lifting devices, for the HI-TRAC pool lid and top lid has been performed. The qualification is based on the Regulatory Guide 3.61 requirement that a load factor of 3 results in stresses less than the yield stress. The results for the HI-TRAC 125 bound the results for the HI-TRAC 125D, the HI-TRAC 100, the HI-TRAC 100D, and the HI-TRAC 100G, since the lid weights used in the calculation are greater than or equal to all other HI-TRAC lid weights. Example commercially available lifting structures are considered and it is shown that thread engagement lengths are acceptable. Loads to lifting devices are permitted to be at a maximum angle of 45 degrees from vertical. A summary of results, pertaining to the various lid lifting operations, is given in the table below:

Summary of HI-STORM 100 Lid Lifting Analyses		
Item	Dead Load (lb)	Minimum Safety Factor
HI-STORM 100 (100S) Top Lid Lifting	23,000 (29,000 [†])	4.925 (3.906)
HI-STORM 100S Version B Top Lid Lifting	32,000 ^{††}	4.061
HI-TRAC Pool Lid Lifting	12,500	3.594 (Note 1)
HI-TRAC Top Lid Lifting	2,750	11.3
[†] Bounding weight of HI-STORM 100S top lid with 200 pcf concrete.		
^{††} Bounding weight of HI-STORM 100S, Version B top lid with 185 pcf concrete.		

Note 1: Safety Factor is calculated based on a conservative thread engagement of 1”.

The analysis demonstrates that thread engagement is sufficient for the threaded holes used solely for lid lifting and that commercially available lifting devices engaging the threaded holes, are available. We note that all reported safety factors are based on an allowable strength equal to 33.3% of the yield strength of the lid material when evaluating shear capacity of the internal threads and based on the working loads of the commercially available lifting devices associated with the

respective threaded holes.

3.4.3.8 HI-TRAC Pool Lid Analysis – Lifting MPC From the Spent Fuel Pool (Load Case 01 in Table 3.1.5)

During lifting of the MPC from the spent fuel pool, the HI-TRAC pool lid supports the weight of a loaded MPC plus water (see Figure 3.4.21). Calculations are performed to show structural integrity under this condition for both the HI-TRAC 100 and the HI-TRAC 125 transfer casks. In accordance with the general guidelines set down at the beginning of Subsection 3.4.3, the pool lid is considered as both Region A and Region B for evaluating safety factors. The analysis shows that the stress in the pool lid top plate is less than the Level A allowable stress under pressure equivalent to the heaviest MPC, contained water, and lid self-weight (Region B evaluation). Stresses in the lids and bolts are also shown to be below yield under three times the applied lifted load (Region A evaluation using Regulatory Guide 3.61 criteria). The threaded holes in the HI-TRAC pool lid are also examined for acceptable engagement length under the condition of lifting the MPC from the pool. It is demonstrated that the pool lid peripheral bolts have adequate engagement length into the pool lid to permit the transfer of the required load. The safety factor is defined based on the strength limits imposed by Regulatory Guide 3.61.

The following table summarizes the results of the analyses for the HI-TRAC pool lid for each of the five transfer cask types. Results given in the following table compare calculated stress (or load) and allowable stress (or load). In all cases, the safety factor is defined as the allowable value divided by the calculated value.

HI-TRAC Pool Lid Lifting a Loaded MPC Evaluation[†]			
Item	Value (ksi)	Allowable (ksi)	Safety Factor
Lid Bending Stress – HI-TRAC 125/125D – Region B Analysis – Pool Lid Top Plate	10.1	26.3	2.604
Lid Bending Stress – HI-TRAC 125/125D – Region B Analysis – Pool Lid Bottom Plate	5.05	26.3	5.208
Lid Bending Stress – HI-TRAC 100/100D – Region B Analysis- Pool Lid Top Plate	10.06	26.3	2.614
Lid Bending Stress – HI-TRAC 100/100D – Region B Analysis- Pool Lid Bottom Plate	6.425	26.3	4.093
Lid Bending Stress – HI-TRAC 100G – Region B Analysis – Pool Lid Top Plate	9.096	26.3	2.891
Lid Bending Stress – HI-TRAC 100G – Region B Analysis – Pool Lid Bottom Plate	4.548	26.3	5.783
Lid Bolt Stress – HI-TRAC 125 – (3D*)	18.92	82.3	4.35
Lid Bolt Stress – HI-TRAC 100 – (3D*)	18.21	82.3	4.519
Lid Bolt Force – HI-TRAC 125D – (3D*)	25.77‡	79.2‡	3.073
Lid Bolt Force – HI-TRAC 100D – (3D*)	24.80‡	79.2‡	3.194
Lid Bolt Force – HI-TRAC 100G – (3D*)	25.77‡	58.38‡	2.26

Lid Bending Stress – HI-TRAC 125/125D – Region A Analysis – Pool Lid Bottom Plate (3D*)	15.15	32.6	2.152
Lid Bending Stress – HI-TRAC 100/100D – Region A Analysis- Pool Lid Top Plate (3D*)	30.19	32.6	1.080
Lid Bending Stress – HI-TRAC 100/100D – Region A Analysis- Pool Lid Bottom Plate (3D*)	19.28	32.6	1.691
Lid Bending Stress – HI-TRAC 100G – Region A Analysis- Pool Lid Top Plate (3D*)	27.29	32.6	1.195
Lid Bending Stress – HI-TRAC 100G – Region A Analysis- Pool Lid Bottom Plate (3D*)	13.64	32.6	2.390
Lid Thread Engagement Length (HI-TRAC 125)	137.4‡	422.3‡	3.074

[†] Region A and B defined at beginning of Subsection 3.4.3.

[‡] Calculated and allowable value for this item in (kips).

3.4.3.9 HI-TRAC Transfer Lid Analysis – Lifting MPC Away from Spent Fuel Pool (Load Case 01 in Table 3.1.5)

During transfer to or from a storage overpack using a HI-TRAC 125 or a HI-TRAC 100, the HI-TRAC transfer lid supports the weight of a loaded MPC. Figure 3.4.21 illustrates the lift operation. In accordance with the general lifting analysis guidelines, the transfer lid should be considered as both a Region A (Regulatory Guide 3.61 criteria) and a Region B location (ASME Section III, Subsection NF for Class 3 plate and shell structures) for evaluation of safety factors. The HI-TRAC 125 transfer lid and the HI-TRAC 100 transfer lid are analyzed separately because of differences in geometry. The HI-TRAC 125D, HI-TRAC 100D, and HI-TRAC 100G employ specially designed mating devices in combination with the pool lid to transfer a loaded MPC to or from a storage overpack. Thus, a transfer lid analysis is not performed for the HI-TRAC 125D, the HI-TRAC 100D, or the HI-TRAC 100G. Results for the HI-TRAC 125D, HI-TRAC 100D, and HI-

TRAC 100G pool lids are presented in the previous subsection.

It is shown that the transfer lid doors can support a loaded MPC together with the door weight without exceeding ASME NF stress limits and the more conservative limits of Regulatory Guide 3.61. It is also shown that the connecting structure transfers the load to the cask body without overstress. The following tables summarize the results for both HI-TRAC casks:

HI-TRAC 125 Transfer Lid – Lifting Evaluation[†]			
Item	Value (ksi)	Allowable (ksi)	Safety Factor
HI-TRAC 125 – Door Plate – (3D*)	9.381	32.7	3.486
HI-TRAC 125 – Door Plate – Region B	3.127	26.25	8.394
HI-TRAC 125 – Wheel Track (3D*)	26.91	36.0	1.338
HI-TRAC 125 – Door Housing Bottom Plate-Region B	7.701	26.25	3.409

HI-TRAC 100 – Lid Top Plate (3D*)	19.395	32.7	1.686

[†] Region A and B defined at beginning of Subsection 3.4.3

3.4.3.10 HI-TRAC Bottom Flange Evaluation during Lift (Load Case 01 in Table 3.1.5)

During a lifting operation, the HI-TRAC transfer cask body supports the load of a loaded MPC, and the transfer lid (away from the spent fuel pool) or the pool lid plus contained water (lifting from the spent fuel pool). In either case, the load is transferred to the bottom flange of HI-TRAC through the bolts and a state of stress in the flange and the supporting inner and outer shells is developed. Figure 3.4.21 illustrates the lifting operation. This area of the HI-TRAC 125 is analyzed to demonstrate that the required limits on stress are maintained for both ASME and Regulatory Guide 3.61. The bottom flange is considered as an annular plate subject to a total bolt load acting at the bolt circle and supported by reaction loads developed in the inner and outer shells of HI-TRAC. The solution for maximum flange bending stress is found in the classical literature and stresses and corresponding safety factors developed for the bottom flange and for the outer and inner shell weld shear stress. Since the welds are partial penetration, weld stress evaluation bounds an evaluation of direct stress. The table below summarizes the results of the evaluation.

Safety Factors in HI-TRAC Bottom Flange During a Lift Operation			
Item	Value(ksi)	Allowable(ksi)	Safety Factor
Bottom Flange – Region B	7.798	26.25	3.37
Bottom Flange (3D*)	23.39	33.15	1.42
Outer Shell (3D*)	4.773	33.15	6.94

The bottom flanges of the HI-TRAC 125D, HI-TRAC 100D, and HI-TRAC 100G are different from the HI-TRAC 125 in several respects. Namely, the thickness of the bottom flange is reduced, and the groove weld connecting the bottom flange to the inner shell is smaller. In addition, the bottom flange of the HI-TRAC 125D, HI-TRAC 100D, and HI-TRAC 100G is reinforced by eight gusset plates, whereas the HI-TRAC 125 bottom flange is not reinforced. Therefore, to account for these differences, the evaluation described above has been repeated for the HI-TRAC 125D, the HI-TRAC 100D, and HI-TRAC 100G. The results are summarized in the tables below. Note that the following results are conservative since the HI-TRAC 125D, HI-TRAC 100D, and HI-TRAC 100G bottom flange evaluations neglect the reinforcing strength of the gusset plates.

Safety Factors in HI-TRAC 125D Bottom Flange During a Lift Operation			
Item	Value(ksi)	Allowable(ksi)	Safety Factor
Bottom Flange – Region B	9.594	26.25	2.74
Bottom Flange (3D*)	28.78	33.15	1.15
Outer Shell (3D*)	4.710	33.15	7.04
Safety Factors in HI-TRAC 100D Bottom Flange During a Lift Operation			

Item	Value(ksi)	Allowable(ksi)	Safety Factor
Bottom Flange – Region B	8.646	26.25	3.04
Bottom Flange (3D*)	25.94	33.15	1.28
Outer Shell (3D*)	5.499	33.15	6.03
Safety Factors in HI-TRAC 100G Bottom Flange During a Lift Operation			
Item	Value(ksi)	Allowable(ksi)	Safety Factor
Bottom Flange – Region B	10.27	26.25	2.56
Bottom Flange (3D*)	30.81	32.60	1.06
Inner Shell (3D*)	29.382	32.60	1.11

3.4.3.11 Conclusion

Synopses of lifting device, device/component interface, and component stresses, under all contemplated lifting operations for the HI-STORM 100 System have been presented in the foregoing. The HI-STORM storage overpack and the HI-TRAC transfer cask have been evaluated for limiting stress states. The results show that all factors of safety are greater than 1.

3.4.4 Heat

The thermal evaluation of the HI-STORM 100 System is reported in Chapter 4.

3.4.4.1 Summary of Pressures and Temperatures

Design pressures and design temperatures for all conditions of storage are listed in Tables 2.2.1 and 2.2.3, respectively.

3.4.4.2 Differential Thermal Expansion

Consistent with the requirements of Reg. Guide 3.61, Load Cases F1 (Table 3.1.3) and E4 (Table 3.1.4) are defined to study the effect of differential thermal expansion among the constituent components in the HI-STORM 100 System. The temperatures necessary to perform the differential thermal expansion analyses for the MPC in the HI-STORM 100 and HI-TRAC casks are provided in Chapter 4. The material presented in Subsection 4.4.5 demonstrates that a physical interference between discrete components of the HI-STORM 100 System (e.g. storage overpack and enclosure vessel) will not develop due to differential thermal expansion during any operating condition.

3.4.4.2.1 Normal Hot Environment

Closed form calculations are performed in Subsection 4.4.6 to demonstrate that initial gaps between the HI-STORM 100 storage overpack or the HI-TRAC transfer cask and the MPC canister, and between the MPC canister and the fuel basket, will not close due to thermal expansion of the system components under loading conditions, defined as F1 and E4 in Tables 3.1.3 and 3.1.4, respectively. To assess this in the most conservative manner, the thermal solutions computed in Chapter 4, including the thermosiphon effect, are surveyed for the following information.

- The radial temperature distribution in each of the fuel baskets at the location of peak center metal temperature.
- The highest and lowest mean temperatures of the canister shell for the hot environment condition.

Using the above temperature information, simplified thermoelastic solutions of equivalent axisymmetric problems are used to obtain conservative estimates of gap closures. The following procedure, which conservatively neglects axial variations in temperature distribution, is utilized.

1. Use the surface temperature information for the fuel basket to define a parabolic distribution in the fuel basket that bounds (from above) the actual temperature distribution. Using this result, generate a conservatively high estimate of the radial and axial growth of the different fuel baskets using classical closed form solutions for thermoelastic deformation in cylindrical bodies.
2. Use the temperatures obtained for the canister to predict an estimate of the radial and axial growth of the canister to check the canister-to-basket gaps.
3. Use the temperatures obtained for the canister to predict an estimate of the radial and axial growth of the canister to check the canister-to-storage overpack and canister-to-HI-TRAC gaps.
4. For given initial clearances, compute the operating clearances.

The results are summarized in Table 4.4.10 for normal storage conditions. The clearances between the MPC basket and canister structure, as well as between the MPC shell and storage overpack or HI-TRAC inside surface, are sufficient to preclude a temperature induced interference from differential thermal expansions under normal operating conditions.

3.4.4.2.2 Fire Accident

It is shown in Chapter 4 that the fire accident has a small effect on the MPC temperatures because of the short duration of the fire accidents and the large thermal inertia of the storage overpack. Therefore, a structural evaluation of the MPC under the postulated fire event is not required. The conclusions reached in Subsection 3.4.4.2.1 are also appropriate for the fire accident with the MPC housed in the storage overpack. Analysis of fire accident temperatures of the MPC housed within the HI-TRAC for thermal expansion is unnecessary, as the HI-TRAC, directly exposed to the fire, expands to increase the gap between the HI-TRAC and MPC.

As described in the footnote under Table 2.2.3 in Chapter 2, during a fire accident, no specific temperature limits apply to the overpack structure and the structure is only required to remain structurally stable, i.e., the maximum temperature shall be less than 1475°F at the instant of its most heated state.

As expected, the external surfaces of the HI-STORM 100 storage overpack that are directly exposed to the fire event experience maximum rise in temperature. The outer shell and top plate in the top lid are the external surfaces that are in direct contact with heated air from fire. The table below, extracted from data provided in Chapter 4, provides the maximum temperatures attained at the key locations in HI-STORM 100 storage overpack under the postulated fire event.

Component	Maximum Fire Condition Temperature (Deg. F)
Storage Overpack Inner Shell	300
Storage Overpack Radial Concrete Mid-Depth	184
Storage Overpack Outer Shell	570
Storage Overpack Lid	<570

The following conclusions are readily reached from the above table.

- The maximum metal temperature of the components described above is less than 1475°F which ensures structural stability.
- The local concrete temperature is below its short term temperature limit specified in Table 2.2.3.
- The presence of a stitch weld between the overpack inner shell and the overpack top plate ensures that there will be no pressure buildup in the concrete annulus due to the concrete losing water that then turns to steam.

The above summary confirms that the postulated fire event will not jeopardize the structural integrity of the HI-STORM 100 Overpack or significantly diminish its shielding effectiveness.

The above conclusions, as relevant, also apply to the HI-TRAC fire considered in Chapter 4. Water jacket over-pressurization is precluded by the safety valve set point. The non-structural effects of loss of water have been evaluated in Chapter 5 and shown to meet regulatory limits. Therefore, it is concluded that the postulated fire event will not cause significant loss in storage overpack or HI-TRAC shielding function.

3.4.4.3 Stress Calculations

This subsection presents calculations of the stresses in the different components of the HI-STORM 100 System from the effects of mechanical load case assembled in Section 3.1. Loading cases for the MPC fuel basket, the MPC enclosure vessel, the HI-STORM 100 storage overpack and the HI-TRAC transfer cask are listed in Tables 3.1.3 through 3.1.5, respectively. The load case identifiers defined in Tables 3.1.3 through 3.1.5 denote the cases considered.

The purpose of the analyses is to provide the necessary assurance that there will be no unacceptable risk of criticality, unacceptable release of radioactive material, unacceptable radiation levels, or impairment of ready retrievability of fuel from the MPC and the MPC from the HI-STORM 100

storage overpack or from the HI-TRAC transfer cask.

For all stress evaluations, the allowable stresses and stress intensities for the various HI-STORM 100 System components are based on bounding high metal temperatures to provide additional conservatism (Table 3.1.17 for the MPC basket, for example).

In addition to the loading cases germane to stress evaluations mentioned above, three cases pertaining to the stability of HI-STORM 100 are also considered (Table 3.1.1).

The results of various stress calculations on components are reported. The calculations are either performed directly as part of the text, or carried out in a separate calculation report that provides details of strength of materials evaluations or finite element numerical analysis. The specific calculations reported in this subsection are:

1. MPC stress calculations
2. HI-STORM 100 storage overpack stress calculations
3. HI-TRAC stress calculations

The MPC calculations reported in this document are complemented by analyses in the HI-STAR 100 Dockets. As noted earlier in this chapter, calculations for MPC components that are reported in HI-STAR 100 FSAR and SAR (Docket Numbers 72-1008 or 71-9261) are not repeated here unless geometry or load changes warrant reanalysis. For example, analysis of the MPC lid under normal conditions is not included in this submittal since neither the MPC lid loading nor geometry is affected by the MPC being placed in HI-TRAC or HI-STORM 100. MPC stress analyses reported herein focus on the basket and canister stress distributions due to the design basis (45g) lateral deceleration imposed by a non-mechanistic tip-over of the HI-STORM 100 storage overpack or a horizontal drop of HI-TRAC. In the submittals for the HI-STAR 100 FSAR and SAR (Docket Numbers 72-1008 and 71-9261, for storage and transport, respectively), the design basis deceleration was 60g. In this submittal the design basis deceleration is 45g. However, since the geometry of the MPC external boundary condition, viz. canister-to-storage overpack gap, has changed, a reanalysis of the MPC stresses under the lateral deceleration loads is required. This analysis is performed and the results are summarized in this subsection.

The HI-STORM 100 storage overpack and the HI-TRAC transfer cask have been evaluated for certain limiting load conditions that are germane to the storage and operational modes specified for the system in Tables 3.1.1 and 3.1.5. The determination of component safety factors at the locations considered in the HI-STORM 100 storage overpack and in the HI-TRAC transfer cask is based on the allowable stresses permitted by the ASME Code Section III, Subsection NF for Class 3 plate and shell support structures.

3.4.4.3.1 MPC Stress Calculations

The structural function of the MPC in the storage mode is stated in Section 3.1. The calculations presented here demonstrate the ability of the MPC to perform its structural function. The purpose of the analyses is to provide the necessary assurance that there will be no unacceptable risk of criticality, unacceptable release of radioactive material, or impairment of ready retrievability.

3.4.4.3.1.1 Analysis of Load Cases E.3.b, E.3.c (Table 3.1.4) and F.3.b, F.3.c (Table 3.1.3)

Analyses are performed for each of the MPC designs. The following subsections describe the model, individual loads, load combinations, and analysis procedures applicable to the MPC. Unfortunately, unlike vertical loading cases, where the analyses performed in the HI-STAR 100 dockets remain fully applicable for application in HI-STORM 100, the response of the MPC to a horizontal loading event is storage overpack-geometry dependent. Under a horizontal drop event, for example, the MPC and the fuel basket structure will tend to flatten. The restraint to this flattening offered by the storage overpack will clearly depend on the difference in the diameters of the storage overpack internal cavity and that of the outer surface of the MPC. In the HI-STORM 100 storage overpack, the diameter difference is larger than that in HI-STAR 100; therefore, the external restraint to MPC ovalization under a horizontal drop event is less effective. For this reason, the MPC stress analysis for lateral loading scenarios must be performed anew for the HI-STORM 100 storage overpack; the results from the HI-STAR 100 analyses will not be conservative. The HI-TRAC transfer casks and HI-STAR 100 overpack inner diameters are identical. Therefore, the analysis of the MPC in the HI-STAR 100 overpack under 60g's for the side impact (Docket 72-1008) bounds the analysis of the MPC in the HI-TRAC under 45g's.

Description of Finite Element Models of the MPCs Under Lateral Loading

A finite element model of each MPC is used to assess the effects of the accident loads. The models are constructed using ANSYS [3.4.1], and they are identical to the models used in Holtec's HI-STAR 100 submittals in Docket Numbers 72-1008 and 71-9261. The following model description is common to all MPCs except for the MPCs using basket shims welded to the MPC fuel basket and MPCs using extruded aluminum shims, which are evaluated in a separate analysis outside of ANSYS. A basket shim is defined as any structural member that is welded to the outside surface of the fuel basket panel.

The MPC structural model is two-dimensional. It represents a one-inch long cross section of the MPC fuel basket and MPC canister.

The MPC model includes the fuel basket, the basket support structures, and the MPC shell. A basket support is defined as any structural member (excluding the lift lugs) that is welded to the inside surface of the MPC shell. A portion of the storage overpack inner surface is modeled to provide the correct restraint conditions for the MPC. Figures 3.4.1 through 3.4.9 show typical MPC models. The fuel basket support structure shown in the figures is a multi-plate structure consisting of solid shims or support members having two separate compressive load supporting members. For conservatism in the finite element model some dual path compression members (i.e., "V" angles) are simulated as single columns. Therefore, the calculated stress intensities in the fuel basket angle supports from the finite element solution are conservatively overestimated in some locations.

The ANSYS model is not intended to resolve the detailed stress distributions in weld areas.

Individual welds are not included in the finite element model. A separate analysis for basket welds and for the basket supports is performed outside of ANSYS.

No credit is taken for any load support offered by the neutron absorber panels, sheathing, and the aluminum heat conduction elements. Therefore, these so-called non-structural members are not represented in the model. The bounding MPC weight used, however, does include the mass contributions of these non-structural components.

The model is built using five ANSYS element types: BEAM3, PLANE82, CONTAC12, CONTAC26, and COMBIN14. The fuel basket and MPC shell are modeled entirely with two-dimensional beam elements (BEAM3). Plate-type basket supports are also modeled with BEAM3 elements. Eight-node plane elements (PLANE82) are used for the solid-type basket supports. The gaps between the fuel basket and the basket supports are represented by two-dimensional point-to-point contact elements (CONTAC12). Contact between the MPC shell and the storage overpack is modeled using two-dimensional point-to-ground contact elements (CONTAC26) with an appropriate clearance gap.

Two orientations of the deceleration vector are considered. The 0-degree drop model includes the storage overpack-MPC interface in the basket orientation illustrated in Figure 3.1.2. The 45-degree drop model represents the storage overpack-MPC interface with the basket oriented in the manner of Figure 3.1.3. The 0-degree and the 45-degree drop models are shown in Figures 3.4.1 through 3.4.6. Table 3.4.1 lists the element types and number of elements for current MPCs.

A contact surface is provided in the model used for drop analyses to represent the interface between the storage overpack channels and the MPC. As the MPC makes contact with the storage overpack, the MPC shell deforms to mate with the channels that are welded at equal intervals around the storage overpack inner surface. The nodes that define the elements representing the fuel basket and the MPC shell are located along the centerline of the plate material. As a result, the line of nodes that forms the perimeter of the MPC shell is inset from the real boundary by a distance that is equal to half of the shell thickness. In order to maintain the specified MPC shell/storage overpack gap dimension, the radius of the storage overpack channels is decreased by an equal amount in the model.

The three discrete components of the HI-STORM 100 System, namely the fuel basket, the MPC shell, and the storage overpack or HI-TRAC transfer cask, are engineered with small diametral clearances which are large enough to permit unconstrained thermal expansion of the three components under the rated (maximum) heat duty condition. A small diametral gap under ambient conditions is also necessary to assemble the system without physical interference between the contiguous surfaces of the three components. The required gap to ensure unrestricted thermal expansion between the basket and the MPC shell is small and will further decrease under maximum heat load conditions, but will introduce a physical nonlinearity in the structural events involving lateral loading (such as side drop of the system) under ambient conditions. It is evident from the system design drawings that the fuel basket that is non-radially symmetric is in proximate contact with the MPC shell at a discrete number of locations along the circumferences. At these locations, the MPC shell, backed by the channels attached to the storage overpack, provides a support line to the fuel basket during lateral drop events. Because the fuel basket, the MPC shell, and the storage

overpack or HI-TRAC are all three-dimensional structural weldments, their inter-body clearances may be somewhat uneven at different azimuthal locations. As the lateral loading is increased, clearances close at the support locations, resulting in the activation of the support from the storage overpack or HI-TRAC.

The bending stresses in the basket and the MPC shell at low lateral loading levels which are too small to close the support location clearances are secondary stresses since further increase in the loading will activate the storage overpack's or HI-TRAC's transfer cask support action, mitigating further increase in the stress. Therefore, to compute primary stresses in the basket and the MPC shell under lateral drop events, the gaps should be assumed to be closed. However, in the analyses, we have conservatively assumed that an initial gap of 0.1875" exists, in the direction of the applied deceleration, at all support locations between the fuel basket and the MPC shell and that the clearance gap between the shell and the storage overpack at the support locations is 3/16". In the evaluation of safety factors for the MPC-24, MPC-32, and MPC-68, the total stress state produced by the applied loading on these configurations is conservatively compared with primary stress levels, even though the self-limiting stresses should be considered secondary in the strict definition of the Code. To illustrate the conservatism, we have eliminated the secondary stress (that develops to close the clearances) in the comparison with primary stress allowable values and report safety factors for the MPC-24E that are based only on primary stresses necessary to maintain equilibrium with the inertia forces.

ANSYS requires that for a static solution all bodies be constrained to prevent rigid body motion. Therefore, in the 0 degree and 45 degree drop models, two-dimensional linear spring elements (COMBIN14) join the various model components, i.e., fuel basket and enclosure vessel, at the point of initial contact. This provides the necessary constraints for the model components in the direction of the impact. By locating the springs at the points of initial contact, where the gaps remain closed, the behavior of the springs is identical to the behavior of a contact element. Linear springs and contact elements that connect the same two components have equal stiffness values.

Description of Individual Loads and Boundary Conditions Applied to the MPCs

The method of applying each individual load to the MPC model is described in this subsection. The individual loads are listed in Table 2.2.14. A free-body diagram of the MPC corresponding to each individual load is given in Figures 3.4.7-3.4.9. In the following discussion, reference to vertical and horizontal orientations is made. Vertical refers to the direction along the cask axis, and horizontal refers to a radial direction.

Quasi-static structural analysis methods are used. The effects of any dynamic load factors (DLFs) are included in the final evaluation of safety factors. All analyses are carried out using the design basis decelerations in Table 3.1.2.

The MPC models used for side drop evaluations are shown in Figures 3.4.1 through 3.4.6. In each model, the fuel basket and the enclosure vessel are constrained to move only in the direction that is parallel to the acceleration vector. The storage overpack inner shell, which is defined by three nodes needed to represent the contact surface, is fixed in all degrees of freedom. The fuel basket, enclosure vessel, and storage overpack inner shell are all connected at one location by linear springs, as described in Subsection 3.4.4.3.1.1 (see Figure 3.4.1, for example). Detailed side drop

evaluations here focus on an MPC within a HI-STORM 100 storage overpack. Since the analyses performed in Docket Number 72-1008 for the side drop condition in the HI-STAR 100 storage overpack demonstrates a safe condition under a 60g deceleration, no new analysis is required for the MPC and contained fuel basket and fuel during a side drop in the HI-TRAC, which is limited to a 45g deceleration (HI-TRAC and HI-STAR 100 overpacks have the same inside dimensions).

Accelerations

During a side impact event, the stored fuel is directly supported by the cell walls in the fuel basket. Depending on the orientation of the drop, 0 or 45 degrees (see Figures 3.4.8 and 3.4.9), the fuel is supported by either one or two walls. In the finite element model this load is effected by applying a uniformly distributed pressure over the full span of the supporting walls. The magnitude of the pressure is determined by the weight of the fuel assembly, the axial length of the fuel basket support structure, the width of the cell wall, and the impact acceleration. It is assumed that the load is evenly distributed along an axial length of basket equal to the fuel basket support structure. For example, the pressure applied to an impacted cell wall during a 0-degree side drop event is calculated as follows:

$$p = \frac{a_n W}{L c}$$

where:

p = pressure

a_n = ratio of the impact acceleration to the gravitational acceleration

W = weight of a stored fuel assembly

L = axial length of the fuel basket support structure

c = width of a cell wall

For the case of a 45-degree side drop the pressure on any cell wall equals p (defined above) divided by the square root of 2.

It is evident from the above that the effect of deceleration on the fuel basket and canister metal structure is accounted for by amplifying the gravity field in the appropriate direction.

Internal Pressure

Design internal pressure is applied to the MPC model. The inside surface of the enclosure vessel shell is loaded with pressure. The magnitude of the internal pressure applied to the model is taken from Table 2.2.1.

For this load condition, the center node of the fuel basket is fixed in all degrees of freedom to

numerically satisfy equilibrium.

Temperature

Temperature distributions are developed in Chapter 4 and applied as nodal temperatures to the finite element model of the MPC enclosure vessel (confinement boundary). Maximum design heat load has been used to develop the temperature distribution used to demonstrate compliance with ASME Code stress intensity levels.

Analysis Procedure

The analysis procedure for this set of load cases is as follows:

1. The stress intensity and deformation field due to the combined loads is determined by the finite element solution. Results are postprocessed and tabulated in the calculation package associated with this FSAR.
2. The results for each load combination are compared to allowables. The comparison with allowable values is made in Subsection 3.4.4.4.

3.4.4.3.1.2 Analysis of Load Cases E1.a, E1.c, E2, and Accident MPC Internal Pressure (Table 3.1.4)

Since the MPC shell is a pressure vessel, the classical Lamé's calculations should be performed to demonstrate the shell's performance as a pressure vessel. We note that dead load has an insignificant effect on this stress state. We first perform calculations for the shell under internal pressure. Subsequently, we examine the entire confinement boundary as a pressure vessel subject to both internal pressure and temperature gradients. Finally, we perform confirmatory hand calculations to gain confidence in the finite element predictions.

The stress from internal pressure is found for normal and accident pressures conditions using classical formulas:

Define the following quantities:

P = pressure, r = MPC radius, and t = shell thickness.

Using classical thin shell theory, the circumferential stress, $\sigma_1 = Pr/t$, the axial stress $\sigma_2 = Pr/2t$, and the radial stress $\sigma_3 = -P$ are computed for both normal and accident internal pressures. The results are given in the following table (conservatively using the outer radius for r):

Classical Shell Theory Results for Normal and Accident Internal Pressures				
Item	σ_1 (psi)	σ_2 (psi)	σ_3 (psi)	$\sigma_1 - \sigma_3$ (psi)
P= 110 psi	7522	3761	-110	7632
P= 200 psi	13675	6838	-200	13875

Maximum MPC weight, $W_{MPC} = 90,000$ lbs per Table 3.2.1

Outer diameter of MPC shell, $OD_{MPC} = 68.375''$

Thickness of MPC shell, $t_{MPC} = 0.5''$

Dynamic load factor, $DLF = 1.15$ (Table 2.0.1)

For Load Case E2, the maximum axial stress (σ_a) in the MPC shell is calculated below.

$$\sigma_a = \sigma_2 + \frac{W_{MPC} \cdot DLF}{\frac{\pi}{4} \cdot [OD_{MPC}^2 - (OD_{MPC} - 2 \cdot t_{MPC})^2]}$$

$$\sigma_a = 4,732 \text{ psi}$$

Therefore, the maximum primary membrane stress (σ_{PM}) in the MPC shell for Load Cases E1.a, E1.c and E2 is,

$$\sigma_{PM} = \max(\sigma_a, \sigma_1 - \sigma_3) = 7,632 \text{ psi}$$

The primary membrane stress allowable for MPC shell at 500 °F (per Table 3.1.17) is,

$$\sigma_{all} = 17,500 \text{ psi}$$

Therefore, the safety factor against maximum primary membrane stress in the MPC shell for Load Cases E1.a, E1.c and E2 is,

$$SF_{shell} = (\sigma_{all} / \sigma_{PM}) = 2.29$$

- Finite Element Analysis (Load Case E1.a and E1.c of Table 3.1.4)

The MPC shell, the top lid, and the baseplate together form the confinement boundary (enclosure vessel) for storage of spent nuclear fuel. In this section, the bounding normal operating conditions consisting of dead weight, design and short-term normal internal pressure limits, and thermal effects for the hot condition of storage, are evaluated. The top and bottom plates of the MPC enclosure vessel (EV) are modeled using plane axisymmetric elements, while the shell is modeled using the axisymmetric thin shell element. The thickness of the top lid varies in the different MPC types and can be either a single thick lid, or two dual lids welded around their common periphery; the minimum thickness top lid is modeled in the finite element analysis. As applicable, the results for the MPC top lid are modified to account for the fact that in the dual lid configuration, the two lids act independently under mechanical loading. The temperature distributions for all MPC constructions are nearly identical in magnitude and gradient and reflect the thermosiphon effect inside the MPC. Temperature differences across the thickness of both the baseplate and the top lid exist during HI-STORM 100's operations. There is also a thermal gradient from the center of the top lid and baseplate out to the shell wall. The metal temperature profile is essentially parabolic from the centerline of the MPC out to the MPC shell. There is also a parabolic temperature profile

along the length of the MPC canister. Figure 3.4.11 shows a sketch of the confinement boundary structure with identifiers A-I locating points where temperature input data is used to represent a continuous temperature distribution for analysis purposes. The overall dimensions of the confinement boundary are also shown in the figure.

The temperatures for confinement thermal stress analysis are determined from the thermal numerical analyses supporting the results in Chapter 4. Based on the maximum through thickness thermal gradients, a reference temperature profile is defined for all MPC types and used as input for thermal stress analysis. In reality, the temperature profile for a particular MPC will vary based upon the total heat load and the fuel loading pattern and will differ from the temperature profile analyzed herein. In order to insure that the slight variations in the temperature profile do not adversely affect the design of the MPC enclosure vessel, the allowable stress intensity values used to compute the safety factors reported in Tables 3.4.7 and 3.4.8 correspond to base metal temperatures that exceed the applied temperature profile for each MPC component at all locations.

Because of the intimate contact between the two lid plates when the MPC lid is a two-piece unit, there is no significant thermal discontinuity through the thickness; thermal stresses arising in the MPC top lid will be bounding when there is only a single lid. Therefore, for thermal stresses, results from the analysis that considers the lid as a one-piece unit are used and are amplified to reflect the increase in stress in the dual lid configuration.

Figure 3.4.12 shows details of the finite element model of the top lid (considered as a single piece), canister shell, and baseplate. The top lid is modeled with 40 axisymmetric quadrilateral elements; the weld connecting the lid to the shell is modeled by a single element solely to capture the effect of the top lid attachment to the canister offset from the middle surface of the top lid. The MPC canister is modeled by 50 axisymmetric shell elements, with 20 elements concentrated in a short length of shell appropriate to capture the so-called “bending boundary layer” at both the top and bottom ends of the canister. The remaining 10 shell elements model the MPC canister structure away from the shell ends in the region where stress gradients are expected to be of less importance. The baseplate is modeled by 20 axisymmetric quadrilateral elements. Deformation compatibility at the connections is enforced at the top by the single weld element, and deformation and rotation compatibility at the bottom by additional shell elements between nodes 106-107 and 107-108.

The geometry of the model is listed below (terms are defined in Figure 3.4.12):

$H_t =$	9.5” (the minimum total thickness lid is assumed)
$R_L =$	0.5 x 67.25” (Bill of Materials for Top Lid)
$L_{MPC} =$	190.5” (Design Drawings in Section 1.5)
$t_s =$	0.5”
$t_{BP} =$	2.5”
$\beta =$	$2\sqrt{R_s t_s} \approx 12"$ (the “bending boundary layer”)

Stress analysis results are obtained for two cases as follows:

- a. internal pressure = 100 psi
- b. internal pressure = 110 psi plus short-term normal condition temperatures

For this configuration, dead weight of the top lid acts to reduce the stresses due to pressure. For example, the equivalent pressure simulating the effect of the weight of the top lid is an external pressure of 3 psi, which reduces the pressure difference across the top lid to 97 psi under long-term normal internal pressure limit and 107 psi under short-term normal internal pressure limit. The dead weight of the top lid is neglected to provide additional conservatism in the results. The dead weight of the baseplate, however, adds approximately 0.73 psi to the effective internal pressure acting on the base. The effect of dead weight is still insignificant compared to the 100 psi design pressure limit and 110 psi short-term normal condition pressure limit, and is therefore neglected. The thermal loading in the confinement vessel is obtained by developing a parabolic temperature profile to the entire length of the MPC canister and to the top lid and baseplate. The temperature data provided at locations A-I in Figures 3.4.11 and 3.4.12 are sufficient to establish the profiles. Through-thickness temperatures are assumed linearly interpolated between top and bottom surfaces of the top lid and baseplate. Finally, in the analysis, all material properties and expansion coefficients are considered to be temperature-dependent in the model.

Results for stress intensities are reported for the case of design internal pressure limit alone (Load Case E.1.a in Table 3.1.4) and for the combined loading of short-term normal pressure limit plus temperature (Load Case E1.c in Table 3.1.4). Tables 3.4.7 and 3.4.8 report results at the inside and outside surfaces of the top lid and baseplate at the centerline and at the extreme radius. Canister results are reported in the “bending boundary layer” and at a location near mid-length of the MPC canister. In the tables, the calculated value is the value from the finite element analysis, the categories are P_m = primary membrane; $P_L + P_b$ = local membrane plus primary bending; and $P_L + P_b + Q$ = primary plus secondary stress intensity. The allowable strength value is obtained from the appropriate table in Section 3.1 for Level A conditions, and the safety factor SF is defined as the allowable strength divided by the calculated value. Allowable strengths for Alloy X are taken at 550 degrees F, 400 degrees F, and 500 degrees F, respectively, for the MPC lid, baseplate, and canister shell. These temperatures bound the actual component temperatures during both of the above loading cases. The results given in Tables 3.4.7 and 3.4.8 demonstrate the ruggedness of the MPC as a confinement boundary. It is noted that secondary stresses are conservatively presented in Table 3.4.7 (for Design condition) even though it is not required by Table 2.2.10. The Level B off-normal condition is bounded by the short-term normal condition which has an identical pressure limit, comparable temperatures, and is evaluated against Level A allowables. Since mechanically induced stresses in the top lid are increased when a dual lid configuration is considered, the stress results obtained from an analysis of a single top lid must be corrected to reflect the maximum stress state when a dual lid configuration is considered. The modifications required are based on the following logic:

Consider the case of a simply supported circular plate of thickness h under uniform lateral pressure “ q ”. Classical strength of materials provides the solution for the maximum stress, which occurs at the center of the plate, in the form:

$$\sigma_s = 1.2375 \cdot q \cdot \left(\frac{a}{h} \right)^2 \quad \text{where } a \text{ is the radius of the plate and } h \text{ is the plate thickness.}$$

Now consider the MPC simply supported top lid as fabricated from two plates “1” and “2”, of thickness h_1 and h_2 , respectively, where the lower surface of plate 2 is subjected to the internal pressure “ q ”, the upper surface of plate 1 is the outer surface of the helium retention boundary, and the lower surface of plate 1 and the upper surface of plate 2 are in contact. The following sketch shows the dual lid configuration for the purposes of this discussion:

From classical plate theory, if it is assumed that the interface pressure between the two plates is uniform and that both plates deform to the same central deflection, then if

$$h_1 + h_2 = h, \text{ and if } h_2/h_1 = r$$

the following relations exist between the maximum stress in the two individual plates, σ_1 , σ_2 and the maximum stress σ_s in the single plate of thickness “ h ” (assuming that all three plates are the same material):

$$\frac{\sigma_1}{\sigma_s} = \frac{(1+r)^2}{(1+r^3)} \qquad \frac{\sigma_2}{\sigma_s} = \frac{(1+r)^2}{(1+r^3)} r$$

Since the two lid thicknesses are the same in the dual lid configuration, $r = 1.0$ so that the stresses in plates 1 and 2 are both two times larger than the maximum stress computed for the single plate lid having the same total thickness. In Tables 3.4.7 and 3.4.8, bounding results for the single lid configuration are reported; a doubling of the calculated stress values (and a halving of the top lid safety factors) results when the dual lid configuration is considered.

Per the design drawings in Section 1.5, the top plate in the dual lid configuration is stainless steel (Alloy X), and the bottom plate is fabricated from stainless steel or carbon steel with a stainless steel covering. Although the top and bottom plates may be different materials, the stress amplification factor of 2, which is used to convert the results from the one-piece MPC lid to the dual lid configuration as explained above, is conservative since carbon steel has a higher Young’s modulus than stainless steel. Therefore, the carbon steel bottom plate would be stiffer, and the stress in the top plate would be less versus the dual lid configuration with stainless steel top and bottom plates.

- Evaluation of MPC Baseplate Alternate Support Configuration

The stress state in the MPC baseplate and adjacent canister is evaluated to assess the effect of the

discrete support of the MPC under the action of vertical loading plus pressure and temperature. The alternate MPC supports consist of bearing pads (shims) at six locations around the periphery plus a central support to transfer vertical loads to the HI-STORM. The baseplate of the MPC has been previously analyzed under loading from the fuel basket and the fuel assemblies assuming the baseplate plate continuously supported around the periphery by the MPC canister shell (e.g., this condition arises during lifting and lowering of the MPC into the storage overpack). To evaluate the effect of a discrete support configuration, a finite element model of $\frac{1}{2}$ of the baseplate is constructed using shell elements and includes a sufficient portion of the MPC canister to simulate the canister-to-baseplate joint and the bending boundary layer in the canister shell. Vertical loads from fuel assemblies and fuel basket are applied to the baseplate as a uniform pressure and a ring loading, respectively (these loads have been applied in the same manner in the evaluation of the baseplate under the MPC lowering condition for HI-STORM 100 system). The total vertical load is resisted at the peripheral and central discrete support locations. Under normal conditions of storage, the baseplate/canister is subject to normal service pressure and temperature plus the one-g dead weight loading. The state of stress in the MPC under design pressure, and short-term pressure limit and operating temperatures, have been previously considered using an axis-symmetric finite element model. The results are discussed above (see “Finite Element Analysis”) and summarized in Tables 3.4.7 (Design condition) and 3.4.8 (Level A condition). In Table 3.4.8, although the actual metal temperatures were used to develop the solution for the thermal stresses, the allowable stresses were conservatively chosen at the design temperature limits rather than at the actual operating temperatures.

The stress intensities arising in the MPC baseplate and in the lower portion of the canister from the added vertical load are added to the previously determined stress intensities arising from internal pressure and temperature (reported in Table 3.4.8 and adjusted downward for actual service pressure) to obtain the total stress intensity for the Level A normal operating condition. The computed stress intensities are then amplified to simulate the vertical seismic event and again summed with the results from Table 3.4.8 to obtain the total stress intensity for the Level D condition.

The primary and secondary stress intensities in the MPC baseplate and canister shell are computed for the Level A short-term normal operating condition. The Level B off-normal condition is bounded by the short-term normal condition which has an identical pressure limit, comparable temperatures, and is evaluated against Level A allowables. The maximum primary stress intensity in the MPC baseplate is also determined for the Level D vertical seismic event. All computed safety factors are above 1.0.

3.4.4.3.1.3 Elastic Stability and Yielding of the MPC Basket under Compression Loads (Load Case F3 in Table 3.1.3)

This load case corresponds to the scenario wherein the loaded MPC is postulated to drop causing a compression state in the fuel basket panels.

a. Elastic Stability

Following the provisions of Appendix F of the ASME Code [3.4.3] for stability analysis of Subsection NG structures, (F-1331.5(a)(1)), a comprehensive buckling analysis is performed using ANSYS. For this analysis, ANSYS's large deformation capabilities are used. This feature allows ANSYS to account for large nodal rotations in the fuel basket, which are characteristic of column buckling. The interaction between compressive and lateral loading, caused by the deformation, is exactly included. Subsequent to the large deformation analysis, the basket panel that is most susceptible to buckling failure is identified by a review of the results. The lateral displacement of a node located at the mid-span of the panel is measured for the range of impact decelerations. The buckling or collapse load is defined as the impact deceleration for which a slight increase in its magnitude results in a disproportionate increase in the lateral displacement.

The stability requirement for the MPC fuel basket under lateral loading is satisfied if two-thirds of the collapse deceleration load is greater than the design basis horizontal acceleration (Table 3.1.2). This analysis was performed for the HI-STAR 100 submittal (Docket Number 72-1008) under a 60g deceleration loading. Within the HI-STAR 100 FSAR (Docket Number 72-1008), Figures 3.4.27 through 3.4.32 are plots of lateral displacement versus impact deceleration for the MPC-24, MPC-32, and MPC-68. It should be noted that the displacements (in the HI-STAR 100 FSAR) in Figures 3.4.27 through 3.4.31 are expressed in 1×10^{-1} inch and Figure 3.4.32 is expressed in 1×10^{-2} inch. The plots in the HI-STAR 100 FSAR clearly show that the large deflection collapse load of the MPC fuel basket is greater than 1.5 times the design basis deceleration for all baskets in all orientations. The results for the MPC-24E are similar. Thus, the requirements of Appendix F are met for lateral deceleration loading under Subsection NG stress limits for faulted conditions.

An alternative solution for the stability of the fuel basket panel is obtained using the methodology espoused in NUREG/CR-6322 [3.4.13]. In particular, we consider the fuel basket panels as wide plates in accordance with Section 5 of NUREG/CR-6322. We use eq.(19) in that section with the "K" factor set to the value appropriate to a clamped panel. Material properties are selected corresponding to a metal temperature of 600 degrees F which bounds computed metal temperatures at the periphery of the basket. In general, the basket periphery sees the largest loading in an impact scenario. The critical buckling stress is:

$$\sigma_{cr} = \left(\frac{\pi}{K} \right)^2 \frac{E}{12(1-\nu^2)} \left(\frac{h}{a} \right)^2$$

where h is the panel thickness, a is the unsupported panel length, E is the Young's Modulus of Alloy X at 600 degrees F, ν is Poisson's Ratio, and $K=0.65$ (per Figure 6 of NUREG/CR-6322).

The MPC-24 has a small h/a ratio; the results of the finite element stress analyses under design basis deceleration load show that this basket is subject to the highest compressive load in the panel. Therefore, the critical buckling load is computed using the geometry of the MPC-24. The following table shows the results from the finite element stress analysis and from the stability calculation.

Panel Buckling Results From NUREG/CR-6322			
Item	Finite Element Stress (ksi)	Critical Buckling Stress (ksi)	Factor of Safety
Stress	12.585	44.44	3.531

For a stainless steel member under an accident condition load, the recommended safety factor is 2.12. We see that the calculated safety factor exceeds this value; therefore, we have independently confirmed the stability predictions of the large deflection analysis based on classical plate stability analysis by employing a simplified method.

Stability of the basket panels, under longitudinal deceleration loading, is demonstrated in the following manner. Under 60g deceleration in Docket Number 71-9261, the axial compressive stress was computed for all fuel basket types, and the bounding result was determined as:

$$4,074 \text{ psi} \quad (\text{for MPC 24E})$$

For the 45g design basis decelerations for HI-STORM 100, the basket axial stresses are reduced by 25%.

The above values represent the amplified weight, including the nonstructural sheathing and the neutron absorber material, divided by the bearing area resisting axial movement of the basket. To demonstrate that elastic instability is not a concern, the buckling stress for an MPC-24 flat panel is computed.

For elastic stability, Reference [3.4.8] provides the formula for critical axial stress as

$$\sigma_{cr} = \frac{4 \pi^2 E}{12 (1 - \nu^2)} \left(\frac{T}{W} \right)^2$$

where T is the panel thickness and W is the width of the panel, E is the Young's Modulus at the metal temperature and ν is the metal Poisson's Ratio. The following table summarizes the calculation for the critical buckling stress using the formula given above:

Elastic Stability Result for a Flat Panel	
Reference Temperature	752 degrees F
T (MPC-24)	5/16 inch
W	10.777 inch
E	24,436,000 psi
Critical Axial Stress	74,280 psi

It is noted the critical axial stress is an order of magnitude greater than the computed basket axial stress reported in the foregoing and demonstrates that elastic stability under longitudinal deceleration load is not a concern for any of the fuel basket configurations.

b. Yielding

The safety factor against yielding of the basket under longitudinal compressive stress from a design basis inertial loading is given, using the bounding result for the MPC-24E, by

$$SF = 17,100/4,074 = 4.197$$

Therefore, plastic deformation of the fuel basket under design basis deceleration is not credible.

3.4.4.3.1.4 MPC Baseplate Analysis (Load Case E2)

Minimum safety factors have been reported for Load Case E2 in Subsection 3.4.3.6 where an evaluation has been performed for stresses under three times the apparent load D*. A bounding analysis is performed in the HI-STAR 100 FSAR (Docket Number 72-1008, Appendix 3.I) to evaluate the stresses in the MPC baseplate during a vertical end drop (Load Case E3.a). During a fire (Load Case E5), the MPC baseplate is subjected to the accident internal pressure, dead load, and the fire temperature (which serves only to lower the allowable strengths). The results for Load Cases E3.a and E5 are summarized below:

MPC Baseplate Minimum Safety Factors – Load Cases E3.a and E5			
Item	Value (ksi)	Allowable (ksi)	Safety Factor
Center of Baseplate – Primary Bending (Load Case E3.a) (Note 1)	35.93	67.32	1.87
Center of Baseplate – Primary Bending (Load Case E5)	46.38	54.23	1.17

Notes:

1. Detailed analysis presented in Appendix 3.I of HI-STAR 100 FSAR (Docket 72-1008).

3.4.4.3.1.5 Analysis of the MPC Top Closure (Load Case E2)

The FSAR for the HI-STAR 100 System (Docket Number 72-1008, Appendix 3.E) contains stress analysis of the MPC top closure during lifting. Loadings in that analysis are also valid for the HI-STORM 100 System. In addition, the results from top closure lid structural evaluations under the short-term normal condition pressure limit (per Table 2.2.1) are presented in Subsection 3.4.3.6 and Table 3.4.4. From Table 2.2.1, the off-normal internal pressure limit is 110 psi, or ten percent greater than the long-term normal design pressure limit. Whereas Level A service limits are used to establish allowables for the normal design pressure, Level B service limits are used for off-normal loads. Since Subsection NB of the ASME Code permits an identical 10% increase in allowable stress intensity values for stress intensities generated by Level B Service Loadings, it stands to reason that the safety factors reported for normal pressure are also valid for the case of off-normal design internal pressure.

3.4.4.3.1.6 Structural Analysis of the Fuel Support Spacers (Load Case E3.a)

Upper and lower fuel support spacers are utilized to position the active fuel region of the spent nuclear fuel within the poisoned region of the fuel basket. It is necessary to ensure that the spacers will continue to maintain their structural integrity after an accident event. Ensuring structural integrity implies that the spacer will not buckle under the maximum compressive load, and that the maximum compressive stress will not exceed the compressive strength of the spacer material (Alloy X). Detailed calculations in Docket Number 72-1008, Appendix 3.J, demonstrate that large structural margins in the fuel spacers are available for the entire range of spacer lengths which may be used in HI-STORM 100 applications (for the various acceptable fuel types). The calculations for the HI-STORM 100 45g load are bounded by those for the HI-STAR 100 60g load.

3.4.4.3.1.7 External Pressure (Load Case E1.b, Table 3.1.4)

The design external pressure for the MPC is zero psig. The outer surface of the MPC shell is conservatively subject to a net external pressure of 2 psig. The methodology for analysis of the MPC under this external pressure is provided in the HI-STAR 100 FSAR Docket Number 72-1008. Using the identical methodology with input loads and decelerations appropriate to the HI-STORM, safety factors > 1.0 are obtained for all relevant load cases.

3.4.4.3.1.8 Miscellaneous MPC Structural Evaluations

Calculations are performed to determine the minimum fuel basket weld size, the capacity of the sheathing welds, the stresses in the MPC cover plates, and the stresses in the fuel basket supports (or basket shims). The following paragraphs briefly describe each of these evaluations.

The fillet welds in the fuel basket honeycomb are made by an autogenous operation that has been shown to produce highly consistent and porosity free weld lines. However, Subsection NG of the ASME Code permits only 40% quality credit on double fillet welds which can be only visually examined (Table NG-3352-1). Subsection NG, however, fails to provide a specific stress limit on such fillet welds. In the absence of a Code mandated limit, Holtec International's standard design procedure requires that the weld section possess as much load resistance capability as the parent metal section. Since the loading on the honeycomb panels is essentially that of section bending, it is possible to develop a closed form expression for the required weld throat thickness “t” corresponding to panel thickness “h”.

The sheathing is welded to the fuel basket cell walls to protect and position the neutron absorber material. Force equilibrium relationships are used to demonstrate that the sheathing weld is adequate to support a 45g deceleration load applied vertically and horizontally to the sheathing and the confined neutron absorber material. The analysis assumes that the weld is continuous and then modifies the results to reflect the amplification due to intermittent welding.

The MPC cover plates are welded to the MPC lid during loading operations. The cover plates are part of the confinement boundary for the MPC. No credit is taken for the pressure retaining abilities of the quick disconnect couplings for the MPC vent and drain. Therefore, the MPC cover plates must meet ASME Code, Section III, Subsection NB limits for normal, off-normal, and accident

conditions. Conservatively, the accident condition pressure loading is applied, and it is demonstrated that the Level A limits for Subsection NB are met where possible.

The fuel basket internal to the MPC canister is supported by a combination of angle fuel basket supports and flat plate or solid bar fuel basket supports. Alternatively, the fuel basket internal to the MPC canister can be supported by basket shims. These fuel basket supports (or basket shims) are subject to significant load only when a lateral acceleration is applied to the fuel basket and the contained fuel. The quasi-static finite element analyses of the MPC's, under lateral inertia loading, focused on the structural details of the fuel basket and the MPC shell. Basket supports were modeled in less detail, which served only to properly model the load transfer path between fuel basket and canister. Safety factors reported for the fuel basket supports from the finite element analyses, are overly conservative, and do not reflect available capacity of the fuel basket angle support or the basket shim. A strength of materials analysis of the fuel basket angle supports (or basket shims) is performed to complement the finite element results. Weld stresses in the load path are computed, direct stress in the support members is evaluated, and stability of the support legs is examined for all fuel basket support configurations.

The MPC-32 fuel basket may also be supported by a set of extruded aluminum shims. These shims provide similar support to the MPC basket to that of the MPC basket shims that are welded to the basket and those welded to the MPC shell. The extruded aluminum shims span approximately the same height as the MPC basket and will therefore, have an equivalent, if not better, load distribution for design basis structural events when compared to the other basket shims or basket supports used in other acceptable designs. The extruded shims are also not welded to the MPC internal components and will therefore be more structurally robust than the MPC basket shims or supports used in other acceptable designs. Therefore, the extruded aluminum shims exhibit greater structural support than the MPC basket support or MPC basket shim designs.

The results of these evaluations are summarized in the tables below.

Minimum Weld Sizes for Fuel Baskets			
Basket Type	Panel Thickness (h), in	t/h Ratio	Minimum Weld Size (t), in
MPC-24	5/16	0.568	0.177
MPC-68	1/4	0.533	0.133
MPC-32	9/32	0.580	0.163
MPC-24E	5/16	0.519	0.162

Miscellaneous Stress Results for MPC			
Item	Stress (ksi)	Allowable Stress (ksi)	Safety Factor
Shear Stress in Sheathing Weld	7.724	27.93	3.62
Bending Stress in MPC Cover Plate (Level A)	15.49	24.6	1.59
Bending Stress in MPC Cover Plate (Level D)	28.16	59.04	2.10

Shear Stress in MPC Cover Plate Weld	7.55	18.93	2.51
Shear Stress in Fuel Basket Angle Support Weld	19.78	26.67	1.35
Combined Stress in Fuel Basket Support Plates	32.393	59.1	1.82
Load on Basket Support Legs (Stability)	2.185 kips/in	8.886 kips/in	4.07
Shear Stress in Basket Shim Weld	31.78	32.385	1.019
Combined Stress in Basket Shim	31.246	63	2.02
Load on Basket Shim (Stability)	8.015 kips/in	225.393 kips/in	28.12

3.4.4.3.1.9 Structural Integrity of Damaged Fuel Containers

The damaged fuel containers or canisters (DFCs) to be deployed in the HI-STAR 100 System transport package have been evaluated to demonstrate that the containers are structurally adequate to support the mechanical loads postulated during normal operations, while in long-term storage, and during a hypothetical end drop. The evaluations address the following damaged/failed fuel containers for transportation in the HI-STAR 100 System:

- Holtec-designed MPC-24E (PWR) DFC
- Holtec-designed MPC-68 (BWR) DFC
- Transnuclear-designed DFC for Dresden Unit 1 fuel
- Transnuclear-designed Thoria Rod Canister for Dresden Unit 1

The structural load path in each of the analyzed containers is evaluated using basic strength of materials formulations. The various structural components are modeled as axial or bending members and their stresses are computed. Depending on the particular DFC, the load path includes components such as the container sleeve and collar, various weld configurations, load tabs, closure components and lifting bolts. Axial plus bending stresses are computed, together with applicable bearing stresses and weld stresses. Comparisons are then made with the appropriate allowable strengths at temperature. Input data for all DFCs comes from the applicable drawings. The design temperature for lifting evaluations is set at 150°F (since the DFC is in the spent fuel pool). The design temperature for accident conditions is set at 725°F.

For those DFCs designed to be handled when loaded, the DFC lift point(s) must be designed in accordance with Item 3 in Section 5.1.6 of NUREG-0612 [3.1.1]. The remaining components of the damaged fuel container are governed by the stress limits of the ASME Code Section III, Subsection NG [3.4.10] and Section III, Appendix F [3.4.3], as applicable.

The following table presents the minimum safety factors, from all of the stress computations, for each of the above listed DFCs.

DFC Type	Loading Condition – DFC Component	Calculated Stress (ksi)	Allowable Stress (ksi)	Safety Factor = (Allowable Stress) / (Calculated Stress)	Remarks
Holtec-designed MPC-24E (PWR) DFC					
	60g End Drop – Baseplate-to-Container Sleeve Welds	3.95	26.59	6.73	ASME Level D stress limit
Holtec-designed MPC-68 (BWR) DFC					
	60g End Drop – Baseplate-to-Container Sleeve Welds	1.59	26.59	16.7	ASME Level D stress limit
Transnuclear-designed DFC for Dresden Unit 1	Normal Lift – Lid Frame Assembly	0.527	4.583	8.70	Bearing stress
	60g End Drop – Bottom Assembly	12.32	37.92	3.08	ASME Level D stress limit
Transnuclear-designed Thoria Rod Canister for Dresden Unit 1	Normal Lift – Lid Frame Assembly	0.373	4.583	12.3	Bearing stress
	60g End Drop – Bottom Assembly	8.73	37.92	4.34	ASME Level D stress limit

The table above demonstrates that the DFCs are structurally adequate to support the mechanical loads postulated during normal operations and during a hypothetical end drop. Moreover, since the HI-STAR design basis handling accident bounds the corresponding load for HI-STORM (60g vs. 45g), the DFCs can be carried safely in both the HI-STAR and HI-STORM Systems.

3.4.4.3.1.10 Analysis of MPC Baseplate and Closure Lid (Load Case E5)

During a fire (Load Case E5), the MPC baseplate is subjected to the accident pressure plus dead load, and the fire temperature (which serves only to lower the allowable strengths). The results of this analysis are summarized below:

MPC Baseplate Minimum Safety Factors – Load Cases E5			
Item	Value (ksi)	Allowable (ksi)	Safety Factor
Center of Baseplate – Primary Bending (Load Case E5)	46.58	54.25	1.16

The closure lid and the closure lid peripheral weld are also examined for maximum stresses developed during the storage fire. The closure lid is modeled as a single simply supported plate and is subject to dead load plus accident internal pressure. Results are presented for both the single and dual lid configuration (in parentheses). The results for minimum safety factor are reported in the table below.

MPC Top Closure Lid – Minimum Safety Factors – Load Case E5			
Item	Stress (ksi) or Load (lb.)	Allowable Stress (ksi) or Load Capacity (lb.)	Safety Factor
Lid Bending Stress – Load Case E5	3.158/(6.316)	54.225	17.17/(8.58)
Lid-to-Shell Peripheral Weld Load – Load Case E5	713,047	1,477,000 [†]	2.07

[†] Based on 0.625" single groove weld and conservatively includes a quality factor of 0.45.

We note from the above that all safety factors are greater than 1.0.

3.4.4.3.2 HI-STORM 100 Storage Overpack Stress Calculations

The structural functions of the storage overpack are stated in Section 3.1. The analyses presented here demonstrate the ability of components of the HI-STORM 100 storage overpack to perform their structural functions in the storage mode. Load Cases considered are given in Table 3.1.5. The nomenclature used to identify the load cases (Load Case Identifier) considered is also given in Table 3.1.5.

The purpose of the analyses is to provide the necessary assurance that there will be no unacceptable release of radioactive material, unacceptable radiation levels, or impairment of ready retrievability of the MPC from the storage overpack. Results obtained using the HI-STORM 100 configuration are identical to or bound results for the HI-STORM 100S configuration.

3.4.4.3.2.1 HI-STORM 100 Compression Under the Static Load of a Fully Loaded HI-TRAC Positioned on the Top of HI-STORM 100 (Load Case 01 in Table 3.1.5)

During the loading of HI-STORM 100, a HI-TRAC transfer cask with a fully loaded MPC may be placed on the top of a HI-STORM 100 storage overpack. During this operation, the HI-TRAC may be held by a single-failure-proof lifting device so a handling accident is not credible. The HI-STORM 100 storage overpack must, however, possess the compression capacity to support the additional dead load. The following analysis provides the necessary structural integrity demonstration; safety factors are large and results for the HI-STORM 100 overpack are representative of the margins for the 100S and 100S Version B (including Version B Type IS) overpacks.

Define the following quantities for analysis purposes:

W_{HT} = Bounding weight of HI-TRAC 125D (loaded w/ MPC-32) = 236,000 lb (Table 3.2.2)

W_{MD} = Weight of mating device = 15,000 lb

$W_{TOTAL} = W_{HT} + W_{MD} = 251,000$ lb

The total weight of the HI-TRAC 125D plus the mating device is greater than the weight of a loaded HI-TRAC 125 with the transfer lid. Therefore, the following calculations use the weight

for the HI-TRAC 125D as input.

The dimensions of the compression components of HI-STORM 100 are as follows:

outer diameter of outer shell =	$D_o = 132.5"$
thickness of outer shell =	$t_o = 0.75"$ (1" for HI-STORM 100S Version B)
outer diameter of inner shell =	$D_i = 76"$
thickness of inner shell =	$t_i = 1.25"$ (1" for HI-STORM 100S Version B and 0.75" for HI-STORM 100S Version B Type IS)
thickness of radial ribs =	$t_r = 0.75"$ (ribs are not full-length for HI-STORM 100S Version B and 100S Version B Type IS; HI-STORM 100S can be fabricated with full or partial length ribs)

In what follows, detailed results are provided using the classic HI-STORM 100 dimensions. While Bill of Material 1575 provides the option to fabricate the inner and outer shells from 1" thick material, the above dimensions (i.e., t_o and t_i) are used because they minimize the total cross sectional metal area.

The metal area of the outer shell is

$$A_o = \frac{\pi}{4} (D_o^2 - (D_o - 2t_o)^2) = \frac{\pi}{4} (132.5^2 - 131^2) \\ = 310.43 \text{ in}^2$$

The metal area of the radial ribs is

$$A_r = 4 t_r (D_o - 2 t_o - D_i) / 2 = \frac{3}{2} (131 - 76) = 82.5 \text{ in}^2$$

The metal area of the inner shell is

$$A_i = \frac{\pi}{4} (76^2 - 73.5^2) = 293.54 \text{ in}^2$$

In the HI-STORM 100, there are four radial ribs that extend full length and can carry load. For the HI-STORM 100S, the HI-STORM 100S Version B and the HI-STORM 100S Version B Type IS, the radial ribs are not counted as part of the compression load carrying area since they are not required to be full-length. The concrete radial shield can also support compression load. The area of concrete available to support compressive loading is

$$\begin{aligned}
 A_{\text{concrete}} &= \frac{\pi}{4} ((D_o - 2t_o)^2 - (D_i)^2) - A_r \\
 &= \frac{\pi}{4} (131^2 - 76^2) - 82.5 \text{ in}^2 \\
 &= (8,994 - 82.5) \text{ in}^2 = 8,859.5 \text{ in}^2
 \end{aligned}$$

The areas computed above are calculated at a section below the air outlet vents. To correct the above areas for the presence of the air outlet vents (HI-STORM 100 only since HI-STORM 100S and HI-STORM 100S, Version B and Version B Type IS have the air outlet vents located in the lid), we note that Bill-of-Materials 1575 in Chapter 1 gives the size of the horizontal plate of the air outlet vents as:

Peripheral width = $w = 16.5''$

Radial depth = $d = 27.5''$ (over concrete in radial shield)

Using these values, the following final areas are obtained:

$$A_o = A_o(\text{no vent}) - 4t_o w = 260.93 \text{ sq. inch}$$

$$A_i = A_i(\text{no vent}) - 4t_i w = 211.04 \text{ sq. inch}$$

$$A_{\text{concrete}} = A_{\text{concrete}}(\text{no vent}) - 4dw = 7044.2 \text{ sq. inch}$$

The loading case is a Level A load condition. The load is apportioned to the steel and to the concrete in accordance with the values of EA for the two materials ($E(\text{steel}) = 28,000,000 \text{ psi}$ and $E(\text{concrete}) = 3,605,000 \text{ psi}$).

$$\begin{aligned}
 EA(\text{steel}) &= 28 \times 10^6 \text{ psi} \times (260.93 + 211.04 + 82.5) \text{ in}^2 \\
 &= 15,525.2 \text{ lb} \times 10^6 \text{ lbs.}
 \end{aligned}$$

$$\begin{aligned}
 EA(\text{concrete}) &= 3.605 \times 10^6 \times (7044.2) \text{ in}^2 \\
 &= 25,394.3 \times 10^6 \text{ lb.}
 \end{aligned}$$

Therefore, the total HI-TRAC load will be apportioned as follows:

$$F_{\text{STEEL}} = (15,525.2/40,919.5) \times 251,000 = 95,231.5 \text{ lb.}$$

$$F_{\text{CONCRETE}} = (25,394.3/40,919.5) \times 251,000 = 155,768.5 \text{ lb.}$$

Therefore, if the load is apportioned as above, with all load-carrying components in the path acting, the compressive stress in the steel is

If we conservatively neglect the compression load bearing capacity of concrete, then

$$\sigma_{\text{STEEL}} = \frac{251,000}{554.5} = 452.7 \text{ psi}$$

If we include the concrete, then the maximum compressive stress in the concrete is:

$$\sigma_{\text{CONCRETE}} = \frac{F_{\text{CONCRETE}}}{A_{\text{CONCRETE}}} = 22.1 \text{ psi}$$

It is clear that HI-STORM 100 storage overpack can support the dead load of a fully loaded HI-TRAC 125D and the mating device placed on top for MPC transfer into or out of the HI-STORM 100 storage overpack cavity. The calculated stresses at a cross-section through the air outlet ducts are small and give rise to large factors of safety. The metal cross-section at the base of the HI-STORM storage overpack will have a slightly larger metal area (because the width of the air-inlet ducts is smaller) but will be subject to additional dead load from the weight of the supported metal components of the HI-STORM storage overpack plus the loaded HI-TRAC weight. At the base of the storage overpack, the additional stress in the outer shell and the radial plates is due solely to the weight of the component. Based on the maximum concrete density, the additional stress in these components is computed as:

$$\Delta\sigma = (200\text{lb./cu.ft.}) \times 18.71 \text{ ft./144 sq.in./sq.ft.} = 26.0 \text{ psi}$$

This stress will be further increased by a small amount because of the material cut away by the air-inlet ducts; however, the additional stress still remains small. The inner shell, however, is subject to additional loading from the top lid of the storage overpack and from the radial shield. From the Structural Calculation Package (HI-981928)(see Subsection 3.6.4 for the reference), and from Table 3.2.1, the following weights are obtained (for conservatism, use the 100S, Version B lid weight with 185 pcf concrete even though the shell geometry is for the classic HI-STORM 100):

HI-STORM 100S, Version B Top Lid weight < 32,000 lb.

HI-STORM 100 Inner Shell weight < 19,000 lb.

HI-STORM 100 Shield Shell weight < 11,000 lb.

Note that the shield shell was removed from the HI-STORM 100 design as of June 2001. However, it is conservative to include the shield shell weight in the following calculations.

Using the calculated inner shell area at the top of the storage overpack for conservatism, gives the metal area of the inner shell as:

$$A_i = A_i(\text{no vent}) - 4t_i w = 211.04 \text{ sq. inch}$$

Therefore, the additional stress from the HI-STORM 100S, Version B storage overpack components, at the base of the overpack, is:

$$\Delta\sigma = 294 \text{ psi}$$

and a maximum compressive stress in the inner shell predicted as:

Maximum stress = 453 psi + 294 psi = 747 psi

The safety factor at the base of the storage overpack inner shell (minimum section) is

$$SF = 17,500\text{psi}/747\text{ psi} = 23.4$$

The preceding analysis is bounding for the 100 Ton HI-TRAC transfer cask because of the lower HI-TRAC weight.

The preceding analysis is representative of all overpacks since the bounding lid weight from the Version B has been used. Based on the computed safety factor, it is concluded that all versions of the HI-STORM 100 and HI-STORM 100S can safely support the heaviest HI-TRAC while performing a vertical fuel transfer operation.

3.4.4.3.2.2 HI-STORM 100 Lid Integrity Evaluation (Load Case 02.c, Table 3.1.5)

A non-mechanistic tip over of the HI-STORM 100 results in high decelerations at the top of the storage overpack. The storage overpack lid diameter is less than the storage overpack outer diameter. This ensures that the storage overpack lid does not directly strike the ground but requires analysis to demonstrate that the lid remains intact and does not separate from the body of the storage overpack. Figure 3.4.19 shows the scenario.

The HI-STORM 100 overpack has two lid designs, which rely on different mechanisms to resist separation from the overpack body. The original design relies solely on the lid studs to resist the shear and axial loads on the lid. In the new design, the bolt holes are enlarged and a shear ring is welded to the underside of the lid top plate. These changes insure that the lid studs only encounter axial (tensile) loads. The in-plane load is resisted by the shear ring as it bears against the top plate. The HI-STORM 100S and the HI-STORM 100S, Version B has only one lid design, which utilizes a shear ring. Calculations have been performed for both HI-STORM 100 lid configurations, as well as the HI-STORM 100S and the HI-STORM 100S, Version B lid geometry, to demonstrate that the lid can withstand a non-mechanistic tip-over. Similar to HI-STORM 100S overpack lid design, the HI-STORM 100S Version B Type IS lid design also has bolt holes that are enlarged and spacer plates that are connected to the lid bottom plate. The in-plane load (in the event of non-mechanistic tipover or tornado missile impact) is resisted by the spacer plates as they bear against the overpack inner shell and the lid bottom plate.

The deceleration level for the non-mechanistic tip-over bounds all other decelerations, directed in the plane of the lid, experienced under other accident conditions such as flood or earthquake as can be demonstrated by evaluating the loads resulting from these natural phenomena events.

It is shown that the weight of the HI-STORM 100 lid, amplified by the design basis deceleration, can be supported entirely by the shear capacity available in the four studs[†]. If only a single stud is

[†] The tip-over event is non-mechanistic by definition since the HI-STORM 100 System is designed to preclude tip-over under all normal, off-normal, and accident conditions of storage, including extreme natural phenomena events. Thus, the tip-over event cannot be categorized as an operating or test condition as contemplated by ASME Section III, Article NCA-2141. The bolted connection between the overpack top lid and the overpack body

loaded initially during a tipover (because of tolerances), the stud hole will enlarge rather than the stud fail in shear. Therefore, it is assured that all four bolts will resist the tipover load regardless of the initial position of the HI-STORM 100 lid.

The following tables summarize the limiting results obtained from the detailed analyses, and from the similar detailed analysis for the HI-STORM 100 lid with shear ring, for the HI-STORM 100S(243), and for the HI-STORM 100S, Version B(229). The results for the longer HI-STORM 100S and HI-STORM 100S, Version B bound the corresponding results for the shorter versions of these units.

HI-STORM 100 Top Lid Integrity (No Shear Ring)			
Item	Value (ksi)	Allowable (ksi)	Safety Factor
Lid Shell-Lid Top Plate Weld Shear Stress	6.733	29.4	4.367
Lid Shell-Lid Top Plate Combined Stress	9.11	29.4	3.226
Attachment Bolt Shear Stress	44.82	60.9	1.359
Attachment Bolt Combined Shear and Tension Interaction at Interface with Anchor Block	-----	-----	1.21

HI-STORM 100 Top Lid Integrity (With Shear Ring)			
Item	Value (ksi)	Allowable (ksi)	Safety Factor
Lid Top Plate-to-Lid Shell Weld Combined Stress	7.336	29.4	4.007
Shield Block Shells-to-Lid Top Plate Weld Combined Stress	1.768	29.4	16.63
Attachment Bolt Tensile Stress	28.02	107.13	3.823
Shear Ring-to-Lid Top Plate Weld Stress	32.11	40.39	1.258
Shear Ring Bearing Stress	25.43	63.0	2.477
Top Plate-to-Outer Shell Weld Stress	35.61	40.39	1.134
HI-STORM 100S(243) Top Lid Integrity[†]			
Item	Value (ksi)	Allowable (ksi)	Safety Factor
Inner and Outer Shell Weld to Base	17.61	29.4	1.669
Shield Block Shell-to-Lid Weld Shear Stress	7.692	29.4	3.822
Attachment Bolt Tensile Stress	37.38	107.13	2.866
Shear Ring-to-Overpack Shell Weld Stress	33.24	42.0	1.264
Shear Ring Bearing Stress	19.36	63.0	3.254

provided by the top lid studs and nuts serves no structural function during normal or off-normal storage conditions, or for credible accident events. Therefore, the ASME Code does not apply to the construction of the HI-STORM top plate-to-overpack connection (the lid studs, nuts, and the through holes in the top plate). However, for conservatism, the stress limits from ASME III, Subsection NF are used for the analysis of the lid bolts.

Lid Shield Ring-to-Shear Ring Weld Stress	20.95	42.0	2.004
---	-------	------	-------

† Results are based on a bounding weight of 28,000 lb for the HI-STORM 100S top lid.

HI-STORM 100S, Version B(229) Top Lid Integrity†			
Item	Value (ksi)	Allowable (ksi)	Safety Factor
Lid Outer Ring to Lid Shield Ring Weld	34.12	34.8	1.02
Shield Block Shell-to-Lid Weld Shear Stress	34.7	34.8	1.003
Attachment Bolt Tensile Stress	45.61	107.13	2.349
Shear Ring-to-Overpack Shell Weld Stress	33.56	42.0	1.251
Shear Ring Bearing Stress	22.6	63.0	2.788
Lid Shield Ring-to-Shear Ring Weld Stress	35.67	42.0	1.177

† Results are based on a bounding weight of 32,000 lb for the HI-STORM 100S, Version B top lid.

Similar calculations have been performed for the HI-STORM 100S, Version B Type IS lid. All factors of safety are greater than 1.0. The results from these calculations are summarized in Supplement 36 of [3.4.17].

3.4.4.3.2.3 Vertical Drop of HI-STORM 100 Storage Overpack (Load Case 02.a of Table 3.1.5)

A loaded HI-STORM 100, with the top lid in place, drops vertically and impacts the ISFSI. Figure 3.4.20 illustrates the drop scenario. The regions of the structure that require detailed examination are the storage overpack top lid, the inlet vent horizontal plate, the pedestal shield, the inlet vent vertical plate, and all welds in the load path. These components are examined for the Level D event of a HI-STORM 100 drop developing the design basis deceleration.

The table provided below summarizes the results of the analyses for the weight and configuration of the HI-STORM 100. The results for the HI-STORM 100S are bounded by the results given below, except as noted. Any calculation pertaining to the pedestal is bounding since the pedestal dimensions and corresponding weights are less in the HI-STORM 100S. The HI-STORM 100S, Version B, however, has sufficient differences in configuration to merit a separate evaluation using similar analyses; therefore, a separate summary table of results is provided for the HI-STORM 100S, Version B.

HI-STORM 100 Load Case 02.a Evaluation			
Item	Value (ksi)	Allowable (ksi)	Safety Factor
Lid Bottom Plate	6.00	58.7	9.777†

Bending Stress Intensity			
Lid Bottom Plate Collapse Load	10450x1.06 (in.*lb./in.)	12730 (in.*lb./in.)	1.15 [†]
Weld- lid bottom plate-to-lid shell	10.91	29.4	2.695
Lid Shell – Membrane Stress Intensity	1.90	39.1	20.58
Lid Top (2" thick) Plate Bending Stress Intensity	11.27	58.7	5.208*
Inner Shell –Membrane Stress Intensity	11.46	39.1	3.41
Outer Shell –Membrane Stress Intensity	3.401	39.1	11.495
Inlet Vent Horizontal Plate Bending Stress Intensity	46.20	58.7	1.271
Inlet Vent Vertical Plate Membrane Stress Intensity	12.86	39.1	3.04
Pedestal Shield – Compression	1.252	1.266	1.011
Weld – outer shell-to-baseplate	2.569	29.4	11.443
Weld – outer shell-to-baseplate (100S)	3.854	29.4	7.629
Weld – inner shell-to-baseplate	6.644	29.4	4.425
Weld – inner shell-to-baseplate (100S)	8.627	29.4	3.408
Weld-Pedestal shell-to-baseplate	2.281	29.4	12.887

[†] Note that the dynamic load factor for the lid top plate is negligible and for the lid bottom plate is 1.06. This dynamic load factor has been incorporated in the above table.

* For the HI-STORM 100S, this safety factor is conservatively evaluated to be 1.357 because of increased load on the upper of the two lid plates.

Applicable analyses are performed for the HI-STORM 100S, Version B for the amplified loads resulting from the vertical drop of a fully loaded cask with the top lid in place.

HI-STORM 100S, Version B Load Case 02.a Evaluation			
Item	Value (ksi)	Allowable (ksi)	Safety Factor
Lid Vent Shield Bending Stress Intensity	14.25	36.0	2.52
Lid Inner Ring Compression	18.54	24.0	1.29
Inner Shell Compression	8.757	24.0	2.74
Outer Shell Compression	2.604	24.0	9.21
Weld – outer shell-to-baseplate	7.796	29.4	3.77
Weld – inner shell-to-baseplate	6.679	29.4	4.402

An assessment of the potential for instability of the compressed inner and outer shells under the

compressive loading during the drop event has also been performed. The methodology is from ASME Code Case N-284 (Metal Containment Shell Buckling Design Methods, Division I, Class MC (8/80)). This Code Case has been previously accepted by the NRC as an acceptable method for evaluation of stability in vessels. The results obtained are conservative in that the loading in the shells is assumed to be uniformly distributed over the entire length of the shells. In reality, the component due to the amplified weight of the shell varies from zero at the top of the shell to the maximum value at the base of the shell. It is concluded that large factors of safety exist so that elastic or plastic instability of the inner and outer shells does not provide a limiting condition. The results for the HI-STORM 100 bound similar results for the HI-STORM 100S since the total weight of the “S” configuration is decreased (see Subsection 3.2). The same methodology has been used for an assessment of the HI-STORM 100S Version B with the same conclusion; namely, that elastic or plastic instability of the inner and outer shells is not a concern under the postulated design basis load cases.

The results do not show any gross regions of stress above the material yield point that would imply the potential for gross deformation of the storage overpack subsequent to the handling accident. MPC stability has been evaluated in the HI-STAR 100 FSAR for a drop event with 60g deceleration and shown to satisfy the Code Case N-284 criteria. Therefore, ready retrievability of the MPC is maintained as well as the continued performance of the HI-STORM 100 storage overpack as the primary shielding device.

The results for the HI-STORM 100S Version B Type IS are bounded by the results presented above for the HI-STORM 100S Version B as the two cask designs are similar. Furthermore, the steel shield blocks in the HI-STORM 100S Version B baseplate are replaced with concrete blocks in Version B Type IS baseplate which makes the Version B Type IS baseplate less stiffer and as a result softens the impact under a drop event. The outer and inner cask body shell thicknesses are also reduced for HI-STORM 100S Version B Type IS making its stiffness characteristics bounded by HI-STORM 100S Version B. Therefore, the deceleration limits in HI-STORM 100 FSAR for HI-STORM 100S Version B remain applicable for HI-STORM 100S Version B Type IS and a separate evaluation for the HI-STORM 100S Version B Type IS is not required.

3.4.4.3.3 HI-TRAC Transfer Cask Stress Calculations

The structural functions of the transfer cask are stated in Section 3.1. The analyses presented here demonstrate the ability of components of the HI-TRAC transfer cask to perform their structural functions in the transfer mode. Load Cases considered are given in Table 3.1.5.

The purpose of the analyses is to provide the necessary assurance that there will be no unacceptable release of radioactive material, unacceptable radiation levels, or impairment of ready retrievability.

3.4.4.3.3.1 Analysis of Pocket Trunnions (Load Case 01 of Table 3.1.5)

The HI-TRAC 125 and HI-TRAC 100 transfer casks have pocket trunnions attached to the outer shell and to the water jacket. During the rotation of HI-TRAC from horizontal to vertical or vice versa (see Figure 3.4.18), these trunnions serve to define the axis of rotation. The HI-TRAC is also supported by the lifting trunnions during this operation. Two load conditions are considered: Level

A when all four trunnions support load during the rotation; and, Level B when the hoist cable is assumed slack so that the entire load is supported by the rotation trunnions. A dynamic amplification of 15% is assumed in both cases appropriate to a low-speed operation. Figure 3.4.23 shows a free body of the trunnion and shows how the applied force and moment are assumed to be resisted by the weld group that connects the trunnion to the outer shell. Drawings 1880 (sheet 10) and 2145 (sheet 10) show the configuration. An optional construction for the HI-TRAC 100 permits the pocket trunnion base to be split to reduce the “envelope” of the HI-TRAC. For that construction, bolts and dowel pins are used to insure that the force and moment applied to the pocket trunnions are transferred properly to the body of the transfer cask. The analysis also evaluates the bolts and dowel pins and demonstrates that safety factors greater than 1.0 exist for bolt loads, dowel bearing and tear-out, and dowel shear. Allowable strengths and loads are computed using applicable sections of ASME Section III, Subsection NF.

The HI-TRAC 100G transfer cask has bottom trunnions attached to the inner shell, the outer shell and to the water jacket. During rotation of HI-TRAC from horizontal to vertical or vice versa, these trunnions serve to define the axis of rotation. The HI-TRAC is also supported by the lifting trunnions during this operation. Single load condition is considered: when the hoist cable is assumed slack so that the entire load is supported by the bottom trunnions during rotation. Allowable strengths and loads are computed using applicable sections of ASME Section III, Subsection NF.

Unlike the HI-TRAC 125, the HI-TRAC 100, and the HI-TRAC 100G, the HI-TRAC 125D and HI-TRAC 100D are designed and fabricated without pocket trunnions. An L-shaped rotation frame is used to upend and downend the HI-TRAC 125D and HI-TRAC 100D, instead of pocket trunnions. Thus, a pocket trunnion analysis is not applicable to the HI-TRAC 125D or the HI-TRAC 100D.

The table below summarizes the results for the HI-TRAC 125, the HI-TRAC 100, and the HI-TRAC 100G:

Pocket Trunnion Weld Evaluation Summary			
Item	Value (ksi)	Allowable (ksi)[†]	Safety Factor
HI-TRAC 125 Pocket Trunnion-Outer Shell Weld Group Stress	7.979	23.275	2.917
HI-TRAC 125 Pocket Trunnion-Water Jacket Weld Group Stress	5.927	23.275	3.9
HI-TRAC 100 Pocket Trunnion-Outer Shell Weld Group Stress	6.603	23.275	3.525
HI-TRAC 100 Pocket Trunnion-Water Jacket Weld Group Stress	5.244	23.275	4.438
HI-TRAC 100 Pocket Trunnion-Bolt Tension at Optional Split	45.23	50.07	1.107

HI-TRAC 100 Pocket Trunnion–Bearing Stress on Base Surfaces at Dowel	6.497	32.7	5.033
HI-TRAC 100 Pocket Trunnion–Tear-out Stress on Base Surfaces at Dowel	2.978	26.09	8.763
HI-TRAC 100 Pocket Trunnion–Shear Stress on Dowel Cross Section at Optional Split	29.04	37.93	1.306
HI-TRAC 100G Bottom Trunnion–Inner Shell, Outer Shell, and Water Jacket Weld Group Stress	21.41	27.93	1.30

† Allowable stress is reported for the Level B loading, which results in the minimum safety factor.

To provide additional information on the local stress state adjacent to the rotation trunnion, a new finite element analysis is undertaken to provide details on the state of stress in the metal structure surrounding the rotation trunnions for the HI-TRAC 125. The finite element analysis has been based on a model that includes major structural contributors from the water jacket enclosure shell panels, radial channels, end plates, outer and inner shell, and bottom flange. In the finite element analysis, the vertical trunnion load has been oriented in the direction of the HI-TRAC 125 longitudinal axis. The structural model has been confined to the region of the HI-TRAC adjacent to the rotation trunnion block; the extent of the model in the longitudinal direction has been determined by calculating the length of the “bending boundary layer” associated with a classical shell analysis. This was considered to be a sufficient length to capture maximum shell stresses arising from the Level B (off-normal) rotation trunnion loading. The local nature of the stress around the trunnion block is clearly demonstrated by the finite element results.

Consistent with the requirements of ASME Section III, Subsection NF, for Class 3 components, safety factors for primary membrane stress have been computed. Primary stresses are located away from the immediate vicinity of the trunnion; although the NF Code sets no limits on primary plus secondary stresses that arise from the gross structural discontinuity immediately adjacent to the trunnion, these stresses are listed for information. The results are summarized in the table below for the Level B load distribution for the HI-TRAC 125.

ITEM –HI-TRAC 125	CALCULATED VALUE	ALLOWABLE VALUE
Longitudinal Stress - (ksi) (Primary Stress – Inner Shell)	-0.956	23.275
Tangential Stress (ksi) (Primary Stress - Inner Shell)	-1.501	23.275
Longitudinal Stress (ksi) (Primary Stress – Outer Shell)	-0.830	23.275
Tangential Stress (ksi) (Primary Stress - Outer Shell)	-0.436	23.275
Longitudinal Stress - (ksi) (Primary Stress – Radial Channels)	2.305	23.275
Tangential Stress (ksi) (Primary Stress -	-0.631	23.275

ITEM –HI-TRAC 125	CALCULATED VALUE	ALLOWABLE VALUE
Radial Channels)		
Longitudinal Stress - (ksi) (Primary plus Secondary Stress - Inner Shell)	1.734	No Limit (34.9)*
Tangential Stress (ksi) (Primary plus Secondary Stress - Inner Shell)	-1.501	NL
Longitudinal Stress (ksi) (Primary plus Secondary Stress - Outer Shell)	2.484	NL
Tangential Stress (ksi) (Primary plus Secondary Stress - Outer Shell)	-2.973	NL
Longitudinal Stress - (ksi) (Primary plus Secondary Stress - Radial Channels)	-13.87	NL
Tangential Stress (ksi) (Primary plus Secondary Stress - Radial Channels)	-2.303	NL

* The NF Code sets no limits (NL) for primary plus secondary stress (see Table 3.1.17). Nevertheless, to demonstrate the robust design with its large margins of safety, we list here, for information only, the allowable value for Primary Membrane plus Primary Bending Stress appropriate to temperatures up to 650 degrees F.

The only stress of any significance is the longitudinal stress in the radial channels. This stress occurs immediately adjacent to the trunnion block/radial channel interface and by its localized nature is identifiable as a stress arising at the gross structural discontinuity (secondary stress).

The finite element analysis has also been performed for the HI-TRAC 100 transfer cask. The following table summarizes the results:

ITEM –HI-TRAC 100	CALCULATED VALUE	ALLOWABLE VALUE
Longitudinal Stress - (ksi) (Primary Stress – Inner Shell)	-0.756	23.275
Tangential Stress (ksi) (Primary Stress - Inner Shell)	-2.157	23.275
Longitudinal Stress (ksi) (Primary Stress – Outer Shell)	-0.726	23.275
Tangential Stress (ksi) (Primary Stress - Outer Shell)	-0.428	23.275
Longitudinal Stress - (ksi) (Primary Stress – Radial Channels)	2.411	23.275
Tangential Stress (ksi) (Primary Stress - Radial Channels)	-0.5305	23.275
Longitudinal Stress - (ksi) (Primary plus Secondary Stress - Inner Shell)	2.379	NL
Tangential Stress (ksi) (Primary plus Secondary Stress - Inner Shell)	-2.157	NL

Longitudinal Stress (ksi) (Primary plus Secondary Stress - Outer Shell)	3.150	NL
Tangential Stress (ksi) (Primary plus Secondary Stress - Outer Shell)	-3.641	NL
Longitudinal Stress - (ksi) (Primary plus Secondary Stress - Radial Channels)	-15.51	NL
Tangential Stress (ksi) (Primary plus Secondary Stress - Radial Channels)	-2.294	NL

The finite element analyses of the metal structure adjacent to the trunnion block did not include the state of stress arising from the water jacket internal pressure. These stresses are conservatively computed based on a two-dimensional strip model that neglects the lower annular plate. The water jacket bending stresses are summarized below:

Tangential Bending Stress in Water Jacket Outer Panel from Water Pressure (including hydrostatic and inertia effects)	Calculated Value (ksi)
HI-TRAC 125	14.18
HI-TRAC 100	13.63

To establish a minimum safety factor for the outer panels of the water jacket for the Level A condition, we must add primary membrane circumferential stress from the trunnion load analysis to primary circumferential bending stress from the water jacket bending stress. Then, the safety factors may be computed by comparison to the allowable limit for primary membrane plus primary bending stress. The following results are obtained:

Results for Load Case 01 in Water Jacket (Load Case 01) – Level A Load			
Circumferential Stress in Water Jacket Outer Enclosure	CALCULATED VALUE (ksi)	ALLOWABLE VALUE (ksi)	SAFETY FACTOR (allowable value/calculated value)
HI-TRAC 125	14.57	26.25	1.80
HI-TRAC 100	13.94	26.25	1.88

To arrive at minimum safety factors for primary membrane plus bending stress in the outer panel of the water jacket for the Level B condition, we amplify the finite element results the trunnion load analysis, add the appropriate stress from the two-dimensional water jacket calculation, and compare the results to the increased Level B allowable. The following results are obtained:

Results for Load Case 01 in Water Jacket (Load Case 01) – Level B Load			
Circumferential Stress in Water Jacket Outer Enclosure	CALCULATED VALUE (ksi)	ALLOWABLE VALUE (ksi)	SAFETY FACTOR (allowable value/calculated value)
HI-TRAC 125	14.81	35.0	2.36

HI-TRAC 100	14.16	35.0	2.47
-------------	-------	------	------

All safety factors are greater than 1.0; the Level A load condition governs.

3.4.4.3.3.2 Lead Slump in HI-TRAC 125 - Horizontal Drop Event (Case 02.b in Table 3.1.5)

During a side drop of the HI-TRAC 125 transfer cask, the lead shielding must be shown not to slump and cause significant amounts of shielding to be lost in the top area of the lead annulus. Slumping of the lead is not considered credible in the HI-TRAC transfer cask because of:

- a. the shape of the interacting surfaces
- b. the ovalization of the shell walls under impact
- c. the high coefficient of friction between lead and steel
- d. The inertia force from the MPC inside the HI-TRAC will compress the inner shell at the impact location and locally “pinch” the annulus that contains the lead; this opposes the tendency for the lead to slump and open up the annulus at the impact location.

Direct contact of the outer shell of the HI-TRAC with the ISFSI pad is not credible since there is a water jacket that surrounds the outer shell. The water jacket metal shell will experience most of the direct impact. Nevertheless, to conservatively analyze the lead slump scenario, it is assumed that there is no water jacket, the impact occurs far from either end of the HI-TRAC so as to ignore any strengthening of the structure due to end effects, the impact occurs directly on the outer shell of the HI-TRAC, and the contact force between HI-TRAC and the MPC is ignored. All of these assumptions are conservative in that their imposition magnifies any tendency for the lead to slump.

To confirm that lead slump is not credible, a finite element analysis of the lead slump problem, incorporating the conservatism listed above, during a postulated HI-TRAC 125 horizontal drop (see Figure 3.4.22) is carried out. The HI-TRAC 125 cask body modeled consists only of an inner steel shell, an outer steel shell, and a thick lead annulus shield contained between the inner and outer shell. A unit length of HI-TRAC is modeled and the contact at the lead/steel interface is modeled as a compression-only interface. Interface frictional forces are conservatively neglected. As the HI-TRAC 125 has a greater lead thickness, analysis of the HI-TRAC 125 is considered to bound the HI-TRAC 100 and the HI-TRAC 100D. Furthermore, since there are no differences between the HI-TRAC 125 and the HI-TRAC 125D with respect to the finite element model, the results are valid for both 125-Ton transfer casks.

The analysis is performed in two parts:

First, to maximize the potential for lead/steel separation, the shells are ignored and the gap elements grounded. This has the same effect as assuming the shells to be rigid and maximizes the potential and magnitude of any separation at the lead/steel interface (and subsequent slump). This also maximizes the contact forces at the portion of the interface that continues to have compression forces developed. The lead annulus is subjected to a 45g deceleration and the deformation, stress field, and interface force solution developed. This solution establishes a conservative result for the movement of the lead relative to the metal shells.

In the second part of the analysis, the lead is removed and replaced by the conservative (high) interface forces from the first part of the analysis. These interface forces, together with the 45g deceleration-induced inertia forces from the shell self weight are used to obtain a solution for the stress and deformation field in the inner and outer metal shells.

The results of the analysis are as follows:

- a. The maximum predicted lead slump at a location 180 degrees from the impact point is 0.1". This gap decreases gradually to 0.0" after approximately 25 degrees from the vertical axis. The decrease in the diameter of the inner shell of the transfer cask (in the direction of the deceleration) is approximately 0.00054". This demonstrates that ovalization of the HI-TRAC shells does not occur. Therefore, the lead shielding deformation is confined to a local region with negligible deformation of the confining shells.
- b. The stress intensity distribution in the shells demonstrates that high stresses are concentrated, as anticipated, only near the assumed point of impact with the ISFSI pad. The value of the maximum stress intensity (51,000 psi) remains below the allowable stress intensity for primary membrane plus primary bending for a Level D event (58,700 psi). Thus, the steel shells continue to perform their function and contain the lead. The stress distribution, obtained using the conservatively large interface forces, demonstrates that permanent deformation could occur only in a localized region near the impact point. Since the "real" problem precludes direct impact with the outer shell, the predicted local yielding is simply a result of the conservatism imposed in the model.

It is concluded that a finite element analysis of the lead slump under a 45g deceleration in a side drop clearly indicates that there is no appreciable change in configuration of the lead shielding and no overstress of the metal shell structure. Therefore, retrievability of the MPC is not compromised and the HI-TRAC transfer cask continues to provide shielding.

3.4.4.3.3 HI-TRAC Lid Stress Analysis During HI-TRAC Drop Accident (Load Case 02.b in Table 3.1.5)

The stress in the HI-TRAC 125 transfer lid is analyzed when the lid is subject to the deceleration loads of a side drop. Figure 3.4.22 is a sketch of the scenario. The analysis shows that the cask body, under a deceleration of 45g's, will not separate from the transfer lid during the postulated side drop. This event is considered a Level D event in the ASME parlance.

The bolts that act as doorstops to prevent opening of the doors are also checked for their load capacity. It is required that sufficient shear capacity exists to prevent both doors from opening and exposing the MPC.

The only difference between the HI-TRAC 100 and the HI-TRAC 125 transfer lid doors is that the HI-TRAC 100 has less lead and has no middle steel plate. A similar analysis of the HI-TRAC

100 shows that all safety factors are greater than 1.0. The table given below summarizes the results for both units:

Transfer Lid Attachment Integrity Under Side Drop			
Item – Shear Capacity	Value (kip) or (ksi)	Capacity (kip) or (ksi)	Safety Factor= Capacity/Value
HI-TRAC 125 Attachment (kip)	1,272.0	1,475.0	1.159
HI-TRAC 125 Door Lock Bolts (ksi)	20.24	48.3	2.387
HI-TRAC 100 Attachment (kip)	1,129.0	1,503.0	1.331
HI-TRAC 100 Door Lock Bolts (ksi)	13.81	48.3	3.497

All safety factors are greater than 1.0 and are based on actual interface loads. For the HI-TRAC 125 and the HI-TRAC 100, the interface load (primary impact at transfer lid) computed from the handling accident analysis is bounded by the values given below:

BOUNDING INTERFACE LOADS COMPUTED FROM HANDLING ACCIDENT ANALYSES	
Item	Bounding Value (kip)
HI-TRAC 125	1,300
HI-TRAC 100	1,150

The HI-TRAC 125D, HI-TRAC 100D, and HI-TRAC 100G transfer casks do not utilize a transfer lid. Instead, the MPC is transferred to or from a storage overpack using the HI-TRAC pool lid and a special mating device. Therefore, an analysis is performed to demonstrate that the pool lid will not separate from the cask body during the postulated side drop. The results of the analyses are summarized in the following tables for the HI-TRAC 125D and the HI-TRAC 100D. The side drop of HI-TRAC 100G is not credible because it will always be handled by a single failure proof system.

HI-TRAC 125D Pool Lid Attachment Integrity Under Side Drop			
Item	Calculated Value	Allowable Limit	Safety Factor
Lateral Shear Force (kips)	562.5	1013	1.801
Maximum Bolt Tensile Stress (ksi)	2.548	108.9	42.739

Combined Tension and Shear Interaction	0.309	1.00	3.236
--	-------	------	-------

HI-TRAC 100D Pool Lid Attachment Integrity Under Side Drop			
Item	Calculated Value	Allowable Limit	Safety Factor
Lateral Shear Force (kips)	360.0	1013	2.814
Maximum Bolt Tensile Stress (ksi)	1.477	108.9	73.731
Combined Tension and Shear Interaction	0.135	1.00	7.407

3.4.4.3.3.4 Stress Analysis of the HI-TRAC Water Jacket (Load Case 03 in Table 3.1.5)

The water jacket is assumed subject to internal pressure from pressurized water and gravity water head. Calculations are performed for the HI-TRAC 125, the HI-TRAC 125D, the HI-TRAC 100, the HI-TRAC 100D, and the HI-TRAC 100G to determine the water jacket stress under internal pressure plus hydrostatic load. Results are obtained for the water jacket configuration and the connecting welds for all HI-TRAC transfer casks. The table below summarizes the results of the analyses.

In addition to the water jacket pressure and the water head, the section in the vicinity of bottom trunnion for HI-TRAC 100G is evaluated for the loads during down-ending and up-ending of loaded cask. Per Paragraph 2.2.2.6, the bottom trunnions are designed to withstand 100% of the cask weight in vertical orientation and 75% of the cask weight in horizontal orientation under off-normal conditions (ASME NF Level B [3.4.2]). An evaluation of the water jacket and its weld connection with bottom plate under these load conditions is presented in Supplement 37 of [3.4.16] and the key results are documented in the table below.

Water Jacket Stress Evaluation			
Item	Value (ksi)	Allowable (ksi)	Safety Factor
HI-TRAC 125 Water Jacket Enclosure Shell Panel Bending Stress	14.18	26.25	1.851
HI-TRAC 100 Water Jacket Enclosure Shell Panel Bending Stress	13.63	26.25	1.926
HI-TRAC 125 Water Jacket Bottom Flange Bending Stress	18.3	26.25	1.434
HI-TRAC 100 Water Jacket Bottom Flange Bending Stress	16.92	26.25	1.551
HI-TRAC 125 Weld Stress – Bottom Flange to Outer Shell Double Fillet Weld	14.79	21.0	1.42
HI-TRAC 125 - Radial Rib Direct Stress	2.198	17.5	7.961
HI-TRAC 100 - Radial Rib Direct Stress	1.975	17.5	8.861
HI-TRAC 125D Water Jacket Bottom Flange Bending Stress	18.88	26.25	1.39

HI-TRAC 125D Water Jacket Enclosure Shell Panel Bending Stress	10.80	26.25	2.43
HI-TRAC 125D Weld Stress – Enclosure Panel to Radial Rib Plug Welds	1.093	17.5	16.01
HI-TRAC 125D Weld Stress – Bottom Flange to Outer Shell Single Fillet Weld	3.133	21.0	6.70
HI-TRAC 100D Water Jacket Bottom Flange Bending Stress	16.69	26.25	1.57
HI-TRAC 100D Water Jacket Enclosure Shell Panel Bending Stress	12.75	26.25	2.06
HI-TRAC 100D Weld Stress – Enclosure Panel to Radial Rib Plug Welds	0.680	17.5	25.7
HI-TRAC 100D Weld Stress – Bottom Flange to Outer Shell Single Fillet Weld	2.836	21.0	7.40
HI-TRAC 100G Water Jacket Bottom Flange Bending Stress	15.65	26.25	1.678
HI-TRAC 100G Water Jacket Enclosure Shell Panel Bending Stress	7.351	26.25	3.571
HI-TRAC 100G Weld Stress – Top Flange/Bottom Plate to Water Jacket Shell Groove Weld	4.991	13.04	2.613
HI-TRAC 100G Water Jacket Enclosure Shell Panel Combined Stress (Governing Load Condition) ¹	30.6	34.9	1.14
HI-TRAC 100G Weld Stress – Bottom Plate to Water Jacket Shell Groove Weld (Governing Load Condition) ¹	25.83	27.93	1.08
HI-TRAC 100G - Radial Rib Direct Stress	2.585	17.5	6.77

¹ Conservatively bounding weights and loads are used in the analysis.

3.4.4.3.3.5 HI-TRAC Top Lid Separation (Load Case 02.b in Table 3.1.5)

The potential of top lid separation under a 45g deceleration side drop event requires evaluation. It is concluded by analysis that the connection provides acceptable protection against top lid separation. It is also shown that the bolts and the lid contain the MPC within the HI-TRAC cavity during and after a drop event. The results from the HI-TRAC 125 bound the corresponding results from the HI-TRAC 100 because the top lid bolts are identical in the two units and the HI-TRAC 125 top lid weighs more. The analysis also bounds the HI-TRAC 125D and the HI-TRAC 100D because the postulated side drop of the HI-TRAC 125, during which the transfer lid impacts the target surface, produces a larger interface load between the MPC and the top lid of the HI-TRAC than the nearly horizontal drop of the HI-TRAC 125D and the HI-TRAC 100D. The side drop event is not credible for HI-TRAC 100G because a single failure proof system will be used for handling. The table below provides the results of the bounding analysis.

HI-TRAC Top Lid Separation Analysis			
Item	Value	Capacity	Safety Factor= Capacity/Value
Attachment Shear Force (lb.)	123,750	957,619	7.738
Tensile Force in Stud (lb.)	132,000	1,117,222	8.464
Bending Stress in Lid (ksi)	35.56	58.7	1.65
Shear Load per unit Circumferential Length in Lid (lb./in)	533.5	29,400	55.10

3.4.4.4 Comparison with Allowable Stresses

Consistent with the formatting guidelines of Reg. Guide 3.61, calculated stresses and stress intensities from the finite element and other analyses are compared with the allowable stresses and stress intensities defined in Subsection 3.1.2.2 per the applicable sections of [3.4.2] and [3.4.4] for defined normal and off-normal events and [3.4.3] for accident events (Appendix F).

3.4.4.4.1 MPC

In Amendment #5 to the HI-STORM CoC, the weight limits for fuel assemblies to be stored in the MPCs were increased from 1,680 lbs to 1,720 lbs per assembly for PWR fuel. In order to account for this increase in fuel weight, the results of the MPC stress analysis under lateral loading, which is described in Subsection 3.4.4.3.1.1, are uniformly scaled based on the percentage weight increase. Specifically, the results for the PWR MPCs are scaled by a factor of 1.024 ($=1720/1680$). This approach is acceptable because (i) the finite element analysis results are based on linear elastic material properties and (ii) the percentage increases in total weight, considering the stored fuel, fuel basket, and MPC shell, are less than the factors above. Finally, since the stresses associated with closing the support clearance gaps between the fuel basket and the MPC shell and between the MPC shell and the overpack are secondary stress components, as explained in Subsection

3.4.4.3.1.1, the use of a linear scale factor is an appropriate means of computing the primary stresses in the fuel basket and MPC shell.

Table 3.4.6 provides summary data extracted from the numerical analysis results for the fuel basket, enclosure vessel, and fuel basket supports after scaling to adjust for the increased fuel assembly weights. The results presented in Table 3.4.6 are based on the design basis deceleration and do not include any dynamic amplification due to internal elasticity of the structure (i.e., local inertia effects). Calculations suggest that a uniform conservative dynamic amplifier for the fuel basket would be 1.08 independent of the duration of impact. If we recognize that the tip-over event for HI-STORM 100 is a long duration event, then a dynamic amplifier of 1.04 is appropriate. The summary data provided in Table 3.4.3 and 3.4.4 gives the lowest safety factor computed for the fuel basket and for the MPC, respectively. Safety factors reported for the MPC shell in Table 3.4.4 are based on allowable strengths at 500 deg. F. Modification of the fuel basket safety factor for dynamic amplification leaves considerable margin. Factors of safety greater than 1 indicate that calculated results are less than the allowable strengths.

A perusal of the results in Tables 3.4.3 and 3.4.4 under different load combinations for the fuel basket and the enclosure vessel reveals that all factors of safety are above 1.0 even if we use the most conservative value for dynamic amplification factor. The relatively modest factor of safety in the fuel basket under side drop events (Load Case F3.b and F3.c) in Table 3.4.3 warrants further explanation since a very conservative finite element model of the structure has been utilized in the analysis.

The legacy 2-D finite element model dating back to the 1990s employed to simulate the MPC and the fuel basket, and other simplifications such as modeling the overpack as a rigid body and fuel as a pressure loading in some loading simulations used in this FSAR, lead to an understatement and associated uncertainty in the computed safety margins which can be alleviated by a 3-D analysis (under the §72.48 process). The use of a 3-D analysis has been utilized on the ANSYS and LS-DYNA platform (as appropriate) and approved by the NRC in the HI-STORM FW docket.

It should be noted that the change of the BWR fuel weight in Table 2.1.22 applies only to the specified DFC bearing locations but does not require the design basis gross weight of the MPC used in the structural analyses to be changed. Therefore, other safety analyses such as non-mechanistic tip-over and lifting and handling appurtenances remain unaffected and do not need to be revisited.

The wall thickness of the storage cells, which is by far the most significant variable in a fuel basket's structural strength, is significantly greater in the MPCs than in comparable fuel baskets licensed in the past. In spite of their relatively high flexural rigidities, computed margins in the fuel baskets are rather modest. This is because of some assumptions in the analysis that lead to an overstatement of the state of stress in the fuel basket. For example:

- i. The section properties of longitudinal fillet welds that attach contiguous cell walls to each other are completely neglected in the finite element model (Figure 3.4.7). The fillet welds strengthen the cell wall section modulus at the very locations where maximum stresses develop.

- ii. The radial gaps at the fuel basket-MPC shell and at the MPC shell-storage overpack interface are explicitly modeled. As the applied loading is incrementally increased, the MPC shell and fuel basket deform until a "rigid" backing surface of the storage overpack is contacted, making further unlimited deformation under lateral loading impossible. Therefore, some portion of the fuel basket and enclosure vessel (EV) stress has the characteristics of secondary stresses (which by definition, are self-limited by deformation in the structure to achieve compatibility). For conservativeness in the incremental analysis, we make no distinction between deformation controlled (secondary) stress and load controlled (primary) stress in the stress categorization of the MPC-24, 32, and 68 fuel baskets. We treat all stresses, regardless of their origin, as primary stresses. Such a conservative interpretation of the Code has a direct (adverse) effect on the computed safety factors. As noted earlier, the results for the MPC-24E are properly based only on primary stresses to illustrate the conservatism in the reporting of results for the MPC-24, 32, and 68 baskets.
- iii. A uniform pressure simulates the SNF inertia loading on the cell panels, which is a most conservative approach for incorporating the SNF/cell wall structure interaction.

The above assumptions act to depress the computed values of factors of safety in the fuel basket finite element analysis and render conservative results.

The reported factors of safety do not include the effect of dynamic load amplifiers. The duration of impact and the predominant natural frequency of the basket panels under drop events result in the dynamic load factors that do not exceed 1.08. Therefore, since all reported factors of safety for all fuel basket types are greater than the DLF, the MPC is structurally adequate for its intended functions.

Tables 3.4.7 and 3.4.8 report stress intensities and safety factors for the confinement boundary subject to internal pressure alone and internal pressure plus the normal operating condition temperature with the most severe thermal gradient. The final values for safety factors in the various locations of the confinement boundary provide assurance that the MPC enclosure vessel is a robust pressure vessel.

3.4.4.4.2 Storage Overpack and HI-TRAC

The result from analyses of the storage overpack and the HI-TRAC transfer cask is shown in Table 3.4.5. The location of each result is indicated in the table. Safety factors for lifting operations where three times the lifted load is applied are reported in Section 3.4.3.

The table shows that all allowable stresses are much greater than their associated calculated stresses and that safety factors are above the limit of 1.0.

3.4.4.5 Elastic Stability Considerations

3.4.4.5.1 MPC Elastic Stability

Stability calculations for the MPC have been carried out in the HI-STAR 100 FSAR, Docket Number 72-1008. Using identical methodology with input loads and decelerations appropriate to the HI-STORM, safety factors > 1.0 are obtained for all relevant load cases. Note that for HI-STORM, the design external pressure differential is reduced to 0.0 psi, and the peak deceleration under accident events is reduced from 60g's (HI-STAR) to 45g's.

3.4.4.5.2 HI-STORM 100 Storage Overpack Elastic Stability

HI-STORM 100 (and 100S, the 100S Version B and Version B Type IS) storage overpack shell buckling is not a credible scenario since the two steel shells plus the entire radial shielding act to resist vertical compressive loading. Subsection 3.4.4.3.2.3 develops values for compressive stress in the steel shells of the storage overpack. Because of the low value for compressive stress coupled with the fact that the concrete shielding backs the steel shells, we can conclude that instability is unlikely. Note that the entire weight of the storage overpack can also be supported by the concrete shielding acting in compression. Therefore, in the unlikely event that a stability limit in the steel was approached, the load would simply shift to the massive concrete shielding. Notwithstanding the above comments, stability analyses of the storage overpack have been performed for bounding cases of longitudinal compressive stress with nominal circumferential compressive stress and for bounding circumferential compressive stress with nominal axial compressive stress. This latter case is for a bounding all-around external pressure on the HI-STORM 100 outer shell. The latter case is listed as Load Case 05 in Table 3.1.5 and is performed to demonstrate that explosions or other environmental events that could lead to an all-around external pressure on the outer shell do not cause a buckling instability. ASME Code Case N-284, a methodology accepted by the NRC, has been used for this analysis. The storage overpack shells for the HI-STORM 100 are examined individually assuming that the four radial plates provide circumferential support against a buckling deformation mode. The analysis of the storage overpack outer shell for a bounding external pressure of

$$p_{\text{ext}} = 30 \text{ psi}$$

together with a nominal compressive axial load that bounds the dead weight load at the base of the outer shell, gives a safety factor against an instability of:

$$\text{Safety Factor} = (1/0.466) \times 1.34 = 2.88$$

The factor 1.34 is included in the above result since the analysis methodology of Code Case N-284 builds in this factor for a stability analysis for an accident condition. The suite of stability analyses have also been performed for the HI-STORM 100S Version B. No credit is taken for any support provided by the concrete shielding and the effect of support by radial ribs is conservatively neglected (since the ribs in the HI-STORM 100S Version B do not extend the full height of the overpack). It is shown that the safety factor computed for the classic HI-STORM 100 is a lower bound for all of the HI-STORM 100S versions.

The external pressure for the overpack stability considered here significantly bounds the short-time 10-psi differential pressure (between outer shell and internal annulus) specified in Table 2.2.1.

The same postulated external pressure condition can also act on the HI-TRAC during movement from the plant to the ISFSI pad. In this case, the lead shielding acts as a backing for the outer shell of the HI-TRAC transfer cask just as the concrete does for the storage overpack. The water jacket metal structure provides considerable additional structural support to the extent that it is reasonable to state that instability under external pressure is not credible. If it is assumed that the all-around water jacket support is equivalent to the four locations of radial support provided in the storage overpack, then it is clear that the instability result for the storage overpack bounds the results for the HI-TRAC transfer cask. This occurs because the R/t ratio (mean radius-to-wall thickness) of the HI-TRAC outer shell is less than the corresponding ratio for the HI-STORM storage overpack. Therefore, no HI-TRAC analysis is performed.

3.4.5 Cold

A discussion of the resistance to failure due to brittle fracture is provided in Subsection 3.1.2.3.

The value of the ambient temperature has two principal effects on the HI-STORM 100 System, namely:

- i. The steady-state temperature of all material points in the cask system will go up or down by the amount of change in the ambient temperature.
- ii. As the ambient temperature drops, the absolute temperature of the contained helium will drop accordingly, producing a proportional reduction in the internal pressure in accordance with the Ideal Gas Law.

In other words, the temperature gradients in the system under steady-state conditions will remain the same regardless of the value of the ambient temperature. The internal pressure, on the other hand, will decline with the lowering of the ambient temperature. Since the stresses under normal storage condition arise principally from pressure and thermal gradients, it follows that the stress field in the MPC under -40 degree F ambient would be smaller than the "heat" condition of storage, treated in the preceding subsection. Additionally, the allowable stress limits tend to increase as the component temperatures decrease.

Therefore, the stress margins computed in Section 3.4.4 can be conservatively assumed to apply to the "cold" condition as well.

Finally, it can be readily shown that the HI-STORM 100 System is engineered to withstand "cold" temperatures (-40 degrees F), as set forth in the Technical Specification, without impairment of its storage function.

Unlike the MPC, the HI-STORM 100 storage overpack is an open structure; it contains no pressure. Its stress field is unaffected by the ambient temperature, unless low temperatures produce

brittle fracture due to the small stresses which develop from self-weight of the structure and from the minute difference in the thermal expansion coefficients in the constituent parts of the equipment (steel and concrete). To prevent brittle fracture, all steel material in HI-STORM 100 is qualified by impact testing as set forth in the ASME Code (Table 3.1.18).

The structural material used in the MPC (Alloy X) is recognized to be completely immune from brittle fracture in the ASME Codes.

As no liquids are included in the HI-STORM 100 storage overpack design, loads due to expansion of freezing liquids are not considered. The HI-TRAC transfer cask utilizes demineralized water in the water jacket. However, the specified lowest service temperature for the HI-TRAC is 0 degrees F and a 25% ethylene glycol solution is required for the temperatures from 0 degrees F to 32 degrees F. Therefore, loads due to expansion of freezing liquids are not considered.

There is one condition, however, that does require examination to insure ready retrievability of the fuel. Under a postulated loading of an MPC from a HI-TRAC transfer cask into a cold HI-STORM 100 storage overpack, it must be demonstrated that sufficient clearances are available to preclude interference when the “hot” MPC is inserted into a “cold” storage overpack. To this end, a bounding analysis for free thermal expansions has been performed in Subsection 4.4.6, wherein the MPC shell is postulated at its maximum design basis temperature and the thermal expansion of the overpack is ignored. The results from the evaluation of free thermal expansion are summarized in Table 4.4.10. The final radial clearance (greater than 0.25” radial) is sufficient to preclude jamming of the MPC upon insertion into a cold HI-STORM 100 storage overpack.

3.4.6 HI-STORM 100 Kinematic Stability under Flood Condition (Load Case A in Table 3.1.1)

The flood condition subjects the HI-STORM 100 System to external pressure, together with a horizontal load due to water velocity. Because the HI-STORM 100 storage overpack is equipped with ventilation openings, the hydrostatic pressure from flood submergence acts only on the MPC. As stated in subsection 3.1.2.1.1.3, the design external pressure for the MPC bounds the hydrostatic pressure from flood submergence. Subsection 3.4.4.5.2 has reported a positive safety factor against instability from external pressure in excess of that expected from a complete submergence in a flood. The analysis performed below is also valid for the HI-STORM 100S and the HI-STORM 100S, Version B.

The water velocity associated with flood produces a horizontal drag force, which may act to cause sliding or tip-over. In accordance with the provisions of ANSI/ANS 57.9, the acceptable upper bound flood velocity, V , must provide a minimum factor of safety of 1.1 against overturning and sliding. For HI-STORM 100, we set the upper bound flood velocity design basis at 15 feet/sec. Subsequent calculations conservatively assume that the flow velocity is uniform over the height of the storage overpack.

The overturning horizontal force, F , due to hydraulic drag, is given by the classical formula:

$$F = C_d A V^2$$

where:

V^* is the velocity head = $\frac{\rho V^2}{2g}$; (ρ is water weight density, and g is acceleration due to gravity).

A: projected area of the HI-STORM 100 cylinder perpendicular to the fluid velocity vector.

Cd: drag coefficient

The value of Cd for flow past a cylinder at Reynolds number above 5E+05 is given as 0.5 in the literature (viz. Hoerner, Fluid Dynamics, 1965).

The drag force tending to cause HI-STORM 100's sliding is opposed by the friction force, which is given by

$$F_f = \mu K W$$

where:

μ = limiting value of the friction coefficient at the HI-STORM 100/ISFSI pad interface (conservatively taken as 0.25, although literature citations give higher values).

K = buoyancy coefficient (documented in HI-981928, Structural Calculation Package for HI-STORM 100 (see citation in Subsection 3.6.4)).

W: Minimum weight of HI-STORM 100 with an empty MPC.

Sliding Factor of Safety

The factor of safety against sliding, β_1 , is given by

$$\beta_1 = \frac{F_f}{F} = \frac{\mu K W}{C_d A V^*}$$

It is apparent from the above equation, β , will be minimized if the empty weight of HI-STORM 100 is used in the above equation.

As stated previously, $\mu = 0.25$, $C_d = 0.5$.

V^* corresponding to 15 ft./sec. water velocity is 218.01 lb per sq. ft.

A = length x diameter of HI-STORM 100 = 132.5" x 231.25"/144 sq. in./sq.ft. = 212.78 sq. ft.

$K =$ buoyancy factor = 0.64 (per calculations in HI-981928)

$W =$ empty weight of overpack w/ lid = 270,000 lbs. (Table 3.2.1)

Substituting in the above formula for β , we have

$$\beta_1 = 1.86 > 1.1 \text{ (required)}$$

Since the weight of the HI-STORM 100S or HI-STORM 100S, Version B, plus the weight of an empty MPC-32 (i.e., the lightest MPC) is greater than 270,000 lb, the above calculation is also valid for these two units for the entire range of concrete densities.

Overturning Factor of Safety

For determining the margin of safety against overturning b_2 , the cask is assumed to pivot about a fixed point located at the outer edge of the contact circle at the interface between HI-STORM 100 and the ISFSI. The overturning moment due to a force F_T applied at height H^* is balanced by a restoring moment from the reaction to the cask buoyant force KW acting at radius $D/2$.

$$F_T H^* = KW \frac{D}{2}$$

$$F_T = \frac{K W D}{2 H^*}$$

W is the empty weight of the storage overpack.

We have,

$$W = 270,000 \text{ lb. (Table 3.2.1)}$$

$$H^* = 119.2" \text{ (maximum height of mass center per Table 3.2.3)}$$

$$D = 132.5" \text{ (Holtec Drawing 1495)}$$

$$K = 0.64 \text{ (calculated in HI-981928)}$$

$$F_T = 96,040 \text{ lb.}$$

F_T is the horizontal drag force at incipient tip-over.

$$F = C_d A V^* = 23,194 \text{ lbs. (drag force at 15 feet/sec)}$$

The safety factor against overturning, β_2 , is given as:

$$\beta_2 = \frac{F_T}{F} = 4.14 > 1.1 \text{ (required)}$$

This result bounds the result for the HI-STORM 100S, for the HI-STORM 100S Version B, as well as for the densified concrete shielding option, since the calculation uses a conservative lower bound weight and a bounding height for the center of gravity. Similar overturning and sliding calculations have been performed for the HI-STORM 100S Version B Type IS in Supplement 33 of [3.4.17] to obtain limiting flood water velocity while maintaining factors of safety equal to or greater than 1.1.

In the next subsection, results are presented to show that the load F (equivalent to an inertial deceleration of $F/360,000 \text{ lb} = 0.0644 \text{ g}$'s applied to the loaded storage overpack) does not lead to large global circumferential stress or ovalization of the storage overpack that could prevent ready retrievability of the MPC. It is shown in Subsection 3.4.7 that a horizontal load equivalent to 0.47 g 's does not lead to circumferential stress levels and ovalization of the HI-STORM storage overpack to prevent ready retrievability of the MPC. The load used for that calculation clearly bounds the side load induced by flood.

3.4.7 Seismic Event and Explosion - HI-STORM 100

3.4.7.1 Seismic Event (Load Case C in Table 3.1.1)

Overturning Analysis

The HI-STORM 100 System plus its contents may be assumed to be subject to a seismic event consisting of three orthogonal statistically independent acceleration time-histories. For the purpose of performing a conservative analysis to determine the maximum ZPA that will not cause incipient tipping, the HI-STORM 100 System is considered as a rigid body subject to a net horizontal quasi-static inertia force and a vertical quasi-static inertia force. This is consistent with the approach used in previously licensed dockets. The vertical seismic load is conservatively assumed to act in the most unfavorable direction (upwards) at the same instant. The vertical seismic load is assumed to be equal to or less than the net horizontal load with ε being the ratio of vertical component to one of the horizontal components. For use in calculations, define D_{BASE} as the contact patch diameter, and H_{CG} as the height of the centroid of an empty HI-STORM 100 System (no fuel). Conservatively, assume

$$D_{\text{BASE}} = 132.5" \text{ (Drawing 1495, Sheet 1 specifies } 133.875" \text{ including overhang for welding)}$$

Tables 3.2.1 and 3.2.3 give HI-STORM 100 weight data and center-of-gravity heights.

The weights and center-of-gravity heights are reproduced here for calculation of the composite center-of-gravity height of the storage overpack together with an empty MPC.

<u>Weight (pounds)</u>	<u>C.G. Height (Inches); H</u>
Overpack - $W_o = 270,000$	116.8
MPC-24 - $W_{24} = 42,000$	$109.0 + 24 = 133.0^\dagger$
MPC-68 - $W_{68} = 39,000$	$111.5 + 24 = 135.5$
MPC-32 - $W_{32} = 36,000$	$113.2 + 24 = 137.2$
MPC-24E - $W_{24E} = 45,000$	$108.9 + 24 = 132.9$

The height of the composite centroid, H_{CG} , is determined from the equation

$$H_{cg} = \frac{W_o \times 116.8 + W_{MPC} \times H}{W_o + W_{MPC}}$$

Performing the calculations for all of the MPCs gives the following results:

<u>H_{cg} (inches)</u>	
MPC-24 with storage overpack	118.98
MPC-68 with storage overpack	119.16
MPC-32 with storage overpack	119.20
MPC-24E with storage overpack	119.10

A conservative overturning stability limit is achieved by using the largest value of H_{CG} (call it H) from the above. Because the HI-STORM 100 System is a radially symmetric structure, the two horizontal seismic accelerations can be combined vectorially and applied as an overturning force at the C.G. of the cask. The net overturning static moment is

$$W G_H H$$

where W is the total system weight and G_H is the resultant zero period acceleration seismic loading (vectorial sum of two orthogonal seismic loads) so that $W G_H$ is the inertia load due to the resultant horizontal acceleration. The overturning moment is balanced by a vertical reaction force, acting at the outermost contact patch radial location $r = D_{BASE}/2$. The resistive moment is minimized when the vertical zero period acceleration G_V tends to reduce the apparent weight of the cask. At that instant, the moment that resists "incipient tipping" is:

$$W (1 - G_V) r$$

Performing a static moment balance and eliminating W results in the following inequality to ensure a "no-overturning condition:

[†] From Table 3.2.3, it is noted that MPC C.G. heights are measured from the base of the MPC. Therefore, the thickness of the overpack baseplate and the concrete MPC pedestal must be added to determine the height above ground.

$$G_H + \frac{r}{H} G_V \leq \frac{r}{H}$$

Using the values of r and H for the HI-STORM 100 ($r = 66.25"$, $H = 119.20"$), representative combinations of G_H and G_V that satisfy the limiting equality relation are computed and tabulated below:

Acceptable Net Horizontal G-Level (HI-STORM100), G_H	Acceptable Vertical G-Level, G_V
0.467	0.16
0.445	0.20
0.417	0.25
0.357	0.357

We repeat the above computations using the weight and c.g. location of the HI-STORM 100S(232). Because of the lowered center of gravity positions, the maximum net horizontal “G” levels are slightly increased.

Performing the calculations for all of the MPCs gives the following results:

<u>MPC</u>	<u>H_{cg} (inches)</u>
MPC-24 with storage overpack	113.89
MPC-68 with storage overpack	114.07
MPC-32 with storage overpack	114.11
MPC-24E with storage overpack	114.01

Using the values of r and H for the HI-STORM 100S(232) ($r = 66.25"$, $H = 114.11"$), representative combinations of G_H and G_V that satisfy the limiting equality relation are computed and tabulated below:

Acceptable Net Horizontal G-Level (HI-STORM 100S(232)), G_H	Acceptable Vertical G-Level, G_V
0.488	0.16
0.464	0.20
0.435	0.25
0.367	0.367

The limiting values of G_H and G_V for the HI-STORM 100S(243), which is taller than the HI-STORM 100S(232), are the same as the HI-STORM 100.

If the HI-STORM 100 or the HI-STORM 100S is fabricated using high density concrete (i.e.,

above 160.8 pcf dry), the C.G. height of the overpack decreases and thereby enables the cask system to withstand higher g-loads. This conclusion becomes immediately clear when the maximum acceptable vertical g-level is expressed in the following form:

$$G_v = 1 - \frac{H}{r} G_H$$

For fixed values of G_H and r , the value of G_v increases as H decreases. Therefore, the representative combinations of G_H and G_v given above for the HI-STORM 100 and the HI-STORM 100S are conservative for the densified concrete shielding option.

Since the HI-STORM 100S, Version B has further reduced the centroid of the loaded units, it is expected that acceptable G-Levels are further increased. The following calculations provide the limiting G-level combinations for the HI-STORM 100S Version B with standard weight concrete. As noted previously, the result for standard weight concrete will bound the corresponding result for the high density concrete (densified) shielding option.

We repeat the above computations using the weight and c.g. location of the HI-STORM 100S(218). Because of the lowered center of gravity positions, the maximum net horizontal “G” levels are slightly increased.

Performing the calculations for all of the MPCs gives the following results:

H_{cg} (inches)

MPC-24 with storage overpack	109.88
MPC-68 with storage overpack	110.12
MPC-32 with storage overpack	110.23
MPC-24E with storage overpack	109.93

Using the values of r and H for the HI-STORM 100S, Version B(218) ($r = 66.25"$, $H = 110.23"$), representative combinations of G_H and G_v that satisfy the limiting equality relation are computed and tabulated below:

Acceptable Net Horizontal G-Level (HI-STORM 100S, Version B(218)), G_H	Acceptable Vertical G-Level, G_v
0.505	0.16
0.481	0.20
0.451	0.25
0.376	0.375

The limiting values of G_H and G_v for the HI-STORM 100S, Version B(229), which is taller than

the HI-STORM 100S, Version B(218), are bounded by the values listed for the HI-STORM 100.

The HI-STORM 100S, Version B Type IS (218) and Version B Type IS (229) have lower center of gravity positions than the HI-STORM 100S, Version B (218) and Version B (229) while maintaining the same base footprint. Therefore, the limiting values of G_H and G_V for the HI-STORM 100S, Version B Type IS (218) and Version B Type IS (229) are bounded by the limiting values of G_H and G_V for the HI-STORM 100S, Version B (218) and Version B (229). Explicit stability evaluations for HI-STORM 100S Version B Type IS are presented in Supplement 34 of [3.4.17].

Primary Stresses in the HI-STORM 100 Structure Under Net Lateral Load Over 180 degrees of the Periphery

Under a lateral loading, the storage overpack will experience axial primary membrane stress in the inner and outer shells as it resists bending as a “beam-like” structure. Under the same kind of lateral loading over one-half of the periphery of the cylinder, the shells will tend to ovalize under the loading and develop circumferential stress. Calculations for stresses in both the axial and circumferential direction are required to demonstrate satisfaction of the Level D structural integrity requirements and to provide confidence that the MPC will be readily removable after a seismic event, if necessary. An assessment of the stress state in the structure under the seismic induced load will be shown to bound the results for any other condition that induces a peripheral load around part of the HI-STORM 100 storage overpack perimeter. The specific analyses are performed using the geometry and loading for the HI-STORM 100; the results obtained for stress levels and the safety assessment are also applicable to an assessment of the HI-STORM 100S.

A simplified calculation to assess the flexural bending stress in the HI-STORM 100 structure under the limiting seismic event (at which tipping is incipient) is presented in the following:

A representative net horizontal acceleration of 0.47g is used to determine the primary stresses in the HI-STORM 100 storage overpack. The corresponding lateral seismic load, F , is given by

$$F = 0.47 W$$

This load will be maximized if the upper bound HI-STORM 100 weight ($W = 410,000$ lbs. (Table 3.2.1)) is used. Accordingly,

$$F = (0.47) (410,000) = 192,700 \text{ lbs.}$$

No dynamic amplification is assumed as the overpack, considered as a beam, has a natural frequency well into the rigid range.

The moment, M , at the base of the HI-STORM 100 due to this lateral force is given by

$$M = \frac{F H}{2}$$

where H = height of HI-STORM 100 (taken conservatively as 235 inches). Note that the loading has now been approximated as a uniform load acting over the full height of the cask.

The flexural stress, σ , is given by the ratio of the moment M to the section modulus of the steel shell structure, z, which is computed to be 12,640 in³ for the HI-STORM 100 overpack with inner and outer shell thicknesses of 1-1/4" and 3/4", respectively. The use of this value is conservative since the steel section modulus associated with the optional 1" thick inner and outer shell design is slightly higher.

Therefore,

$$\sigma = \frac{(192,700)(235)}{(12,640)(2)} = 1,791 \text{ psi}$$

We note that the strength of concrete has been neglected in the above calculation.

The maximum axial stress in the storage overpack shell will occur on the "compressive" side where the flexural bending stress algebraically sums with the direct compression stress σ_d from vertical compression.

From the representative acceleration tables, the vertical seismic accelerations corresponding to the net 0.47g horizontal acceleration is below 0.25g.

Therefore, using the maximum storage overpack weight (bounded by 410,000 lbs. from data in Table 3.2.1)

$$\sigma_d = \frac{(410,000)(1.25)}{554.47} = 924 \text{ psi}$$

where 554.47 sq. inch is the metal area (cross section) of the steel structure in the HI-STORM 100 storage overpack as computed in Subsection 3.4.4.3.2.1. The total axial stress, therefore, is

$$\sigma_T = 1,791 + 924 = 2,715 \text{ psi}$$

Per Table 3.1.12, the allowable membrane stress intensity for a Level D event is 39,750 psi at 350 degrees F.

The Factor of Safety, β , is, therefore

$$\beta = \frac{39,750}{2,715} = 14.6$$

Examination of the stability calculations for the overpack outer shell under a 45-g vertical end drop demonstrates that no instability will result from this compressive load induced by a seismic or other environmental load leading to bending of the storage overpack as a beam.

The previous calculation has focused on the axial stress in the members developed assuming that the storage overpack does not overturn but resists the lateral load by remaining in contact with the ground and bending like a beam. Since the lateral loading is only over a portion of the periphery, there is also the potential for this load to develop circumferential stress in the inner and outer shells to resist ovalization of the shells. To demonstrate continued retrievability of the MPC after a seismic event, it must be shown that either the stresses remain in the elastic range or that any permanent deformation that develops due to plasticity does not intrude into the MPC envelope after the event is ended. In the following subsection, classical formulas for the deformation of rings under specified surface loadings are used to provide a conservative solution for the circumferential stresses in the HI-STORM 100. Specifically, the solution for a point-supported ring subject to a gravitational induced load, as depicted in the sketch below, is implemented. This solution provides a conservative estimate of the circumferential stress and the deformation of the ring that will develop under the actual applied seismic load.

Ring supported at base and loaded by its own weight, w , given per unit circumferential length.

The solution considers the geometry and load appropriate to a unit length of the inner and outer shells of the HI-STORM 100 storage overpack with a total weight equal to the overpack bounding weight (no MPC) subject to a 45g deceleration inertial loading. The numerical results for the 45g tipover event can be directly applied here by multiplying by the factor “X”, where “X” reflects the differences in the deceleration and the weights used for the tipover event and for the seismic load case here in this subsection.

$$X = (0.47g/45g) \times (410,000\text{lb.}/270,000\text{lb.}) = 0.0159$$

Using this factor on the tipover solution gives the following bounding results for maximum stresses (without regard for sign and location of the stress) and deformations:

$$\text{Maximum circumferential stress due to bending moment} = (29,310 \text{ psi} \times X) = 466 \text{ psi}$$

$$\text{Maximum circumferential stress due to mean tangential force} = (18,900 \text{ lb.}/2 \text{ sq.inch}) \times X = 150.3 \text{ psi}$$

$$\text{Change in diameter in the direction of the load} = -0.11'' \times X = -0.0017''$$

Change in diameter perpendicular to the direction of the load = $+0.06'' \times X = 0.0010''$

From the above results, it is clear that no permanent ovalization of the storage overpack occurs during the seismic event and that circumferential stresses will remain elastic and are bounded by the stresses computed based on considering the storage overpack as a simple beam. Therefore, the safety factors based on maximum values of axial stress are appropriate. The magnitudes of the diameter changes that are suggested by the ring solution clearly demonstrate that ready retrievability of the MPC is maintained after the seismic event.

Because of the low values for the calculated axial stress, the conclusions of the previous section are also valid for the HI-STORM 100S, and for the HI-STORM 100S, Version B and Version B Type IS.

Potential for Concrete Cracking

It can be readily shown that the concrete shielding material contained within the HI-STORM 100 structure will not crack due to the flexuring action of HI-STORM 100 during a bounding seismic event that leads to a maximum axial stress in the storage overpack. For this purpose, the maximum axial strain in the steel shell is computed by dividing the tensile stress developed by the seismic G forces (for the HI-STORM 100, for example) by the Young's Modulus of steel.

$$\zeta = \frac{1,791 - 858}{28 \text{ E} + 06} = 33.3 \text{ E} - 06$$

where the Young's Modulus of steel is taken from Table 3.3.2 at 350 degrees F.

The acceptable concrete strain in tension is estimated from information in ACI-318.1 for plain concrete. The ratio of allowable tensile stress to concrete Young's Modulus is computed as

$$\text{Allowable Concrete Strain} = (5 \times (0.75) \times (f)^{1/2}) / (57,000(f)^{1/2}) = 65.8 \text{ E} - 06$$

In the above expression, f is the concrete compressive strength.

Therefore, we conclude that considerable margins against tensile cracking of concrete under the bounding seismic event exist.

Sliding Analysis

An assessment of sliding of the HI-STORM 100 System on the ISFSI pad during a postulated seismic event is performed using a one-dimensional "slider block on friction supported surface" dynamic model. The results for the shorter HI-STORM 100S are comparable. The HI-STORM 100 is simulated as a rigid block of mass ' m ' placed on a surface, which is subject to a sinusoidal acceleration of amplitude ' a '. The coefficient of friction of the block is assumed to be reduced by a factor α to recognize the contribution of vertical acceleration in the most adverse manner (vertical acceleration acts to reduce the downward force on the friction interface). The equation of motion

for such a "slider block" is given by:

$$m\ddot{x} = R + m a \sin \omega t$$

where:

\ddot{x} : relative acceleration of the slider block (double dot denotes second derivative of displacement 'x' in time)

a: amplitude of the sinusoidal acceleration input

ω : frequency of the seismic input motion (radians/sec)

t: time coordinate

R is the resistive Coulomb friction force that can reach a maximum value of $\mu(mg)$ (μ = coefficient of friction) and which always acts in the direction of opposite to $\dot{x}(t)$.

Solution of the above equation can be obtained by standard numerical integration for specified values of m, a, α and μ . The calculation is performed for representative horizontal and vertical accelerations of 0.47g and 0.16g, respectively. The input values are summarized below.

$$a = 0.47g$$

$$\alpha = 0.84 = 1 - \text{vertical acceleration} (= 0.16g)$$

$$m = 360,000 \text{ lbs/g}$$

$$\mu = 0.25$$

For establishing the appropriate value of ω , reference is made to the USAEC publication TID-7024, "Nuclear Reactor and Earthquakes", page 35, 1963, which states that the significant energy of all seismic events in the U.S. essentially lies in the range of 0.4 to 10 Hz. Taking the mid-point value

$$\omega = (6.28) (0.5) (0.4+10) = 32.7 \text{ rad/sec.}$$

The numerical solution of the above equation yields the maximum excursion of the slider block x_{\max} as 0.12 inches, which is negligible compared to the spacing between casks.

Calculations performed at lower values of ω show an increase in x_{\max} with reducing ω . At 1 Hz, for example, $x_{\max} = 3.2$ inches. It is apparent from the above that there is a large margin of safety against inter-module collision within the HI-STORM 100 arrays at an ISFSI, where the minimum installed spacing is over 2 feet (Table 1.4.1).

The above dynamic analysis indicates that the HI-STORM 100 System undergoes minimal lateral vibration under a seismic input with net horizontal ZPA g-values as high as 0.47 even under a

bounding (from below) low interface surface friction coefficient of 0.25. Data reported in the literature (ACI-349R (97), Commentary on Appendix B) indicates that values of the coefficient of friction, μ , as high as 0.7 are obtained at steel/concrete interfaces.

To ensure against unreasonably low coefficients of friction, the ISFSI pad design may require a “broom finish” at the user’s discretion. The bottom surface of the HI-STORM 100 is manufactured from plate stock (i.e. non-machine finish). A coefficient of friction value of 0.53 is considered to be a conservative numerical value for the purpose of ascertaining the potential for incipient sliding of the HI-STORM 100 System. If a higher value is used, the coefficient of friction is required to be verified by test (see Table 2.2.9).

The relationship between the vertical ZPA, G_v , (conservatively assumed to act opposite to the normal gravitational acceleration), and the resultant horizontal ZPA G_H to insure against incipient sliding is given from static equilibrium considerations as:

$$G_H + \mu G_v \leq \mu$$

Using a conservative value of μ equal to 0.53, the above relationship provides governing ZPA limits for a HI-STORM 100 (or 100S) System arrayed in a freestanding configuration. The table below gives representative combinations that meet the above limit.

G_H (in g’s)	G_v (in g’s)
0.445	0.16
0.424	0.20
0.397	0.25
0.350	0.34

Since the sliding inequality is independent of the weight and centroid of the cask system, the results above remain valid for HI-STORM overpacks with high density concrete and with different heights.

If the values for the DBE event at an ISFSI site satisfy the above inequality relationship for incipient sliding with coefficient of friction equal to 0.53, then the non-sliding criterion set forth in NUREG-1536 is assumed to be satisfied a’priori. However, if the ZPA values violate the inequality by a small amount, then it is permissible to satisfy the non-sliding criterion by implementing measures to roughen the HI-STORM 100/ISFSI pad interface to elevate the value of μ to be used in the inequality relation. To demonstrate that the value of μ for the ISFSI pad meets the required value implied by the above inequality, a series of Coulomb friction tests (under the QA program described in Chapter 13) shall be performed as follows:

Pour a concrete block with horizontal dimensions no less than 2’ x 2’ and a block thickness no less than 0.5’. Finish the top surface of the block in the same manner as the ISFSI pad surface will be prepared.

Prepare a 6” x 6” x 2” SA516 Grade 70 plate specimen (approximate weight = 20.25 lb.) to simulate the bottom plate of the HI-STORM 100 overpack. Using a calibrated friction gage

attached to the steel plate, perform a minimum of twenty (20) pull tests to measure the static coefficient of friction at the interface between the concrete block and the steel plate. The pull tests shall be performed on at least ten (10) different locations on the block using varying orientations for the pull direction.

The coefficient of friction to be used in the above sliding inequality relationship will be set as the average of the results from the twenty tests.

The satisfaction of the “no-sliding” criterion set down in the foregoing shall be carried out along with the “no-overturning” qualification (using the static moment balance method in the manner described at the beginning of this subsection) and documented as part of the ISFSI facility’s 10CFR72.212 evaluation.

Alternative Evaluation of Overturning and Sliding

In this subsection, an evaluation of the propensity for the free standing cask to be in a state of either incipient overturning or incipient sliding has been performed using a simple static analysis that is independent of time phasing of the input acceleration time histories and considers only the Zero Period Acceleration (ZPA) obtained from the response spectra. For both incipient overturning and incipient sliding, the following inequality must be satisfied to ensure satisfaction of the static criteria.

$$G_H + \mu G_V \leq \mu$$

For the incipient overturning evaluation, μ =(radius of cask base/height to loaded cask center-of-gravity). For the incipient sliding evaluation, μ = Coulomb coefficient of friction =0.53 at the cask/ISFSI pad interface (unless testing justifies use of a higher value). The inequality has been derived assuming that the cask is resting on a flat and level surface that is subject to a seismic event characterized by a response spectra set with the net horizontal and vertical Zero Period Acceleration (ZPA) denoted by G_H and G_V , respectively.

This “screening” evaluation provides a conservative criterion to insure that top-of-pad acceleration time histories from the aggregate effect of soil structure interaction and free field acceleration would not predict initiation of overturning or sliding. If on-the-pad acceleration time histories are available, the applicable inequality (for overturning and sliding) may be satisfied at each time instant during the Design Basis Earthquake with G_H and G_V representing coincident values of the magnitude of the net horizontal and vertical acceleration vectors. One way of satisfying the use of the top-of-pad acceleration time history approach is to follow the guidelines described in the NRC supplemental technical summary resulting from the public meeting on ISFSI Pad Structural Analysis, dated February 27, 2013 [3.4.15].

3.4.7.2 Explosion (Load Case 05 in Table 3.1.5)

In the preceding subsection, it has been demonstrated that incipient tipping of the storage overpack will not occur under a side load equal to 0.47 times the weight of the cask. For a fully loaded cask with high density concrete, this side load is equal to

$$F = 192,700 \text{ lb.}$$

If it is assumed that this side load is uniformly distributed over the height of the cask and that the cask centroid is approximately at the half-height of the overpack, then an equivalent pressure, P , acting over 180 degrees of storage overpack periphery, can be defined as follows:

$$P \times (DH) = F$$

Where D = overpack outside diameter, and H = minimum height of a storage overpack (HI-STORM 100S Version B(218)).

For $D = 132.5''$ and $H = 218''$, the equivalent pressure is

$$P = 192,700 \text{ lb}/(132.5'' \times 218'') = 6.67 \text{ psi}$$

Therefore, establishing 5 psi as the design basis steady state pressure differential (Table 2.2.1) across the overpack diameter is reasonable.

Since the actual explosion produces a transient wave, the use of a static incipient tip calculation is very conservative. To evaluate the margin against tip-over from a short-time pressure pulse, a Working Model analysis of the two-dimensional dynamic motion of the HI-STORM subject to a given initial angular velocity is carried out. Figures 3.4.25 and 3.4.26 provide details of the model and the solution for a HI-STORM 100 System (simulated as a rigid body) having a weight and inertia property appropriate to a minimum weight cask of height $H=235''$. The results show that an initial angular velocity of 0.626 radians/second does not lead to a tipover of the storage overpack. The results bound those obtained for the HI-STORM 100S(232) and for the HI-STORM 100S Version B (229) since the overall cask height is reduced. The results for the HI-STORM 100S(243) are roughly equal to the results for the HI-STORM 100 since the differences in height and weight are negligible. The results for the HI-STORM 100S Version B and Version B Type IS will be bounded by the results presented because of lower centroid location.

Continuing, the initial angular velocity can be related to a square wave pressure pulse of magnitude P and time duration T by the following formula:

$$I\omega = (P \times D \times H) \times (0.5 \times H) \times T$$

The above formula relates the change in angular motion resulting from an impulsive moment about the base of the overpack. D is the diameter of the outer shell, H is the height of the storage overpack, and I is the mass moment of inertia of the storage overpack about the mass center (assumed to be at half-height). For $D=132.5''$, $H=235''$, $P=10 \text{ psi}$, $T=1 \text{ second}$, and $I=64,277,000 \text{ lb.inch sec}^2$, the resulting initial angular velocity is:

$$\omega = 0.569 \text{ radians/second}$$

Therefore, an appropriate short time pressure limit is 10 psi with pulse duration less than or equal to 1 second. Table 2.2.1 sets this as the short-time external pressure differential.

The overpack is also qualified to sustain without tip-over a lateral impulse load of 60 psi (differential pressure for 85 milliseconds maximum) [3.4.5].

The analysis in Subsection 3.4.7.1 evaluates ovalization of the shell by considering the seismically applied load as a line loading along the height of the overpack that is balanced by inertial body forces in the metal ring. The same solutions can be used to examine the circumferential stress state that would be induced to resist an external pressure that developed around one-half of the periphery. Such a pressure distribution may be induced by a pressure wave crossing the cask from a nearby explosion. It is shown here that a uniform pressure load over one-half of the overpack outer shell gives rise to an elastic stress state and deformation state that is bounded by a large margin by the results just presented for the seismic event in Subsection 3.4.7.1.

The case of an external pressure load from an explosion pressure wave (Load Case 05 in Table 3.1.5) is examined by combining the solutions for two different load cases. The combined case that results is a balance of pressure load over one-half the perimeter and inertial body forces. The sketch below describes this:

Both cases are considered under identical total loads (with the angle in case 3 set to 90 degrees). Therefore, adding the results from the two cases results in the desired combined case; namely, the balance of a peripheral external pressure with internal all around loading simulating an inertia load (since the reactions are identical in magnitude and opposite in direction, there is a complete cancellation of the concentrated loads).

Examination of the results shows that the algebraic sum of the two solutions gives results that are smaller in magnitude than the case 1 solution for a line loading balanced by inertially induced body forces. The applied loading used to develop the solution for case 1 is 56,180 lb. per inch of storage overpack axial length. This load is equivalent to an external pressure $P = 424$ psi applied over one-half of the outer perimeter of the shell as is shown below:

$$P \times D = 56,180 \text{ lb./inch} \quad D = 132.5'' \quad \text{Therefore, } P = 424 \text{ psi}$$

Since this is higher by a large margin than any postulated external pressure load, circumferential stresses induced by the differential pressure specified in Table 2.2.1 are insignificant. Specifically, by adding the results from the two solutions (ring load case 1 for a point support reaction to a body

force + ring load case 3 for a point support reaction to a lateral pressure over one-half of the perimeter), it is determined that the circumferential bending stress from case 1 is reduced by the factor “R” to obtain the corresponding stress from the combined case. R is computed as the ratio of moment magnitudes from the combined case to the results of case 1 alone.

$$R = (\text{maximum bending moment from case 1} + \text{case 3}) / (\text{maximum bending moment from case 1}) \\ = 0.75/6.197 = 0.12$$

Examination of the graphs from the moment distribution from the two solutions shows that the individual terms always subtract and nearly cancel each other at every location.

Therefore, it is concluded that the maximum circumferential stress that develops under a pressure of 424 psi applied over one-half of the perimeter, and conservatively assumed balanced by inertia loading, is

$$\text{Stress} = 29,310 \text{ psi} \times 0.12 = 3517 \text{ psi}$$

The stress due to a differential pressure of 10 psi (Table 2.2.1) is only 2.36% of the above value and needs no further evaluation for stress limits or deformation to demonstrate retrievability of the MPC. Because of the large margin obtained for a specific set of values appropriate to the HI-STORM 100, the same conclusion is reached for the HI-STORM 100S and the HI-STORM 100S, Version B and Version B Type IS; that is, differential pressures of the postulated magnitude will not affect retrievability of the stored MPC.

3.4.7.3 Anchored HI-STORM Systems Under High-Seismic DBE (Load Case C in Table 3.1.1)

The anchored HI-STORM System (Figures 1.1.4 and 1.1.5) is assumed to be subjected to quasi-static inertial seismic loads corresponding to the ZPA design basis limits given in Table 2.2.8. The results from this quasi-static analysis are used to evaluate structural margins for the preloaded anchor studs and the sector lugs. In the quasi-static evaluation, the effect of the “rattling” of the MPC inside of the overpack is accounted for by the imposition of a dynamic load factor of 2.0 on the incremental stresses that arise during the seismic event. In addition to the quasi-static analysis, confirmatory 3-D dynamic analyses are performed using base acceleration excitation histories developed from two sets of response spectra. Figure 3.4.30 shows the two sets of response spectra that are assumed to be imposed at the top of the ISFSI pad. One set of response spectra is the Regulatory Guide 1.60 spectra for 5% damping with zero period acceleration conservatively amplified to 1.5 in each direction. This spectra set has been used as the input spectra at many nuclear plants in the U.S. (although generally, the ZPA was much below 1.0). Three statistically independent acceleration time histories (two horizontal labeled as “H1”, “H2”) and one vertical (labeled as “VT”) have been developed. A twenty-second duration event was considered. Figures 3.4.31 to 3.4.33 show the time histories. The second set of response spectra used for time history analysis has similar levels of zero period acceleration but has higher peak spectral acceleration values in the low frequency range (2-3 Hz). This spectra set is the design basis set for a Pacific coast U.S. plant. Figures 3.4.34 to 3.4.36 (labeled as “FN”, “FP” for the two horizontal acceleration histories and “FV” for the vertical acceleration time history), show the corresponding

time histories simulating a long duration seismic event (170 seconds).

The objectives of the quasi-static and dynamic seismic analyses are the following:

- i. Quantify the structural safety factor in the anchor studs and in the sector lugs that constitute the fastening system for the loaded HI-STORM 100A overpack. The structural safety factor is defined as the ratio of the permitted stress (stress intensity) per Subsection “NF” of the ASME Code to the maximum stress (stress intensity) developed in the loaded component.
- ii. Compute the safety factor against fatigue failure of the anchor studs from a single seismic event.
- iii. Quantify the interface loads applicable to the ISFSI pad to enable the ISFSI owner to design the ISFSI pad under the provisions of ACI-349 (85). The bounding interface loads computed for the maximum intensity seismic event (ZPA) and for extreme environmental loads may be used in pad design instead of the site-specific loads calculated for the loadings applicable to the particular ISFSI.

The above design objectives are satisfied by performing analyses of a loaded HI-STORM 100A System using a conservative set of input data and a conservative dynamic model. Calculations using the quasi-static model assume that the net horizontal inertia loads and the vertical inertia load correspond to the weight of the loaded cask times the appropriate ZPA. The results from the analyses are set down as the interface loads, and may be used in the ISFSI pad design work effort by the ISFSI owner. The information on the seismic analysis is presented in five paragraphs as follows:

Input data for analysis
 Quasi-static model and results
 Dynamic model and modeling assumptions.
 Results of dynamic analysis
 Summary of interface loads

a. Input Data for Analysis:

Key input data for the seismic analysis of a loaded HI-STORM 100A System is summarized in Table 3.4.10. As can be seen from Table 3.4.10, the input data used in the analysis is selected to bound the actual data, wherever possible, so as to maximize the seismic response. For example, a bounding weight of the loaded MPC and HI-STORM 100A overpack is used because an increase in the weight of the system directly translates into an increased inertial loading on the structure.

For quasi-static analysis, bounding ZPA values of 1.5 in all three directions are used with the vertical event directed upward to maximize the stud tension. The resulting ZPAs are then further amplified by the dynamic load factor (DLF=2.0) to reflect "rattling" of the MPC within the overpack. Input data for anchor stud lengths are representative. We consider long and short studs in order to evaluate the effect of stud spring rate.

For the confirmatory dynamic analyses, the time history base excitations are shown in Figures 3.4.31 through 3.4.36 and the propensity for “rattling” is included in the model.

b. Quasi-Static Model and Results:

We consider the HI-STORM100A baseplate as a rigid plate resting on the ISFSI pad with the twenty-eight studs initially preloaded so as to impart a compressive load at the baseplate pad interface that is balanced by a tensile load in the studs prior to the seismic event occurring. The discrete studs are replaced by a thin ring located at the stud circle radius for analysis purposes. The thickness of the thin ring is set so that the ring area is equal to the total stress area of the twenty-eight studs. Figure 3.4.37 shows a view of a segment of the baseplate with the outline of the ring. The ISFSI pad is represented by a linear spring and a rotational spring with spring constants determined from the exact solution for a rigid circular punch pressed into a elastic half-space. We assume that subsequent to pre-tensioning the studs, the seismic event occurs, represented by a net horizontal load DH and a net vertical load DV. In the analysis, the input loads DH and DV are:

$$G_H = (1.5^2 \times 2)^{1/2} \times DLF = 4.242 ; \quad G_V = 1.5 \times DLF = 3.0$$

$$DH = G_H \times 360,000 \text{ lb.} ; \quad DV = -G_V \times 360,000 \text{ lb}$$

DH is the magnitude of the vector sum of the two horizontal ZPA accelerations multiplied by the bounding HI-STORM 100A weight. Similarly, DV is an upward directed load due to the vertical ZPA acceleration. The upward direction is chosen in order to maximize the stud tension as the assemblage of studs and foundation resists overturning from the moment induced by DH applied at the centroid of the cask. Figure 3.4.38 shows the free-body diagram associated with the seismic event. Essentially, we consider an analysis of a pre-compressed interface and determine the interface joint behavior under the imposition of an external loading (note that this kind of analysis is well established in the pressure vessel and piping area where it is usually associated with establishing the effectiveness of a gasketed joint). An analysis is performed to determine the maximum stud tension that results if the requirement of no separation between baseplate and pad is imposed under the imposed loading. The following result is obtained from static equilibrium, for a preload stress of 60 ksi, when the “no separation condition” is imposed:

$$\frac{2a/3h_{cg} (F_{\text{preload}}/W + 1)(1 + \alpha_1)}{G_H - 2a/3h_{cg} (G_V (1 + \alpha_1)/(1 + \alpha))} = 1.016$$

In the above equation,

$$F_{\text{preload}} = (\text{Total stress area of twenty-eight, 2" diameter studs}) \times 60 \text{ ksi} = 4,200,000 \text{ lb.}$$

$$W = \text{Bounding weight of loaded HI-STORM 100A} = 360,000 \text{ lb.}$$

$$a = 73.25 \text{ inches,}$$

$$h_{cg} = 118.5 \text{ inches}$$

The coefficients α and α_1 relate the stiffness of the totality of studs to the stiffness of the foundation under direct loading and under rotation. The result given above is for the representative case of stud free length “L”, equal to

$L = 42$ inches, which gives α and α_1 equal to 0.089 and 0.060, respectively.

A simplified confirmatory analysis of the above problem can be performed by considering the limiting case of a rigid baseplate and a rigid ISFSI pad. In the limit of a rigid ISFSI pad (foundation), the coefficients α and α_1 go to zero. A related solution for the case of a rigid baseplate and a rigid foundation can be obtained when the criteria is not incipient separation, but rather, a more “liberal” incipient rotation about a point on the edge of the baseplate. That solution is given in “Mechanical Design of Heat Exchangers and Pressure Vessel Components”, by Singh and Soler (Arcturus Publishers, 1984). The result is (for 60 ksi pre-stress in each stud):

$$\frac{a/h_{cg} (F_{\text{preload}}/W + 1)}{G_H - a/h_{cg} (G_V)} = 1.284$$

Although not a requirement of any design code imposed herein, the right hand side of the previous relationships can be viewed as the safety factor against incipient separation (or rotation about an edge) at the radius “a”. Note that since we have assumed a bounding event, there is an additional margin of 1.5 in results since the Reg. Guide 1.60 event has not been applied with a ZPA in excess of 1.0.

For the real seismic event associated with a western U.S. plant having a slightly lower horizontal ZPA and a reduced vertical ZPA (see Figure 3.4.30). Using the same DLF = 2.0 to account for “rattling” of the confined MPC:

$$G_H = 4.1 \quad ; \quad G_V = 2.6,$$

the aforementioned safety factors are:

$$\begin{aligned} \text{SF (incipient separation)} &= 1.076 \\ \text{SF (incipient edging)} &= 1.372 \end{aligned}$$

The increment of baseplate displacement and rotation, up to incipient separation, is computed from the equilibrium and compatibility equations associated with the free body in Figure 3.4.38 and the change in stud tension computed. The following formula gives the stud tensile stress in terms of the initial preload and the incremental change from the application of the horizontal and vertical seismic load.

$$\sigma_{\text{stud}} = \sigma_{\text{preload}} + \alpha \frac{W}{NA_{\text{stress}}} \left(\frac{-G_V}{1 + \alpha} + \left(\frac{3h_{cg}}{2a} \right) \left(\frac{c}{a} \right) \left(\frac{G_H}{1 + \alpha_1} \right) \right)$$

In the above formula,

N = number of studs = 28 (maximum number based on HI-STORM dimensions). For lower seismic inputs, this might be reduced (in groups of 4 to retain symmetry).

A_{stress} = tensile stress area of a 2" diameter stud

$2c$ = stud circle diameter

The results demonstrate that there is a relatively small change in stud stress from the initial pre-tension condition with the ISFSI pad foundation resisting the major portion of the overturning moment. For the geometry considered (maximum stud free length and nominal pre-stress), the maximum tensile stress in the stud increases by 9.1%. The following table summarizes the results from the quasi-static analysis using minimum ultimate strength for the stud to compute the safety factors. Note that under the seismic load, the direct stress in the stud is limited to 70% of the stud ultimate strength (per Appendix F of the ASME Code Section III). The allowable pad compressive stress is determined from the ACI Code assuming confined concrete and the minimum concrete compressive strength from Table 2.0.4. Because of the large compressive load at the interface from the pre-tensioning operation, the large frictional resistance inhibits sliding of the cask. Consequently, there will be no significant shear stress in the studs. Safety factors for sliding are obtained by comparing the ratio of horizontal load to vertical load with the coefficient of friction between steel and concrete (0.53). Values in parenthesis represent results obtained using ZPA values associated with the real seismic event for the western U.S. plant instead of the bounding Reg. Guide 1.60 event.

SUMMARY OF RESULTS FOR STUDS AND INTERFACE FROM QUASI-STATIC SEISMIC EVALUATION WITH DLF = 2.0, Stud Prestress = 60 ksi			
Item	Calculated Value	Allowable Value	Safety Factor = (Allowable Value/Calculated Value)
Stud Stress(ksi) (42" stud free length)	65.48 (65.18)	87.5	1.336 (1.343)
Maximum Pad Pressure (ksi)(42" stud free length)	3.126 (3.039)	4.76	1.52 (1.57)
Stud Stress (ksi)(16" stud free length)	73.04 (72.34)	87.5	1.20 (1.21)
Maximum Pad Pressure(ksi) (16" stud free length)	2.977 (2.898)	4.76	1.60 (1.64)
Overpack Sliding	0.439 (0.407)	0.53	1.21 (1.31)

The effect of using a minimum stud free length in the embedment design is to increase the values of the coefficients α and α_1 because the stud stiffness increases. The increase in stud stiffness, relative to the foundation stiffness results in an increase in incremental load on the studs. This is a natural and expected characteristic of preloaded configurations. It is noted that the stud safety factors are based on minimum ultimate strength and can be increased, without altering the calculated results, by changing the stud material.

The quasi-static analysis methodology has also been employed to evaluate the effects of variation in the initial pre-stress on the studs. The following tables reproduce the results above for the cases

of lower bound stud pre-stress (55 ksi) and upper bound stud pre-stress (65 ksi) on the studs. Only the results using the values associated with the Reg. Guide 1.60 bounding event are reported.

SUMMARY OF RESULTS FOR STUDS AND INTERFACE FROM QUASI- STATIC SEISMIC EVALUATION WITH DLF = 2.0, Stud Prestress = 55 ksi			
Item	Calculated Value	Allowable Value	Safety Factor = (Allowable Value/Calculated Value)
Stud Stress(ksi) (42" stud free length)	60.48	87.5	1.45
Maximum Pad Pressure (ksi)(42" stud free length)	3.012	4.76	1.58
Stud Stress (ksi)(16" stud free length)	68.07	87.5	1.29
Maximum Pad Pressure(ksi) (16" stud free length)	2.862	4.76	1.663
Overpack Sliding	0.488	0.53	1.09

SUMMARY OF RESULTS FOR STUDS AND INTERFACE FROM QUASI- STATIC SEISMIC EVALUATION WITH DLF = 2.0, Stud Prestress = 65 ksi			
Item	Calculated Value	Allowable Value	Safety Factor = (Allowable Value/Calculated Value)
Stud Stress(ksi) (42" stud free length)	70.48	87.5	1.24
Maximum Pad Pressure (ksi)(42" stud free length)	3.24	4.76	1.47
Stud Stress (ksi)(16" stud free length)	78.07	87.5	1.12
Maximum Pad Pressure(ksi) (16" stud free length)	3.091	4.76	1.54
Overpack Sliding	0.399	0.53	1.33

The results above confirm the expectations that an increase in preload increases the safety factor against sliding. The calculated coefficient of friction in the above tables is computed as the ratio of applied horizontal load divided by available vertical load. For all combinations examined, ample margin against incipient separation at the interface exists.

Based on the results from the quasi-static analysis, an assessment of the safety factors in the sector lugs is obtained by performing a finite element analysis of a repeated element of one of the sector lugs. Figure 3.4.39 shows the modeled section and the finite element mesh. The stud load is conservatively applied as a uniform downward pressure applied over a 5"x5" section of the extended baseplate simulating the washer between two gussets. This is conservative as the rigidity of the washer is neglected. The opposing pressure loading from the interface pressure is applied as a pressure over the entire extended baseplate flat plate surface. Only one half the thickness of each gusset plate is included in the model. The outer shell is modeled as 3/4" thick, which corresponds to the minimum thickness option per Bill of Material 1575.

Two cases are considered: (1) the pre-loaded state (a Normal Condition of Storage-Level A stress limits apply); and, (2), the seismic load condition at the location of the maximum tensile load in a stud (an Accident Condition of Storage – Level D stress intensity limits apply). Figures 3.4.40 and 3.4.41 present the stress results for the following representative input conditions:

Level A analysis - Preload stress/bolt = 60 ksi

Level D analysis - Maximum Bolt stress (includes seismic increment) = 65.5 ksi

In the Level A analysis, the resisting local foundation pressure exactly balances the preload. For the Level D analysis, the opposing local foundation pressure = 190 psi (average over the area between gussets). This represents the reduced pressure under the highest loaded stud under the induced rotation of the storage system.

The most limiting weld stress is obtained by evaluating the available load capacity of the fillet weld attaching the extended baseplate annulus region to the gussets (approximately 25 inches of weld per segment) using a limit strength equal to 42% of the ultimate strength of the base material.

The following table summarizes the limiting safety factors for the sector lugs. Allowable values for primary bending stress and stress intensity are from Tables 3.1.10 and 3.1.12 for SA-516 Grade 70 at 300 degrees F.

SUMMARY OF RESULTS FOR SECTOR LUGS FROM QUASI-STATIC SEISMIC EVALUATION			
Item	Calculated Value	Allowable Value	Safety Factor = (Allowable Value/Calculated Value)
Maximum Primary Membrane + Bending Stress Away From Loaded Region and Discontinuity (ksi) – Case 1 - Preload	15.62	26.3	1.68
Maximum Primary Membrane + Bending Stress Intensity Away From Loaded Region and Discontinuity (ksi) – Case 2 - Preload + Seismic	36.67	60.6	1.65
Maximum Weld Shear Load (kips)	150.8	194.9	1.29

c. Dynamic Model and Modeling Assumptions:

The dynamic model of the HI-STORM 100A System consists of the following major components.

- i. The HI-STORM 100 overpack is modeled as a six degree-of-freedom (rigid body) component.
- ii. The loaded MPC is also modeled as a six degree-of-freedom (rigid body) component that is free to rattle inside the overpack shell. Gaps between the two

bodies reflect the nominal dimensions from the drawings.

- iii. The contact between the MPC and the overpack is characterized by a coefficient of restitution and a coefficient of friction. For the dynamic analysis, the coefficient of restitution is set to 0.0, reflecting the large areas of nearly flat surface that come into contact and have minimal relative rebound. The coefficient of friction is set to 0.5 between all potentially contacting surfaces of the MPC/overpack interface.
- iv. The anchor studs, preloaded to axial stress σ_i (Table 3.4.10), induce a contact stress between the overpack base and the ISFSI pad. The loaded cask-pad interface can support a certain amount of overturning moment before an uplift (loss of circularity of the contact patch) occurs. The anchor studs are modeled as individual linear springs connecting the periphery of the extended baseplate to the ISFSI pad section. The resistance of the foundation is modeled by a vertical linear spring and three rotational springs connected between the cask baseplate center point and the surface of the flat plate modeling the driven ISFSI pad. The ISFSI pad is driven with the three components of acceleration time history applied simultaneously.

The HI-STORM 100A dynamic model described above is implemented on the public domain computer code WORKING MODEL (also known as VisualNastran) (See Subsection 3.6.2 for a description of the algorithm).

Figures 3.4.42 and 3.4.43 show the rigid body components of the dynamic model before and after assembly. The linear springs are not shown. Mass and inertia properties of the rigid bodies are consistent with the bounding property values in Table 3.4.10.

d. Results of Dynamic Analysis:

Figures 3.4.44 –3.4.47 show results of the dynamic analysis using the Reg. Guide 1.60 seismic time histories as input accelerations to the ISFSI pad. Figure 3.4.44 shows variation in the vertical foundation compressive force. Figure 3.4.45 shows the corresponding load variation over time for the stud having the largest instantaneous tensile load. An initial preload of approximately 150,000 lb is applied to each stud (corresponding to 60,160 psi stud tensile stress). This induces an initial compression load at the interface approximately equal to 571,000 lb. (including the dead weight of the loaded HI-STORM). Figures 3.4.44 and 3.4.45 clearly demonstrate that the foundation resists the majority of the oscillatory and impactive loading as would be expected of a preloaded configuration. Figure 3.4.46 shows the impulse (between the MPC and HI-STORM 100A) as a function of time. It is clear that the “spikes” in both the foundation reaction and the stud load over the total time of the event are related to the impacts of the rattling MPC. The results provide a graphic demonstration that the rattling of the MPC inside the overpack must be accounted for in any quasi-static representation of the event. The quasi-static results presented herein for the anchored system, using a DLF = 2.0, are in excellent agreement with the dynamic simulation results.

We note that the dynamic simulation, which uses an impulse-momentum relationship to simulate the rattling contact, leads to results having a number of sharp peaks. Given that the stress intensity

limits in the Code assume static analyses, filtering of the dynamic results is certainly appropriate prior to comparing with any static allowable strength. We conservatively do not perform any filtering of the results prior to comparison with the quasi-static analysis; we note only that any filtering of the dynamic results to eliminate high-frequency effects resulting from the impulse-momentum contact model would increase the safety factors. Finally, Figure 3.4.47 shows the ratio of the net interface horizontal force (needed to maintain equilibrium) to the instantaneous compression force at the ISFSI pad interface with the base of the HI-STORM 100A. This ratio, calculated at each instant of time from the dynamic analysis results using the Reg. Guide 1.60 event, represents an instantaneous coefficient of friction that is required to ensure no interface relative movement. Figure 3.4.47 demonstrates that the required coefficient of friction is below the available value 0.53. Thus, the dynamic analysis confirms that the foundation interface compression, induced by the preloading action, is sufficient to maintain a positive margin against sliding without recourse to any resistance from the studs.

The results of the dynamic analysis using acceleration time histories from the Reg. Guide 1.60 response spectra (grounded at 1.5 g's) confirm the ability of the quasi-static solution, coupled with a dynamic load factor, to correctly establish structural safety factors for the anchored cask. The dynamic analysis confirms that stud stress excursions from the preload value are minimal despite the large overturning moments that need to be balanced.

A second dynamic simulation has been performed using the seismic time histories appropriate to a pacific coast U.S. nuclear plant (Figures 3.4.34-3.4.36). The ZPA of these time histories are slightly less than the Reg. Guide 1.60 time histories but the period of relatively strong motion extends over a longer time duration. The results from this second simulation exhibit similar behavior as those results presented above and provide a second confirmation of the validity of the safety factors predicted by the quasi-static analysis. Reference [3.4.14] (see Subsection 3.8) provides archival information and backup calculations for the results summarized here.

Stress cycle counting using Figure 3.4.45 suggests 5 significant stress cycles per second provides a bounding number for fatigue analysis. A fatigue reduction factor of 4 is appropriate for the studs (per ASME Code rules). Therefore, a conservative analysis of fatigue for the stud is based on an alternating stress range of:

$S(\text{alt}) = 0.5 \times (22,300 \text{ psi}) \times 4 = 44,600 \text{ psi}$ for 5 cycles per second. The value for the stress range is obtained as the difference between the largest tensile stress excursions from the mean value as indicated in the figure.

To estimate fatigue life, we use a fatigue curve from the ASME Code for high strength steel bolting materials (Figure I.9.4 in Appendix I, ASME Code Section III Appendices) For an amplified alternating stress intensity range of 44,600 psi, Figure I.9.4 predicts cyclic life of 3,000 cycles. Therefore, the safety factor for failure of a stud by fatigue during one Reg. Guide 1.60 seismic event is conservatively evaluated as:

$$SF(\text{stud fatigue}) = 3,000/100 = 30.$$

For the long duration event, even if we make the conservative assumption of a nine-fold increase

in full range stress cycles, the safety factor against fatigue failure of an anchor stud from a single seismic event is 3.33. Recognizing that the fatigue curve itself is developed from test data with a safety factor of 20 on life and 4 on stress, the results herein demonstrate that fatigue failure of the anchor stud, from a single seismic event, is not credible.

e. Summary of Interface Loads for ISFSI Pad Design:

Bounding interface loads are set down for use by the ISFSI pad designer and are based on the validated quasi-static analysis and a dynamic load factor of 2.0:

BOUNDING INTERFACE LOADS FOR ISFSI PAD STRUCTURAL/SEISMIC DESIGN	
D (Cask Weight)	360 kips
D (Anchor Preload @ 65 ksi)	4,550 kips
E (Vertical Load)	1,080 kips
E (Net Horizontal Surface ShearLoad)	1,527.35 kips
E (Overturning Moment)	15,083 kip-ft.

3.4.8 Tornado Wind and Missile Impact (Load Case B in Table 3.1.1 and Load Case 04 in Table 3.1.5)

During a tornado event, the HI-STORM 100 System is assumed to be subjected to a constant wind force. It is also subject to impacts by postulated missiles. The maximum wind speed is specified in Table 2.2.4 and the three missiles, designated as large, intermediate, and small, are described in Table 2.2.5.

In contrast to a freestanding HI-STORM 100 System, the anchored overpack is capable of withstanding much greater lateral pressures and impulsive loads from large missiles. The quasi-static analysis result, presented in the previous subsection, can be used to determine a maximum permitted base overturning moment that will provide at least the same stud safety factors. This is accomplished by setting $G_v = 0.0$, $DLF = 1$ and finding an appropriate G_H that gives equal or better stud safety factors. The resulting value of G_H establishes the limit overturning moment for combined tornado missile plus wind, M_L . ($G_H \times \text{Weight} \times h_{cg}$) is conservatively set as the maximum permissible moment at the base of the cask due to combined action of lateral wind and tornado missile loading. Thus, if the lateral force from a tornado missile impact is F at height h and that from steady tornado wind action is a resultant force W acting at cask mid-height ($0.5H$), and the two loads are acting synergistically to overturn the cask, then their magnitudes must satisfy the inequality

$$0.5WH + Fh \leq M_L$$

where the limit moment is established to ensure that the safety factors for seismic load remain bounding.

$$M_L = 18,667 \text{ kip-ft.}$$

Tornado missile impact factors should be factored into “F” prior to determining the validity of the above inequality for any specific site.

In the case of a freestanding system, the post impact response of the HI-STORM 100 System is

required to assess stability. Both the HI-STORM 100 storage overpack, and the HI-TRAC transfer cask are assessed for missile penetration.

The results for the post-impact response of the HI-STORM 100 storage overpack demonstrate that the combination of tornado missile plus either steady tornado wind or instantaneous tornado pressure drop causes a rotation of the HI-STORM 100 to a maximum angle of inclination less than 3 degrees from vertical. This is much less than the angle required to overturn the cask. The results for the HI-STORM 100 are bounding since the HI-STORM 100S, and the HI-STORM 100S Version B and Version B Type IS have a lower center of gravity when loaded. Since a lower bound cask weight of 302,000 lbs is used, the results are also bounding for HI-STORM overpacks that utilize high density concrete.

The maximum force (not including the initial pulse due to missile impact) acting on the projected area of the storage overpack is computed to be:

$$F = 91,920 \text{ lbs.}$$

The instantaneous impulsive force due to the missile strike is not computed here; its effect is felt as an initial angular velocity imparted to the storage overpack at time equal to zero. The net resultant force due to the simultaneous pressure drop is not an all-around distributed loading that has a net resultant, but rather is more likely to be distributed only over 180 degrees (or less) of the storage overpack periphery. The circumferential stress and deformation field will be of the same order of magnitude as that induced by a seismic loading. Since the magnitude of the force due to F is less than the magnitude of the net seismically induced force considered in Subsection 3.4.7, the storage overpack global stress analysis performed in Subsection 3.4.7 remains governing. In the next subsection, results are provided for the circumferential stress and ovalization of the portion of the storage overpack due to the bounding estimate for the impact force of the intermediate missile.

3.4.8.1 HI-STORM 100 Storage Overpack

This subsection considers the post impact behavior of the HI-STORM 100 System after impact from tornado missiles. During an impact, the system consisting of missile plus storage overpack and MPC satisfies conservation of linear and angular momentum. The large missile impact is assumed to be inelastic. This assumption conservatively transfers all of the momentum from the missile to the system. The intermediate missile and the small missile are assumed to be unyielding and hence the entire initial kinetic energy is assumed to be absorbed by motion of the cask and local yielding and denting of the storage overpack surface. It is shown that cask stability is maintained under the postulated wind and large missile loads. The conclusion is also valid for the HI-STORM 100S, and for the HI-STORM 100S Version B and Version B Type IS with or without the densified concrete shielding option since their lower centers of gravity inherently provide additional stability margin.

The penetration potential of the missile strikes (Load Case 04 in Table 3.1.5) is examined first. The detailed calculations show that there will be no penetration through the concrete surrounding the inner shell of the storage overpack or penetration of the top closure plate. Therefore, there will be no impairment to the confinement boundary due to missile strikes during a tornado. Since the

inner shell is not compromised by the missile strike, there will be no permanent deformation of the inner shell. Therefore, ready retrievability is assured after the missile strike. The following paragraphs summarize the analysis work for the HI-STORM 100.

- a. The small missile will dent any surface it impacts, but no significant puncture force is generated. The 1" missile can enter the air ducts, but geometry prevents a direct impact with the MPC.
- b. The following table summarizes the denting and penetration analysis performed for the intermediate missile. Denting is used to connote a local deformation mode encompassing material beyond the impacting missile envelope, while penetration is used to connote a plug type failure mechanism involving only the target material immediately under the impacting missile. The results are applicable to the HI-STORM 100 and to the HI-STORM 100S. The HI-STORM 100S version B has a thicker outer shell than the classic HI-STORM 100, and a lid configuration that consists of a 1" lid cover plate backed by concrete and a 3" thick lid vent shield plate that acts as a barrier to a top lid missile strike. Therefore, the tabular results presented below are bounding for the HI-STORM 100S Version B.

Location	Denting (in.)	Thru-Thickness Penetration
Storage overpack outer Shell	13.75 [†]	Yes (>0.75 in.)
Radial Concrete	18.54 ^{††}	No (<27.25 in.)
Storage overpack Top Lid	<2.0	No (<4 in.)

[†] Based on minimum outer shell thickness of 3/4". Penetration is less for HI-STORM 100 and 100S overpacks with 1" thick outer shell.

^{††} Based on concrete compressive strength equal to 50% of minimum value specified in Table 3.3.5 to account for exposure to high temperatures.

The primary stresses that arise due to an intermediate missile strike on the side of the storage overpack and in the center of the storage overpack top lid are determined next. The analysis of the storage lid for the HI-STORM 100 bounds that for the HI-STORM 100S; because of the additional energy absorbing material (concrete) in the direct path of a potential missile strike on the top lid of the HI-STORM 100S lid, the energy absorbing requirements of the circular plate structure are much reduced. The analysis demonstrates that Level D stress limits are not exceeded in either the overpack outer shell or the top lid. The safety factor in the storage overpack, considered as a cantilever beam under tip load, is computed, as is the safety factor in the top lids, considered as two centrally loaded plates. The applied load, in each case, is the missile impact load. Similar calculations are performed for the HI-STORM 100S Version B using the same model and methodology. A summary of the results for axial stress in the storage overpack is given in the table below with numbers in parentheses representing the results of calculations for the geometry of the HI-STORM 100S Version B:

HI-STORM 100 MISSILE IMPACT - Global Axial Stress Results			
Item	Value (ksi)	Allowable (ksi)	Safety Factor
Outer Shell – Side Strike	14.35 [†] (15.17)	37.95	2.64 [†] (2.50)
Top Lid - End Strike	44.14(47.57)	57.0 (50.65)	1.29(1.065)

[†] Based on HI-STORM 100 overpack with inner and outer shell thicknesses of 1-1/4” and 3/4”, respectively. Result is bounding for HI-STORM 100 overpacks made with 1” thick inner and outer shells because the section modulus of the steel structure is greater.

Similar conclusions are obtained for the HI-STORM 100S Version B Type IS based on the evaluations presented in Supplements 31 and 32 of [3.4.17].

To demonstrate ready retrievability of the MPC, we must show that the storage overpack suffers no permanent deformation of the inner shell that would prevent removal of the MPC after the missile strike. To demonstrate ready retrievability (for both HI-STORM 100 and for HI-STORM 100S) a conservative evaluation of the circumferential stress and deformation state due to the missile strike on the outer shell is performed. A conservative estimate for the 8” diameter missile impact force, “Pi”, on the side of the storage overpack is calculated as:

$$P_i = 1,063,000 \text{ lb.}$$

This force is conservative in that the target overpack is assumed rigid; any elasticity serves to reduce the peak magnitude of the force and increase the duration of the impact. The use of the upper bound value is the primary reason for the high axial stresses resulting from this force. To demonstrate continued ability to retrieve the MPC subsequent to the strike, circumferential stress and deformation that occurs locally in the ring section near the location of the missile strike are investigated.

Subsection 3.4.7 presents stress and displacement results for a composite ring of unit width consisting of the inner and outer shells of the storage overpack. The solution assumes that the net loading is 56,184 lb. applied on the 1” wide ring (equivalent to a 45g deceleration applied uniformly along the height on a storage overpack weight of 270,000 lb.). This solution can be applied directly to evaluate the circumferential stress and deformation caused by a tornado missile strike on the outer shell. Using the results for the 45g tipover event, an attenuation factor to adjust the results is developed that reflects the difference in load magnitude and the width of the ring that is effective in resisting the missile strike force. The strike force P_i is resisted by a combination of inertia force and shear resistance from the portion of the storage overpack above and below the location of the strike. The ring theory solution to determine the circumferential stress and deformation conservatively assumes that inertia alone, acting on an effective length of ring, balances the applied point load P_i . The effective width of ring that balances the impact load is conservatively set as the diameter of the impacting missile (8”) plus the effect of the “bending boundary layer” length. This boundary layer length is conservatively set as a multiple of twice the square root of the product of mean radius times the average thickness of two shells making up the cylindrical body of the storage overpack. The mean radius of the composite cylinder and the

average thickness of the inner and outer shells are

$$R_{\text{mean}} = 48''$$

$$T = .5 \times (.75'' + 1.25'') = 1''$$

The bending boundary layer “ β ” in a shell is generally accepted to be given as $(2(R_{\text{mean}}T)^{1/2}) = 13.85''$ for this configuration. That is, the effect of a concentrated load is resisted mainly in a length along the shell equal to the bending boundary layer. For a strike away from the ends of the shell, a boundary layer length above and below the strike location would be effective (i.e., double the boundary layer length). However, to conservatively account for resistance above and below the location of the strike, this calculated result is only increased by 1.5 in the following analysis (rather than 2). Therefore, the effective width of ring is assumed as:

$$13.85'' \times 1.5 + 8'' = 28.78''$$

The solution for the 45g tipover event (performed for a unit ring width and a load of 56,184 lb.) is directly applicable if we multiply all stress and displacement results by the factor “Y” where

$$Y = (1''/28.78'') \times (1,063,000 \text{ lb.}/56,184 \text{ lb.}) = 0.658$$

Using this factor gives the following bounding results for maximum circumferential stresses (without regard for sign and location of the stress) and deformations due to the postulated tornado missile strike on the side of the storage overpack outer shell:

$$\text{Maximum circumferential stress due to bending moment} = (29,310 \text{ psi} \times Y) = 19,272 \text{ psi}$$

$$\text{Maximum circumferential stress due to mean tangential force} = (18,900 \text{ lb.}/2 \text{ sq.inch}) \times Y = 6,214 \text{ psi}$$

$$\text{Change in diameter in the direction of the load} = -0.11'' \times Y = -0.072''$$

$$\text{Change in diameter perpendicular to the direction of the load} = +0.06'' \times Y = 0.039''$$

Based on the above calculation, the safety factor on maximum stress for this condition is

$$SF = 37,950 \text{ psi}/19,272 \text{ psi} = 1.97$$

The allowable stress for the above calculation is the Level D membrane stress intensity limit from Table 3.1.12 at 450°F. This is a conservative result since the stress intensity is localized and need not be compared to primary membrane stress intensity. Even with the overestimate of impact strike force used in the calculations here, the stresses remain elastic and the calculated diameter changes are small and do not prevent ready retrievability of the MPC. Note that because the stresses remain in the elastic range, there will be no post-strike permanent deformation of the inner shell.

The above calculations remain valid for the HI-STORM 100S, Version B and Version B Type IS

using normal weight concrete and are bounding for the case where densified concrete is used.

3.4.8.2 HI-TRAC Transfer Cask

3.4.8.2.1 Intermediate Missile Strike

HI-TRAC is always held by the handling system while in a vertical orientation completely outside of the fuel building (see Chapter 2 and Chapter 8). Therefore, considerations of instability due to a tornado missile strike are not applicable. However, the structural implications of a missile strike require consideration.

The penetration potential of the 8" missile strike on HI-TRAC (Load Case 04 in Table 3.1.5) is examined at two locations:

1. the lead backed outer shell of HI-TRAC.
2. the flat transfer lid consisting of multiple steel plates with a layer of lead backing.

In each case, it is shown that there is no penetration consequence that would lead to a radiological release. The following paragraphs summarize the analysis results.

- a. The small missile will dent any surface it impacts, but no significant puncture force is generated.
- b. The following table summarizes the denting and penetration analysis performed for the intermediate missile. Denting connotes a local deformation mode encompassing material beyond the impacting missile envelope, while penetration connotes a plug type failure mechanism involving only the target material immediately under the impacting missile. Where there is through-thickness penetration, the lead and the inner plate absorb any residual energy remaining after penetration of the outer plate in the 100 Ton HI-TRAC transfer lid. The table summarizes the bounding results for both transfer casks.

Location	Denting (in.)	Thru-Thickness Penetration
Outer Shell - lead backed	0.498	No (<1.0 in.) No (<0.75 in.) (HI-TRAC 100G)
Outer Transfer Lid Door	0.516	No (<0.75 in.) (HI-TRAC 125) Yes (>0.5 in.) (HI-TRAC 100)

Based on the above results, the intermediate missile will penetrate the ½" thick bottom plate of the HI-TRAC 100D pool lid. However, the lead and the pool lid top plate will absorb any residual energy remaining after penetration of the bottom plate. The 8" missile will not penetrate the pool lid for the HI-TRAC 125D and the HI-TRAC 100G because it has a thicker bottom plate than the HI-TRAC 125 transfer lid door. In addition, the results for the 8" missile strike on the HI-TRAC outer shell are valid for the HI-TRAC 125D and the HI-TRAC 100D since the HI-TRAC 100, HI-TRAC 125, HI-TRAC 100D, and HI-TRAC 125D transfer casks have the same outer shell

thickness. It is also demonstrated that the 8" missile will not penetrate the HI-TRAC 100G outer shell.

While the transfer cask is being transported in a horizontal orientation, the MPC lid is exposed. We conservatively assume no protective plate in place during this transport operation and evaluate the capacity of the lid peripheral groove weld to resist the impact load. The calculated result is as follows:

HI-TRAC MISSILE IMPACT - Capacity Results			
Item	Value (lb)	Capacity (lb)	Safety Factor = Capacity/Value
Top Lid Weld	2,262,000	2,789,000	1.23

The final calculation in this subsection is an evaluation of the circumferential stress and deformation consequences of the horizontal missile strike on the periphery of the HI-TRAC shell. It is assumed that the HI-TRAC is simply supported at its ends (while in transit) and is subject to a direct impact from the 8" diameter missile. To compute stresses, an estimate of the peak impact force is required. The effect of the water jacket to aid in the dissipation of the impact force is conservatively neglected. The only portion of the HI-TRAC cylindrical body that is assumed to resist the impact load is the two metal shells. The lead is assumed only to act as a separator to maintain the spacing between the shells. The previous results from the lead slump analysis demonstrate that this conservative assumption on the behavior of the lead is valid. The peak value of the impact force is a function of the stiffness of the target. The target stiffness in this postulated event has the following contributions to the stiffness of the structure.

- a. a global stiffness based on a beam deformation mode, and
- b. a local stiffness based on a shell deformation mode

The global spring constant (i.e., the inverse of the global deflection of the cask body as a beam under a unit concentrated load) is a function of location of the strike along the length of the cask. The spring constant value varies from a minimum for a strike at the half-height to a maximum value for a strike near the supports (the trunnions). Since the peak impact force is larger for larger stiffness, it is conservative to maximize the spring constant value. Therefore, in the calculation, we neglect this spring constant for the computation of peak impact force and focus only on the spring constant arising from the local deformation as a shell, in the immediate vicinity of the strike. To this end, the spring constant is estimated by considering the three-dimensional effects of the shell solution to be replaced by the two-dimensional action of a wide ring. The width of the ring is equal to the "bending boundary layer" length on either side of the strike location plus the diameter of the striking missile. Following the analysis methodology already utilized subsection 3.4.8.1, the following information is obtained:

The mean radius of the composite cylinder and the average thickness of the inner and outer shells, are (use the 100 Ton HI-TRAC data since it provides an upper bound on stress and deformation):

$$R_{\text{mean}} = 36.893$$

$$T = .5 \times (.75'' + 1.00'') = 0.875''$$

The bending boundary layer “ β ” in a shell is generally accepted to be given as $(2(R_{\text{mean}}T)^{1/2})$. To account for resistance above and below the location of the strike, this calculated result is conservatively increased by multiplying by 1.5. Therefore, the effective width of ring is:

$$11.22'' \times 1.5 + 8'' = 24.84''$$

The missile impact is modeled as a point load, acting on the ring, of magnitude equal to $P_i = 20,570$ lb. The use of a point load in the analysis is conservative in that it overemphasizes the local stress. The actual strike area is an 8” diameter circle (or larger, if the effect of the water jacket were included).

The force is assumed resisted by inertia forces in the ring section. From the results, a spring constant can be defined as the applied load divided by the change in diameter of the ring section in the direction of the applied load. Based on this approach, the following local spring constant is obtained:

$$K = P_i/D1_H = P_i/0.019'' = 1,083,000 \text{ lb./inch}$$

To determine the peak impact force, a dynamic analysis of a two-body system has been performed using the “Working Model” dynamic simulation code. A two mass-spring damper system is considered with the defined spring constant representing the ring deformation effect. Figure 3.4.24 shows the results from the dynamic analysis of the impact using the computer code “Working Model”. The small square mass represents the missile, while the larger mass represents the portion of the HI-TRAC “ring” assumed to participate in the local impact. The missile weight is 275.5 lb. and the participating HI-TRAC weight is set to the weight of the equivalent ring used to determine the spring constant.

The peak impact force that results in each of the two springs used to simulate the local elasticity of the HI-TRAC (ring) is:

$$F(\text{spring}) = 124,400 \text{ lb.}$$

Since there are two springs in the model, the total impact force is:

$$P(\text{impact}) = 248,800 \text{ lb.}$$

To estimate circumferential behavior of the ring under the impact, the previous solution (using a load of 20,570 lb.) is used and amplified by the factor “Z”, where:

$$Z = 248,800 \text{ lb.}/20,570 \text{ lb.} = 12.095$$

Consequently, the maximum circumferential stress due to the ring moment, away from the impact

location, is:

$$3,037\text{psi} \times (69,260 \text{ in-lb}/180,900 \text{ in-lb}) \times Z = 14,230 \text{ psi}$$

At the same location, the mean stress adds an additional component (the ring area is computed based on the effective width of the ring).

$$(5,143 \text{ lb.}/43.47 \text{ sq.in}) \times Z = 1431 \text{ psi}$$

Therefore, the safety factor on circumferential stress causing ovalization of an effective ring section that is assumed to resist the impact is:

$$\text{SF}(\text{ring stress}) = 39,750 \text{ psi}/(1431\text{psi} + 14,230\text{psi}) = 2.54$$

The allowable stress for this safety factor calculation is obtained from Table 3.1.12 for primary membrane stress intensity for a Level D event at 350 degrees F material temperature. Noting that the actual circumferential stress in the ring remains in the elastic range, it is concluded that the MPC remains readily retrievable after the impact since there is no permanent ovalization of the cavity after the event. As noted previously, the presence of the water jacket adds an additional structural barrier that has been conservatively neglected in this analysis.

3.4.8.2.2 Large Missile Strike

The effects of a large tornado missile strike on the side (water jacket outer enclosure) of a loaded HI-TRAC has been simulated using a transient finite element model of the transfer cask and loaded MPC. The transient finite element code LS-DYNA3D has been used (approved by the NRC for use in impact analysis (see Appendix 3.A, reference [3.A.4] for the benchmarking of this computer code)). An evaluation of MPC retrievability and global stress state (away from the impact area) are of primary interest. The finite element model includes the loaded MPC, the HI-TRAC inner and outer shells, the HI-TRAC water jacket, the lead shielding, and the appropriate HI-TRAC lids. The water in the water jacket has been neglected for conservatism in the results. The large tornado missile has been simulated by an impact force-time pulse applied on an area representing the frontal area of an 1800-kg. vehicle. The force-time data used has been previously approved by the USNRC (Bechtel Topical Report BC-TOP-9A, "Design of Structures for Missile Impact", Revision 2, 9/1974). The frontal impact area used in the finite element analysis is that area recommended in NUREG-0800, SRP 3.5.1.4, Revision 2, 1981).

A summary of the results is presented below for the HI-TRAC 100 and HI-TRAC 125 transfer casks. Since the dimensions of the inner shell, the outer shell, the lead shielding, and the water jacket enclosure panels are the same in both the HI-TRAC 125 and the HI-TRAC 125D, the results from the HI-TRAC 125 are considered accurate for the HI-TRAC 125D. Likewise, the results from the HI-TRAC 100 are valid for the HI-TRAC 100D. The construction of HI-TRAC 100G is slightly different compared to HI-TRAC 100, but the conclusions obtained for HI-TRAC 100 are still applicable to HI-TRAC 100G. The allowable value listed for the stress intensity for this Level D event comes from Table 3.1.17.

The results from the dynamic analysis have been summarized below.

SUMMARY OF RESULTS FROM LARGE TORNADO MISSILE IMPACT ANALYSIS		
ITEM – HI-TRAC 100	CALCULATED VALUE	ALLOWABLE VALUE
Maximum Stress Intensity in Water Jacket (ksi)	33.383	58.7
Maximum Stress Intensity in Inner Shell (ksi)	15.6	58.7
Maximum Plastic Strain in Water Jacket	0.0	-
Maximum Plastic Strain in Inner Shell	0.0	-

ITEM – HI-TRAC 125	CALCULATED VALUE	ALLOWABLE VALUE
Maximum Stress Intensity in Water Jacket (ksi)	33.697	58.7
Maximum Stress Intensity in Inner Shell (ksi)	18.669	58.7
Maximum Plastic Strain in Water Jacket	0.0	-
Maximum Plastic Strain in Inner Shell	0.0	-

The above results demonstrate that:

1. The retrievability of the MPC in the wake of a large tornado missile strike is not adversely affected since the inner shell does not experience any plastic deformation.
2. The maximum primary stress intensity, away from the impact interface on the HI-TRAC water jacket, is below the applicable ASME Code Level D allowable limit for NF, Class 3 structures.

3.4.9 HI-TRAC Drop Events (Load Case 02.b in Table 3.1.5)

During transit, the HI-TRAC 125 or HI-TRAC 100 transfer cask may be carried horizontally with the transfer lid in place. Analyses have been performed to demonstrate that under a postulated carry height; the design basis 45g deceleration is not exceeded. The analyses have been performed using two different simulation models. A simplified model of the drop event is performed using the computer simulation code “Working Model 2D”. The analysis using “Working Model 2D” assumed the HI-TRAC and the contained MPC acted as a single rigid body. A second model of the drop event uses DYNA3D, considers the multi-body analysis of HI-TRAC and the contained MPC as individual bodies, and is finite element based. In what follows, we outline the problem and the results obtained using each solution methodology. The various drop events for HI-TRAC 100G are not credible because it will always be handled by single failure-proof lifting equipment.

3.4.9.1 Working Model 2D Analysis of Drop Event

The analysis model conservatively neglects all energy absorption by any component of HI-TRAC; all kinetic energy is transferred to the ground through the spring-dampers that simulate the foundation (ground). If the HI-TRAC suffers a handling accident causing a side drop to the ground, impact will only occur at the top and bottom ends of the vessel. The so-called “hard points” are the top end lifting trunnions, the bottom end rotation trunnions, and the projecting ends of the transfer lid. Noting that the projecting hard points are of different dimensions and will impact the target at different times because of the HI-TRAC geometry, any simulation model must allow for this possibility.

A dynamic analysis of a horizontal drop, with the lowest point on the HI-TRAC assumed 50” above the surface of the target (larger than the design basis limit of 42”), is considered for the HI-TRAC 125 and for the HI-TRAC 100. Figure 3.4.22 shows the transfer cask orientation. The HI-TRAC is considered as a rigid body (calculations demonstrate that the lowest beam mode frequency is well above 33 Hz so that no dynamic amplification need be included). The effects of the ISFSI pad and the underlying soil are included using a simple spring-damper model based on a static classical Theory of Elasticity solution. The “worst” orientation of a horizontally carried HI-TRAC with the transfer cask impacting an elastic surface is considered. The HI-TRAC is assumed to initially impact the target with the impact force occurring over the rectangular surface of the transfer lid (11.875” x 81”). “Worst” is defined here as meaning an impact at a location having the maximum value of an elastic spring constant simulating the resistance of the target interface. The geometry and material properties reflect the USNRC accepted reference pad and soil (Table 2.2.9 - the pad thickness used is 36” and the Young’s Modulus of the elastic soil is the upper limit value $E=28,000$ psi). The use of an elastic representation of the target surface is conservative as it minimizes the energy absorption capacity of the target and maximizes the deceleration loads developed during the impact. The spring constant is also calculated based on an assumption that impact at the lower end of HI-TRAC first occurs at the pocket trunnion. The results demonstrate that this spring constant is lower and therefore would lead to a lower impact force. Therefore, the dynamic analysis of the handling accident is performed assuming initial impact with the flat rectangular short end of the transfer lid. Subsequent to the initial impact, the HI-TRAC rotates in accordance with the dynamic equations of equilibrium and a secondary impact at the top of the transfer cask occurs. The impact is at the edge of the water jacket.

The following table summarizes the results from the dynamic analyses (using the Working Model 2D computer code).

HI-TRAC Handling Analysis – Working Model Analysis of Horizontal Drop			
Item	Value	Allowable	Safety Factor
HI-TRAC 125 – Primary Impact Deceleration (g’s)	32.66	45	1.38
HI-TRAC 125 – Secondary Impact Deceleration (g’s)	26.73	45	1.68
HI-TRAC 100 – Primary Impact Deceleration (g’s)	33.18	45	1.36
HI-TRAC 100 – Secondary Impact Deceleration (g’s)	27.04	45	1.66
Axial Membrane Stress Due to HI-TRAC 125 Bending as a Beam - Level D Drop (psi)	19.06	39.75	2.085

Axial Membrane Stress Due to HI-TRAC 100 Bending as a Beam - Level D Drop (psi)	15.77	39.75	2.52
---	-------	-------	------

In the table above, the decelerations are measured at points corresponding to the base and top of the fuel assemblies contained inside the MPC. The dynamic drop analysis reported above, using the Working Model 2D rigid body-spring model proved that decelerations are below the design basis value and that global stresses were within allowable limits.

3.4.9.2 DYNA3D Analysis of Drop Event

An independent evaluation of the drop event to delineate the effect of target non-linearity and the flexibility of the transfer cask has been performed using DYNA3D. Both the HI-TRAC 125 and HI-TRAC 100 transfer casks are modeled as part of the cask-pad-soil interaction finite element model set forth in NUREG/CR-6608 and validated by an NRC reviewed and approved Holtec topical report (see reference [3.A.4] in Appendix 3.A). The model uses the identical MPC and target pad/soil models employed in the accident analyses of the HI-STORM 100 overpack. The HI-TRAC inner and outer shells, the contained lead, the transfer lid, the water jacket metal structure, and the top lids are included in the model. The water jacket is assumed empty for conservatism.

Two side drop orientations are considered (see Figures 3.4.27 and 3.4.28). The first drop assumes that the plane of the lifting and rotation trunnions is horizontal with primary impact on the short side of the transfer lid. This maximizes the angle of slapdown, and represents a credible drop configuration where the HI-TRAC cask is dropped while being carried horizontally. The second drop orientation assumes primary impact on the rotation trunnion and maximizes the potential for the lifting trunnion to participate in the secondary impact. This is a non-credible event that assumes complete separation from the transfer vehicle and a ninety-degree rotation prior to impact. Nevertheless, it is the only configuration where the trunnions could be involved in both primary and secondary impacts.

For each simulation performed, the lowest point on the HI-TRAC cask (either the transfer lid edge or the rotation trunnion) is set at 42" above the target interface. Decelerations are measured at the top lid, the cask centroidal position, and the transfer lid. Normal forces were measured at the primary impact interface, at the secondary impact interface, and at the top lid/MPC interface. Decelerations are filtered at 350 Hz.

The following key results summarize the analyses:

ITEM	HI-TRAC 125		HI-TRAC 100		ALLOWABLE
Initial Orientation of Trunnions	Horizontal	Vertical	Horizontal	Vertical	
Max. Top Lid Vertical Deceleration – Secondary Impact (g's)	25.5	32	36.5	45 [†]	45
Centroid Vertical Deceleration – at Time of Secondary Impact (g's)	9.0	13.0	10.0	17.5	45
	30.8	23.5	35.0	31.75	45

Max. Transfer Lid Vertical Deceleration – Primary Impact (g's)					
Maximum Normal Force at Primary Impact Site (kips)	1,950	1,700	1,700	1,700	-
Maximum Normal Force at Secondary Impact Site (kips)	1,300	1,850	1,500	1,450	-
Maximum MPC/Top Lid Interface Force (kips)	132	-	39	-	-
Maximum Diametral Change of Inner Shell (inch)	0.228	0.113	Not Computed	0.067	0.3725
Maximum Von Mises Stress (ksi)	37.577	38.367	40.690	40.444	58.7*

† The deceleration at the top of the basket is estimated at 41 g's

* Allowable Level D Stress Intensity for Primary Plus Secondary Stress Intensity

The results summarized above demonstrate that both the HI-TRAC 125 and HI-TRAC 100 transfer casks are sufficiently robust to perform their function during and after the postulated handling accidents. We also note that the results, using the Working Model single rigid body dynamic model (see Subsection 3.4.9.1), are in reasonable agreement with the results predicted by the DYNA3D multi-body finite element dynamic model although performed for a different drop height with deceleration measurements at different locations on the HI-TRAC.

The results reported above for maximum interface force at the top lid/MPC interface are used as input to a separate analysis, which demonstrates that the top lid contains the MPC during and after a handling accident. The results reported above for the maximum normal force at the primary impact site (the transfer lid) have been used to calculate the maximum interface force at the bottom flange/transfer lid interface. This result is needed to insure that the interface forces used to evaluate transfer lid separation are indeed bounding. To obtain the interface force between the HI-TRAC transfer lid and the HI-TRAC bottom flange, it is sufficient to take a free-body of the transfer lid and write the dynamic force equilibrium equation for the lid. Figure 3.4.29 shows the free body with appropriate notation. The equation of equilibrium is:

$$M_{TL} a_{TL} = F_I - G_I$$

where

M_{TL} = the mass of the transfer lid

a_{TL} = the time varying acceleration of the centroid of the transfer lid

F_I = the time varying contact force at the interface with the target

G_I = the time varying interface force at the bottom flange/transfer lid interface

Solving for the interface force give the result

$$G_I = F_I - M_{TL} a_{TL}$$

Using the appropriate transfer lid mass and acceleration, together with the target interface force at the limiting time instant, provides values for the interface force. The table below provides the results of this calculation for the HI-TRAC 125 and HI-TRAC 100 transfer casks.

Item	Calculated from Equilibrium (kips)
HI-TRAC 125 – Trunnions Horizontal	1,183.
HI-TRAC 125 – Trunnions Vertical	1,272.
HI-TRAC 100 – Trunnions Horizontal	1,129.
HI-TRAC 100 – Trunnions Vertical	1,070.

3.4.9.3 Horizontal Drop of HI-TRAC 125D

The previous subsection addressed the 42” horizontal drop of the HI-TRAC 125 and HI-TRAC 100, including an evaluation of the bolted connection between the transfer lid, which sustains the primary impact, and the cylindrical body of the loaded HI-TRAC. The HI-TRAC 125D does not have a bolted connection between the bottom flange and the cylindrical body of the cask. However, the transverse protrusions (bottom flange, lifting trunnions, and optional attachment lugs/support tabs at the top of the cask) spawn different impact scenarios. The uncontrolled lowering of the cask is assumed to occur from a height of 42” measured to the lowest location on the HI-TRAC 125D in the horizontal orientation.

The maximum decelerations for the HI-TRAC 125D are comparable to the drop results for the HI-TRAC 125 when the plane of the lifting and rotation trunnions is vertical. Although the HI-TRAC 125D has no rotation trunnions, its bottom flange extends radially beyond the water jacket shell by approximately the same amount as the HI-TRAC 125 rotation trunnions and thereby establishes a similar “hard point” for primary impact in terms of distance from the cask centerline. More important, because the bottom flange is positioned closer to the base of the HI-TRAC 125D than the rotation trunnions are in the HI-TRAC 125, the slap-down angle for the HI-TRAC 125D is less. The shallower angle decreases the participation of the lifting trunnion during the secondary impact, and increases the participation of the water jacket shell. Since the water jacket shell is a more flexible structure than the lifting trunnion, the deceleration of the HI-TRAC 125D cask during secondary impact is slightly less than the calculated deceleration of the HI-TRAC 125. In the HI-TRAC 125D, there is no bolted connection at the bottom flange/cask body interface that is active in load transfer from the flange to the cask body. It is therefore concluded that this drop scenario for the HI-TRAC 125D is bounded by the similar evaluation for the HI-TRAC 125. The same rationale applies to the HI-TRAC 100D versus the HI-TRAC 100. In fact, the protruding segments of the HI-TRAC 100D bottom flange are not in the same impact plane as the lifting trunnions; therefore, a secondary impact involving a lifting trunnion is not possible. Therefore, the drop scenarios analyzed for the HI-TRAC 100 bound any 42” horizontal drop of a HI-TRAC 100D.

A second HI-TRAC 125D drop scenario, where the two attachment lugs/support tabs are oriented in a vertical plane, is the most limiting scenario. This drop event is unique to HI-TRAC 125D serial numbers 3 and 4, since these are the only two transfer casks fabricated with attachment lugs/support tabs. The tab dimensions are such that primary impact occurs at the top end of the cask when the support tabs impact the target surface, followed by a slap-down and a secondary impact at the bottom flange. Note that this drop scenario does not exist for the HI-TRAC 100D since it has no attachment lugs/support tabs.

The evaluation of the limiting HI-TRAC 125D drop scenario is performed using the computer code Working Model 3D (WM) (now known as Visual Nastran Desktop). First, the WM code is used to simulate the “Scenario A” drop of the HI-TRAC 125 in order to establish appropriate parameters to “benchmark” WM against the DYNA3D solution. The table below summarizes the results of the Working Model/DYNA3D benchmark comparison. Figure 3.4.48 shows the benchmark configuration after the drop event.

Comparison of HI-TRAC 125 Drop Results (Scenario A)		
	DYNA3D	Working Model
Vertical Deceleration of Top Lid (secondary impact) g's	32	33.49
Vertical Deceleration at Bottom Lid (primary impact on rotation trunnion) g's	23.5	23.59

The benchmarked Working Model simulation was then modified to simulate the second drop scenario of the HI-TRAC 125D with support tabs in a vertical plane; primary impact now occurred at the top end with secondary impact at the bottom flange. Figure 3.4.49 shows the configuration of the HI-TRAC 125D after this scenario. The impact parameters were unchanged from the benchmark model except for location. The acceleration results from the 42” horizontal drop of the HI-TRAC 125D in this second drop scenario are summarized below.

Results From HI-TRAC 125D 42” Drop	
Vertical Deceleration of Top Lid (primary impact on support tab) g's	36.75
Vertical Deceleration of Pool Lid (secondary impact on bottom flange) g's	29.27

The resulting g loads at the top of the active fuel region for the HI-TRAC 125D, with primary impact on the support tabs, are increased over the loads computed for the HI-TRAC 125 but remain well below the design basis limit.

Finally, stress calculations similar to those presented in Subsection 3.4.9.1 for the HI-TRAC 125 have also been performed for the HI-TRAC 125D using the above maximum decelerations. The table below summarizes the results:

Item	Value	Allowable	Safety Factor
------	-------	-----------	---------------

Axial Membrane Stress Due to HI-TRAC 125D Bending as a Beam - Level D Drop (psi)	26.13	39.75	1.521
Shear Stress in Outer Shell Circumferential Weld Due to HI-TRAC 125D Bending as a Beam - Level D Drop (psi)	27.43	29.40	1.072

3.4.10 HI-STORM 100 Non-Mechanistic Tip-over and Vertical Drop Event (Load Cases 02.a and 02.c in Table 3.1.5)

Pursuant to the provision in NUREG-1536, a non-mechanistic tip-over of a loaded HI-STORM 100 System on to the ISFSI pad is considered in this report. Analyses are also performed to determine the maximum deceleration sustained by a vertical free fall of a loaded HI-STORM 100 System from an 11" height onto the ISFSI pad. The objective of the analyses is to demonstrate that the plastic deformation in the fuel basket is sufficiently limited to permit the stored SNF to be retrieved by normal means, does not have an adverse effect on criticality safety, and that there is no significant loss of radiation shielding in the system.

Ready retrievability of the fuel is presumed to be ensured: if global stress levels in the MPC structure meet Level D stress limits during the postulated drop events; if any plastic deformations are localized; and if no significant permanent ovalization of the overpack into the MPC envelope space, remains after the event.

Subsequent to the accident events, the storage overpack must be shown to contain the shielding so that unacceptable radiation levels do not result from the accident.

Appendix 3.A provides a description of the dynamic finite element analyses undertaken to establish the decelerations resulting from the postulated event. A non-mechanistic tip-over is considered together with an end drop of a loaded HI-STORM 100 System. A dynamic finite element analysis of each event is performed using a commercial finite element code well suited for such dynamic analyses with interface impact and non-linear material behavior. This code and methodology have been fully benchmarked against Lawrence Livermore Laboratories test data and correlation [3.4.12].

The table below provides the values of computed peak decelerations at the top of the fuel basket for the vertical drop and the non-mechanistic tipover scenarios. It is seen that the peak deceleration is below 45 g's.

Filtered Results for Drop and Tip-Over Scenarios for HI-STORM

Drop Event	Max. Deceleration at the Top of the Basket (g's)	
	Set A(36" Thick Pad)	Set B(28" Thick Pad)
End Drop for 11 Inches	43.98	41.53
Non-Mechanistic Tip-over	42.85	39.91

The tipover analysis performed in Appendix 3.A is based on the HI-STORM 100 geometry and a bounding weight. The fact that the HI-STORM 100S(232) is shorter and has a lower center of gravity suggests that the impact kinetic energy is reduced so that the target would absorb the energy with a lower maximum deceleration. However, since the actual weight of a HI-STORM 100S(232) is less than that of a HI-STORM 100 by a significant amount, the predicted maximum rigid body deceleration would tend to increase slightly. Since there are two competing mechanisms at work, it is not a foregone conclusion that the maximum rigid body deceleration level is, in fact, reduced if a HI-STORM 100S(232) suffers a non-mechanistic tipover onto the identical target as the HI-STORM 100. The situation is clearer for the HI-STORM 100S(243), which is virtually equal in weight to the HI-STORM 100, yet its center of gravity when loaded is almost one inch lower. In what follows, we present a summary of the analysis undertaken to demonstrate conclusively that the result for maximum deceleration level in the HI-STORM 100 tipover event does bound the corresponding value for the HI-STORM 100S(232), and, therefore, we need only perform a detailed dynamic finite element analysis for the HI-STORM 100.

Appendix 3.A presents a result for the angular velocity of the cylindrical body representing a HI-STORM 100 just prior to impact with the defined target. The result is expressed in Subsection 3.A.6 in terms of the cask geometry, and the ratio of the mass divided by the mass moment of inertia about the corner point that serves as the rotation origin. Since the mass moment of inertia is also linearly related to the mass, the angular velocity at the instant just prior to target contact is independent of the cask mass. Subsequent to target impact, we investigate post-impact response by considering the cask as a cylinder rotating into a target that provides a resistance force that varies linearly with distance from the rotation point. We measure “time” as starting at the instant of impact, and develop a one-degree-of freedom equation for the post-impact response (for the rotation angle into the target) as:

$$\ddot{\theta} + \omega^2 \theta = 0$$

where

$$\omega^2 = \frac{kL^3}{3I_A}$$

The initial conditions at time=0 are: the initial angle is zero and the initial angular velocity is equal to the rigid body angular velocity acquired by the tipover from the center-of-gravity over corner position. In the above relation, L is the length of the overpack, I is the mass moment of inertia defined in Appendix 3.A, and k is a “spring constant” associated with the target resistance. If we solve for the maximum angular acceleration subsequent to time = 0, we obtain the result in terms of the initial angular velocity as:

$$\ddot{\theta}_{\max} = \omega \dot{\theta}_0$$

If we form the maximum linear acceleration at the top of the four-inch thick lid of the overpack, we can finally relate the decelerations of the HI-STORM 100 and the HI-STORM 100S(232) solely in terms of their geometry properties and their mass ratio. The value of “k”, the target spring

rate is the same for both overpacks so it does not appear in the relationship between the two decelerations. After substituting the appropriate geometry and calculated masses, we determine that the ratio of maximum rigid body decelerations at the top surface of the four-inch thick top lid plates is:

$$A_{\text{HI-STORM 100S(232)}}/A_{\text{HI-STORM 100}} = 0.946$$

Therefore, as postulated, there is no need to perform a separate DYNA3D analysis for the HI-STORM 100S hypothetical tipover.

Moreover, according to Appendix 3.A, analysis of a single mass impacting a spring with a given initial velocity shows that the maximum deceleration “ a_M ” of the mass is related to the dropped weight “ w ” and the drop height “ h ” as follows:

$$a_M \sim \frac{\sqrt{h}}{\sqrt{w}}$$

In other words, as the dropped weight increases, the maximum deceleration of the mass decreases. Therefore, the rigid body decelerations calculated in Appendix 3.A serve as a conservative upper bound for the densified concrete shielding option.

The same considerations apply to the HI-STORM 100S Version B and Version B Type IS. The overall lengths are reduced from the classic HI-STORM 100, but the actual weights may be reduced. Therefore, calculations similar to those given above for the HI-STORM 100S are needed to conclusively demonstrate that the non-mechanistic tipover analysis of the classic HI-STORM 100 remains bounding. The calculations for HI-STORM 100S Version B Type IS, which demonstrate that the design basis limits are satisfied, are documented in Attachment H of [3.A.7]. The results of the calculations for HI-STORM 100S Version B, which demonstrate that the design basis limits are met, are presented below together with maximum G levels computed for the 11” vertical drop:

ITEM	$A_{\text{HI-STORM 100S VERSION B(218)}}/A_{\text{HI-STORM 100}}$	$A_{\text{HI-STORM 100S VERSION B(229)}}/A_{\text{HI-STORM 100}}$	Max. Calculated G Level 11” Drop
HI-STORM 100S Version B(218)	0.91	-	44.378
HI-STORM 100S Version B(229)	-	0.98	43.837

As discussed in Chapter 1, the channels attached to the inner shell of the HI-STORM 100S and HI-STORM 100 S Version B overpack may be replaced with cylindrical guide tubes as shown in the drawings in Section 1.5. A separate LS-DYNA analysis documented in Attachment E of [3.A.7] demonstrates that the top of the MPC fuel basket in the HI-STORM 100 S Version B with cylindrical guide tubes will not experience a g-load higher than the design limit for the non-mechanistic tipover. The HI-STORM 100S Version B analysis bounds the conditions of the HI-STORM 100S non-mechanistic tip-over case.

The g-load experienced by the cask during the non-mechanistic tip-over event is heavily dependent on the compressive strengths of the plain concrete in the overpack and of the reinforced concrete in the ISFSI pad, both of which increase monotonically as the system ages. The girdle beam structure may be used with the HI-STORM 100S Version B to provide an additional flexible medium, with a function similar to the cylindrical guide tubes, and further reduce the g-loads experienced by the system by absorbing some of the energy during impact. The girdle beam structure has the beneficial effect of making the concrete compressive strength a secondary parameter such that even after a long period of aging and a substantial increase in the concrete strengths, the impact on tip-over g-load is small.

A simple elastic strength of materials calculation is performed to demonstrate that the cylindrical storage overpack will not permanently deform to the extent that the MPC cannot be removed by normal means after a tip-over event. The results demonstrate that the maximum diametrical closure of the cylindrical cavity is less than the initial clearance between the overpack MPC support channels and the MPC canister. Primary circumferential membrane stresses in the MPC shell remain in the elastic range during a tip-over (see Table 3.4.6 summary safety factors); therefore, no permanent global ovalization of the MPC shell occurs as a result of the drop.

To demonstrate that the shielding material will continue to perform its function after a tip-over accident, the stress and strain levels in the metal components of the storage overpack are examined at the end of the tip-over event. The results obtained in Appendix 3.A for impact decelerations conservatively assumed a rigid storage overpack model to concentrate nearly all energy loss in the target. However, to assess the state of stress and strain in the storage overpack after an accident causing a tip-over, the tip-over analysis was also performed using a non-rigid storage overpack model using overpack material properties listed in Appendix 3.A. Figure 3.4.13 shows the calculated von Mises stress in the top lid and outer shell at 0.08 seconds after the initiation of impact. Figure 3.4.14 shows the residual plastic strains in the same components. Figures 3.4.15 and 3.4.16 provide similar results for the inner shell, the radial plates, and the support channels[†]. The results show that while some plastic straining occurs, accompanied by stress levels above the yield stress of the material, there is no tearing in the metal structure which confines the radiation shielding (concrete). Therefore, there is no gross failure of the metal shells enclosing the concrete. The shielding concrete will remain inside the confines of the storage overpack and maintain its performance after the tipover event. Although the preceding results are based on an overpack model having inner and outer shell thicknesses of 1-1/4" and 3/4", respectively, the conclusion holds for the optional HI-STORM design with 1" thick inner and outer shells since having a thicker steel shell at the primary point of impact provides more strength and greater protection against a cavity breach. The results from these analyses are also applicable to the HI-STORM 100S and the HI-STORM 100S, Version B since the structural material at the top of the cask that would be locally deformed after a tipover event is essentially the same. The results from these analyses are also applicable to the HI-STORM 100S, Version B Type IS since the thickness of the outer shell (3/4") at the primary point of impact that would locally deform after a tipover event is essentially

[†] During fabrication the channels are attached to the inner shell by one of two methods, either the channels are welded directly to the inner shell or they are welded to a pair of L-shaped angles (i.e., channel mounts) that are pre-fastened to the inner shell. The results presented in Figures 3.4.16a and 3.4.16b bound the results from both methods of attachment.

the same.

3.4.11 Storage Overpack and HI-TRAC Transfer Cask Service Life

The term of the 10CFR72, Subpart L C of C, granted by the NRC is 20 years; therefore, the License Life (please see glossary) of all components is 20 years. Nonetheless, the HI-STORM 100 and 100S Storage overpacks and the HI-TRAC transfer cask are engineered for 40 years of design life, while satisfying the conservative design requirements defined in Chapter 2, including the regulatory requirements of 10CFR72. In addition, the storage overpack and HI-TRAC are designed, fabricated, and inspected under the comprehensive Quality Assurance Program discussed in Chapter 13 and in accordance with the applicable requirements of the ACI and ASME Codes. This assures high design margins, high quality fabrication, and verification of compliance through rigorous inspection and testing, as describe in Chapter 9 and the design drawings in Section 1.5. Technical Specifications defined in Chapter 12 assure that the integrity of the cask and the contained MPC are maintained throughout the components' design life. The design life of a component, as defined in the Glossary, is the minimum duration for which the equipment or system is engineered to perform its intended function if operated and maintained in accordance with the FSAR. The design life is essentially the lower bound value of the service life, which is the expected functioning life of the component or system. Therefore, component longevity should be: licensed life < design life < service life. (The licensed life, enunciated by the USNRC, is the most pessimistic estimate of a component's life span.) For purposes of further discussion, we principally focus on the service life of the HI-STORM 100 System components that, as stated earlier, is the reasonable expectation of equipment's functioning life span.

The service life of the storage overpack and HI-TRAC transfer cask is further discussed in the following sections.

3.4.11.1 Storage Overpack

The principal design considerations that bear on the adequacy of the storage overpack for the service life are addressed as follows:

Exposure to Environmental Effects

In the following text, all references to HI-STORM 100 also apply to HI-STORM 100S and to the HI-STORM 100S Version B. All exposed surfaces of HI-STORM 100 are made from ferritic steels that are readily painted. Concrete, which serves strictly as a shielding material, is completely encased in steel. Therefore, the potential of environmental vagaries such as spalling of concrete, are ruled out for HI-STORM 100. Under normal storage conditions, the bulk temperature of the HI-STORM 100 storage overpack will, because of its large thermal inertia, change very gradually with time. Therefore, material degradation from rapid thermal ramping conditions is not credible for the HI-STORM 100 storage overpack. Similarly, corrosion of structural steel embedded in the concrete structures due to salinity in the environment at coastal sites is not a concern for HI-STORM 100 because HI-STORM 100 does not rely on rebars (indeed, it contains no rebars). As discussed in Appendix 1.D, the aggregates, cement and water used in the storage cask concrete are carefully controlled to provide high durability and resistance to temperature effects. The

configuration of the storage overpack assures resistance to freeze-thaw degradation. In addition, the storage overpack is specifically designed for a full range of enveloping design basis natural phenomena that could occur over the 40-year design life of the storage overpack as defined in Subsection 2.2.3 and evaluated in Chapter 11.

Material Degradation

The relatively low neutron flux to which the storage overpack is subjected cannot produce measurable degradation of the cask's material properties and impair its intended safety function. Exposed carbon steel components are coated to prevent corrosion. The controlled environment of the ISFSI storage pad mitigates damage due to direct exposure to corrosive chemicals that may be present in other industrial applications.

Maintenance and Inspection Provisions

The requirements for periodic inspection and maintenance of the storage overpack throughout the 40-year design life are defined in Chapter 9. These requirements include provisions for routine inspection of the storage overpack exterior and periodic visual verification that the ventilation flow paths of the storage overpack are free and clear of debris. ISFSIs located in areas subject to atmospheric conditions that may degrade the storage cask or canister should be evaluated by the licensee on a site-specific basis to determine the frequency for such inspections to assure long-term performance. In addition, the HI-STORM 100 System is designed for easy retrieval of the MPC from the storage overpack should it become necessary to perform more detailed inspections and repairs on the storage overpack.

The above findings are consistent with those of the NRC's Waste Confidence Decision Review [3.4.11], which concluded that dry storage systems designed, fabricated, inspected, and operate in accordance with such requirements are adequate for a 100-year service life while satisfying the requirements of 10CFR72.

3.4.11.2 Transfer Cask

The principal design considerations that bear on the adequacy of the HI-TRAC Transfer Cask for the service life are addressed as follows:

Exposure to Environmental Effects

All transfer cask materials that come in contact with the spent fuel pool are coated to facilitate decontamination. The HI-TRAC is designed for repeated normal condition handling operations with high factor of safety, particularly for the lifting trunnions, to assure structural integrity. The resulting cyclic loading produces stresses that are well below the endurance limit of the trunnion material, and therefore, will not lead to a fatigue failure in the transfer cask. All other off-normal or postulated accident conditions are infrequent or one-time occurrences that do not contribute significantly to fatigue. In addition, the transfer cask utilizes materials that are not susceptible to brittle fracture during the lowest temperature permitted for loading, as discussed in Chapter 12.

Material Degradation

All transfer cask materials that are susceptible to corrosion are coated. The controlled environment in which the HI-TRAC is used mitigates damage due to direct exposure to corrosive chemicals that may be present in other industrial applications. The infrequent use and relatively low neutron flux to which the HI-TRAC materials are subjected do not result in radiation embrittlement or degradation of the HI-TRAC's shielding materials that could impair the HI-TRAC's intended safety function. The HI-TRAC transfer cask materials are selected for durability and wear resistance for their deployment.

Maintenance and Inspection Provisions

The requirements for periodic inspection and maintenance of the HI-TRAC transfer cask throughout the 40-year design life are defined in Chapter 9. These requirements include provisions for routine inspection of the HI-TRAC transfer cask for damage prior to each use, including an annual inspection of the lifting trunnions. Precautions are taken during lid handling operations to protect the sealing surfaces of the pool lid. The leak tightness of the liquid neutron shield is verified periodically. The water jacket pressure relief valves and other fittings used can be easily removed.

3.4.12 MPC Service Life

The term of the 10CFR72, Subpart L C of C, granted by the NRC (i.e., licensed life) is 20 years. Nonetheless, the HI-STORM 100 MPC is designed for 40 years of design life, while satisfying the conservative design requirements defined in Chapter 2, including the regulatory requirements of 10CFR72. Additional assurance of the integrity of the MPC and the contained SNF assemblies throughout the 40-year life of the MPC is provided through the following:

- Design, fabrication, and inspection in accordance with the applicable requirements of the ASME Code as described in Chapter 2 assures high design margins.
- Fabrication and inspection performed in accordance with the comprehensive Quality Assurance program discussed in Chapter 13 assures competent compliance with the fabrication requirements.
- Use of materials with known characteristics, verified through rigorous inspection and testing, as described in Chapter 9, assures component compliance with design requirements.
- Use of welding procedures in full compliance with Section III of the ASME Code ensures high-quality weld joints.

Technical Specifications, as defined in Chapter 12, have been developed and imposed on the MPC that assure that the integrity of the MPC and the contained SNF assemblies are maintained throughout the 40-year design life of the MPC.

The principal design considerations bearing on the adequacy of the MPC for the service life are summarized below.

Corrosion

All MPC materials are fabricated from corrosion-resistant austenitic stainless steel and passivated aluminum. The corrosion-resistant characteristics of such materials for dry SNF storage canister applications, as well as the protection offered by these materials against other material degradation effects, are well established in the nuclear industry. The moisture in the MPC is removed to eliminate all oxidizing liquids and gases and the MPC cavity is backfilled with dry inert helium at the time of closure to maintain an atmosphere in the MPC that provides corrosion protection for the SNF cladding throughout the dry storage period. The preservation of this non-corrosive atmosphere is assured by the inherent sealworthiness of the MPC confinement boundary integrity (there are no gasketed joints in the MPC).

Structural Fatigue

The passive non-cyclic nature of dry storage conditions does not subject the MPC to conditions that might lead to structural fatigue failure. Ambient temperature and insolation cycling during normal dry storage conditions and the resulting fluctuations in MPC thermal gradients and internal pressure is the only mechanism for fatigue. These low-stress, high-cycle conditions cannot lead to a fatigue failure of the MPC that is made from stainless alloy stock (endurance limit well in excess of 20,000 psi). All other off-normal or postulated accident conditions are infrequent or one-time occurrences, which cannot produce fatigue failures. Finally, the MPC uses materials that are not susceptible to brittle fracture.

Maintenance of Helium Atmosphere

The inert helium atmosphere in the MPC provides a non-oxidizing environment for the SNF cladding to assure its integrity during long-term storage. The preservation of the helium atmosphere in the MPC is assured by the robust design of the MPC confinement boundary described in Section 7.1. Maintaining an inert environment in the MPC mitigates conditions that might otherwise lead to SNF cladding failures. The required mass quantity of helium backfilled into the canister at the time of closure and the associated fabrication and closure requirements for the canister are specifically set down to assure that an inert helium atmosphere is maintained in the canister throughout the 40-year design life.

Allowable Fuel Cladding Temperatures

The helium atmosphere in the MPC promotes heat removal and thus reduces SNF cladding temperatures during dry storage. In addition, the SNF decay heat will substantially attenuate over a 40-year dry storage period. Maintaining the fuel cladding temperatures below allowable levels during long-term dry storage mitigates the damage mechanism that might otherwise lead to SNF cladding failures. The allowable long-term SNF cladding temperatures used for thermal acceptance of the MPC design are conservatively determined, as discussed in Section 4.3.

Neutron Absorber Boron Depletion

The effectiveness of the fixed borated neutron absorbing material used in the MPC fuel basket design requires that sufficient concentrations of boron be present to assure criticality safety during worst case design basis conditions over the 40-year design life of the MPC. Information on the characteristics of the borated neutron absorbing material used in the MPC fuel basket is provided in Subsection 1.2.1.3.1. The relatively low neutron flux, which will continue to decay over time, to which this borated material is subjected, does not result in significant depletion of the material's available boron to perform its intended safety function. In addition, the boron content of the material used in the criticality safety analysis is conservatively based on the minimum specified boron areal density (rather than the nominal), which is further reduced by 25% for analysis purposes, as described in Section 6.1. Analysis discussed in Section 6.3.2 demonstrates that the boron depletion in the neutron absorber material is negligible over a 50-year duration. Thus, sufficient levels of boron are present in the fuel basket neutron absorbing material to maintain criticality safety functions over the 40-year design life of the MPC.

The above findings are consistent with those of the NRC's Waste Confidence Decision Review, which concluded that dry storage systems designed, fabricated, inspected, and operated in the manner of the requirements set down in this document are adequate for a 100-year service life, while satisfying the requirements of 10CFR72.

3.4.13 Design and Service Life

The discussion in the preceding sections seeks to provide the logical underpinnings for setting the design life of the storage overpacks, the HI-TRAC transfer cask, and the MPCs as forty years. Design life, as stated earlier, is a lower bound value for the expected performance life of a component (service life). If operated and maintained in accordance with this Final Safety Analysis Report, Holtec International expects the service life of its HI-STORM 100 and HI-STORM 100S Version's components to substantially exceed their design life values.

Table 3.4.1

FINITE ELEMENTS IN THE MPC STRUCTURAL MODELS

MPC Type	Model Type		
Element Type	Basic	0 Degree Drop	45 Degree Drop
MPC-24	1068	1114	1113
BEAM3	1028	1028	1028
PLANE82	0	0	0
CONTAC12	40	38	38
CONTAC26	0	45	45
COMBIN14	0	3	2

TABLE 3.4.2
HI-STORM 100 SYSTEM MATERIAL COMPATIBILITY
WITH OPERATING ENVIRONMENTS

Material/Component	Fuel Pool (Borated and Unborated Water)[†]	ISFSI Pad (Open to Environment)
<u>Alloy X:</u> - MPC Fuel Basket - MPC Baseplate - MPC Shell - MPC Lid - MPC Fuel Spacers	Stainless steels have been extensively used in spent fuel storage pools with both borated and unborated water with no adverse reactions or interactions with spent fuel.	The MPC internal environment will be an inert (helium) atmosphere and the external surface will be exposed to ambient air. No adverse interactions identified.
<u>Aluminum:</u> - Heat Conduction Elements	Aluminum and stainless steel form a galvanic couple. However, aluminum will be used in a passivated state. Upon passivation, aluminum forms a thin ceramic (Al_2O_3) barrier. Therefore, during the short time they are exposed to pool water, significant corrosion of aluminum or production of hydrogen is not expected (see operational requirements under “Neutron Absorber Material” below).	In a non-aqueous atmosphere, galvanic corrosion is not expected.
<u>Neutron Absorber Material:</u>	Extensive in-pool experience on spent fuel racks with no adverse reactions. See Chapter 8 for additional requirements for combustible gas monitoring and required actions for control of combustible gas accumulation under the MPC lid.	No adverse potential reactions identified.

[†] HI-TRAC/MPC short-term operating environment during loading and unloading.

TABLE 3.4.2 (CONTINUED)
HI-STORM 100 SYSTEM MATERIAL COMPATIBILITY
WITH OPERATING ENVIRONMENTS

Material/Component	Fuel Pool (Borated and Unborated Water)[†]	ISFSI Pad (Open to Environment)
<u>Steels:</u> - SA350-LF2 - SA350-LF3 - SA203-E - SA515 Grade 70 - SA516 Grade 70 - SA193 Grade B7 - SA106 (HI-TRAC)	All exposed steel surfaces (except seal areas, and pocket trunnions) will be coated with paint specifically selected for performance in the operating environments. Even without coating, no adverse reactions (other than nominal corrosion) have been identified. Lid bolts are plated and the threaded portion of the bolt anchor blocks is coated to seal the threaded area.	Internal surfaces of the HI-TRAC will be painted and maintained. Exposed external surfaces (except those listed in fuel pool column) will be painted and will be maintained with a fully painted surface. No adverse reactions identified.
<u>Steels:</u> - SA516 Grade 70 - SA203-E - SA350-LF3 - A36 Storage Overpack	HI-STORM 100 storage overpack is not exposed to fuel pool environment.	Internal and external surfaces will be painted (except for bolt locations that will have protective coating). External surfaces will be maintained with a fully painted surface. No adverse reaction identified.
<u>Stainless Steels:</u> - SA240 304 - SA193 Grade B8 - 18-8 S/S - SA182 F60 (For HI-TRAC 100G trunnions only) Miscellaneous Components	Stainless steels have been extensively used in spent fuel storage pools with both borated and unborated water with no adverse reactions.	Stainless steel has a long proven history of corrosion resistance when exposed to the atmosphere. These materials are used for bolts and threaded inserts. No adverse reactions with steel have been identified. No impact on performance.

[†] HI-TRAC/MPC short-term operating environment during loading and unloading.

TABLE 3.4.2 (CONTINUED)
HI-STORM 100 SYSTEM MATERIAL COMPATIBILITY
WITH OPERATING ENVIRONMENTS

Material/Component	Fuel Pool (Borated and Unborated Water)[†]	ISFSI Pad (Open to Environment)
<u>Nickel Alloy:</u> - SB637-NO7718 - SA564-630 H1100 (for HI-TRAC 125D only) Lifting Trunnion	No adverse reactions with borated or unborated water.	Exposed to weathering effects. No adverse reactions with storage overpack closure plate. No impact on performance.
<u>Brass/Bronze:</u> - Pressure Relief Valve HI-TRAC	Small surface of pressure relief valve will be exposed. No significant adverse impact identified.	Exposed to external weathering. No loss of function expected.
<u>Holtite-A:</u> - Solid Neutron Shield	The neutron shield is fully enclosed. No adverse reaction identified. No adverse reactions with thermal expansion foam or steel.	The neutron shield is fully enclosed in the outer enclosure. No adverse reaction identified. No adverse reactions with thermal expansion foam or steel.

[†] HI-TRAC/MPC short-term operating environment during loading and unloading.

TABLE 3.4.2 (CONTINUED)
HI-STORM 100 SYSTEM MATERIAL COMPATIBILITY
WITH OPERATING ENVIRONMENTS

Material/Component	Fuel Pool (Borated and Unborated Water)[†]	ISFSI Pad (Open to Environment)
<u>Paint:</u> - as per Appendix 1.C	<p>Paint used for the HI-TRAC exterior surface has acceptable performance for short-term exposure in mild borated pool water.</p> <p>Paint selected for HI-TRAC internal surfaces has excellent high temperature resistance properties. Will only be exposed to demineralized water during in-pool operations as annulus is filled prior to placement in the spent fuel pool and the inflatable seal prevents fuel pool water in-leakage. No adverse interaction identified which could affect MPC/fuel assembly performance.</p>	<p>Good performance on surfaces. Discoloration is not a concern.</p>
<u>Elastomer Seals:</u>	No adverse reactions identified.	Only used during fuel pool operations.
<u>Lead:</u>	Enclosed by carbon steel. Lead is not exposed to fuel pool water. Lead has no interaction with carbon steel.	Enclosed by carbon steel. Lead is not exposed to ambient environment. Lead has no interaction with carbon steel.
<u>Concrete:</u>	Storage overpack is not exposed to fuel pool water.	Concrete is enclosed by carbon steel and not exposed to ambient environment. Concrete has no interaction with carbon steel.

[†] HI-TRAC/MPC short-term operating environment during loading and unloading.

Enclosure Vessel - Local Membrane Plus Primary Bending (P_L+P_b)	2.46*.967 (1278)	2.92*.967 (1247)	1.02 (1925)	1.45 (1925)
Basket Supports – Primary Membrane (P_m)	N/A	N/A	6.61 (1710)	8.61 (1699)
Basket Supports - Local Membrane Plus Primary Bending (P_L+P_b)	N/A	N/A	1.09 (1715)	1.43 (1704)

Notes:

1. Corresponding ANSYS element number shown in parentheses.
2. Multiplier of 0.967 reflects increase in Enclosure Vessel Design Temperature from 450 deg. F to 500 deg. F (Table 2.2.3); tabulated results for MPC-68 are based on higher temperature (500 deg. F) for Enclosure Vessel
3. Safety factors for the MPC-24 have been reduced (divided by factor of 1.024) to adjust for the fuel assembly weight increase (see Subsection 3.4.4.4.1)
4. Multiplier of 0.987 reflects increase in Fuel Basket Design Temperature from 725 deg. F to 752 deg. F (Table 2.2.3).

TABLE 3.4.6 (CONTINUED)
MINIMUM SAFETY FACTORS FOR MPC COMPONENTS DURING TIP-OVER
45g DECELERATIONS

Component - Stress Result	MPC-32	
	0 Degrees	45 Degrees
Fuel Basket - Primary Membrane (P_m)	3.43*0.987 (715)	4.84*0.987 (366)
Fuel Basket - Local Membrane Plus Primary Bending (P_L+P_b)	1.47*0.987 (390)	1.25*0.987 (19)
Enclosure Vessel - Primary Membrane (P_m)	4.01*.967 (1091)	5.46*.967 (1222)
Enclosure Vessel - Local Membrane Plus Primary Bending (P_L+P_b)	1.08*.967 (1031)	1.43*.967 (1288)
Basket Supports - Primary Membrane (P_m)	3.36 (905)	4.74 (905)
Basket Supports - Local Membrane Plus Primary Bending (P_L+P_b)	1.27 (901)	1.67 (908)

Notes:

1. Corresponding ANSYS element number shown in parentheses.
2. Multiplier of 0.967 reflects increase in Enclosure Vessel Design Temperature from 450 deg. F to 500 deg. F (Table 2.2.3).
3. Safety factors for the MPC-32 has been reduced (divided by factor of 1.024) to adjust for the fuel assembly weight increase (see Subsection 3.4.4.4.1)
4. Multiplier of 0.987 reflects increase in Fuel Basket Design Temperature from 725 deg. F to 752 deg. F (Table 2.2.3).

TABLE 3.4.6 (CONTINUED)
MINIMUM SAFETY FACTORS FOR MPC-24E COMPONENTS DURING TIP-OVER
45g DECELERATIONS

Components – Stress Result	0 Degrees	45 Degrees
Fuel Basket – Primary Membrane (P_m)	-10,554 (3.50*0.987)	-7,608 (4.86*0.987)
Fuel Basket – Primary Membrane plus Primary Bending ($P_L + P_b$)	38,029 (1.46*0.987)	32,745 (1.70*0.987)
Enclosure Vessel – Primary Membrane (P_m)	6,611 (6.57*.967)	6,612 (6.57*.967)
Enclosure Vessel – Primary Membrane plus Primary Bending ($P_L + P_b$)	23,680 (2.75*.967)	16,868 (3.87*.967)

Notes:

1. All stresses are reported in psi units and are based on closed gaps (primary stresses only).
2. The numbers shown in parentheses are the corresponding safety factors.
3. Multiplier of 0.967 reflects the increase in Enclosure Vessel Design Temperature from 450 deg. F to 500 deg. F (Table 2.2.3).
4. Stress results/safety factors for the MPC-24E have been multiplied/divided by a factor of 1.024 to adjust for the fuel assembly weight (See subsection 3.4.4.4.1).
5. Multiplier of 0.987 reflects increase in Fuel Basket Design Temperature from 725 deg. F to 752 deg. F (Table 2.2.3).

3.5 FUEL RODS

The regulations governing spent fuel storage cask approval and fabrication (10 CFR 72.236) require that a storage cask system “will reasonably maintain confinement of radioactive material under normal, off-normal, and credible accident conditions” (§72.236(l)). Per Regulatory Guide 3.61, Section 3.5, “When fuel cladding is considered in the design criteria for confinement of radioactive material under normal or accident condition, provide an analysis or test results showing that the cladding will maintain its integrity.” Although the cladding of intact fuel rods does provide a barrier against the release of radioactive fission products, the confinement evaluation for the HI-STORM System (Chapter 7) takes no credit for fuel cladding integrity in satisfying the regulatory confinement requirement.

As described in Section 7.1, the confinement boundary in the HI-STORM System consists of the MPC Enclosure Vessel. The Enclosure Vessel is designed and, to the extent practicable, manufactured in accordance with the most stringent ASME B&PV Code (Section III, Subsection NB). As required by NB, all materials are 100% UT inspected and all butt welds are subjected to 100% volumetric inspection. The field closure features redundant barriers (the MPC lid and port cover plates are the primary barriers, the closure ring is the secondary barrier). Section 7.1 further describes that the MPC design, welding, testing and inspection requirements meet the guidance of ISG-18 [7.1.2] such that leakage from the confinement boundary may be considered non-credible. Section 7.2 addresses confinement for normal and off-normal conditions, and states “Since the MPC confinement vessel remains intact, and the design basis temperatures and pressure are not exceeded, leakage from the MPC confinement boundary is not credible”. Confinement for accident conditions is addressed in Section 7.3, which states “there is no mechanistic failure that results in a breach of, and associated leakage of radioactive material from the MPC confinement boundary”.

The assured integrity of the MPC Confinement Boundary eliminates the reliance on the fuel cladding to prevent release of radiological matter to the environment. Since the cladding is not considered as part of the confinement during normal, off-normal, or accident conditions, there is no need for providing an analysis for computing the allowable g-load for the fuel rods to demonstrate cladding integrity and none is included in this FSAR.

3.6 SUPPLEMENTAL DATA

3.6.1 Additional Codes and Standards Referenced in HI-STORM 100 System Design and Fabrication

The following additional codes, standards and practices were used as aids in developing the design, manufacturing, quality control and testing methods for HI-STORM 100 System:

a. Design Codes

- (1) AISC Manual of Steel Construction, 1964 Edition and later.
- (2) ANSI N210-1976, "Design Requirements for Light Water Reactor Spent Fuel Storage Facilities at Nuclear Power Stations".
- (3) American Concrete Institute Building Code Requirements for Structural Concrete, ACI-318-95.
- (4) Code Requirements for Nuclear Safety Related Concrete Structures, ACI349-85/ACI349R-85, ACI349.1R-80, and ACI 349-97.
- (5) ASME NQA-1, Quality Assurance Program Requirements for Nuclear Facilities.
- (6) ASME NQA-2-1989, Quality Assurance Requirements for Nuclear Facility Applications.
- (7) ANSI Y14.5M, Dimensioning and Tolerancing for Engineering Drawings and Related Documentation Practices.
- (8) ACI Detailing Manual - 1980.
- (9) Crane Manufacturer's Association of America, Inc., CMAA Specification #70, Specifications for Electric Overhead Traveling Cranes, Revised 1988.

b. Material Codes - Standards of ASTM

- (1) E165 - Standard Methods for Liquid Penetrant Inspection.
- (2) A240 - Standard Specification for Heat-Resisting Chromium and Chromium-Nickel Stainless Steel Plate, Sheet and Strip for Fusion-Welded Unfired Pressure Vessels.

- (3) A262 - Detecting Susceptibility to Intergranular Attack in Austenitic Stainless Steel.
 - (4) A276 - Standard Specification for Stainless and Heat-Resisting Steel Bars and Shapes.
 - (5) A479 - Steel Bars for Boilers & Pressure Vessels.
 - (6) A564, Standard Specification for Hot-Rolled and Cold-Finished Age-Hardening Stainless and Heat-Resisting Steel Bars and Shapes.
 - (7) C750 - Standard Specification for Nuclear-Grade Boron Carbide Powder.
 - (8) A380 - Recommended Practice for Descaling, Cleaning and Marking Stainless Steel Parts and Equipment.
 - (9) C992 - Standard Specification for Boron-Based Neutron Absorbing Material Systems for Use in Nuclear Spent Fuel Storage Racks.
 - (10) E3, Preparation of Metallographic Specimens.
 - (11) E190, Guided Bend Test for Ductility of Welds.
 - (12) NCA3800 - Metallic Material Manufacturer's and Material Supplier's Quality System Program.
- c. Welding Codes: ASME Boiler and Pressure Vessel Code, Section IX - Welding and Brazing Qualifications, 1995 Edition.
- d. Quality Assurance, Cleanliness, Packaging, Shipping, Receiving, Storage, and Handling Requirements
- (1) ANSI 45.2.1 - Cleaning of Fluid Systems and Associated Components during Construction Phase of Nuclear Power Plants.
 - (2) ANSI N45.2.2 - Packaging, Shipping, Receiving, Storage and Handling of Items for Nuclear Power Plants (During the Construction Phase).
 - (3) ANSI - N45.2.6 - Qualifications of Inspection, Examination, and Testing Personnel for Nuclear Power Plants (Regulatory Guide 1.58).

- (4) ANSI-N45.2.8, Supplementary Quality Assurance Requirements for Installation, Inspection and Testing of Mechanical Equipment and Systems for the Construction Phase of Nuclear Power Plants.
- (5) ANSI - N45.2.11, Quality Assurance Requirements for the Design of Nuclear Power Plants.
- (6) ANSI-N45.2.12, Requirements for Auditing of Quality Assurance Programs for Nuclear Power Plants.
- (7) ANSI N45.2.13 - Quality Assurance Requirements for Control of Procurement of Equipment Materials and Services for Nuclear Power Plants (Regulatory Guide 1.123).
- (8) ANSI N45.2.15-18 - Hoisting, Rigging, and Transporting of Items for Nuclear Power Plants.
- (9) ANSI N45.2.23 - Qualification of Quality Assurance Program Audit Personnel for Nuclear Power Plants (Regulatory Guide 1.146).
- (10) ASME Boiler and Pressure Vessel, Section V, Nondestructive Examination, 1995 Edition.
- (11) ANSI - N16.9-75 Validation of Calculation Methods for Nuclear Criticality Safety.

e. Reference NRC Design Documents

- (1) NUREG-0800, Radiological Consequences of Fuel Handling Accidents.
- (2) NUREG-0612, "Control of Heavy Loads at Nuclear Power Plants", USNRC, Washington, D.C., July, 1980.
- (3) NUREG-1536, "Standard Review Plan for Dry Cask Storage Systems", USNRC, January 1997, Final Report.

f. Other ANSI Standards (not listed in the preceding)

- (1) 8.1 (N16.1) - Nuclear Criticality Safety in Operations with Fissionable Materials Outside Reactors.
- (2) 8.17, Criticality Safety Criteria for the Handling, Storage, and Transportation of LWR Fuel Outside Reactors.
- (3) N45.2 - Quality Assurance Program Requirements for Nuclear Facilities - 1971.

- (4) N45.2.9 - Requirements for Collection, Storage and Maintenance of Quality Assurance Records for Nuclear Power Plants - 1974.
- (5) N45.2.10 - Quality Assurance Terms and Definitions - 1973.
- (6) 57.2 (N210) - Design Requirements for Light Water Reactor Spent Fuel Storage Facilities at Nuclear Power Plants.
- (7) N14.6 (1993) - American National Standard for Special Lifting Devices for Shipping Containers Weighing 10,000 pounds (4500 kg) or more for Nuclear Materials.
- (8) N626-3, Qualification and Duties of Personnel Engaged in ASME Boiler and Pressure Vessel Code Section III, Div. 1, Certifying Activities.

g. Code of Federal Regulations

- (1) 10CFR20 - Standards for Protection Against Radiation.
- (2) 10CFR21 - Reporting of Defects and Non-compliance.
- (3) 10CFR50 - Appendix A - General Design Criteria for Nuclear Power Plants.
- (4) 10CFR50 - Appendix B - Quality Assurance Criteria for Nuclear Power Plants and Fuel Reprocessing Plants.
- (5) 10CFR61 - Licensing Requirements for Land Disposal of Radioactive Material.
- (6) 10CFR71 - Packaging and Transportation of Radioactive Material.

h. Regulatory Guides

- (1) RG 1.13 - Spent Fuel Storage Facility Design Basis (Revision 2 Proposed).
- (2) RG 1.25 - Assumptions Used for Evaluating the Potential Radiological Consequences of a Fuel Handling Accident in the Fuel Handling and Storage Facility of Boiling and Pressurized Water Reactors.
- (3) RG 1.28 - (ANSI N45.2) - Quality Assurance Program Requirements.
- (4) RG 1.29 - Seismic Design Classification (Rev. 3).
- (5) RG 1.31 - Control of Ferrite Content in Stainless Steel Weld Material.

- (6) RG 1.38 - (ANSI N45.2.2) Quality Assurance Requirements for Packaging, Shipping, Receiving, Storage and Handling of Items for Water-Cooled Nuclear Power Plants.
- (7) RG 1.44 - Control of the Use of Sensitized Stainless Steel.
- (8) RG 1.58 - (ANSI N45.2.6) Qualification of Nuclear Power Plant Inspection, Examination, and Testing Personnel.
- (9) RG 1.61 - Damping Values for Seismic Design of Nuclear Power Plants, Rev. 0, 1973.
- (10) RG 1.64 - (ANSI N45.2.11) Quality Assurance Requirements for the Design of Nuclear Power Plants.
- (11) RG 1.71 - Welder Qualifications for Areas of Limited Accessibility.
- (12) RG 1.74 - (ANSI N45.2.10) Quality Assurance Terms and Definitions.
- (13) RG 1.85 - Materials Code Case Acceptability - ASME Section 3, Div. 1.
- (14) RG 1.88 - (ANSI N45.2.9) Collection, Storage and Maintenance of Nuclear Power Plant Quality Assurance Records.
- (15) RG 1.92 - Combining Modal Responses and Spatial Components in Seismic Response Analysis.
- (16) RG 1.122 - Development of Floor Design Response Spectra for Seismic Design of Floor-Supported Equipment or Components.
- (17) RG 1.123 - (ANSI N45.2.13) Quality Assurance Requirements for Control of Procurement of Items and Services for Nuclear Power Plants.
- (18) RG 1.124 - Service Limits and Loading Combinations for Class 1 Linear-Type Component Supports, Revision 1, 1978.
- (19) Reg. Guide 3.4 - Nuclear Criticality Safety in Operations with Fissionable Materials at Fuels and Materials Facilities.
- (20) RG 3.41 - Validation of Calculational Methods for Nuclear Criticality Safety, Revision 1, 1977.

- (9) SRP 9.1.3 - Spent Fuel Pool Cooling and Cleanup System.
- (10) SRP 9.1.4 - Light Load Handling System.
- (11) SRP 9.1.5 - Overhead Heavy Load Handling System.
- (12) SRP 15.7.4 - Radiological Consequences of Fuel Handling Accidents.

k. AWS Standards

- (1) D1.1 - Structural Welding Code, Steel.

- (2) A2.4 - Standard Symbols for Welding, Brazing and Nondestructive Examination.
- (3) A3.0 - Standard Welding Terms and Definitions.
- (4) A5.12 - Tungsten Arc-welding Electrodes.
- (5) QC1 - Standards and Guide for Qualification and Certification of Welding Inspectors.

1. Others

- (1) ASNT-TC-1A - Recommended Practice for Nondestructive Personnel Qualification and Certification.
- (2) SSPC SP-2 - Surface Preparation Specification No. 2 Hand Tool Cleaning.
- (3) SSPC SP-3 - Surface Preparation Specification No. 3 Power Tool Cleaning.
- (4) SSPC SP-10 - Near-White Blast Cleaning.

3.6.2 Computer Programs

Three computer programs, all with a well established history of usage in the nuclear industry, have been utilized to perform structural and mechanical analyses documented in this report. These codes are ANSYS, DYNA3D, and WORKING MODEL. ANSYS is a public domain code which utilizes the finite element method for structural analyses.

WORKING MODEL, Version V.3.0/V.4.0

This code is used in this 10CFR72 submittal to compute the dynamic load resulting from intermediate missile impact on the overpack closure and to evaluate the maximum elastic spring rate associated with the target during a HI-TRAC handling accident event.

WORKING MODEL has been previously utilized in similar dynamic analyses of the HI-STAR 100 system (Docket No. 72-1008).

"WORKING MODEL" (V3.0/V4.0) is a Computer Aided Engineering (CAE) tool with an integrated user interface that merges modeling, simulation, viewing, and measuring. The program includes a dynamics algorithm that provides automatic collision and contact handling, including detection, response, restitution, and friction.

Numerical integration is performed using the Kutta-Merson integrator which offers options for variable or fixed time-step and error bounding.

The Working Model Code is commercially available. Holtec has performed independent QA validation of the code (in accordance with Holtec's QA requirements) by comparing the solution of several classical dynamics problems with the numerical results predicted by Working Model. Agreement in all cases is excellent.

Additional theoretical material is available in the manual: "Users Manual, Working Model, Version 3", Knowledge Revolution, 66 Bovet Road, Suite 200, San Mateo, CA, 94402.

This code has been acquired by MSC Software and has now been designated "VisualNastran Desktop". The most current version, which has been used in this revision, is VN 2003. The descriptions given above are still valid.

DYNA3D

"DYNA3D" is a nonlinear, explicit, three-dimensional finite element code for solid and structural mechanics. It was originally developed at Lawrence Livermore Laboratories and is ideally suited for study of short-time duration, highly nonlinear impact problems in solid mechanics. DYNA3D is commercially available for both UNIX work stations and Pentium class PCs running Windows 95 or Windows NT. The PC version has been fully validated at Holtec following Holtec's QA procedures for commercial computer codes. This code is used to analyze the drop accidents and the tip-over scenario for the HI-STORM 100. Benchmarking of DYNA3D for these storage analyses is discussed and documented in Appendix 3.A. DYNA3D is also known as LS-DYNA and is currently supported and distributed by Livermore Software. Each update is independently subject to QA validation.

3.6.3 Appendices Included in Chapter 3

3.A HI-STORM Deceleration Under Postulated Vertical Drop Event and Tipover

3.6.4 Calculation Packages

In addition to the calculations presented in Chapter 3, supporting calculation packages have been prepared to document other information pertinent to the analyses. As new components are added (e.g., the HI-STORM 100S versions and additional MPC's), supporting calculation packages back up the summary results reported herein.

The calculation packages contain additional details on component weights, supporting calculations for some results summarized in the chapter, and miscellaneous supporting data that supplements the results summarized in Chapter 3 of the FSAR. All of the finite element tabular data, node and element data, supporting figures, and numerical output for all fuel baskets are contained in the calculation package supplement supporting Revision 1 of the FSAR.

3.7 COMPLIANCE WITH NUREG-1536

Supporting information to provide reasonable assurance with respect to the adequacy of the HI-STORM 100 System to store spent nuclear fuel in accordance with the stipulations of the Technical Specifications (Chapter 12) is provided throughout this FSAR. An itemized table (Table 3.0.1 at the beginning of this chapter) has been provided to locate and collate the substantiating material to support the technical evaluation findings listed in NUREG-1536 Chapter 3, Article VI.

The following statements are germane to an affirmative safety evaluation:

- The design and structural analysis of the HI-STORM 100 System is in full compliance with the provisions of Chapter 3 of NUREG-1536 except as listed in the Table 1.0.2 (list of code compliance exceptions).
- The list of Regulatory Guides, Codes, and standards presented in Section 3.6 herein is in full compliance with the provisions of NUREG-1536.
- All HI-STORM 100 structures, systems, and components (SSC) that are important to safety (ITS) are identified in Table 2.2.6. Section 1.5 contains the design drawings that describe the HI-STORM 100 SSCs in complete detail. Explanatory narrations in Subsections 3.4.3 and 3.4.4 provide sufficient textual details to allow an independent evaluation of their structural effectiveness.
- The requirements of 10CFR72.24 with regard to information pertinent to structural evaluation is provided in Chapters 2, 3, and 11.
- Technical Specifications pertaining to the structures of the HI-STORM 100 System have been provided in Section 12.3 herein pursuant to the requirements of 10CFR72.26.
- A series of analyses to demonstrate compliance with the requirements of 10CFR72.122(b) and (c), and 10CFR72.24(c)(3) have been performed which show that SSCs designated as ITS possess an adequate margin of safety with respect to all load combinations applicable to normal, off-normal, accident, and natural phenomenon events. In particular, the following information is provided:
 - i. Load combinations for the fuel basket, enclosure vessel, and the HI-STORM 100/HI-TRAC overpacks for normal, off-normal, accident, and natural phenomenon events are compiled in Tables 2.2.14, 3.1.1, and 3.1.3 through 3.1.5, respectively.
 - ii. Stress limits applicable to the materials are found in Subsection 3.3.
 - iii. Stresses at various locations in the fuel basket, the enclosure vessel, and the HI-STORM 100/HI-TRAC overpacks have been computed by analysis.

iv. Factors of safety in the components of the HI-STORM 100 System are reported as below:

- | | | |
|----|-----------------------------------|---------------------------------------|
| a. | Fuel basket | Tables 3.4.3 and 3.4.6 |
| b. | Enclosure vessel | Tables 3.4.4, 3.4.6, 3.4.7, and 3.4.8 |
| c. | HI-STORM 100 overpack/
HI-TRAC | Table 3.4.5 |
| d. | Miscellaneous
components | Table 3.4.9 |
| e. | Lifting devices | Subsection 3.4.3 |
- The structural design and fabrication details of the fuel baskets whose safety function in the HI-STORM 100 System is to maintain nuclear criticality safety, have been carried out to comply with the provisions of Subsection NG of the ASME Code (loc. cit.) Section III. The structural factors of safety, summarized in Tables 3.4.3 and 3.4.6 for all credible load combinations under normal, off-normal, accident, and natural phenomenon events demonstrate that the Code limits are satisfied in all cases. As the stress analyses have been performed using linear elastic methods and the computed stresses are well within the respective ASME Code limits, it follows that the physical geometry of the fuel basket will not be altered under any load combination to create a condition adverse to criticality safety. This conclusion satisfies the requirement of 10CFR72.124(a), with respect to structural margins of safety for SSCs important to nuclear criticality safety.
 - Structural margins of safety during handling, packaging, and transfer operations, mandated by the provisions of 10CFR Part 72.236(b), require that the lifting and handling devices are engineered to comply with the stipulations of ANSI N14.6, NUREG-0612, Regulatory Guide 3.61, and NUREG-1536, and that the components being handled meet the applicable ASME Code service condition stress limits. The requirements of the governing codes for handling operations are summarized in Subsection 3.4.3 herein. A summary table of factors of safety for all ITS components under lifting and handling operations, presented in Subsection 3.4.3, shows that adequate structural margins exist in all cases.
 - Consistent with the requirements of 10CFR72.236(i), the confinement boundary for the HI-STORM 100 System has been engineered to maintain confinement of radioactive materials under normal, off-normal, and postulated accident conditions. This assertion of confinement integrity is made on the strength of the following

information provided in this FSAR.

- i. The MPC Enclosure Vessel which constitutes the confinement boundary is designed and fabricated in accordance with Section III, Subsection NB (Class 1 nuclear components) of the ASME Code to the maximum extent practicable.
 - ii. The MPC lid of the MPC Enclosure Vessel is welded using a strength groove weld and is subjected to volumetric examination or multiple liquid penetrant examinations, pressure testing, and liquid penetrant (root and final) testing to establish a maximum confidence in weld joint integrity.
 - iii. The closure of the MPC Enclosure Vessel consists of *two* independent isolation barriers.
 - iv. The confinement boundary is constructed from stainless steel alloys with a proven history of material integrity under environmental conditions.
 - v. The load combinations for normal, off-normal, accident, and natural phenomena events have been compiled (Table 2.2.14) and applied on the MPC Enclosure Vessel (confinement boundary). The results, summarized in Tables 3.4.4 through 3.4.9, show that the factor of safety (with respect to the appropriate ASME Code limits) is greater than one in all cases. Design Basis natural phenomena events such as tornado-borne missiles (large, intermediate, or small) have also been analyzed to evaluate their potential for breaching the confinement boundary. Analyses presented in Subsection 3.4.8, and summarized in unnumbered tables in Subsection 3.4.8, show that the integrity of the confinement boundary is preserved under all design basis projectile impact scenarios.
- The information on structural design included in this FSAR complies with the requirements of 10CFR72.120 and 10CFR72.122, and can be ascertained from the information contained in Table 3.7.1.
 - The provisions of features in the HI-STORM 100 structural design, listed in Table 3.7.2, demonstrate compliance with the specific requirements of 10CFR72.236(e), (f), (g), (h), (i), (j), (k), and (m).

Item	Compliance	Location of Supporting Information in This Document
	<ul style="list-style-type: none"> Concrete testing in accordance with ACI-349(85) 	Appendix 1.D
iv. Adequate structural protection against environmental conditions and natural phenomena.	Analyses presented in Chapter 3 demonstrate that the confinement boundary will preserve its integrity under all postulated off-normal and natural phenomena events listed in Chapters 2.	Section 2.2 Chapter 11
v. Adequate protection against fires and explosions	<ul style="list-style-type: none"> The extent of combustible (exothermic) material in the vicinity of the cask system is procedurally controlled (the sole source of hydrocarbon energy is diesel in the tow vehicle). Analyses show that the heat energy released from the postulated fire accident condition surrounding the cask will not result in impairment of the confinement boundary and will not lead to structural failure of the overpack. The effect on shielding will be localized to the external surfaces directly exposed to the fire which will result in a loss of the water in the water jacket for the HI-TRAC, and no significant change in the HI-STORM 100 overpack. Explosion effects are shown to be bounded by the Code external pressure design basis and there is no adverse effect on ready retrievability of the MPC. APPENDIX 3.A: HI-STORM DECELERATION UNDER POSTULATED VERTICAL DROP EVENT AND TIPOVER

3.A.1 INTRODUCTION

Handling accidents with a HI-STORM overpack containing a loaded MPC are credible events (Section 2.2.3). The stress analyses carried out in Chapter 3 of this safety analysis report assume that the inertial loading on the load bearing members of the MPC, fuel basket, and the overpack due to a handling accident are limited by the Table 3.1.2 decelerations. The maximum deceleration experienced by a structural component is the product of the rigid body deceleration sustained by the structure and the dynamic load factor (DLF) applicable to that structural component. The DLF is a function of the contact impulse and the structural characteristics of the component.

The rigid body deceleration is a strong function of the load-deformation characteristics of the impact interface, weight of the cask, and the drop height or angle of free rotation. For the HI-STORM 100 System, the weight of the structure and its surface compliance characteristics are known. However, the contact stiffness of the ISFSI pad (and other surfaces over which the HI-STORM 100 may be carried during its movement to the ISFSI) is site-dependent. The contact resistance of the collision interface, which is composed of the HI-STORM 100 and the impacted surface compliance, therefore, is not known a priori for a specific site. Analyses for the rigid body decelerations are, therefore, presented here using a reference ISFSI pad (which is the pad used in a recent Lawrence Livermore National Laboratory report and is the same reference pad used in the HI-STAR 100 FSAR). The finite element model (grid size, extent of model, soil properties, etc.) follows the LLNL report.

An in-depth investigation by the Lawrence Livermore Laboratory (LLNL) into the mechanics of impact between a cask-like impactor on a reinforced concrete slab founded on a soil-like subgrade has identified three key parameters, namely, the thickness of the concrete slab, t_p , compressive strength of the concrete f_c' and equivalent Young's Modulus of the subgrade E . These three parameters are key variables in establishing the stiffness of the pad under impact scenarios. The LLNL reference pad parameters, which we hereafter denote as Set A, provide one set of values of t_p , f_c' , and E that are found to satisfy the deceleration criteria applicable to the HI-STORM 100 cask. Another set of parameters, referred to as Set B herein, is also shown to satisfy the g-load limit requirements. In fact, an infinite number of combinations of t_p , f_c' , and E can be compiled that would meet the g-load limit qualification. However, in addition to satisfying the g-limit criterion, the pad must be demonstrated to possess sufficient flexural and shear stiffness to meet the ACI 318-95 strength limits under factored load combinations. The minimum strength requirement to comply with ACI 318-95 provisions places a restriction on the lower bound values of t_p , f_c' , and E that must be met in an ISFSI pad design.

Our focus in this appendix, however, is to quantify the peak decelerations that would be experienced by a loaded HI-STORM 100 cask under the postulated impact scenarios for the two pad designs defined by parameter Sets A and B, respectively. The information presented in this appendix also serves to further authenticate the veracity of the Holtec DYNA3D model described in the 1997 benchmark report [3.A.4.]

3.A.2 Purpose

The purpose of this appendix is to demonstrate that the rigid body deceleration experienced by the HI-STORM 100 System during a handling accident or non-mechanistic tip-over are below the design basis deceleration of 45g's (Table 3.1.2). Two accidental drop scenarios of a loaded HI-STORM 100 cask on the ISFSI pad are considered in this appendix. They are:

- i. Tipover: A loaded HI-STORM 100 is assumed to undergo a non-mechanistic tipover event and impacting the ISFSI pad with an incipient impact angular velocity, which is readily calculated from elementary dynamics.
- ii. End drop: The loaded HI-STORM 100 is assumed to drop from a specified height h , with its longitudinal axis in the vertical orientation, such that its bottom plate impacts the ISFSI pad.

The dynamic load factors are a function of the predominant natural frequency of vibration of the component for a given input load pulse shape. Dynamic load factors are applied, as necessary, to the results of specific component analyses performed using the loading from the design basis rigid body decelerations. Therefore, for the purposes of this appendix, it is desired to demonstrate that the rigid body deceleration experienced in each of the drop scenarios is below the HI-STORM 100 45g design basis.

3.A.3 Background and Methodology

In 1997 Lawrence Livermore National Laboratory (LLNL) published the experimentally obtained results of the so-called fourth series billet tests [3.A.1] together with a companion report [3.A.2] documenting a numerical solution that simulated the drop test results with reasonable accuracy. Subsequently, USNRC personnel published a paper [3.A.3] affirming the NRC's endorsement of the LLNL methodology. The LLNL simulation used modeling and simulation algorithms contained within the commercial computer code DYNA3D [3.A.6].

The LLNL cask drop model is not completely set forth in the above-mentioned LLNL reports. Using the essential information provided by the LLNL [3.A.2] report, however, Holtec is able to develop a finite element model for implementation on LS-DYNA3D [3.A.5] which is fully consistent with LLNL's (including the use of the Butterworth filter for discerning rigid body deceleration from "noisy" impact data). The details of the LS-DYNA3D dynamic model, henceforth referred to as the Holtec model, are contained in the proprietary benchmark report [3.A.4] wherein it is shown that the peak deceleration in every case of billet drop analyzed by LLNL is replicated within a small tolerance by the Holtec model. The case of the so-called

"generic" cask, for which LLNL provided predicted response under side drop and tipover events, is also bounded by the Holtec model. In summary, the benchmarking effort documented in [3.A.4] is in full compliance with the guidance of the Commission [3.A.3].

Having developed and benchmarked an LLNL-consistent cask impact model, a very similar model is developed and used to prognosticate the HI-STORM drop scenarios. The reference elasto-plastic-damage characteristics of the target concrete continuum used by LLNL, and used in the HI-STAR 100 FSAR are replicated herein. The HI-STORM 100 target model is identical in all aspects to the reference pad approved for the HI-STAR 100 FSAR.

In the tipover scenario the cask surface structure must be sufficiently pliable to cushion the impact and limit the rigid body deceleration. The angular velocity at the contact time is readily calculated using planar rigid body dynamics and is used as an initial condition in the LS-DYNA3D simulation.

The end drop event produces a circular impact patch equal to the diameter of the overpack baseplate. The elasto-plastic-damage characteristics of the concrete target and the drop height determine the maximum deceleration. A maximum allowable height "h" is determined to limit the deceleration to a value below the design basis.

A description of the work effort and a summary of the results are presented in the following sections. In all cases, the reported decelerations are below the design basis of 45g's at the top of the MPC fuel basket.

3.A.4 Assumptions and Input Data

3.A.4.1 Assumptions

The assumptions used to create the model are completely described in Reference [3.A.4] and are shown there to be consistent with the LLNL simulation. There are key aspects, however, that are restated here:

The maximum deceleration experienced by the cask during a collision event is a direct function of the structural rigidity (or conversely, compliance) of the impact surface. The compliance of the ISFSI pad is quite obviously dependent on the thickness of the pad, t_p , the compressive strength of the concrete, f_c' and stiffness of the sub-grade (expressed by its effective Young's modulus, E). The structural rigidity of the ISFSI pad will increase if any of the three above-mentioned parameters (t_p , f_c' or E) is increased. For the reference pad, the governing parameters (i.e., t_p , f_c' and E) are assumed to be identical to the pad defined by LLNL [3.A.2], which is also the same as the pad utilized in the benchmark report [3.A.4]. We refer to the LLNL ISFSI pad parameters as Set A. (Table 3.A.1).

As can be seen from Table 3.A.1, the nominal compressive strength f_c' in Set A is limited to 4200 psi. However, experience has shown that ISFSI owners have considerable practical difficulty in limiting the 28 day strength of poured concrete to 4200 psi, chiefly because a principal element of

progress in reinforced concrete materials technology has been in realizing ever increasing concrete nominal strength. Inasmuch as a key objective of the ISFSI pad is to limit its structural rigidity (and not f_c' per se), and limiting f_c' to 4200 psi may be problematic in certain cases, an alternative set of reference pad parameters is defined (Set B in Table 3.A.1), which permits a higher value of f_c' but much smaller values of pad thickness, t_p and sub-grade Young's modulus, E .

The ISFSI owner has the option of constructing the pad to comply with the limits of Set A or Set B without performing site-specific cask impact analyses. It is recognized that, for a specific ISFSI site, the reinforced concrete, as well as the underlying engineered fill properties, may be different at different locations on the pad or may be uniform, but non-compliant with either Set A or Set B. In that case, the site-specific conditions must be performed to demonstrate compliance with the design limits of the HI-STORM system (e.g., maximum rigid body g-load less than 45 g's). The essential data which define the pad (Set A and Set B) used to qualify the HI-STORM 100 are provided in Table 3.A.1.

The HI-STORM 100 steel structural elements (outer shell, inner shell, radial plates, lid, etc.), are fabricated from SA-516 Grade 70. The steel is described as a bi-linear elastic-plastic material with limited strain failure by five material parameters (E , S_y , S_u , ϵ_u , and ν). The numerical values used in the finite element model are shown in Table 3.A.2. The concrete located inside of the overpack for this dynamic analysis is defined to be identical with the concrete pad. This is conservative since the concrete assumed in the reference pad is reinforced. Therefore, the strength of the concrete inside the HI-STORM 100 absorbs less energy if it is also assumed to be reinforced.

3.A.4.2 Input Data

Table 3.A.1 characterizes the properties of the full-scale reference target pad used in the analysis of the full size HI-STORM 100 System. The principal strength parameters that define the stiffness of the pad, namely, t_p , E and f_c' are input in the manner described in [3.A.2] and [3.A.4].

Table 3.A.2 contains the material description parameters for the steel types; SA-516-70 used in the numerical investigation.

Table 3.A.3 details the geometry of the HI-STORM 100 used in the drop simulations. This data is taken from applicable HI-STORM 100 drawings.

3.A.5 Finite Element Model

The finite-element model of the Holtec HI-STORM 100 overpack (baseplate, shells, radial plates, lid, concrete, etc.), concrete pad and a portion of the subgrade soil is constructed using the pre-processor integrated with the LS-DYNA3D software [3.A.5]. The deformation field for all postulated drop events (the end-drop and the tipover) exhibits symmetry with the vertical plane passing through the cask diameter and the concrete pad length. Using this symmetry condition of the deformation field only a half finite-element model is constructed. The finite-element model is organized into nineteen independent parts (the baseplate components, the outer shell, the inner

shell, the radial plates, the channels, the lid components, the basket steel plates, the basket fuel zone, the concrete pad and the soil). The final model contains 30351 nodes, 24288 solid type finite-elements, 1531 shell type finite-elements, seven (7) materials, ten (10) properties and twenty-four (24) interfaces. The finite-element model used for the tipover-drop event is depicted in Figures 3.A.1 through 3.A.4. Figures 3.A.5 through 3.A.8 show the end-drop finite-element model.

The soil grid, shown in Figure 3.A.9, is a rectangular prism (800 inches long, 375 inches wide and 470 inches deep), is constructed from 13294 solid type finite-elements. The material defining this part is an elastic isotropic material. The central portion of the soil (400 inches long, 150 inches wide and 170 inches deep) where the stress concentration is expected to appear is discretized with a finer mesh.

The concrete pad is 320 inches long, 100 inches wide and is 36 inches thick. This part contains 8208 solid finite-elements. A uniform sized finite-element mesh, shown in Figure 3.A.10, is used to model the concrete pad. The concrete behavior is described using a special constitutive law and yielding surface (MAT_PSEUDO_TENSOR) contained within LS-DYNA3D. The geometry, the material properties, and the material behavior are identical to the LLNL reference pad (Material 16 IIB).

The half portion of the steel cylindrical overpack contains 1531 shell finite-elements. The steel material description (SA-516-70) is realized using a bi-linear elasto-plastic constitutive model (MAT_PIECEWISE_LINEAR_PLASTICITY). Figure 3.A.11 depicts details of the steel components of the cask finite-element mesh, with the exception of the inner shell, channels and lid components, which are shown in Figures 3.A.12 and 3.A.13. The concrete filled between the inner and the outer shells, and contained in the baseplate and lid components is modeled using 1664 solid finite-elements and is depicted in Figure 3.A.14. The concrete material is defined identical to the pad concrete.

The MPC and the contained fuel are modeled in two parts that represent the lid and baseplate, and the fuel area. An elastic material is used for both parts. The finite-element mesh pertinent to the MPC contains 1122 solid finite-elements and is shown in Figure 3.A.15. The mass density is appropriate to match a representative weight of 356,521 lb. that is approximately mid-way between the upper and lower weight estimates for a loaded HI-STORM 100.

The total weight used in the analysis is approximately 2,000 lb. lighter than the HI-STORM 100 containing the lightest weight MPC.

Analysis of a single mass impacting a spring with a given initial velocity shows that both the maximum deceleration " a_M " of the mass and the time duration of contact with the spring " t_c " are related to the dropped weight " w " and drop height " h " as follows:

$$a_M \sim \frac{\sqrt{h}}{\sqrt{w}}; t_c \sim \sqrt{w}$$

Therefore, the most conservatism is introduced into the results by using the minimum weight. It is emphasized that the finite element model described in the foregoing is identical in its approach to the "Holtec model" described in the benchmark report [3.A.4]. Gaps between the MPC and the overpack are included in the model.

3.A.6 Impact Velocity

a. Linear Velocity: Vertical Drops

For the vertical drop event, the impact velocity, v , is readily calculated from the Newtonian formula:

$$v = \sqrt{2gh}$$

where

$$\begin{aligned} g &= \text{acceleration due to gravity} \\ h &= \text{free-fall height} \end{aligned}$$

b. Angular Velocity: Tip-Over

The tipover event is an artificial construct wherein the HI-STORM 100 overpack is assumed to be perched on its edge with its C.G. directly over the pivot point A (Figure 3.A.16). In this orientation, the overpack begins its downward rotation with zero initial velocity. Towards the end of the tip-over, the overpack is horizontal with its downward velocity ranging from zero at the pivot point (point A) to a maximum at the farthest point of impact (point E in Figure 3.A.17). The angular velocity at the instant of impact defines the downward velocity distribution along the contact line.

In the following, an explicit expression for calculating the angular velocity of the cask at the instant when it impacts on the ISFSI pad is derived. Referring to Figure 3.A.16, let r be the length AC where C is the cask centroid. Therefore,

$$r = \left(\frac{d^2}{4} + h^2 \right)^{1/2}$$

The mass moment of inertia of the HI-STORM 100 System, considered as a rigid body, can be written about an axis through point A, as

$$I_A = I_c + \frac{W}{g} r^2$$

where I_c is the mass moment of inertia about a parallel axis through the cask centroid C and W is the weight of the cask ($W = Mg$).

Let $\theta_1(t)$ be the rotation angle between a vertical line and the line AC. The equation of motion for rotation of the cask around point A, during the time interval prior to contact with the ISFSI pad, is

$$I_A \frac{d^2 \theta_1}{dt^2} = Mgr \sin \theta_1$$

This equation can be rewritten in the form

$$\frac{I_A}{2} \frac{d(\dot{\theta}_1)^2}{d\theta_1} = Mgr \sin \theta_1$$

which can be integrated over the limits $\theta_1 = 0$ to $\theta_1 = \theta_{2f}$ (See Figure 3.A.17).

The final angular velocity $\dot{\theta}_1$ at the time instant just prior to contact with the ISFSI pad is given by the expression

$$\dot{\theta}_1(t_B) = \sqrt{\frac{2 Mgr}{I_A} (1 - \cos \theta_{2f})}$$

where, from Figure 3.A.17

$$\theta_{2f} = \cos^{-1} \left(\frac{d}{2r_1} \right)$$

This equation establishes the initial conditions for the final phase of the tip-over analysis; namely, the portion of the motion when the cask is decelerated by the resistive force at the ISFSI pad interface.

Using the data germane to HI-STORM 100 (Table 3.A.3), and the above equations, the angular velocity of impact is calculated as 1.49 rad/sec.

3.A.7 Results

3.A.7.1 Set A Pad Parameters

It has been previously demonstrated in the benchmark report [3.A.4] that bounding rigid body decelerations are achieved if the cask is assumed to be rigid with only the target (ISFSI pad) considered as an energy absorbing media. Therefore, for the determination of the bounding

decelerations reported in this appendix, the HI-STORM storage overpack was conservatively made rigid except for the radial channels that position the MPC inside of the overpack. The MPC material behavior was characterized in the identical manner used in the Livermore Laboratory analysis as was the target ISFSI pad and underlying soil. The LS-DYNA3D time-history results are processed using the Butterworth filter (in conformance with the LLNL methodology) to establish the rigid body motion time-history of the cask. The material points on the cask where the acceleration displacement and velocity are computed for each of the drop scenarios are shown in Figure 3.A.18.

Node 82533 (Channel A1), which is located at the center of the outer surface of the baseplate, serves as the reference point for end-drop scenarios.

Node 84392 (Channel A2), which is located at the center of the cask top lid outer surface, serves as the reference point for the tipover scenario with the pivot point indicated as Point 0 in Figure 3.A.18.

The final results are shown in Table 3.A.4.

i. Tipover:

The time-histories of the impact force, the displacement and velocity time-histories of Channel A2, and the average vertical deceleration of the overpack lid top plate have been determined for this event [3.A.7].

The deceleration at the top of the fuel basket is obtained by ratioing the average deceleration of the overpack lid top plate. The maximum filtered deceleration at the top of the fuel basket is 42.85g's, which is below the design basis limit.

ii. End Drop:

The drop height $h = 11$ " is considered in the numerical analysis. This is considered as an acceptable maximum carry height for the HI-STORM 100 System if lifted above a surface with design values of t_p , f_c' , and E equal to those presented in Table 3.A.1 for Parameter Set "A". The maximum filtered deceleration at the top of the fuel basket is 43.98g's, which is below the design basis limit.

The computer code utilized in this analysis is LS-DYNA3D [3.A.5] validated under Holtec's QA system. Table 3.A.4 summarizes the key results from all impact simulations for the Set A parameters discussed in the foregoing.

The filter frequencies (to remove unwanted high-frequency contributions) for the Holtec cask analyses analyzed in this TSAR is the same as used for the corresponding problem analyzed in [3.A.2] and [3.A.4]. To verify the Butterworth filter parameters (350 Hz cutoff frequency, etc.) used in processing the numerical data, a Fourier power decomposition was generated.

3.A.7.2 Set B Parameters

As stated previously, Set B parameters produce a much more compliant pad than the LLNL reference pad (Set A). This fact is borne out by the tipover and end drop analyses performed on the pad defined by the Set B parameters. Table 3.A.4 provides the filtered results for the two impact scenarios. In every case, the peak decelerations corresponding to Set B parameters are less than those for Set A (also provided in Table 3.A.4).

Impact force and acceleration time history curves for Set B have the same general shape as those for Set A and are contained in the calculation package [3.A.7]. All significant results are summarized in Table 3.A.4.

3.A.8 Computer Codes and Archival Information

The input and output files created to perform the analyses reported in this appendix are archived in Holtec International calculation package [3.A.7].

3.A.9 Conclusion

The DYNA3D analysis of HI-STORM 100 reported in this appendix leads to the following conclusion:

- a. If a loaded HI-STORM undergoes a free fall for a height of 11 inches in a vertical orientation on to a reference pad defined by Table 3.A.1, the maximum rigid body deceleration is less than 45g's for both Set A and Set B pad parameters.
- b. If a loaded HI-STORM 100 overpack pivots about its bottom edge and tips over on to a reference pad defined by Table 3.A.1, then the maximum rigid body deceleration of the cask centerline at the plane of the top of the MPC fuel basket cellular region is less than 45g's for both Set A and Set B parameters.

Table 3.A.4 provides key results for all drop cases studied herein for both pad parameter sets (A and B). If the pad designer maintains each of the three significant parameters (t_p , f_c' , and E) below the limit for the specific set selected (Set A or Set B), then the stiffness of the pad at any ISFSI site will be lower and the computed decelerations at the ISFSI site will also be lower. Furthermore, it is recognized that a refinement of the cask dynamic model will accrue further reduction in the computed peak deceleration. For example, incorporation of the structural flexibility in the MPC enclosure vessel, fuel basket, etc., would lead to additional reductions in the computed values of the peak deceleration. These refinements, however, add to the computational complexity. Because g-limits are met without the above-mentioned and other refinements in the cask dynamic model, the simplified dynamic model described in this appendix was retained to reduce the overall computational effort.

Table 3.A.1: Essential Variables to Characterize the ISFSI Pad (Set A and Set B)

Item	Parameter Set A	Parameter Set B
Thickness of concrete, (inches)	36	28
Nominal compressive strength of concrete at 28 days, (psi)	4,200	6,000
Max. modulus of elasticity of the subgrade (psi)	28,000	16,000

Notes:

1. The concrete Young's Modulus is derived from the American Concrete Institute recommended formula $57,000\sqrt{f}$ where f is the nominal compressive strength of the concrete (psi).
2. The effective modulus of elasticity of the subgrade will be measured by the classical "plate test" or other appropriate means before pouring of the concrete to construct the ISFSI pad.
3. The pad thickness, concrete compressive strength, and the subgrade soil effective modulus are the upper bound values to ensure that the deceleration limits under the postulated events set forth in Table 3.1.2 are satisfied.

Table 3.A.2: Essential Steel Material Properties for HI-STORM 100 Overpack

Steel Type	Parameter	Value
SA-516-70 at T = 350 deg. F	E	2.800E + 07
	S _y	3.315E+04 psi
	S _u	7.000E+04 psi
	ε _u	0.21
	ν	0.30

Note that the properties of the steel components, except for the radial channels used to position the MPC, do not affect the results reported herein since the HI-STORM 100 is eventually assumed to behave as a rigid body (by internal constraint equations automatically computed by DYNA3D upon issue of a “make rigid” command). In Section 3.4, however, stress and strain results for an additional tip-over analysis, performed using the actual material behavior ascribed to the storage overpack, are presented for the sole purpose of demonstrating ready retrievability of the MPC after the tip-over. As an option, the radial channels may be fabricated from SA240-304 material. The difference in material properties, however, has a negligible effect on the end results.

Table 3.A.3: Key Input Data in Drop Analyses

Overpack weight	267,664 lb
Radial Concrete weight	163,673 lb
Length of the cask	231.25 inches
Diameter of the bottom plate	132.50 inches
Inside diameter of the cask shell	72.50 inches
Outside diameter of the cask shells	132.50 inches
MPC weight (including fuel)	88,857 lb
MPC height	190.5 inches
MPC diameter	68.375 inches
MPC bottom plate thickness	2.5 inches
MPC top plate thickness	9.5 inches

Table 3.A.4: Filtered Results for Drop and Tip-Over Scenarios for HI-STORM 100[†]

Drop Event	Max. Displacement (inch)		Impact Velocity (in/sec)	Max. Deceleration ^{††} at the Top of the (g's) Basket		Duration of Deceleration Pulse (msec)	
	Set A	Set B		Set A	Set B	Set A	Set B
End Drop for 11 inches	0.65	0.81	92.2	43.98	41.53	3.3	3.0
Non-Mechanistic Tip-over	4.25	5.61	304.03	42.85	39.91	2.3	2.0

[†] The passband frequency of the Butterworth filter is 350 Hz.

^{††} The distance of the top of the fuel basket is 206" from the pivot point. The distance of the top of the cask is 231.25" from the pivot point. Therefore, all displacements, velocities, and accelerations at the top of the fuel basket are 89.08% of those at the cask top (206"/231.25").

SUPPLEMENT 3.I

STRUCTURAL EVALUATION FOR THE HI-STORM 100U SYSTEM

3.I.0 OVERVIEW

In this supplement, the structural adequacy of the HI-STORM 100U Vertical Ventilated Module (VVM) is evaluated pursuant to the guidelines of NUREG-1536. The organization of technical information in this supplement mirrors the format and content of Chapter 3 except that it only contains material directly pertinent to the HI-STORM 100U VVM.

The HI-STORM 100U VVM serves as the storage space for the loaded MPC and consists of the CEC (the Container Shell, the Divider Shell and MPC Guides, and a welded Bottom Plate), and a lid consisting of plain concrete encased in structural steel arranged to provide appropriate inlet and outlet air passages (the Closure Lid). These individual components are collectively referred to as VVM Components. Interfacing SSCs that surround and support the VVM, as well as proximate structures, collectively referred to as ISFSI Structures, are explained in Supplement 2.I. Section 1.I.2 contains a complete description of the VVM Components and the ISFSI Structures (accompanied by appropriate figures) and their respective functions within the HI-STORM 100U ISFSI. The essential design details of both the VVM Components and the ISFSI Structures are set down in the licensing drawing in Supplement 1.I. The design basis loadings for the facility are provided in Supplement 2.I.

The applicable codes, standards, and practices governing the structural analysis of the HI-STORM 100U module as well as the design criteria, are also presented in Supplement 2.I. Throughout this supplement, in the context of the VVM components, the term “*safety factor*” is defined as the *ratio of the allowable stress (load) or displacement for the applicable load combination to the maximum computed stress (load) or displacement*.

For the ISFSI Structures made of reinforced concrete, the safety factor is defined as the ratio of the ultimate moment (or shear) capacity to the actual maximum moment (or shear) developed under the factored load combination.

MPC structural integrity has been evaluated in Chapter 3. In this supplement, the integrity of the MPC, due to its rattling motion inside the VVM storage cavity during a seismic event (a new loading condition in the underground storage configuration) is considered.

3.I.1 STRUCTURAL DESIGN

3.I.1.1 Discussion

The HI-STORM 100U system consists of three principal components: the Multi-Purpose Canister (MPC), the HI-STORM 100U storage module, herein denoted as the Vertical Ventilated Module (VVM) (includes the Cavity Enclosure Container (CEC) and the Closure Lid), and the HI-TRAC transfer cask. This supplement to Chapter 3 presents the structural evaluation of a VVM for the

applicable load cases summarized in Supplement 2.I (Table 2.I.5). In Section 3.I.4, the safety factors for each load case for the VVM Components are quantified. In addition, the safety evaluation of the ISFSI Structures is carried out using the factored load combinations from ACI-318 (2005) (see Table 2.I.11). Summary tables of bounding safety factors are provided for governing load combination for the ISFSI Structures. A licensing drawing for the HI-STORM 100U VVM is provided in Section 1.I.5. Table 2.I.1 provides a listing of the applicable regulations, codes and standards for the VVM Components and the ISFSI structures. The design of the VVM components and the ISFSI Structures is fully articulated in the licensing drawing and Table 2.I.2. The applicable Design Basis Earthquake is defined by the free field spectra shown in Figure 2.I.4.

3.I.1.2 Design Criteria

Design (and acceptance) criteria for the HI-STORM 100U VVM Components and the ISFSI structures are summarized in Tables 2.I.1 and 2.I.6.

3.I.1.3 Loads

Individual loads, applicable to the HI-STORM 100U System, are defined in Sections 2.I.4, 2.I.5, and 2.I.6, and load cases applicable to the VVM Components are summarized in Table 2.I.5. Table 2.I.11 contains load combinations applicable to the ISFSI Structures (reinforced concrete structures) in the HI-STORM 100U ISFSI.

3.I.1.4 Allowables

Allowable stresses for carbon steel and Alloy X used in the structural components of the HI-STORM 100U and the stored MPC are provided in Sections 3.1 and 3.3. The relevant data from those sections is reproduced here, as Tables 3.I.3 (a)-(d) to make the supplement self-contained.

3.I.1.5 Brittle Fracture

Brittle fracture considerations for HI-STORM 100U are bounded by HI-STORM 100 and 100S because of the VVM's underground configuration, and the use of the same material types and thicknesses as in the aboveground overpacks.

3.I.1.6 Fatigue

The HI-STORM 100U system is not subject to significant long-term cyclic loads. Therefore, failure due to fatigue is not a concern for the HI-STORM 100U system.

3.I.1.7 Buckling

The CEC Container Shell is the only component of the VVM subject to axial compression. However, since the shell is backed by a substrate, welded to a Bottom Plate at its base, and surrounded by the ISFSI Pad at the top, instability is not considered credible. The Divider Shell

does not experience any axial compressive stress that might induce buckling.

3.I.2 WEIGHTS AND CENTERS OF GRAVITY

Table 3.I.1 provides bounding weights of the individual HI-STORM 100U components.

The locations of the calculated centers of gravity (C.G's) are presented in Table 3.I.2 and are computed using the bounding weights. All centers of gravity are located on the VVM centerline.

Bounding weight values for the CEC and the Closure Lid include an overage on the weight generated by the CAD drawing package.

3.I.3 MECHANICAL PROPERTIES OF MATERIALS

Tables 2.I.3 and 2.I.8 list applicable codes, materials of construction, and ITS designations for all functional parts in the HI-STORM 100U system except for the MPC and its internals, which remain unchanged (listed in Table 2.2.6).

3.I.3.1 VVM Steel Properties

Applicable material property and allowable stress tables in Chapter 3 for the VVM are reproduced in Tables 3.I.3 (a)-(c) for convenience.

3.I.3.2 Unreinforced Concrete

The primary function of the unreinforced concrete in the HI-STORM 100U VVM Closure Lid is shielding. Unreinforced concrete is not considered as a primary load-bearing (structural) member. However, its ability to withstand compressive, bearing and penetrant loads under the design basis and various service conditions is analyzed. The allowable bearing strength of plain concrete for normal loading conditions is calculated in accordance with ACI 318 (2005) [2.I.5]. Table 3.I.4 provides a bearing limit consistent with the concrete compressive strength in the same table. The procedure specified in ASTM C-39 is utilized to verify that the assumed compressive strength will be realized in the actual in-situ pours. Unless specifically called out in Table 3.I.4, Appendix 1.D provides requirements on unreinforced concrete.

3.I.3.3 Reinforced Concrete

Reinforced concrete is used in the construction of the ISFSI Structures, namely, the retaining wall, the TSP, the VIP, and the SFP. All reinforced concrete in the HI-STORM 100U ISFSI will conform to stress criteria of ACI-318 (2005).

3.I.4 GENERAL STANDARDS FOR CASKS

In this section, new or additional material applicable to the HI-STORM 100U system is included.

Section 3.4 contains all required information associated with the MPCs and with the HI-TRAC transfer cask and is not repeated here. Results reported in this supplement section are generally applicable only to the HI-STORM 100U VVM.

3.I.4.1 Chemical and Galvanic Reactions

In order to provide reasonable assurance that the VVM will meet its intended Design Life of 40 years (the License Life is 20 years) and perform its intended safety function(s), chemical and galvanic reactions and other potentially degrading mechanisms must be accounted for in its design and construction.

The HI-STORM 100U VVM is a buried structure and as such chemical and galvanic reactions and other potentially degrading factors are, in some respects, more challenging than for aboveground models. Although the CEC is not a part of the MPC containment boundary, it should not corrode to the extent where localized in-leakage of water occurs or where gross general corrosion prevents the component from performing its primary safety function. In the following, considerations in the VVM's design and construction consistent with the applicable guidance provided in ISG-15 [3.I.3] are summarized.

All VVM components are galvanically compatible. Except for the CEC exterior surfaces, all steel surfaces of the VVM are lined and coated with the same surface preservative that is used in the aboveground HI-STORM overpacks. (The surface preservative used to protect HI-STORM 100S steel surfaces is a proven zinc rich inorganic/metallic material that protects galvanically and has self healing characteristics for added assurance). All exposed surfaces interior to the VVM, as stated in Supplement 1.I, are accessible for the reapplication of surface preservative, if necessary.

The steel Divider Shell requires insulation to perform its primary thermal function. The insulation selected shall be suitable for high temperature and high humidity operation and shall be foil faced, jacketed or otherwise made water resistant to ensure the required thermal resistance is maintained in accordance with Supplement 4.I. The high zinc content in the coating of the Divider Shell provides protection for both the Divider Shell and the jacketing or foil from any potential galvanic corrosion concerns. With respect to radiation resistance, the insulation blanket does not contain any organic binders. The damage threshold for ceramics is known to be approximately 1×10^{10} Rads. Chloride corrosion is not a concern since chloride leachables are limited and sufficiently low and the Divider Shell is not made from stainless steel [3.I.20]. Stress corrosion cracking of the foil or jacketing, whether made from stainless steel or other material is not an applicable corrosion mechanism due to minimal stresses derived from self-weight. The foil or jacketing and attachment hardware shall either have sufficient corrosion resistance (e.g. stainless steel, aluminum or galvanized steel) or shall be protected with a suitable surface preservative. The insulation is adequately secured to prevent significant blockage of the ventilation passages in case of failure of a single attachment (strap, clamp, bolt or other attachment hardware). The following table provides the acceptance criteria for the selection of insulation material for the Divider Shell and ranks them in order of importance.

Acceptance Criteria for the Selection of the Insulation Material	
Rank	Criteria
1	Adequate thermal resistance
2	Adequate high temperature resistance
3	Adequate humidity resistance
4	Adequate radiation resistance
5	Adequate resistance to the ambient environment
6	Sufficiently low chloride leachables
7	Adequate integrity and resistance to degradation and corrosion during long-term storage

Kaowool® ceramic fiber insulation [3.I.20] is selected as one that satisfies the acceptance criteria to the maximum degree. The Kaowool® insulation material provides excellent resistance to chemical attack and is not degraded by oil or water. Alternatively, a Holtec approved equivalent that meets the acceptance criteria set forth in the table above may be used.

The CEC Container Shell, which is exposed to the substrate, requires additional pre-emptive measures to prevent corrosion, if the substrate is of aggressive chemistry. This subsection provides a description of corrosion mitigation measures required to be implemented to protect the HI-STORM 100 VVM. Because the guiding principle in the HI-STORM Systems is to target a service life of 100 years so as to guarantee a design life of 40 years, these corrosion prevention measures are in addition to the preemptively incorporated standard corrosion allowance of 1/8-inch applied to the subterranean parts of the CEC in direct contact with the surrounding substrate. Calculation of the required CEC Container Shell and Bottom Plate thicknesses on a site-specific basis may indicate the availability of an additional corrosion reserve.

Soil Corrosivity and Corrosion Mitigation Measures for the Exterior of the CEC

Corrosion mitigation of the exterior of the CEC warrants special consideration for the following reasons: (i) inaccessibility of the exterior coated surface after installation (ii) potential for a highly aggressive (i.e., corrosive) soil environment at certain sites, and (iii) potential for a high radiation field. Since the buried configuration will not allow for the reapplication of surface preservative, corrosion mitigation measures shall be determined after careful evaluation of the soil's corrosivity at the user's ISFSI site.

To evaluate soil corrosivity, a "10 point" soil-test evaluation procedure, in accordance with the guidelines of Appendix A of ANSI/AWWA C105/A21 [3.I.4], will be utilized. The classical soil evaluation criteria in the aforementioned standard focuses on parameters such as: 1) resistivity, 2) pH, 3) redox (oxidation-reduction) potential, 4) sulfides, 5) moisture content, 6) potential for stray current, and 7) experience with existing installations in the area. Using the procedure outlined in ref. [3.I.4], the ISFSI soil environment corrosivity is categorized as either "mild" for a soil test evaluation resulting in 9 points or less or "aggressive" for a soil test evaluation resulting in 10

points or greater. The following table details the corrosion mitigation measures that shall be implemented based on soil environment corrosivity:

Implementation of Corrosion Mitigation Measures			
Soil Environment Corrosivity	Corrosion Mitigation Measures		
	Coating (see note i)	Concrete Encasement (see note ii)	Cathodic Protection (see note iii)
Mild	Required	Choice of either concrete encasement or cathodic protection; or both	
Aggressive	Required	Optional	Required
Notes: i. An acceptable exterior surface preservative (coating) applied on the CEC. ii. Concrete encasement of the CEC external surfaces to establish a high pH buffer around the metal mass. iii. A suitably engineered impressed current cathodic protection system (ICCP)			

The corrosion mitigation measures tabulated above are further detailed in the following subsections:

i. Coating

In addition to the corrosion allowance, the CEC shall be coated with a radiation resistant surface preservative designed for below-grade and/or immersion service. Inorganic and/or metallic coatings are sufficiently radiation resistant for this application; therefore, radiation testing is not required [3.I.5]. Organic coatings such as epoxy, however, must have proven radiation resistance [3.I.5] or must be tested without failure to at least 10^7 Rad. Radiation resistance to lower radiation levels is acceptable on a site-specific basis. Radiation testing shall be performed in accordance with ASTM D 4082 [3.I.6] or equivalent. The coating should be conservatively treated as a Service Level II coating as described in Reg. Guide 1.54 [3.I.7]. As such, the coating shall be subjected to appropriate quality assurance in accordance with the applicable guidance provided by ASTM D 3843-00 [3.I.8]. The coating should preferably be shop applied in accordance with manufacturer's instructions and, if appropriate, applicable guidance from ANSI C 210-03 [3.I.9]. The Keeler & Long polyamide-epoxy coating, according to the manufacturer's product data sheet [3.I.10], is pre-tested to radiation levels up to 1×10^9 Rads without failure. The following table provides the acceptance criteria for the selection of coatings for the exterior surfaces of the CEC and ranks them in order of importance.

Acceptance Criteria for the Selection of Coatings	
Rank	Criteria
1	suitable for immersion and/or below grade service

Acceptance Criteria for the Selection of Coatings	
Rank	Criteria
2a	compatible with the ICCPS (if used) <ul style="list-style-type: none"> adequate dielectric strength adequate resistance to cathodic disbondment
2b	compatible with concrete encasement (if used) <ul style="list-style-type: none"> adequate resistance to high alkalinity
3	adequate radiation resistance
4	adequate adhesion to steel
5	adequate bendability/ductility/cracking resistance/abrasion resistance
6	adequate strength to resist handling abuse and substrate stress

The Keeler & Long polyamide-epoxy coating is selected as one that satisfies the acceptance criteria to the maximum degree. Alternatively, a Holtec approved equivalent that meets the acceptance criteria set forth in the table above may be used.

ii. Concrete Encasement

The CEC concrete encasement shall provide a minimum of 5 inches of cover to provide a pH buffering effect for additional corrosion mitigation. The above concrete cover thickness has been conservatively determined for a 100-year service life in a strongly aggressive environment based on the concrete corrosion/degradation data provided in the literature [3.I.12, Table 5.3] (1.2 mm/yr surface depth failure rate). The required 5 inch minimum thickness is more conservative than that recommended in ACI Codes, such as ACI 318 [3.3.2], which call for up to 3 inches of concrete cover over steel reinforcement in aggressive environments. Considering that the concrete encasement is restricted to mild soil environments (unless used in conjunction with cathodic protection) and has a non-structural role, the 5 inch concrete encasement thickness is considered more than sufficient to provide reasonable assurance that a 40 year service life can be achieved. The lowest part of the CEC sits in a recessed region of the Support Foundation with an annular gap normally filled with substrate. If present, the CEC concrete encasement slurry will fill this annular gap during construction.

The function of the concrete encasement is for corrosion mitigation only; however, cracks larger than hairline cracks may significantly reduce its effectiveness. To control size and population of cracks, concrete reinforcement is included. The following reinforcement methods may be applied:

- a. Fiber reinforcement: Fiber reinforcement may be of several materials, including steel, glass and plastic (polypropylene). The selection of the fiber reinforcement material shall be such that adequate resistance to radiation and high alkalinity is maintained. If using steel fibers, adequate damage protection of the CEC coating shall be ensured during concrete placement per written procedures. Steel fiber shall be implemented using written procedures and the applicable guidance from ACI 544.3R [3.I.25] or a similar consensus code or standard.

Fiber reinforcement materials other than steel shall be implemented using written procedures, manufacturer recommendations and applicable guidance from ACI, ASCE and/or ASTM. One such document is ASTM C1116-03 [3.I.26].

- b. Steel wire reinforcement: Steel wire reinforcement shall be implemented in accordance with written procedures and the guidance from ACI 318 [3.3.2] or more recent version. For corrosion protection, the steel wire reinforcement shall have a concrete cover of approximately 2 to 3 inches from the interfacing substrate.

Regardless of reinforcement method, the material selected shall be corrosion resistant or otherwise appropriately coated (e.g. epoxy coated steel wire) for corrosion resistance.

The concrete encasement shall be installed in accordance with Holtec approved procedures following applicable guidance from the ACI code (e.g. ACI 318 [3.3.2]), as appropriate, for commercial concrete. Installation procedures shall address mix designs (incorporating Portland cement), testing, mixing, placement, and reinforcement, with the aim to enhance concrete durability and minimize voids and micro-cracks.

iii. Impressed Current Cathodic Protection System (ICCPS)

For a particular ISFSI site, the user may choose to either extend an existing ICCPS to protect the installed ISFSI, or to establish an autonomous ICCPS. The initial startup of the ICCPS must occur within one year after installation of the VVM to ensure timely corrosion mitigation. In addition, the ICCPS should be maintained operable at all times after initial startup except for system shutdowns due to power outages, repair or preventive maintenance and testing, or system modifications. Because there are a multitude of ISFSI variables that will bear upon the design of the ICCPS for a particular site, the essential criteria for its performance and operational characteristics are set down in this FSAR, which the detailed design work for each ISFSI site must follow.

Design Criteria for the Impressed Current Cathodic Protection System
<ul style="list-style-type: none"> a. The cathodic protection system shall be capable of maintaining the CEC at a minimum (cathodic) potential as required by NACE Standard RP0285-2002 [3.I.21]. b. The ICCPS shall include provisions to infer its proper operation and effectiveness on a periodic basis. c. The system shall be designed to mitigate corrosion of the CEC for its design life. d. The cathodic protection system design, installation, operation, testing, and maintenance shall follow the applicable guidelines of: <ul style="list-style-type: none"> - 49CFR195 Subpart H “Corrosion Control”, Oct. 1, 2004 edition [3.I.13] - NACE Standard RP0285-2002 “Corrosion Control of Underground Storage Tank Systems by Cathodic Protection” [3.I.21]

The following standards and/or publications may also be utilized for additional guidance in the design, installation, operation, testing, and maintenance of the ICCPS as needed (in case of conflict, the guidelines of item d above shall prevail):

- API RP1632, “Cathodic Protection of Underground Petroleum Storage Tanks and Piping Systems” [3.I.22]
- NACE RP0169-96, “Control of External Corrosion on Underground or Submerged Piping Systems” [3.I.23]
- 49CFR192 Subpart I, “Requirements for Corrosion Control”, Oct. 1, 2004 edition [3.I.24]
- Other standards or publications referenced by any of the above three standards and publications.

Records of system operating data necessary to adequately track the operable status of the ICCPS shall be maintained in accordance with the user’s quality assurance program.

Finally, the surface preservative used to coat the CEC must meet the requirements described in (i) above but must also be compatible with cathodic protection and resistant to the alkaline conditions created by cathodic protection and/or concrete encasement. Organic coatings, such as the Keeler & Long coating selected for (i) above, are inherently compatible with both cathodic protection [3.I.11] and concrete [3.I.10].

3.I.4.2 Positive Closure

There are no quick-connect/disconnect ports in the confinement boundary of the HI-STORM 100U system. Because the only access to the MPC is through the VVM Closure Lid, which weighs well over 10 tons, inadvertent opening of the VVM cavity is not feasible.

3.I.4.3 Lifting Devices

As required by Reg. Guide 3.61, lifting operations applicable to the VVM lid are analyzed. Because of the nature of the HI-STORM 100U system, lid placement or removal may occur with a loaded MPC inside the VVM cavity; these are the sole operations requiring analysis in accordance with Reg. Guide 3.61 and are examined in this supplement.

As discussed in Subsection 3.4.3, the lifting component itself (the four lift lugs) must meet the primary stress limits prescribed by NUREG-0612 and Regulatory Guide 3.61; the welds in the load path, near the lifting holes, are required to meet the condition that stresses remain below yield under three times the lifted load (per Reg. Guide 3.61). Further, for additional conservatism, away from the lifting location, the ASME Code limit for the Level A service condition applies.

The lifting analysis results summarized below include a 15% inertia amplifier.

HI-STORM 100U VVM Closure Lid Lifting Analysis (Load Case 05 in Table 2.I.5)

The four lifting lugs are conservatively analyzed to ANSI N14.6 stress limits using simple strength of materials calculations. Each of four lugs is considered as a cantilever beam attached to the lid and carries 25% of the lid weight. The bending moment and shear force at the root of the cantilever (where it is attached to the lid) is computed and the maximum stress is conservatively compared with the minimum of the yield strength/6 or the ultimate strength/10. As required, increasing the lid weight by 15% includes inertia effects. Using the calculated bending moment and shear force at the root of the lug, the structural evaluation of the weld attaching the lug to the lid is performed and compared with the requirements of Regulatory Guide 3.61. The results from these two calculations demonstrate that the required safety factors are substantially greater than 1.0 (exceeding the requirements of NUREG-0612 and Reg. Guide 3.61). The details of the calculations are presented in the calculation package supporting this submittal [3.I.27]. Lifting slings that attach to the lugs shall be sized to meet the safety factors set forth in ANSI B30.3.

To evaluate the global state of stress in the lid body, a finite element model of the lid, which includes contact interfaces between steel and concrete, is constructed to evaluate the state of stress under lifting conditions. Figure 3.I.1 shows the constructed ANSYS finite element model. The lifted scenario is simulated by fixing the four lifting locations at the lift lug sling attachment location, and applying an appropriate weight density to match the lifted weight. The results are evaluated for satisfaction of normal condition (ASME Level A) limits at the appropriate locations.

The table below summarizes key results obtained from the lifting analyses for the HI-STORM 100U VVM Closure Lid for a bounding set of input design loads.

HI-STORM 100U VVM Lid Lifting Analyses (Load Case 05 in Table 2.I.5)			
Item	Calculated Value	Allowable	Safety Factor
Bending of Lift Lugs (kip)(ANSI N14.6)	4.000	5.275	1.32 (see Note 1)
Shear in Lift Lugs (kip)(ANSI N14.6)	1.609	3.165	1.97 (see Note 1)
Load in Welds Near Lifting Lugs (kip) (Reg. Guide 3.61)	5.657	6.33	1.12 (see Note 2)
Primary Stress in Lid (ksi)(ASME Level A Limit)	< 10	26.25	> 2.63
Note 1: Computed safety factors represent the margin over that required by NUREG-0612 (0.1 x ultimate load).			
Note 2: Computed safety factor is based on 60% of yield strength for base metal and represents margin over limit set by Reg. Guide 3.61.			

It is concluded that all structural integrity requirements are met during a lift of the HI-STORM 100U VVM Closure Lid. All factors of safety, using applicable criteria from the ASME Code Section III, Subsection NF for Class 3 plate and shell supports, from USNRC Regulatory Guide 3.61, and from NUREG-0612, are greater than 1.0.

3.I.4.4 Heat

i. Summary of Pressures and Temperatures

Tables 2.I.1 and 2.I.2 present applicable design inputs for the HI-STORM 100U VVM. No new inputs are required for the HI-TRAC and the MPC.

ii. Differential Thermal Expansion

All clearances between the MPC and the HI-STORM 100U VVM are equal to or larger than the corresponding clearances in the aboveground HI-STORM 100 systems (see Section 4.4). Therefore, no interferences between the MPC and the VVM will occur due to thermal expansion of the loaded MPC. The Divider Shell is insulated on one surface and is exposed to heated air on the other shell surface. Therefore, an analysis to demonstrate that free axial thermal expansion of the Divider Shell will not close the initial gap between the top end of the Divider Shell and the base of the Closure Lid is provided. The Divider Shell is considered as a heated member, subject to an average temperature increase over its entire length. The actual axial absolute temperature profile can be integrated over the length of the Divider Shell to define the average absolute temperature. Once the average absolute temperature is known, the free thermal growth is computed and compared with the provided gap between the Divider Shell and the Closure Lid.

The average temperature rise above ambient is bounded by DT (ambient is 80°F per Table 2.I.1,

and average metal temperature over the length of the Divider Shell is from Table 4.I.3, footnote):

$$DT = (300^{\circ}\text{F} - 80^{\circ}\text{F}) = 220^{\circ}\text{F}$$

From Table 3.I.3 (a), a bounding coefficient of thermal expansion, appropriate to DT, is:

$$\alpha = 6.27 \times 10^{-6} \text{ in./in.} \cdot ^{\circ}\text{F}$$

The nominal length of the divider shell is:

$$L = 221.5625''$$

Therefore, the free thermal expansion, based on the nominal length is $\alpha \times L \times DT$, and is computed and compared against the nominal gap provided (as shown in the licensing drawing).

Key Result from Free Thermal Growth Analysis of Divider Shell

Item	Bounding Value	Allowable Value*	Safety Factor
Thermal Growth (inch)	< 0.4	0.5	>1.25 (against contact)
*This is the nominal gap provided between the top end of the Divider Shell and the Closure Lid Surface (see Dwg. 4501, sheet 4 in Subsection 1.I.5).			

iii. Stress Calculations – VVM Components

a. HI-STORM 100U VVM Stresses Under Transporter Loading and Substrate Overburden (Load Case 07 in Table 2.I.5)

During HI-STORM 100U system loading, a HI-TRAC transfer cask with a fully loaded MPC is placed over a HI-STORM 100U VVM using a specially designed transporter and a lifting device meeting “single-failure proof” requirements, as applicable. The transfer cask is connected to the CEC using an ancillary mating device (see Figure 3.I.4). Although a handling accident is not credible, the CEC must possess the capacity to support any transporter loads imposed at and below the substrate surface during the short time when the transporter is positioned over a VVM cavity and carrying the weight of the loaded HI-TRAC (i.e., before the HI-TRAC is placed on the mating device). This loading condition leads to a maximum sub-surface lateral pressure on the CEC shell which may potentially cause its ovalization. This configuration also includes the loaded transporter traveling over a previously loaded VVM on its way to an empty CEC.

Table 3.I.1 gives the essential data on the representative transporter including its loaded weight and its track length and width (i.e., size of the load patch (Figure 3.I.5)). The average normal pressure, at the transporter track and TSP interface is computed by dividing the weight of the loaded transporter by the total area of the two load patches.

To determine the stress and displacement field in the CEC due to the combined action of the loaded transporter and the soil overburden, a 3-D ANSYS model of a VVM (see Figure 3.I.2) is prepared.

The finite element model has the following attributes:

- The soil is modeled as an elastic continuum with properties specified in Tables 2.I.2 and 3.I.5. The VVM Interface Pad (VIP), which is separated from the Top Surface Pad (TSP) by a construction joint, is unaffected by the deflection of the TSP under the transporter weight. The VIP essentially is a dead weight on the soil column below and is appropriately incorporated in the model. To appropriately model the VIP within the confines of a linearly elastic construct, it is represented by a material with a very low Young's Modulus, but the correct weight density. This modeling assumption provides the appropriate weight on the substrate from the VIP but provides no additional strength to the TSP or to the CEC.
- The minimum CEC pitch from the licensing drawing is used.
- The TSP, shown in the licensing drawings, is represented by its appropriate elastic properties (Table 3.I.4).
- The soil mass surrounding the ISFSI is assumed to be constrained from expansion across the planes of symmetry (so as to maximize the Poisson compression load on the CEC). The bottom of the soil continuum extends to the SFP.
- The CEC shell is assumed to have its nominal un-corroded thickness; the stress and strain results are subsequently adjusted to reflect the postulated corrosion allowance (see Table 2.I.1).
- To linearize the problem, the soil is assumed to be bonded to all interfacing surfaces.

Table 3.I.10 provides the input data used in the analysis.

The results of the stress analysis are pictorially shown in Figure 3.I.11, where stress intensity in the CEC is plotted. As can be seen from the figure, the maximum primary stress intensity value is 1,390 psi based on the nominal shell thickness of 1 in. Accounting for the corrosion allowance in the CEC shell, the maximum stress intensity (essentially bending in nature) is appropriately adjusted to 1,816 psi $((1 \text{ in}/0.875 \text{ in})^2 \times 1390 \text{ psi})$. When compared with the Level A stress limit from ASME code Section III, Subsection NF (per Table 2.I.5), the maximum computed stress intensity provides a factor of safety:

$$SF = \frac{\text{allowable}}{\text{actual}} = \frac{26.25}{1.82} = 14.4$$

Because the stresses in the CEC shell remain elastic, no reduction in the diametrical opening of the CEC due to plastic deformation is indicated. Therefore, the retrievability of the MPC is assured.

b. HI-STORM 100U Lid Integrity Evaluation for Normal plus Explosion Loads, CEC Container Shell Evaluation Under Bounding Vertical Load (Load Case 02 in Table 2.I.5), and Design Basis Fire (Load Case 06 in Table 2.I.5)

The VVM Closure Lid rests on the CEC and resists vertical loads, arising from dead weight, and from induced loadings from explosions, from seismic accelerations, and from tornado missile impact. In this subsection, the analysis considers only the normal loading condition plus the steady pressure bounding the explosion pressure (see Table 2.I.1). The finite element model shown in Figure 3.I.1 is used to obtain this solution; the Closure Lid vertical support is now all around and is provided by the CEC Container Shell Flange (instead of by the lift lugs). The stresses from the solution are compared, per the criteria in Table 2.I.5, with allowable stress values for plate and shell structures as provided in ASME Section III Code, Subsection NF. The allowable stress intensity is per Table 3.I.3 (c) for Level D conditions at a bounding temperature of 350 °F.

The vertical load on the Container Shell ring flange, which can be computed from equilibrium, does not bound the vertical load under normal conditions when the Closure Lid is removed and replaced by a loaded HI-TRAC plus a Mating Device. The bounding vertical load during the transfer operation is an input for the evaluation of the Container Shell for this load case using Strength of Materials methodology. Key results from the analysis of the Closure Lid under the normal loading condition plus the steady pressure, and the follow-on analysis of the corroded Container Shell under the bounding vertical load (during the MPC transfer operation) are summarized in the following table:

Stress Analysis of the Closure Lid and CEC Container Shell Under Bounding Vertical Load During Normal Operations (Load Case 02 in Table 2.I.5)			
Item	Bounding Value from calculations	Allowable Limit	Safety Factor
Maximum Primary Principal Stress Anywhere in Lid (ksi)	< 12.0	59.65(Level D Stress Intensity Limit) 26.25 (Level A Stress Limit)	> 4.97* > 2.19*
CEC Container Ring Flange Weld (kips)	< 300	3,018	> 10.06
Compression Stress in CEC Container Shell Under Bounding Vertical Load (ksi)	< 1.425**	17.5	> 12.28

Stress Analysis of the Closure Lid and CEC Container Shell Under Bounding Vertical Load During Normal Operations (Load Case 02 in Table 2.I.5)			
Item	Bounding Value from calculations	Allowable Limit	Safety Factor
<p>* The results from the analysis are presented in terms of principal stresses for simplicity. Safety factors are determined by comparison with the Level D stress intensity limits (Table 3.I.3(c)), or with Level A stress limits (Table 3.I.3 (b)). Regardless of the measure used, the safety factors are large.</p> <p>** The bounding compressive stress is based on a fully corroded shell thickness and also conservatively includes the full weight of the CEC in addition to the bounding load at the top.</p>			

From the above results, it is concluded that there is minimum structural demand on the HI-STORM 100U Closure Lid and CEC Container Shell during normal operation (even if the explosion pressure is conservatively considered as a normal condition).

With respect to the fire event (Load Case 06 in Table 2.I.5), where the Closure Lid steel temperature rises to the limit set in Table 2.I.5, it is noted from Tables 3.I.3 (a) and (b) that the Level A stress limit is reduced to 0.68 of the room temperature value, the yield strength is reduced to 0.66 of its room temperature value, and the ultimate strength is reduced to 0.92 of its room temperature value. From the stress values obtained in the lid (even with the explosion 10 psi surface pressure load included), it is evident that a total collapse of the lid due to reduction of the ultimate strength is not credible.

Seismic loading on the VVM is considered in Subsection 3.I.4.7 (Load Case 04 in Table 2.I.5). Subsection 3.I.4.8 considers tornado missile impact (Load Case 03 in Table 2.I.5).

iv. Stress Calculations – ISFSI Structures

The 100U ISFSI consists of plate-type reinforced concrete structures whose minimum section strength properties are defined by Table 2.I.2 and the licensing drawings. The ISFSI is supported by the subgrade underneath the SFP, which may include pilings, if required, to meet the effective stress wave velocity in Table 2.I.2. The loadings on the ISFSI are:

- a. Dead load of the VVM and the concomitant effect of settlement over the Design Life of the system. (D in Table 2.I.11). The method to incorporate the effect of long-term settlement of the subgrade underneath the SFP (may also be referred to as the undergrade), described in Subsection 2.I.2, is used. This method essentially consists of using the deflection properties of the different layers to define equivalent elastic properties of the subgrade underneath the SFP. In the finite element analysis of the SFP, the degraded elastic properties of the subgrade underneath the SFP are utilized to account for the effect of long-term settlement. The long-term settlement of the subgrade underneath the TSP and VIP is also considered in a similar manner.

The Dead load on the SFP from the weight of the loaded VVM's nearly equals the weight of the earth removed. Therefore, the long-term settlement of the SFP is expected to be quite small. Likewise, the dead load on the TSP and the VIP is relatively small (from self-weight of the pads).

The retaining wall under excavated condition (see Subsection 2.I.2) supports the soil overburden pressure (classified herein as Dead load).

- b. Live load from the loaded transporter acts directly on the TSP (see Figure 3.I.4 and 3.I.5). This load also adds to the overall load on the SFP (L in Table 2.I.11). The load from the transporter is the sole live load applicable to the ISFSI structures. For structural qualification, the loaded transporter (live load) is assumed to be situated over the centrally located cavity.
- c. Seismic load is computed using the methodology presented in Subsection 3.I.4.7. This load, denoted as E in Table 2.I.11, is the aggregate of the peak dynamic load exerted on the ISFSI less the dead weight. For conservatism, the load E is applied as a static load in the stress analysis of ISFSI structures even though it is impulsive in nature.

Paragraph 3.I.4.7.3 contains details on the stress analysis of the ISFSI structures to demonstrate ACI code compliance.

3.I.4.5 Cold

Due to its subterranean configuration, the structural components of the VVM are relatively protected from extremes in the ambient temperature in comparison to the HI-STORM 100 or 100S overpacks. Therefore, no new analyses are identified for the HI-STORM 100U system.

3.I.4.6 Flood

The buried configuration of the HI-STORM 100U system renders it immune from sliding under the action of a design basis flood. No new analyses are needed for an actual extreme environmental event.

Although the condition does not necessarily arise due to a flood, a limiting uplift scenario where the VVM CEC is in place and the surrounding substrate produces a buoyant force by unspecified means is considered. For this condition (Load Case 01 in Table 2.I.5), the limiting uplift condition determines the minimum weight that needs to be in place to prevent uplift during construction. This could be in the form of a temporary cover. The upward directed buoyant force exerted on the CEC cavity is computed assuming a weight density of water and compared with the dead weight of the CEC. Under the postulated condition, the net uplift load (Buoyant Force – Weight of CEC) can be calculated. The required temporary weight that is needed to produce a net downward force is calculated in [3.I.27] and specified in Table 2.I.5.

For the case of a loaded VVM with the Closure Lid in place, or for an empty CEC with the Closure Lid in-place, the buoyant force is less than the vertical download, so there is no uplift.

Should the full buoyant force develop from any means, a lateral pressure load is imposed on the CEC bottom plate. Conservatively assuming an empty VVM, the full buoyant force provides a pressure causing bending of the CEC Bottom Plate, which is partially restrained against rotation by the CEC shells (note that in a loaded VVM, the MPC also helps to support the Bottom Plate of the CEC as its weight causes the central shim to act as a support for the Bottom Plate of the CEC). The stress intensity resulting from CEC Bottom Plate bending is compared to the Level D allowable stress intensity. Using the solutions for maximum stress in a clamped and simply supported plate, and averaging the results from the two solutions to approximately account for the rotational restraint provided by the CEC Container Shell, gives the following bounding safety factor for stress in the bottom plate under the postulated buoyancy loading:

Allowable Stress = 66,875 psi (Table 3.I.3(c) @ 125 °F per Table 2.I.5). Safety Factor is calculated to be greater than 4.0.

3.I.4.7 Seismic Event - HI-STORM 100U (Load Case 04 in Table 2.I.5)

The HI-STORM 100U system, plus its contents, may be subject to the Design Basis Earthquake (DBE) defined by the response spectra in Figure 2.I.4. As mentioned in supplement 2.I and further explained in this subsection, the DBE has been defined for the 100U ISFSI to insure that the operative spectra (Figure 2.I.4) essentially envelope the corresponding site DBE spectra at virtually all US sites. Because the VVM is buried in the substrate, tipover of the VVM is not credible. The entire VVM can move laterally with the surrounding and supporting substrate.

Under the action of lateral seismic loads, the CEC Container Shell globally acts as a beam-like structure supported on a foundation driven by the site seismic accelerations. During a seismic event, the lateral loading on the CEC consists of:

- i) Inertia force from CEC self-weight
- ii) Inertia forces from the Closure Lid self-weight
- iii) Inertia forces from the self weight of the VIP
- iv) Interface forces from the rattling of the MPC within its confines of the CEC and the rattling of the contents inside the MPC
- v) Interface forces from the subgrade and from the SFP

The CEC Container Shell develops longitudinal stresses as it bends like a beam to resist the input seismic loads. In addition, the CEC Container Shell tends to ovalize under the loads. Both effects are captured in the seismic analysis.

The Design Basis Seismic Model (DBSM) used to perform the safety analysis of the 100U ISFSI under the Design Basis Earthquake (DBE) defined by Figure 2.I.4 is described in the following.

3.I.4.7.1 Design Basis Seismic Analysis Model

Parametric studies were performed to support the initial certification of the HI-STORM 100U

VVM. These studies defined the Design Basis Seismic Model. In particular, a non-linear dynamic model on LS-DYNA was found to produce much greater response and internal stresses than a linear analysis on SASSI. Further, a 5x5 VVM array model was standardized for dynamic analysis purposes. Accordingly, LS-DYNA is used for all required dynamic analysis of the VVM array. The DBSM consists of three discrete models, namely:

1. A VVM Array Model used to characterize the interaction of the ISFSI with the surrounding soil continuum. This is performed using a 5x5 VVM array (see Figure 3.I.3-B).
2. A VVM Array Model for the optional 100U design where retaining walls are in place (see Figure 3.I.3-C). The lateral subgrade beyond the retaining wall is assumed to be removed all the way down to the bottom of the SFP, which conservatively represents an excavation configuration.
3. A single VVM model with a detailed simulation of the internal parts of the VVM to obtain an accurate characterization of the stress/displacement field (see Figure 3.I.3-D).

The seismic analysis consists of three discrete steps, namely:

- A. Soil-structure model development.
- B. Use of the VVM Array Model to determine the bounding dynamic loads applied to the ISFSI Structures.
- C. Use of the Single VVM Model to compute stresses in the VVM Components.

A. Soil-Structure Model Development

- i. Based on the lower bound shear wave velocity profile of US nuclear power plants (Figure 2.I.6), a two-step earthquake response analysis using the computer code SHAKE2000 and LS-DYNA is performed to establish a bounding seismic loading condition for the 100U underground fuel storage system. The Design Basis Earthquake for the HI-STORM 100U system thus obtained is defined by the seismic response spectra at both the ground surface and the ISFSI foundation surface elevations as shown in Figure 2.I.4. The input seismic acceleration time history used in the first step (SHAKE) analysis is derived from the Regulatory Guide 1.60 seismic response spectrum and designated as the rock outcrop motion. The input acceleration time history is scaled to yield ground surface ZPAs (at the top of grade elevation) specified in Table 2.I.2. The 1-D SHAKE analysis model consists of 21 native soil layers of the 100U ISFSI site with a total thickness of 101 ft; the top of the 6th soil layer is aligned with the bottom of the SFP. The total soil depth of the SSI Model is about five times the height of the underground ISFSI (Due to the limitation of the linear code, a further increase of the soil depth in the SHAKE model leads to questionable seismic response results in the case of a strong seismic motion and weak soil properties). The averaged strain compatible shear wave velocity is 450 ft/s for the soil layers above the SFP and is 485 ft/s for the layers below the SFP, which has been set as the lower-bound soil design data in Table 2.I.2 for a candidate 100U ISFSI site. The finite

element soil model in the second step (LS-DYNA seismic response analysis) uses the average strain-compatible wave velocities obtained from the SHAKE analysis to represent the soil layers above and below the SFP elevation. The acceleration time history at the soil column bottom surface, also obtained from the SHAKE analysis in the first step, is used as the input seismic motion for the LS-DYNA seismic response analysis. The response spectrum plots shown in Figure 2.I.4 are the results of the LS-DYNA seismic response analysis.

Figure 3.I.3-A shows the LS-DYNA soil model for the seismic response analysis. Note that the lateral dimension of the ISFSI soil model is significantly greater than that of the ISFSI. The periphery nodes of the soil model space at the same elevation are constrained to move together to simulate the seismic response of the semi-infinite space of soil. According to the numerical study on various lateral boundary conditions of the finite element soil model [2.I.10], this lateral boundary condition, also known as a “slave boundary condition”, is appropriate to predict the soil response in a seismic event. The same soil model and input seismic motion used in the LS-DYNA seismic response analysis will be used for the LS-DYNA soil-structure interaction analysis for the 100U ISFSI loaded with VVMs. The boundaries of the soil model are sufficiently away from the ISFSI pads to ensure that structural response of the ISFSI will not be significantly affected.

- ii. The spectra in Figure 2.I.4 define the seismic input against which the spectra at a candidate ISFSI site should be compared to determine whether the generic analysis in this FSAR is bounding or additional site specific analysis set down per sub-section 2.I.6 are required.
- iii. Consistent with the sketch in Figure 2.I.5, the 100U soil-structure LS-DYNA model consists of loaded VVMs, concrete pads, and soil spaces with properties as defined in Tables 2.I.2 and 3.I.4. The ISFSI model is developed based on a 5×5 VVM configuration, which has previously been approved under LAR 1014-6 and is considered to be appropriate for capturing the effect of the ISFSI size on the structural analysis results. Depending on the purpose of the analysis, the 100U soil-structure model may include 5x5 fully loaded VVMs or just one loaded VVM. Similarly, a loaded Vertical Cask Transporter (VCT) may be considered in the model to obtain the bounding load applied to the TSP and to demonstrate the seismic stability of the loaded VCT. For the optional ISFSI design including a retaining wall, the soil-structure model is developed based on the governing configuration where the subgrade outside the retaining wall is excavated all the way to the depth of the SFP elevation. Therefore, a total of three 100U soil-structure LS-DYNA models (see Figures 3.I.3-B to 3.I.3-D) are developed to perform the design basis earthquake analysis.
- iv. The corrosion of the CEC is considered by using a reduced thickness (i.e., 1/8” thinner than the nominal thickness) in the soil-structure LS-DYNA models.
- v. Proper element size and time step controls in the dynamic model are implemented

following the guidance in references [3.I.28] and [3.I.29].

B. VVM Array Model

The object of the VVM Array model is to obtain conservative values of the loads on the ISFSI structures under the Design Basis Earthquake (Figure 2.I.4). The VVM Array model has the following essential attributes:

- i. The MPC is represented by a solid rigid cylinder of mass equal to its total mass. This means that all internal masses will move in unison and the inertia forces of the MPC are maximized, which will conservatively result in greater impact loads applied to MPC guides and the CEC base plate.
- ii. The Divider Shell and the CEC shell are modeled as elastic shells but the Closure Lid and the Lid Ring are simulated as rigid bodies. Note that the combination of elastic shells and rigid lid ring used in the finite element model has little effect on the load path between the Divider Shell and the CEC flange during the seismic event.
- iii. The ISFSI pads (i.e., TSP, SFP, etc.) are simulated as a flexible plate-type structure, as is the retaining wall, if used. The retaining wall is added to the finite element model in the optional ISFSI design case (see Table 3.I.6).
- iv. The SFP is fully loaded with a 5×5 VVM array.
- v. A loaded VCT is assumed to be located at the center of the fully populated ISFSI except for the case with retaining walls. The VCT, along with the carried transfer cask, is modeled as a freestanding rigid body.
- vi. The elastic material model is used for all ISFSI concrete structures except for the TSP, which is characterized by an inelastic concrete model to account for energy dissipation in the concrete due to the impact loading from the loaded VCT. For the case where cracking of the concrete needs to be considered, the Young's Modulus of the SFP is reduced to 50% of its nominal value per the guidance in Section 3.4 of [3.I.29].

C. Single VVM Model

The Single VVM model is used to perform the safety evaluation of the VVM components and the stored MPC under the Design Basis Earthquake. The applicable acceptance criteria are provided in Table 2.I.6. To conservatively evaluate the structural integrity of the VVM components, the Young's Modulus for the SFP is assumed to be equal to 50% of its nominal value. This is prompted by the results of VVM Array Model runs (see Table 3.I.7), which indicate that the VVM Components experience amplified responses if the reduced modulus is used for the SFP.

The Single VVM model complies with the provisions set forth in the following:

- i. The SFP is loaded with only one VVM at the edge of the SFP. A loaded VCT, modeled as a freestanding rigid body, is conservatively assumed to be located above the center of the loaded VVM.

- ii. The Cavity Enclosure Container (CEC) is discretized by an appropriate finite element grid to simulate its Container Shell and Bottom Plate, the Divider Shell, and the MPC guides in an explicit manner. The true stress-strain relationship of the material is used to obtain the realistic deformation of these structural members.
- iii. The MPC shell, baseplate, and top lid are modeled using sufficient element discretization so that the peak primary stresses of the MPC components under the seismic loading condition can be captured for structural evaluation.
- iv. The fuel basket is modeled with thin shell finite elements arrayed to simulate inter-cell connectivity in an explicit manner.
- v. Nominal small gaps between the fuel basket and the MPC are explicitly modeled, as is the nominal gap between the MPC and the CEC at the upper and lower MPC guide locations.
- vi. Each fuel assembly is represented by an equivalent homogeneous, isotropic prismatic beam of an equivalent elastic modulus whose fundamental lateral natural frequency accords with that of the actual fuel assembly. A bounding fuel assembly weight is used and the fuel basket is assumed to be fully populated with fuel assemblies.
- vii. The seismic responses of MPC structural components are simulated using the elastic material model so that the stress results can be directly compared with the corresponding ASME NB stress limits.

3.I.4.7.2 Qualification of VVM Components

The CEC Components and parts of the MPC subject to significant loadings during the DBE event are:

- a. CEC shell and Divider Shell (subject to ovalization)
- b. MPC shell (bending of the shell as a beam, resulting in axial membrane stress in the shell)
- c. MPC top and bottom guides
- d. Lateral loading on the fuel basket panels.
- e. Localized strain in the MPC shell (due to impact of the MPC with the MPC guides attached to the Divider Shell)

The safety analysis of each component under the DBE event is summarized below:

- a. CEC shell and Divider Shell: Maximum radial deformation of the two shells is tracked for the single VVM simulation scenario in Table 3.I.6. The ratio of the original ovalization to the actual ovalization gives the safety factor:

$$\begin{aligned}
 \text{Safety Factor} &= \frac{\text{Permissible radial displacement}}{\text{Maximum computed radial displacement from Figure 3.I.23}} \\
 &= \frac{2.5''}{0.1325''} = 18.86
 \end{aligned}$$

- b. Primary stress in the MPC shell: The maximum stress intensity in the MPC shell is computed under the single VVM simulation scenario. The allowable stress intensity for this case corresponds to the Level D condition. The safety factor is computed as:

$$\begin{aligned} \text{Safety Factor} &= \frac{\text{Level D allowable Stress Intensity from Table 3.I.3(d)}}{\text{Maximum computed primary Stress Intensity from Figure 3.I.24}} \\ &= \frac{42,000 \text{ psi}}{12,860 \text{ psi}} = 3.26 \end{aligned}$$

- c. Top and Bottom MPC Guides: The maximum lateral load bearing capacity of the top and bottom plate guides is computed in Supplement 4 of Reference [3.I.27]. The maximum dynamic impact loads from the single VVM model can be extracted from the impact load time history results shown in Figure 3.I.25. The safety factor is calculated as:

$$\begin{aligned} \text{Safety Factor} &= \frac{\text{MPC Guides Lateral Load Bearing Capacity}}{\text{Maximum MPC to MPC Guides Contact Force}} \\ &= \frac{4.41 \times 10^5 \text{ lb}}{108,826 \text{ lb}} = 4.05 \end{aligned}$$

For the tubular MPC top guide design, the MPC impact analysis documented in Supplement 11 of Reference [3.I.27] demonstrates that the tube guide would not experience any global plastic deformation under the Design Basis Earthquake condition. This means that there is no risk of progressive flattening of the guide tubes from repetitive impacts during the seismic event.

- d. Loading on the Fuel Basket panel: The fuel basket panels are qualified to withstand 45 g's of lateral acceleration (during the non-mechanistic tip-over event). The maximum fuel g-load predicted by the LS-DYNA simulation is 2.5 g's as shown in Figure 3.I.26. The factor of safety, therefore, will be equal to the ratio of the two. Hence,

$$\text{Safety Factor} = \frac{45}{2.5} = 18$$

- e. Maximum Local Strain in the Confinement Boundary in the Impact Region:

The small clearance between the MPC and the MPC guides can lead to a high localized strain in the region of the shell where the impact from rattling of the canister under a seismic event occurs. The extent of local strain from impact is minimized by locating

the MPC guide in the vertical direction such that the mid-height of the impact footprint is aligned with the bottom surface of the closure lid. Thus the location of impact is removed from the lid-to-shell weld junction. It is necessary to insure that the maximum value of the local (true) strain in the shell (confinement boundary) region of impact is well below the failure strain. For this purpose, the recommendation in [3.I.31] is used. The methodology for computing the local strain is presented in the following and applied to the seismic problem analyzed in this subsection.

A finite element model of the MPC suitable for implementation in LS-DYNA is prepared with special emphasis on the top region of the canister where a very fine grid is employed. All elements have elasto-plastic and large strain capability. The solid elements in the lid and the lid-to-shell weld are of type 2 (fully integrated) and those in the shell are type 16 (fully integrated). The integration across the shell wall employs the maximum number of points available in LS-DYNA (10 points). A mesh sensitivity study has been performed using a finer grid size for the MPC shell to verify that the results are converged.

The MPC contents, namely the fuel basket and the SNF, are modeled exactly as set forth in the DBSM in the foregoing (articles (iii.), (iv.), and (v.) in Subsection 3.I.4.7.1 C Single VVM Model). To define a conservative scenario of MPC/MPC guide impact, the velocity time history of the top of the MPC is surveyed from the dynamic analysis of the VVM using the DBSM. The maximum velocity thus obtained is assumed to exist as the initial condition in the LS-DYNA simulation. This assumption is most conservative because it assumes that the cyclic motion transmitted by the earthquake does not detract from the canister's momentum before impact occurs (observations show that the canister slows down by the earthquake's cyclic energy input, thus significantly lessening the severity of the impact). In addition, the MPC guide is fixed at its base, which conservatively ignores the deformation of the divider shell and therefore maximizes the impact. The finite element model is shown in Figure 3.I.12. To implement the above model, the search for the maximum velocity in the dynamic solution yielded less than 24.7 in/sec as shown in Figure 3.I.27. Applying an initial velocity of 26.0 in/sec as the initial condition to the above model provided the strain field shown in Figure 3.I.13 for the tubular guide design. The impact between the MPC and the MPC top guides results in an MPC shell maximum plastic (true) strain of less than 1.52×10^{-2} in/in for the tubular guide design and 3.1×10^{-2} in/in for the optional plate guide design (see Calculation 11 of [3.I.27]), respectively, which are only a small fraction of the acceptable value (0.1) per [3.I.31]. Therefore the integrity of the confinement boundary is assured.

3.I.4.7.3 Strength Qualification of the ISFSI Structure

Under the Design Basis Earthquake (Figure 2.I.4), the loads exerted on the Support Foundation Pad and the Top Surface Pad (as illustrated in Figure 3.I.4) are obtained from the LS-DYNA SSI simulations listed in Table 3.I.6. Table 3.I.7 lists the peak ISFSI interface loads obtained from

various LS-DYNA runs listed in Table 3.I.6. In order to incorporate an additional margin of safety in the ISFSI structural analysis, the structural evaluation of ISFSI components uses input loads (see Table 3.I.8) that bound the peak ISFSI interface loads from the LS-DYNA SSI simulations in Table 3.I.7. The use of the bounding loads is in keeping with a similarly bounding value of settlement specified for the strength analysis of the SFP and the TSP (see Table 2.I.2).

The SFP and TSP shall meet the minimum structural requirements set down in Table 2.I.2 and the licensing drawings. The SFP and TSP are required to satisfy ACI-318 (2005) strength limits under all applicable load combinations (Table 2.I.11).

Likewise, the retaining wall, if used, shall meet the minimum concrete and rebar requirements provided in Table 2.I.2 and the licensing drawings. The site specific design may utilize a thicker and more heavily reinforced wall, if necessary, at user's option.

Table 3.I.8 provides the loading data used in the strength analysis of the ISFSI structures. The following discrete analyses are required:

- (i) Compute the long-term settlement of the undergrade supporting the SFP assuming all VVM locations are loaded for the entire Design Life: Determine the “effective” elastic modulus of the subgrade under the SFP to simulate the effect of differential settlement in the structural analyses model. As discussed in Section 2.I.4, the long-term settlement of the undergrade from the loaded VVMs and the dead weight of the SFP is very small because the combined equivalent density of the loaded VVM's and the SFP is nearly equal to the density of the excavated subgrade.
- (ii) Compute the long-term settlement of the subgrade under the TSP/VIP relative to the SFP from subgrade weight in addition to the dead weight of the TSP and VIP. Determine the “effective” elastic modulus of the subgrade between the TSP/VIP and the SFP to simulate the effect of long term differential settlement in the structural analyses model. As discussed in Section 2.I.4, the long-term settlement of the well conditioned subgrade under the TSP is appreciably small because of the small long-term loadings acting on the TSP.
- (iii) Prepare a finite element model of the pads in ANSYS and determine the stress field under the factored Dead and Live loads with the settlement based “degraded” elastic moduli for the soil regions directly beneath the TSP and SFP (Spaces A and C in Figure 2.I.5). For the lateral subgrade adjacent to the HI-STORM 100U ISFSI (Spaces B and D in Figure 2.I.5), the dynamic (strain compatible) elastic moduli from Table 3.I.4 are conservatively used as input to maximize the flexural moments due to differential settlement.
- (iv) Compute the stress field in the pads under factored seismic loads using dynamic elastic modulus corresponding to the minimum shear wave velocity of the subgrade specified in Table 2.I.2.
- (v) Use the bounding loads listed in Table 3.I.8 to compute the stress fields in the pads (SFP and TSP) from the DBE.
- (vi) Combine the factored loads and determine the total stress resultants. Compare with the respective section strengths to establish the factors of safety for the SFP and TSP.

- (vii) Compute the bearing stress (or load) on the subgrade under the TSP using the combined factored loads from the transporter and the TSP/VIP and compare with the corresponding allowable limit to establish the safety factor for the subgrade under the TSP.

A comprehensive summary of the analyses and the associated margins of safety are discussed below:

The structural evaluation of the HI-STORM 100U ISFSI is performed using the commercial computer code ANSYS [3.I.33]. The constituents of the ISFSI namely the Support Foundation Pad (SFP), the subgrade under the SFP (the undergrade), the Top Surface Pad (TSP) and the subgrade lateral to the CEC under the TSP are all modeled using linear elastic SOLID45 elements. The VVM interface pad (VIP), which carries no load except for its self-weight, is conservatively omitted in the model. The lateral subgrade adjacent to the HI-STORM 100U ISFSI (Spaces B and D in Figure 2.I.5) is included in the FE model and extends laterally a distance that exceeds the overall depth of the FE model considered for structural analysis. The element mesh is intentionally kept fine in the areas of load application on the SFP and the TSP. For convenience of load application, the footprint of the CEC base on the SFP is carefully articulated in the finite element model. The substrate under the SFP is terminated at approximately 101 ft below the TSP, which is consistent with the Design Basis Seismic Model discussed in Subsection 3.I.4.7.1. The “base” model (Simulation Model I) considers that all the storage locations in ISFSI are populated and experience identical peak vertical seismic loading from Table 3.I.8, which bounds the peak result obtained from the LS-DYNA SSI solution as discussed previously. Because of the symmetric geometry and loading, a quarter symmetric finite element model is sufficient to represent the fully loaded ISFSI. Figure 3.I.14 shows the finite element model of HI-STORM 100U ISFSI. For a non-symmetric model as in case of Simulation Model II, a full FE model of the HI-STORM 100U ISFSI as shown in Figure 3.I.15 is used. The “degraded” elastic moduli of the subgrade under the SFP and the subgrade between the TSP and SFP is appropriately computed to account for the long-term differential settlement effects as described in Subsection 2.I.4. The long-term settlement and the “effective” subgrade elastic moduli are derived using the governing soil characteristics following guidelines from [2.I.6]. Table 3.I.5 lists the bounding subgrade characteristics and the concomitant elastic moduli effective under dynamic loading. To address different loading patterns on the ISFSI and for completeness, additional partially loaded ISFSI configurations are considered in the evaluations. The partial loaded configurations include a two row loaded ISFSI (two rows of VVM locations adjacent to the symmetry line are loaded), a single row loaded ISFSI (the middle row of VVM locations is loaded) and a single VVM loaded ISFSI (a single VVM location centered near the periphery of the ISFSI is loaded). Figures 3.I.19, 3.I.20 and 3.I.21 illustrate the partial loading configurations for the ISFSI. These loading configurations are hereinafter referred to as Simulation Models II, III, and IV, respectively. Note that the terms “Loading Configuration” and “Simulation Model” are intermittently referred throughout the calculation. For Simulation Models I through IV, the optional retaining walls are not included in the finite element model.

The effects of the retaining wall are evaluated in a fifth Simulation Model (Simulation Model V), which is shown in Figure 3.I.16. In this model, the lateral subgrade surrounding the retaining walls is completely removed to bound any future excavation activities associated with the construction

of a new underground ISFSI, and for consistency with the LS-DYNA SSI simulation model (see Figure 3.I.3-C). For Simulation Model V, the middle row of VVM locations is loaded similar to Simulation Model III (see Figure 3.I.22) which excludes the transporter load as discussed previously.

To simulate the material continuity at the extreme boundary surfaces of the model, translations are constrained at the lateral face of the subgrade. The extreme bottom surface of the model is fixed representing the bedrock (or competent soil) elevation.

The following individual load steps are considered in the analysis:

1. Bounding load transmitted by the VVM, as determined from the LS-DYNA SSI analysis and summarized in Table 3.I.8, is applied as an effective pressure on the footprints of the CEC base at all VVM locations.
2. The load from the transporter is applied as a normal pressure (see Figures 3.I.17, 3.I.19 3.I.20 and 3.I.21) over the transporter load patch on the TSP. For Simulation Model V, the transporter load is not applied to the TSP since no VVM loading/unloading operations are expected to occur during excavation activities associated with the construction on a new underground ISFSI.
3. The dead weight from VIP is applied as normal pressures on the substrate elements directly beneath the VIP.
4. In-plane tensile loads on the SFP and TSP from the retaining wall are applied as lateral pressures on the SFP and TSP boundaries for Simulation Model V.
5. To simulate the self weight of the modeled portion of the ISFSI, a 1g gravity load is applied. The densities of the various constituents are appropriately input in the model to accurately reflect the individual component weights.

It must be noted that the structural analysis of the ISFSI conservatively considers the peak dynamic loads from the LS-DYNA SSI analysis. However, it shall be permitted to use equivalent static loads obtained by removing high frequency components that would not contribute to the structural response using appropriate filters.

Since the peak loads from the LS-DYNA SSI analyses are substantially larger in comparison to the dead and live loads, the load combination LC-3 from Table 2.I.11 governs for the ISFSI structural evaluation. However, the analyses are carried out for load combinations LC-2 and LC-3, and the corresponding results substantiate that the load combination LC-3 is governing.

Figures 3.I.18a through 3.I.22c depict the maximum in-plane stresses in the ISFSI concrete structures (viz. SFP and TSP) for the governing load combination LC-3 for all the ISFSI configurations analyzed. The in-plane axial and bending stress on the SFP and the TSP elements are post-processed to compute the equivalent moments. The induced moments are compared to the respective moment capacities to determine the corresponding factor of safety. Table 3.I.10 summarizes the results for the SFP and the TSP respectively for all ISFSI configurations analyzed.

The minimum flexure safety factor is produced by Simulation Model IV, and it is associated with the TSP. In the Simulation Models I, II, III and IV, the peak load from the LS-DYNA SSI analysis acting on one transporter track (bearing on the TSP) is conservatively applied as a static load on both transporter tracks simultaneously, thereby significantly overestimating the load on the TSP. As mentioned previously, the peak dynamic loads obtained from the LS-DYNA SSI analyses from a DBE event are of impulsive nature. Use of the peak loads for static structural evaluations of the ISFSI is evidently conservative. Furthermore, no credit is taken for the Dynamic Increase Factor of 25% for flexure and 10% for shear permitted by [3.I.32] in the strength qualification of reinforced concrete.

The Table 3.I.11 summarizes the punching shear safety factor for the SFP and TSP. The minimum punching shear safety factor is associated with the TSP under the transporter seismic load, and it is well above 1.0.

The peak transporter load on the TSP from the LS-DYNA SSI analyses plus the load from the TSP are used to compute the maximum bearing stress in the substrate surface under the TSP. According to ACI-360 [2.I.8], the bearing stress can be calculated by uniformly distributing the load over the entire bearing area of the pad. For conservatism, the bearing stress calculation for the 100U subgrade is performed using a bearing area significantly less than that of the smallest TSP (i.e., the TSP of one-VVM ISFSI). The maximum bearing stress in the sub-grade (Table 3.I.12) is smaller than the presumptive bearing stress limit, resulting in minimum safety factor above 2.0 imposed by the ACI code [2.I.8].

The evaluation of the CEC shell under the loads from the transporter load in addition to the subgrade overburden is presented in Subsection 3.I.4.4.

Finally, the structural integrity of the retaining wall is evaluated for the Design Basis Earthquake loading condition; the structural demand to the wall under normal operational conditions is small and therefore not structurally governing. Since the retaining wall is connected with the TSP and SFP through a shear key at the top and dowels at the bottom (see licensing drawing in Section 1.I.5), it can be treated as a simply supported plate (along its top and bottom edges) in the structural analysis. Therefore, the wall essentially experiences bending stress in the DBE event due to lateral soil pressure. The maximum bending moment of the retaining wall, which can be determined based on Figure 3.5-1 of Reference [3.I.28] or based on the retaining wall stress results obtained from the LS-DYNA SSI analysis for Case 3 in Table 3.I.6 (both approaches yield approximately the same result), is shown in Table 3.I.10 to be well below the bending capacity of the wall. The shear connections at the top and bottom of the retaining wall have also been evaluated for the loads induced during a Design Basis Earthquake. The results of the strength evaluation are provided in Table 3.I.13.

3.I.4.8 Tornado Missile Evaluation

3.I.4.8.1 HI-STORM 100U Lid Integrity Evaluation for Tornado Missile Strike (Load Case 03 in Table 2.I.5)

Design basis tornado missiles are specified in Table 2.2.5. The Closure Lid is the only above ground component of the VVM; therefore, missile impact analyses focus on this component. Large and intermediate tornado missiles are assumed to strike the center top surface of the lid at the design basis speed (see Table 2.2.5). For both missile analyses, a finite element model of the Closure Lid is employed (using dimensions from licensing drawings and applicable material properties), and includes contact between concrete and steel (see Figure 3.I.1). LS-DYNA is used to perform dynamic simulations of the impacts to demonstrate that neither missile completely penetrates the composite structure. The ANSYS model shown in Figure 3.I.1 is simplified to develop an input file for the LS-DYNA simulation. Elastic-Plastic Material 24 is used for the steel and Material 72 is used for the concrete. For a conservative result, engineering stress relations for the lid steel work are used with an assumed ultimate strain of 21% (per ASME Code, Sec. II, Part A). As LS-DYNA expects that true stress-strain data is input, the use of true stress-strain data, to obtain a more realistic result, is permitted (if appropriate justification is provided for the true stress-strain relation). The solution obtained using engineering stress strain data is clearly conservative in that material failure is set at the engineering ultimate strain limit rather than reflecting the true strain at failure, which will be considerably larger. A strain rate effect is incorporated by increasing the yield and ultimate strengths by a maximum of 50% (depending on the rate) as suggested by data for SA-36 steel [3.I.19]. This is the same strain rate increase used in the evaluations to assess the performance of the aboveground HI-STORM when impacted by a jet fighter aircraft [3.I.16]. A time history normal pressure loading is applied over the metal annular region around the outlet opening to simulate the large missile, and the global deformation damage to the lid is assessed. The formula from “Topical Report – Design of Structures for Missile Impact”, BC-TOP-9A, Rev. 2, 9/74 [3.I.17] is used to establish appropriate pressure-time data. For the speed and mass associated with the large missile, the impact force-time curve has the form

$$F(t) = 0.625 \text{ sec/ft} \times 184.8 \text{ ft/sec} \times 4000 \text{ lb} \times \sin(20t) = 462,000 \text{ lb} \times \sin(20t) \text{ for } t < 0.0785 \text{ sec.} \\ = 0 \text{ for } t \geq 0.0785 \text{ sec.}$$

This representation of the large missile impact load is appropriate as recent full-scale impact testing of a modern passenger vehicle demonstrates. Figure 3.I.6 shows the force-time history from the full-scale test of a full-size Ford passenger vehicle [3.I.18]. The test was performed at an impact speed of 35 mph and the vehicle had approximately the same weight as the design basis large deformable missile. Since the force is directly proportional to the pre-impact momentum, an estimate of the peak force at 126 mph for the vehicle is obtained by a simple ratio of the impact velocities and missile mass. Estimating the peak value from the plot produces a resulting peak force of 496,000 lb, which is the same order of magnitude as the peak value predicted from the Bechtel Topical Report, although the shape and duration of the curve is different. The results from the analysis using the load-time function from the Bechtel formula show no significant lid damage from the large missile strike on the lid because of the concrete backing. Inspection of the result concludes that the deformed shape after the event does not preclude lid removal, the lid remains in-place, and the MPC has not been impacted. The maximum lid vertical deflection during the strike is less than 0.1 inch and there are a few local regions of permanent effective plastic strain. The details of this calculation are found in [3.I.27]. The large missile impact is not the bounding strike because of the large area of impact and significant energy loss that occurs when the vehicle

is crushed upon impact; the rigid, intermediate missile imparts more local and global damage to the Closure Lid.

The impact of the intermediate missile is conservatively simulated as a rigid 8" diameter cylindrical steel bar weighing 275 lb. (per Table 2.2.5), traveling at 126 mph and striking the Closure Lid at the most vulnerable location, which is through the top vent opening. The strike can be either at the center of the inner shield dome or slightly off-center so as to miss the central steel connecting bar. In order to strike the MPC top lid, the intermediate missile must penetrate the steel weldment and encased concrete (see licensing drawings in Section 1.I.5). Figures 3.I.7 and 3.I.8 show the intermediate impact scenarios considered. Figures 3.I.9 and 3.I.10 show the lid state at the time of maximum bottom plate vertical displacement. For both cases, no dislodgement of the lid is indicated and plastic strains occur only in the immediate vicinity of the strike. A summary of results that bound the computed results for the two intermediate missile strikes is presented in Table 3.I.9.

Next, consider that the intermediate or large missile is traveling horizontally and strikes the side of the Closure Lid. A large missile strike at this location with a horizontal orientation is most likely not credible because of the low profile of the lid. The large missile would rotate as it broke up, resulting only in a glancing blow to the lid. However, an evaluation of the Closure Lid flange ring in either missile side strike is needed to ensure that the Closure Lid will not be driven sideways under the impact and separate from the CEC. A key structural element is the weld connecting the Closure Lid restraint ring to the Closure Lid. The capacity of the welds in the load path that resist the lateral impact load is:

Closure Lid Weld Capacity = 8,381,000 lb.

This capacity is computed assuming a limiting weld stress of 60% of the ultimate tensile strength of the base material. In any of the evaluated missile strikes from above, the peak impact load (filtered at 350 Hz (see similar filtering in the HI-STAR 100 transport license)) does not exceed 1,200,000 lb. Interface loads from top impacts are expected to bound impact loads from side impacts because of the geometry involved; therefore, the safety factor on the CEC Container Shell flange ring, acting to hold the lid in-place, is:

$SF (\text{flange ring}) = \text{Closure Lid Weld Capacity} / \text{Filtered Peak Impact Load} > 6.9$

Finally, a small missile entering the outlet duct will not damage the MPC because there is no direct line-of-sight to the MPC, and even if it arrives at the MPC, it will have undergone multiple impacts with the duct walls, and can only impact the thick MPC lid. Therefore, MPC damage from the small missile is not credible.

An assessment of all simulation results concludes that the postulated missile strikes will not preclude MPC retrievability, will not cause loss of confinement, and will not affect criticality. In no scenario, does the lid become dislodged.

3.I.4.8.2 Tornado Missile Protection during Construction

The number of VVMs in a HI-STORM 100U ISFSI may vary depending on a user's need. While there is a minimum spacing (pitch) requirement (see licensing drawing in Subsection 1.I.5), there is no limitation on the maximum spacing. Furthermore, a module array may have a non-rectangular external contour such as shown in the licensing drawing with a trapezoidal contour. Finally, an ISFSI may be constructed in multiple campaigns to allow the user to align the VVM cavity construction schedule with the plant's fuel storage needs. Any ISFSI constructed in one campaign shall have the following mandatory perimeter protection features:

- i. The Radiation Protection Space (RPS) shall extend to an appropriate distance beyond the outer surface of the CEC shell (see licensing drawing in Subsection 1.I.5). Calculations have been performed [3.I.27] that confirm that a 10' distance beyond the outer surface of the CEC shell is sufficient to prevent the 8" diameter rigid cylindrical missile (defined in Table 2.I.1 and is the most penetrating of the missile types considered in this FSAR) from contacting the CEC shell should this missile strike the exposed cut from the adjacent construction. The penetration analysis conservatively assumed a subgrade with minimum resistance to missile penetration and the formulation described in [3.I.30].
- ii. Unless a retaining wall (see licensing drawing) has been built to confine and retain the subgrade at the boundary of the RPS (or beyond) in the particular direction of excavation, an Excavation Exclusion Zone (EEZ) shall be defined within which any excavation activity during an operating ISFSI is prohibited (see Subsection 2.I.2). The retaining wall is the EEZ boundary if the retaining wall is located at or beyond the RPS.

3.I.4.9 HI-STORM 100U VVM Service Life

The VVM is engineered for 40 years of design life, while satisfying the conservative design requirements defined in Supplement 2.I. For information supporting the 40 year design life addressing chemical and galvanic reactions as well as other potentially degrading factors see Subsection 3.I.4.1. Requirements for periodic inspection and maintenance of the HI-STORM 100U VVM throughout the 40-year design life are defined in Supplement 9.I. The VVM is designed, fabricated, and inspected under the comprehensive Quality Assurance Program discussed in Chapter 13.

3.I.5 FUEL RODS

No new analysis of fuel rods is required for storage of an MPC in a HI-STORM 100U VVM.

3.I.6 SUPPLEMENTAL DATA

3.I.6.1 Additional Codes and Standards Referenced in HI-STORM 100 System Design and Fabrication

No additional Codes and Standards are added for the HI-STORM 100U system.

3.I.6.2 Computer Programs

ANSYS 5.7, 7.0, 9.0, 11.0, and LS-DYNA (previously known as DYNA3D) [3.I.2] are used for the finite element analyses prepared by Holtec and summarized in this supplement.

ANSYS

ANSYS is a public domain code, well benchmarked code, which utilizes the finite element method for structural analyses. It can simulate both linear and non-linear material and geometric behavior. It includes contact algorithms to simulate surfaces making and breaking contact, and can be used for both static and dynamic simulations. ANSYS has been independently QA validated at Holtec International. In this FSAR submittal, ANSYS is used within [3.1.27] and the element size used in the application follows the recommendation of the code developers.

LS-DYNA

LS-DYNA is a nonlinear, explicit, three-dimensional finite element code for solid and structural mechanics. It was originally developed at Lawrence Livermore Laboratories and is ideally suited for study of short-time duration, highly nonlinear impact problems in solid mechanics. LS-DYNA is commercially available and has been independently validated at Holtec following Holtec's QA procedures for commercial computer codes. This code has been used to analyze the Non-Mechanistic Storage tip-over for the HI-STORM 100 Part 72 general license. In this supplement, the code is used to establish the performance of the HI-STORM 100U under a design basis seismic event, and to evaluate the response to a design basis missile.

LS-DYNA is currently supported and distributed by Livermore Software. Each update is independently subject to QA validation at Holtec.

3.I.6.3 Appendices Included in Supplement 3.I

None.

3.I.6.4 Calculation Packages

A calculation package [3.1.27] containing the structural calculations supporting Supplement 3.I has been prepared and archived according to Holtec International's Quality Assurance program (see Chapter 13), and submitted with this application. A second calculation report [3.I.14], documenting the SASSI analyses, has been prepared by a Holtec subcontractor under the subcontractor's QA program.

3.I.7 COMPLIANCE WITH NUREG-1536

The material in this supplement for the HI-STORM 100U system provides the same information

as previously provided for the aboveground HI-STORM 100 systems. Therefore, to the extent applicable, the information provided is in compliance with NUREG-1536.

TABLE 3.I.10 (continued)
MOMENT RESULTS AND CORRESPONDING MINIMUM SAFETY FACTORS FOR THE ISFSI STRUCTURES

‡ The moment capacities for the SFP and TSP are calculated using axial-force-moment interaction diagram corresponding to the axial force and moment induced in the limiting element. An example showing the moment and axial force calculation for the limiting element, using the in-plane stresses, is included under Figure 3.I.18.b. Figures 3.I.18a through 3.I.22c also capture the stress plots for the governing load combination (LC-3 in Table 2.I.11) for all the ISFSI loading configurations analyzed. These figures also identify the limiting element (i.e., maximum loaded element) that corresponds with the results presented above.

Note that the flexural safety factors calculated above are based on the maximum moment induced in a single element, which is very conservative. Averaging over a width of the loaded section would result in much higher safety factors.

† The moment capacity for the Retaining Wall is based on the pure bending.

TABLE 3.I.11
PUNCHING SHEAR SAFETY FACTORS FOR ISFSI STRUCTURES

ISFSI Structure	Punching Safety Factor
SFP†	2.1
TSP	1.32
† Note that the punching shear calculation for the SFP is conservatively based on a bounding load of 950 kips.

Note: The blue footprints show the SFP area loaded with the SSC's and the red footprint represents the loaded TSP area with the transporter (VCT). The soil extending beyond the SFP boundary is not shown in the above plot for clarity.

Figure 3.I.17; ANSYS Finite Element Model of ISFSI Showing the Fully Loaded Configuration (Simulation Model I)

Figure 3.I.18a; Normal Stress (S_y) in the ISFSI in the Direction of the Transporter Path for Simulation Model I – Load Combination LC-3 from Table 2.I.11

Notes:

Element 1766 realizes the maximum loading and produces the limiting safety factor.

Moment (Mx) in the limiting element is calculated as $= \{1017.6 - (-1110.3)\} \times 33^2 / 12 = 193,106.9 \text{ lbf-in/in}$, Axial Force (Fx) in the limiting element is calculated as $= \{(-1110.3) + 1017.6\} \times 33 / 2 = -1529.6 \text{ lbf/in}$, where 33 represents the thickness of the SFP in inches. The axial force and moment values calculated here correspond well with the results shown in Table 3.I.10 for the SFP for Simulation Model I. The small deviation (less than 0.6%) from the results shown in Table 3.I.10 is due to the fact that the results in Table 3.I.10 are computed based on the average surface stresses (top and bottom) considering all 4 nodes that define each element surface. In the calculations above, the maximum and minimum stresses at a single node location (top and bottom) are considered for simplicity.

Figure 3.I.18b; Normal Stress (Sy) in SFP, Simulation Model I – Load Combination LC-3 from Table 2.I.11

Note: Element 67115 realizes the maximum loading and produces the limiting safety factor.

CHAPTER 3.II[†]

STRUCTURAL SAFETY EVALUATION

3.II.0 Introduction

This supplement to Chapter 3 in the main report presents the safety analysis summaries of load cases defined in Chapter 2.II and demonstrates compliance with the acceptance criteria set forth therein. In addition to providing quantitative safety margins, the material in this supplement to Chapter 3 provides acceptable analysis methods and acceptable analysis codes which can be used for analyzing site specific loadings under the purview of 10CFR72.212. In this update of the FSAR, a new Supplement, labelled 14.II on “Material Considerations” has been created in keeping with the latest guidance in NUREG-1536. Accordingly, material suitability related information in Chapter 3 is replaced and superseded by Supplement 14.II. Thus, this chapter is solely focused on structural qualification of the storage system components.

[†] This chapter has been prepared in the format and section organization set forth in Regulatory Guide 3.61. All terms-of-art used in this chapter are consistent with the terminology of the Glossary. Finally, all evaluations and results presented in this Chapter are supported by calculation packages cited in the Reference section.

3.II.1 Structural Loading Cases

Table 2.II.2.1 provides the mechanical loading cases for the HI-STORM Version E and Version E1 storage overpack and the HI-TRAC Version MS transfer cask and their content (enclosure with MPC 32M and Version 1 of MPC-32, MPC-32M CBS, and MPC-68 baskets). Subsection 2.II.2.2 provides the associated acceptance criteria. The allowable stress tables for steel and Alloy X materials in Chapter 3 in the main body of this FSAR are used in the stress analyses.

For Fuel Baskets made of Metamic HT, the deflection based structural criterion applies as set forth in Supplement III (wherein MPC-68M, presently certified and widely deployed, made of Metamic HT has been qualified) as well as in the HI-STORM FW FSAR [3.II.25].

As described in Chapter 1.II, version CBS of the MPC-32M fuel basket replaces loose basket shims with continuous basket shims (CBS) bolted to basket panel extensions on the basket periphery. In normal operating condition, these shims are not subject to any significant loads. The only condition in which this shim configuration experiences significant loads is the non-mechanistic tipover event when the shim extension plates may be subject to cantilever loads. This loading, which bounds all other events including seismic loads, is considered in the tipover analysis presented in Subsection 3.II.4.4.2.iii.

3.II.2 Weights and Centers of Gravity

As stated in Chapter 1.II, the heights of the MPC enclosure, HI-STORM Version E, HI-STORM Version E1, MPC-68M (including MPC-68M CBS) and MPC-32M (including MPC-32M CBS) are dependent on the length of the fuel assembly. The minimum MPC cavity height (which determines the external height of the MPC) is set equal to the nominal fuel length (along with control components, if any) plus Δ , where Δ is between 1.5" (minimum), 2.0" (maximum), Δ is increased above 1.5" so that the MPC cavity height is a full inch or half-inch number. Thus, for the most common PWR fuel (W 17 by 17) whose length including control components is 167.2," $\Delta = 1.8$ " so that the MPC cavity height, c , becomes 169". Δ is provided to account for irradiation and thermal growth of the fuel in the reactor. The cavity heights of the HI-STORM Version E and Version E1 overpack and the HI-TRAC Version MS transfer cask are set greater than the MPC height by fixed amounts to account for differential thermal expansion and manufacturing tolerances. Table 3.II.2.1 provides the minimum height data on HI-STORM Version E, HI-STORM Version E1, HI-TRAC Version MS, and the MPC as the adder to the MPC cavity length, h .

The bounding weights of the loaded MPC containing "reference SNF" with and without water are provided in Table 3.II.2.2. All weights are nominal values computed using the Solidworks™ computer code or using standard material density and geometric shapes for the respective subcomponents of the equipment.

As discussed in Section 1.II.2, the weight of the HI-TRAC Version MS transfer cask is maximized for a particular site to take full advantage of the plant's crane capacity within the architectural limitations of the Fuel Building. Accordingly, the thickness of the lead shield and outer diameter

of the water jacket can be adjusted to maximize shielding gamma and neutron shielding, respectively. The weight of the empty HI-TRAC VERSION MS cask in Table 3.II.2.3 is provided for the “reference PWR fuel” and assumed lead and water jacket radial widths using its Solidworks™ rendering shown in the Licensing drawing in Section 1.II.5. The Solidworks computed weight is converted into the corresponding nominal weight by increasing the computed weight by 3% and rounded up the next number ending in two zeros to account for potential mill-supplied plate over-thickness and excess weld sizes. HI-TRAC weight for other length, lead and water jacket widths combination may be readily obtained from the Solidworks™ model.

Table 3.II.2.4 provides the reference weight of the HI-STORM overpack for storing the reference PWR fuel in MPC-32M and MPC-32M CBS on the ISFSI pad. The weight of the HI-STORM Version E and Version E1 overpack body is provided for two discrete concrete densities. The weight at any other concrete density can be obtained by linear interpolation. Similarly, the weight of the HI-STORM lid is provided for two discrete values of concrete density. The weight corresponding to any other density can be computed by linear interpolation.

The maximum and minimum locations of the centers of gravity (CGs) are presented (in dimensionless form) in Table 3.II.2.5. The radial eccentricity, ϕ , of a cask system is defined as:

$$\phi = \frac{\Delta_r}{D} \times 100 \quad (\phi \text{ is dimensionless})$$

where Δ_r is the radial offset distance between the CG of the cask system and the geometric centerline of the cask, and D is the outside diameter of the cask. In other words, the value of ϕ defines a circle around the axis of symmetry of the cask within which the CG lies (see Figure 3.II.2.1). All centers of gravity are located close to the geometric centerline of the cylindrical cask since the non-axisymmetric effects of the cask system and its contents are very small. The vertical eccentricity, Ψ , of a cask system is defined similarly as:

$$\Psi = \frac{\Delta_v}{H} \times 100 \quad (\Psi \text{ is dimensionless})$$

Where Δ_v is the vertical offset distance between the CG of the cask system and the geometric center of the cask (i.e., cask mid-height), and H is the overall height of the cask. A positive value of Ψ indicates that the CG is located above the cask mid-height, and a negative value indicates that the CG is located below the cask mid-height. Figure 3.II.2.2 illustrates how Ψ is defined.

The values of ϕ and Ψ given in Table 3.II.2.5 are bounding values, which take into consideration material and fabrication tolerances. For a specific site, the Solidworks models from which the Licensing drawings are extracted can be used to obtain precise weight and CG data.

The weight information provided above shall be used for designing the lifting and handling ancillary for the HI-STORM cask components. In addition, the maximum C.G. height per Table 3.2.5 shall be used for the stability analysis of the loaded HI-STORM under DBE conditions. Using the weight data in the previously mentioned tables, Table 3.II.2.6 has been constructed to provide the bounding weights for structural analyses so that every cask component is analyzed using the most conservative data (so as to *minimize the computed safety margins*). The weight data in Table

3.II.2.6 is used in the structural safety analyses in this chapter.

Table 3.II.2.1: Minimum MPC, HI-TRAC, and HI-STORM Height Data Corresponding to Unirradiated Fuel Height, L	
MPC Cavity Height, c	$L + \Delta$ (when not using DFCs or DFIs) $L + \Delta + \beta + \alpha$ (when using DFCs or DFIs) (Notes 1 and 2)
MPC Height (including top lid, excluding closure ring), h	$c + 12.25''$
HI-TRAC Version MS Cavity Height	$h + 1''$
HI-TRAC 100/125 Cavity Height	$h + 15/16''$
HI-STORM Version E and Version E1 Cavity Height	$h + 1''$
HI-STORM Version E Body Height (height from the bottom of the HI-STORM Version E to the top surface of the shear ring at the top of the cask body)	$h + 11.75''$
HI-STORM Version E Height (loaded over the pad)	$h + 33 \frac{1}{2}''$
HI-STORM Version E1 Body Height (height from the bottom of the HI-STORM Version E1 to the top surface of the shear ring at the top of the cask body)	$h + 7.25''$
HI-STORM Version E1 Height (loaded over the pad)	$h + 33''$

Notes:

- 1) The cavity height, c, shall be calculated using the longest fuel assembly length, L, with or without a DFC or DFI, that will be loaded into the MPC. The value of c shall also be rounded up to the nearest $\frac{1}{2}''$.

The variables to determine c are defined as follows:

- The unirradiated fuel assembly height, L.
- The additional clearance factor, Δ , provides axial clearance for potential irradiation growth of the fuel in the reactor and thermal growth in the MPC. Δ is conservatively assumed to be 1.5'' for all fuel assembly types.
- Additional cavity height, β , is required when using DFCs or DFIs to account for the structural components of the DFCs or DFIs. β shall be no more than 5''.
- An additional axial gap, α , required to allow free thermal expansion of the DFC/DFI in the MPC cavity. α shall be no more than 1.5''.

Users that elect to utilize cutouts in the underside of the MPC lid to accommodate additional DFC height do not need to adjust the MPC cavity height. However, axial clearance of the DFC/DFI within the local cavity height of the cutouts, equivalent to α (as defined above), must be provided to allow thermal expansion.

For all fuel assemblies loaded into MPCs, with or without DFC/DFIs, the sum of the free axial space above the top of the fuel assembly (free axial space does not include DFC/DFI hardware) shall be less than 6". Where necessary, fuel shims shall be used to reduce the free axial space.

- 2) In MPC's where fuel spacers are utilized or previous HI-STORM 100 system's changing over to the MPC-32M and HI-STORM 100E, the fuel length, L , may be considered fuel + a required spacer.

Table 3.II.2.2: MPC Weight Data		
Item	Nominal Weight in pounds	Comment
Enclosure Vessel (Alloy X)	20,000	Water weight in the MPC assumes that water volume displaced by the fuel is equal to the fuel weight divided by an average fuel assembly density of 0.396 lb/in ³ .
Water in the MPC (Specific Gravity = 1)	13,300	
Weight of 32 Reference PWR Fuel Assemblies	56,000	
Water mass displaced in the pool by a welded and closed MPC (Specific Gravity= 1)	24,100	

Table 3.II.2.3: HI-TRAC Version MS Weight and Dimension Data

Item	Data (in inch or pounds)	Comment
Ref radial width of lead in the cask's annulus	4"	The data in this table corresponds to the Licensing drawing where the cask cavity height is set by the "reference PWR fuel". The radial thickness of lead and water jacket cavity are as listed in this table. These shielding material thicknesses may be adjusted to optimize shielding within the constraint of the cask laydown space in the Fuel Building and the capacity of the cask crane. The tornado missile analysis in Section 3.II.4 uses the reference data from this table.
Minimum radial width of lead in the cask's annulus	[PROPRIETARY INFORMATION WITHHELD PER 10CFR2.390]	
Minimum radial width of lead in the cask's annulus for Trunnion Option	3 1/2"	
Ref radial width of water jacket in the cask body	[PROPRIETARY INFORMATION WITHHELD PER 10CFR2.390]	
Minimum radial width of water jacket in the cask body	3 7/8"	
Minimum radial width of water jacket in the cask body for Trunnion Option	3 3/4"	
Weight of empty cask with bottom lid attached (empty water jacket)	120,000	
Weight of Water in HI-TRAC Water Jacket	8,100	
HI-TRAC weight with MPC in the pool, water jacket <i>full</i> without accounting for buoyancy effects	230,000	
HI-TRAC weight with MPC in the pool, water jacket <i>empty</i> without accounting for buoyancy effects	222,000	
HI-TRAC weight with "loaded, welded and prepped" MPC (Includes 5% adder for fabrication tolerances)	215,000

	Item	Radial eccentricity (dimensionless), ϕ	Vertical eccentricity (dimensionless), Above (+) or Below (-), ψ
1.	Empty HI-STORM with lid installed	2.0	± 3.0
2.	Empty HI-STORM without top lid	2.0	± 3.0
3.	HI-STORM Version E and Version E1 with fully loaded stored MPC without top lid	2.0	± 2.0
4.	HI-STORM with lid and a fully loaded MPC	2.0	± 3.0
5.	HI-TRAC Version MS with Bottom lid and loaded MPC	2.0	± 2.0
6.	Empty HI-TRAC Version MS without bottom lid	2.0	± 2.0

Table 3.II.2.6: Bounding Weights used for Structural Analyses

	Case	Purpose	Assumed Weight (Kilo-pounds)
1.	Upper bound weight of loaded HI-STORM	Sizing and analysis of lifting and handling locations	450
2.	Lower bound weight of the HI-STORM system with minimum density concrete permitted in this supplement	Stability analysis under missile strike and overturning loads such as moving flood waters	275
3.	Upper bound weight of loaded HI-TRAC Version MS	Analysis for NUREG-0612 compliance of lifting and handling locations (TALs)	270.0
4.	Weight of loaded HI-TRAC Version MS	Stability analysis under missile strike	195.0 ¹
5.	Bounding weight of loaded MPC containing maximum length/weight fuel – maximum possible weight scenario	Analysis for NUREG-0612 compliance of lifting and handling locations (TALs)	120

¹For lighter casks or tornado missiles not bounded by [3.II.24], a site-specific analysis should be performed.

Top View of Cask

Figure 3.II.2.1: Radial Eccentricity of Cask Center of Gravity

Figure 3.II.2.2: Vertical Eccentricity of Cask Center of Gravity

3.II.3 Mechanical Properties of Materials

The information provided in Section 3.2 in the main body of this FSAR remains valid and unchanged.

3.II.4 General Standards for Casks

3.II.4.1 Chemical and Galvanic Reactions

Supplement 14.II provides discussions on chemical and galvanic reactions, material compatibility and operating environments. Section 14.II.12 provides a summary of compatibility of all HI-STORM system materials with the operating environment.

3.II.4.2 Positive Closure

There are no quick-connect/disconnect ports in the Confinement Boundary of the HI-STORM Version E and Version E1 Overpack system. The only access to the MPC is through the storage overpack lid, which weighs less than 18 tons (see Table 3.II.2.4 and Table 3.II.2.4a). The lid is fastened to the storage overpack with large bolts. Inadvertent opening of the storage overpack is not feasible because opening a storage overpack requires mobilization of special tools and heavy-load lifting equipment.

3.II.4.3 Lifting Devices

3.II.4.3.1 Identification of Lifting Devices and Required Safety Factors

The safety evaluation of the lifting and handling operations involving HI-STORM system components is considered in this section. In particular, the appurtenances integral to the cask components used in the lifting operations are evaluated in compliance with NUREG-0612 [3.II.1], Reg. Guide 3.61 [3.II.2], and the ASME Code as applicable. Section 2.II.2.7 provides detailed acceptance criteria lifting apparatus and appurtenances.

The following design features of Threaded Anchor Locations (TALs) are relevant to their stress analysis:

- i. All TALs consist of vertically tapped penetrations in the solid metal blocks. For example, the HI-STORM Version E and Version E1 overpack body (like all HI-STORM models) have tapped holes in the “anchor blocks” that are engaged for lifting. The loaded MPC is lifted at four threaded penetrations in the top lid as depicted on the licensing drawings in Section 1.II.5. Likewise, eight vertically tapped holes in the top flange provide the lift points for HI-TRAC Version MS transfer cask.
- ii. Operations involving loaded HI-STORM Version E and Version E1 cask involve handling evolutions in the vertical orientation. While the lifting devices used by a specific nuclear site shall be custom engineered to meet the architectural constraints of the site, all lifting devices are required to engage the tapped connection points using a vertical tension member such as a threaded rod. Thus, the loading on the cask during lifting is purely vertical.

The stress analysis of the HI-STORM Version E and Version E1 components, therefore, involves applying a vertical load equal to D^*/n at each of the n (number) TAL locations. Thus, for the case

of the HI-STORM Version E and Version E1 overpack, $n = 4$ (four “anchor blocks” as shown in the licensing drawings in Section 1.II.5).

HI-TRAC MS could also be lifted using trunnions that are threaded into trunnion blocks welded to HI-TRAC MS inner and outer shells. Detailed analyses of the optional lifting trunnion are presented in [3.II.23].

The stress limits during a lift for individual components set down in sub-section 2.II.2.7 are recapped in the following for convenience:

- i. Lift points (MPC, HI-STORM Version E, HI-STORM Version E1 and HI-TRAC Version MS): The stress in the threads must be the less than $1/10^{\text{th}}$ of its ultimate strength pursuant to NUREG-0612. The stress limits using Reg. Guide 3.61 do not govern for normal lifting.
- ii. Balance of the parts in the load path in the component: The maximum primary stresses (membrane and membrane plus bending) must be below the Level A service condition stress limit using ASME Code, Section III, Subsections NB [3.II.11] and NF [3.II.10], as applicable, as the reference codes.

To incorporate an additional margin of safety in the reported safety factors, the following assumptions are made for the lifting analysis:

- i. The Bounding weight data for the cask components summarized in Table 3.II.2.6 are used. Because a great majority of site applications will utilize lower weight components (due to shorter fuel length and other architectural limitations such as restricted crane capacity or DAS slab load bearing capacity, or lack of floor space in the loading pit), there will be an additional margin of safety in the lifting point's capacity at specific plant site.
- ii. All material yield strength and ultimate strength values used are the minimum from the ASME Code which are often as much as 20% lower than the actual tested strengths (mill-test reports).

The stress analysis of the lifting operation is carried out using the load combination $D+H$, where H is the "handling load". The term D denotes the dead load. Quite obviously, D must be taken as the bounding value of the dead load of the component being lifted. In all lifting analyses considered in this document, the handling load H is assumed to be $0.15D$. In other words, the inertia amplifier during the lifting operation is assumed to be equal to $0.15g$. This value is consistent with the guidelines of the Crane Manufacturer's Association of America (CMAA) [3.II.29], Specification No. 70, 1988, Section 3.3, which stipulates a dynamic factor equal to 0.15 for slowly executed lifts. Thus, the "apparent dead load" of the component for stress analysis purposes is $D^* = 1.15D$. Unless otherwise stated, all lifting analyses in this FSAR use the "apparent dead load," D^* , as the lifted load.

Unless explicitly stated otherwise, all analyses of lifting operations presented in this supplement follow the load definition and allowable stress provisions of the foregoing. Consistent with the practice adopted throughout this chapter, results are presented in dimensionless form, as safety

factors, defined as

$$\text{Safety Factor, } \beta = \frac{\text{Allowable Stress}}{\text{Computed Stress}}$$

In the following subsections, stress analysis of lifting appurtenances is performed to demonstrate compliance with the above criteria. Summary results are presented for each of the analyses.

3.II.4.3.2 Analysis of Lifting Scenarios

In the following, the safety analysis of the system components subject to normal lifting evolutions is considered. The data on TALs for all cask components is compiled in Table 3.II.4.1 per [3.II.23]. Bounding weights of the components from Table 3.II.2.6 are used herein for the licensing basis generic analysis. However, for specific site-specific applications, the actual weights and strength data from the material's mill-test-reports may be used.

a. MPC Lifts

The governing condition for the MPC lift is when it is being raised or lowered in a radiation shielded space defined by the HI-TRAC Version MS and the HI-STORM Version E/Version E1 stack.

The stress criteria is derived from NUREG-0612, and the ASME Section III Subsection NF, stated in Subsection 3.4.3. The stress analysis is carried out in two parts.

- i. Strength analysis of the TALs (connection points) using classical strength-of-materials: Table 3.II.4.2 provides the input data, intermediate calculated data and finally, the factor-of-safety for the TAL in the MPC's Top Lid, which evidently is quite large.
- ii. A finite element analysis of the MPC as a cylindrical vessel with the weight of the fuel and basket applied on its baseplate which along with the weight of the Confinement Boundary metal is equilibrated by the reaction loads at the TALs. The information provided in paragraph 3.4.3.6 in the main body of this FSAR and the corresponding safety results for all MPC enclosure vessels remains valid and unchanged except for MPC Version 1. Due to the design changes implemented in MPC Version 1 to offset for the increased internal pressure loading, a separate analysis is warranted for this specific MPC Version 1 design. The analysis approach for the MPC Version 1 enclosure design is in full compliance with that presented in Section 3.4.3.6. The following section provides the safety summary for the MPC Version 1 enclosure vessel.

Case (i): Stress Analysis of MPC Lid to Shell Weld

The shear stress in the MPC lid-to-shell weld under normal handling conditions is independently calculated, as shown below.

Per Table 3.II.2.6, the maximum bounding weight of a loaded MPC is

$$W_{MPC} = 120,000 \text{ lb}$$

The diameter and weight of the MPC lid assembly are

$$D = 66.75 \text{ in}$$

$$W_{lid} = 10,000 \text{ lb}$$

From Table 2.2.1, the bounding pressure inside the MPC cavity under normal operating conditions is

$$P = 120 \text{ psig}$$

Thus, the total force acting on the MPC lid-to-shell weld is

$$F = 1.15 \cdot (W_{MPC} - W_{lid}) + P \cdot \left(\frac{\pi \cdot D^2}{4} \right) = 546,427 \text{ lb}$$

which includes a 15% dynamic amplifier. The MPC lid-to-shell weld is a $\frac{3}{4}$ " partial groove weld, which has an effective area equal to

$$A = \pi \cdot D \cdot \left(t_w - \frac{1}{8} \text{ in} \right) \cdot 0.8 = 104.85 \text{ in}^2$$

where t_w is the weld size (= 0.75in). The calculated weld area includes a strength reduction factor of 0.8 per ISG-15 [3.5.3]. Thus, the average shear stress in the MPC lid-to-shell weld is

$$\tau = \frac{F}{A} = 5,212 \text{ psi}$$

The MPC Enclosure Vessel is made from Alloy X material, whose mechanical properties are listed in Table 3.3.1. Based on bounding normal condition temperature (Tables 4.4.3 and 4.5.2), and assuming that the weld strength is equal to the base metal ultimate strength, the allowable shear stress in the weld under normal conditions is:

$$\tau_a = 0.3 \times S_u = 17,670 \text{ psi}$$

Therefore, the safety factor against shear failure of the MPC lid-to-shell weld is

$$SF = \frac{\tau_a}{\tau} = 3.39$$

Case (ii): Finite Element Analysis of MPC Enclosure Vessel

The stress analysis of the MPC Enclosure Vessel under normal handling conditions is performed using ANSYS [3.II.7]. A 2-D axisymmetric finite element model is constructed using ANSYS. The configuration is shown in Figure 3.II.4.22. Values extracted from the finite element analysis are then used to determine the respective safety factors.

The loads are statically applied to the finite element model in the following manner. The self-weight of the Enclosure Vessel is simulated by applying a constant acceleration of 1.15g in the vertical direction. The apparent dead weight of the stored fuel inside the MPC cavity (which includes a 15% dynamic amplifier) is accounted for by applying a uniformly distributed pressure on the top surface of the MPC baseplate. The amplified weight of the fuel basket and the fuel basket shims is applied as a ring load on the MPC baseplate at a radius equal to the half-width of the fuel basket cross section. All internal surfaces of the MPC storage cavity are also subjected to a bounding off-normal condition internal pressure of 120 psig, which exceeds the normal operating pressures. The temperature gradient across the MPC confinement boundary, based on the thermal evaluation, is appropriately applied. Finally, the model is constrained by fixing one node on the top surface of the MPC lid and symmetric boundary conditions are applied. The boundary conditions and the applied loads are graphically depicted in Figure 3.II.4.22.

The resulting stress intensity distribution in the MPC Version 1 Enclosure Vessel under the applied handling loads is shown in Figure 3.II.4.23. The maximum primary stress intensities in the MPC Version 1 Enclosure Vessel are compared with the applicable stress intensity limits from Subsection NB of the ASME Code [3.II.11]. The allowable stress intensities are taken at bounding temperatures. This temperature bound the operating temperatures for the baseplate, shell and the closure lid under normal operating conditions. The maximum calculated stress intensities and the corresponding safety factors are summarized in Table 3.II.4.3 per [3.II.23].

b. Heaviest Weight HI-TRAC Version MS Lift

The HI-TRAC Version MS transfer cask is at its heaviest weight when it is being lifted out of the loading pit with the MPC fully loaded with fuel and water and the MPC lid lying on it for shielding protection. Table 3.II.2.6 provides the bounding weight. The threaded lift points or optional lifting trunnions are provided for the interface locations for lifting.

- i. The stress analysis of the transfer cask consists of two steps:

A strength evaluation of the tapped connection points and optional lifting trunnions are performed using the input data in Table 3.II.4.2. The factors-of-safety for the TAL in the HI-TRAC's Top Flange and optional lifting trunnions are determined and are shown to be greater than 1.0.

- ii. Stress Analysis of HI-TRAC Version MS Body

A strength evaluation of the HI-TRAC Version MS vessel using strength of materials formulas to establish the stress field under D*. As stated in sub-section 2.II.2.7, primary membrane plus primary bending stresses throughout the HI-TRAC Version MS body and the bottom lid shall be below the Level A stress limits for “NF” Class 3 plate and shell structures [3.II.10].

The stress analysis of the HI-TRAC Version MS steel structure during lifting operations is performed using strength of materials. All structural members in the load path are evaluated for the bounding lifted weight (Table 3.II.2.6). In particular, the following stresses are calculated:

- the shear stress in the welds between the top flange and the inner and outer shells
- the primary membrane stress in the inner and outer shells
- the tensile stress in the bottom lid bolts
- the primary bending stress in the bottom lid

To determine the bending stress in the bottom lid, the weight of the loaded MPC plus the weight of the water inside the HI-TRAC Version MS cavity (Table 3.II.2.6) is applied as a uniformly distributed pressure on the top surface of the bottom lid. The bending stress is calculated at the center of the bottom lid assuming that the lid is simply supported at the bolt circle diameter. The calculated stresses are compared with the Level A stress limits for “NF” Class 3 plate and shell structures. The detailed calculations are documented in [3.II.23]. Table 3.II.4.4 summarizes the stress analysis results for the HI-TRAC VERSION MS steel structure under the maximum lifted load.

c. HI-STORM Version E and Version E1 Lifts

Bounding weight of the loaded HI-STORM Version E and Version E1 set down in Table 3.II.2.6 is used for the stress analysis. Another scenario involves lifting of the HI-STORM Lid independently using its lugs.

i. HI-STORM TAL stress analysis:

A strength evaluation of the tapped connection points in the HI-STORM Anchor Blocks is summarized in Table 3.II.4.2 per [3.II.23], which provides the input data, intermediate calculated data and finally, the factor-of-safety. It is evident that the safety margin for this lifting attachment is quite large.

ii. Stress analysis of HI-STORM Version E and Version E1 body:

The stress analysis of the overpack body under normal handling conditions is performed using ANSYS [3.II.7]. The finite element model, which is shown in Figure 3.II.4.1 is ¼-symmetric. Bounding weight of the overpack is used for this analysis.

The self- weight of the overpack is simulated by applying a constant acceleration of 1.15g in the vertical direction. The apparent dead weight of the fully loaded MPC (which includes a 15%

dynamic amplifier) is accounted for by applying a uniformly distributed pressure at the top surface of the HI-STORM MPC bottom support guides. Finally, the model is constrained by fixing top surface of anchor bolts of the HI-STORM Version E, which coincide with the TALs. Symmetric boundary conditions are applied to the two vertical symmetry planes.

The resulting stress distribution in the overpack under the applied handling loads is shown in Figure 3.II.4.2. The maximum primary stresses in the HI-STORM overpack body are compared with the applicable stress limits from Subsection NF of the ASME Code [3.II.10]. The allowable stresses for the load-bearing members are taken at 350°F, which exceeds the maximum operating temperature for the overpack under normal operating conditions. The maximum stresses and the corresponding safety factors are summarized in Table 3.II.4.5 per [3.II.23].

The HI-STORM 100S Version E1 overpack is a design variant of the HI-STORM 100S Version E overpack, with a few key differences:

1. Modified inlet vent assembly to incorporate additional shielding material outside the vent and reduced the number of inlet vent assemblies from eight to four.
2. Added inner base plate to the bottom of the overpack to enhance shielding capabilities.
3. MPC standoffs are replaced with stainless steel tiles to lower the MPC base structure and to reduce overall cask height.
4. The Version E1 incorporates the optional Jacking Assembly for use during bottom lifting.

Stress analysis of the HI-STORM Version E1 overpack body under normal condition top and bottom lifting conditions is performed using the same approach as HI-STORM 100S Version E described in this section. The analyses and results are documented in [3.II.23].

iii. Lid Lift Analysis

The stress analyses of the overpack lid (100S Version E) and the 100S common lid under normal handling conditions and snow load performed using ANSYS [3.II.7]. The finite element models are shown in Figures 3.II.4.3 and 3.II.4.3a, respectively. Bounding weights of the overpack lid (100S Version E) and 100S common lid are used in the analysis. The resulting stress distribution in the steel structure of the overpack lid (100S Version E) and the 100S common lid under the applied handling load are shown in Figure 3.II.4.4 and 3.II.4.4a, respectively. The maximum stresses and the corresponding safety factors are summarized in Table 3.II.4.6 for the overpack lid (100S Version E) and Table 3.II.4.6a for the 100S common lid per [3.II.23]. The resulting stress distribution in the steel structure of the overpack lid (100S Version E) and 100S common lid under snow load are presented in [3.II.23]. For conservatism, the maximum primary stress in the lid is compared against the primary membrane and primary bending stress limits per Subsection NF (class 3 structures) of the ASME Code for Level A conditions. The allowable stresses are taken at a bounding temperature, which exceeds the maximum operating temperature for the overpack top lid under normal operating conditions.

3.II.4.3.3 Safety Summary for Lifting Scenarios

As can be seen from the above evaluations, the computed factors of safety have a large margins over the allowable, 1.0, in every case. In the actual fabricated hardware, the factors of safety will likely be much greater because of the fact that the actual material strength properties are generally substantially greater than the ASME Code minimums. Minor variations in manufacturing, on the other hand, may result in a small subtraction from the above computed factors of safety. A part 72.48 safety evaluation will be required if the cumulative effect of manufacturing deviation and use of the CMTR (or CoC) material strength in a manufactured hardware renders a factor of safety to fall below the above computed value. The above criterion applies to all lift calculations covered in this supplement.

3.II.4.4 Safety Analysis Under Thermal & Mechanical Loadings

3.II.4.4.1 Safety analysis of Thermal and Pressure States

(a) Summary of Pressures and Temperatures

Design pressures and design temperatures for all conditions of storage listed in Tables 2.2.1 and 2.2.3, respectively, in the main report, remain unchanged for all MPC enclosure vessels except for the MPC Version 1.

The normal, off-normal and accident pressures for the Version 1 MPC enclosure, which exceeds the other MPC designs, are summarized in Table 1.II.2.3. The evaluations for other MPC designs presented in the main body of this chapter remain valid.

Accordingly, the MPC Version 1 is evaluated for the pressure and temperature loading conditions, in the following.

i. Design Internal Pressure – Normal/Off-normal Conditions

The MPC Enclosure Vessel, which is designed to meet the stress intensity limits of ASME Subsection NB [3.II.11], is analyzed for a design internal pressure specified in Table 1.II.2.3 using the ANSYS finite element code [3.II.7]. Except for the applied loads and the boundary conditions, the finite element model of the MPC Enclosure Vessel used for this load case is identical to the model described in Paragraph 3.II.4.3.2 for the MPC lifting analysis.

The only load applied to the finite element model for this load case is the bounding MPC design internal pressure for normal and off-normal conditions. All internal surfaces of the MPC storage cavity are subjected to the design internal pressure of 110 psig. The center node on the top surface of the MPC upper lid is fixed against translation in all directions. This set of boundary conditions allows the MPC Enclosure Vessel to deform freely under the applied pressure load. Figure 3.4.II.24 graphically depicts the applied pressure load and the boundary conditions.

The stress intensity distribution in the MPC Enclosure Vessel under design internal pressure is

shown in Figure 3.4.II.25. The maximum primary stress intensities in the MPC Enclosure Vessel are compared with the applicable stress intensity limits from Subsection NB of the ASME Code (Fig. NB-3221-1). The allowable stress intensities are taken at bounding temperature. This temperature bound the operating temperatures for the baseplate, shell and the closure lid under normal operating conditions. The maximum calculated stress intensities in the MPC Enclosure Vessel, and their corresponding allowable limits, are summarized in Table 3.II.4.7 per [3.II.23].

ii. Design Internal Pressure – Short Term Operations

The stress analysis of the MPC Enclosure Vessel under normal handling conditions is performed using ANSYS [3.II.7] and presented in section 3.II.4.3.2. All internal surfaces of the MPC storage cavity are also subjected to a bounding short-term condition internal pressure of 120 psig, which exceeds the normal operating pressures. The temperature gradient across the MPC confinement boundary, based on the thermal evaluation, is also appropriately applied. Thus, a separate analysis with short-term operating conditions is not warranted. The safety factors summarized in Table 3.II.4.3 are bounding values.

iii. Design Internal Pressure - Accident Internal Pressure

The maximum pressure in the MPC Enclosure Vessel under accident conditions is specified in Table 1.II.2.3. The stress analysis under this loading condition uses the same model as the one described in the preceding subsection for design internal pressure. The only change is the magnitude of the applied pressure. Figure 3.II.4.26 graphically depicts the applied pressure load and the boundary conditions.

The stress intensity distribution in the MPC Enclosure Vessel under accident internal pressure is shown in Figure 3.II.4.27. The maximum primary stress intensities in the MPC Enclosure Vessel are compared with the applicable stress intensity limits from Subsection NB of the ASME Code [3.II.11]. The allowable stress intensities are determined based on normal operating temperatures since the MPC accident internal pressure is dictated by the 100% fuel rod rupture accident, which does not cause any significant rise in MPC temperatures. In fact, the temperatures inside the MPC tend to decrease as a result of the 100% fuel rod rupture accident due to the increase in the density and internal pressure of the circulating gas. The maximum calculated stress intensities in the MPC Enclosure Vessel, and their corresponding allowable limits, are summarized in Table 3.II.4.8 per [3.II.23].

(b) Differential Thermal Expansion

The effect of differential thermal expansion among the constituent components in the HI-STORM Version E and Version E1 system is considered in Chapter 4.II wherein the temperatures necessary to perform the differential thermal expansion analyses for the MPC in the HI-STORM Version E and Version E1 overpack and HI-TRAC Version MS casks are computed. The material presented in Section 4.II.4 demonstrates that a constraint to free expansion due to differential growth between discrete components of the HI-STORM Version E and Version E1 system (e.g., storage overpack and enclosure vessel) will not develop under any operating condition.

(i) Normal Hot Environment

Results presented in Section 4.II.4 demonstrate that initial gaps between the HI-STORM Version E and Version E1 storage overpack or the HI-TRAC Version MS transfer cask and the MPC canister, and between the MPC canister and the fuel basket, will not close due to thermal expansion of the system components under normal operating conditions.

The clearances between the MPC basket and canister structure, as well as between the MPC shell and storage overpack or HI-TRAC VERSION MS inside surface, are shown in Section 4.II.4 to be sufficient to preclude a temperature induced interference from differential thermal expansions under normal operating conditions.

(ii) Design Basis Fire

The Fire accident is an extreme thermal event listed as loading case T-2 in Table 2.II.2.2. It is shown in Chapter 4.II that the fire accident has a small effect on the MPC temperatures because of the short duration of the fire accident and the large thermal inertia of the storage overpack.

Therefore, a structural evaluation of the MPC under the postulated fire event is not required. The conclusions reached in item (i) above are also appropriate for the fire accident with the MPC housed in the storage overpack. Analysis of fire accident temperatures of the MPC housed within the HI-TRAC Version MS for thermal expansion is unnecessary, as the HI-TRAC Version MS, directly exposed to the fire, expands to increase the gap between the HI-TRAC VERSION MS and MPC.

As expected, the external surfaces of the HI-STORM Version E storage and Version E1 overpack that are directly exposed to the fire event experience maximum rise in temperature. The outer shell and top plate in the top lid are the external surfaces that are in direct contact with heated air from fire. Table 4.II.6.2 provides the maximum temperatures attained at the key locations in HI-STORM Version E and Version E1 storage overpack under the postulated fire event.

The following conclusions are evident from the above referenced table.

- The maximum metal temperature of the carbon steel shell most directly exposed to the combustion air is well below 700°F (Table 2.2.3 applicable short-term temperature limit).
- The bulk temperature of concrete is well below the normal condition temperature limit of 300°F specified in Table 2.2.3. ACI-349-85 [3.II.8] permits 350°F as the short-term temperature limit; the shielding concrete in the HI-STORM Version E and Version E1 overpack. As the detailed information in Section 4.6 shows, the radial extent in the concrete where the local temperature exceeds 350°F begins at the outer shell/concrete interface and ends in less than one-inch. Therefore, the potential loss in the shielding material's effectiveness is less than 4% of the concrete shielding mass in the overpack annulus.
- The metal temperature of the inner shell does not exceed 300°F at any location, which is well

below the accident condition temperature specified in Table 2.2.3 for the inner shell.

- The presence of a vented space at the top of the overpack body ensures that there will be no pressure buildup in the concrete annulus due to the evaporation of vapor and gaseous matter from the shielding concrete.

Thus, it is concluded that the postulated fire event will not jeopardize the structural integrity of the HI-STORM Version E and Version E1 overpack or significantly diminish its shielding effectiveness.

The above conclusions, as applicable, also apply to the HI-TRAC Version MS fire considered in Chapter 4.II. Water jacket over-pressurization is prevented by the pressure relief devices. The non-structural effects of loss of water have been evaluated in Chapter 5.II and shown to meet regulatory limits. Therefore, it is concluded that the postulated fire event will not cause a state of non-compliance with the applicable regulations.

3.II.4.4.2 Safety Analysis of Loaded HI-STORM Version E, HI-STORM Version E1 and HI-TRAC Version MS Under Mechanical Loadings

Calculations of the stresses and displacements in the different components of the HI-STORM 100S Version E and Version E1 overpack and HI-TRAC Version MS cask under the effects of mechanical load cases summarized in Table 2.II.2.1 are considered in the following. The purpose of the analyses summarized herein is to provide the necessary assurance that there will be no unacceptable risk of criticality, unacceptable release of radioactive material, unacceptable radiation levels, or impairment of ready retrievability of the MPC (for normal and off-normal conditions of storage) from the HI-STORM 100S Version E and Version E1 storage overpack or from the HI-TRAC Version MS transfer cask.

Because many of the analyses must be performed for a particular ISFSI to demonstrate the acceptability of site-specific loads under the provisions of 10CFR72.212, the analyses presented here also set down the acceptable methodologies. Accordingly, the analysis methodologies are configured to exaggerate the severity of the response.

All factors of safety reported in this FSAR utilize nominal dimensions and minimum material strengths. Actual factors of safety in the manufactured hardware are apt to be considerably larger than those reported herein chiefly because of the actual material strengths being much greater than the values used in the safety analyses. A part 72.48 safety assessment will be required if the combined effect of the actual material strength and manufacturing deviation produces a lower safety factor for a design basis loading than that referenced in the safety evaluation in this FSAR.

(i) Loading Case M-1; Tornadic wind and tornado-propelled missile acting synergistically:

This loading is described in Paragraph 2.2.3.5 of this FSAR and the loading data is provided in Tables 2.2.4 and 2.2.5. The acceptance criteria are provided in 2.II.2.2(b). The HI-STORM 100S Version E and Version

E1 system in storage and the HI-TRAC Version MS cask during Part 72 (short term) operations need to be qualified for these loadings.

During a tornado event, the HI-STORM 100 Version E and Version E1 overpack and the HI-TRAC Version MS are assumed to be subjected to a constant wind force. They are also subject to impacts by postulated missiles. The maximum wind speed is specified in Table 2.2.4, and the three missiles, designated as large, intermediate, and small, are described in Table 2.2.5.

a. Large Missile

Overturning Analysis

The large tornado missile acting at the top region of the cask to produce maximum overturning effect is analyzed to determine whether the cask will remain stable. Because the site-specific large missile is apt to be different from the one analyzed herein, the method of analysis presented here will provide the means for the site-specific safety evaluation pursuant to 10CFR72.212.

The overturning analysis of the cask under the tornado wind load and large missile impact is performed by solving the 1-DOF equation of motion for the cask angular rotation. Specifically, the solution of the post-impact dynamics problem is obtained by solving the following equation of motion:

$$I_r \alpha = \left(-W_c \frac{a}{2} \right) + F_{\max} \left(\frac{L}{2} \right)$$

where:

- I_r = cask moment of inertia about the pivot point
- α = angular acceleration of the cask
- W_c = lower bound weight of the cask
- a = diameter of cask at its base
- F_{\max} = force on the cask due to tornado wind/instantaneous pressure drop
- L = height of the cask

The impacting missile enters into the above through the post-strike angular velocity of the cask, which is the relevant initial condition for the cask equation of motion. The solution gives the post-impact position of the cask centroid as a function of time, which indicates whether the cask remains stable.

The following conservative assumptions are made in the analysis:

- The cask is assumed to be a rigid solid cylinder, with uniform mass distribution. This assumption implies that the cask sustains no plastic deformation (i.e. no absorption of energy through plastic deformation of the cask occurs).

- The angle of incidence of the missile is assumed to be such that its overturning effect on the cask is maximized.
- The cask is assumed to pivot about a point at the bottom of the base plate opposite the location of missile impact and the application of wind force in order to conservatively maximize the propensity for overturning.
- Inelastic impact is assumed, with the missile velocity reduced to zero after impact. This assumption conservatively lets the missile impart the maximum amount of angular momentum to the cask, and it is in agreement with missile impact tests conducted by EPRI [3.II.21].
- The analysis is performed using the minimum loaded HI-STORM 100 Version E and Version E1 weight per Table 3.2.8. A lighter cask will tend to rotate further after the missile strike. The weight of the missile is not included in the total post-impact weight.
- The missile and wind loads are assumed to be perfectly aligned in direction.

The results for the post-impact response of the HI-STORM 100 Version E and Version E1 overpack and the HI-TRAC Version MS transfer cask are summarized in Table 3.II.4.9 per [3.II.24] and [3.II.23]. The table shows that both the casks remain in a vertical upright position (i.e., no overturning) in the aftermath of a large missile impact.

Sliding Analysis

A conservative calculation of the extent of sliding of the HI-STORM overpack and the HI-TRAC transfer cask due to the impact of a large missile (Table 2.2.5) and tornado wind (Table 2.2.4) is obtained using a common formulation as explained below. A more realistic impact simulation using LS-DYNA, with less bounding assumptions, has been used in a later subsection to qualify the HI-STORM overpack for a non-mechanistic tip over event. While it is not necessary for demonstrating adequate safety margins for this problem, an LS-DYNA analysis can also be used to calculate the sliding potential of the HI-STORM 100 Version E and Version E1 and HI-TRAC Version MS for a large missile impact. In what follows, both HI-STORM 100 Version E and Version E1 and HI-TRAC Version MS are identified by the generic term “cask”.

The principal assumptions that render these calculations for sliding conservative are:

- The weight of the cask used in the analysis is assumed to be the lowest bound.
- The cask is assumed to absorb the energy of impact purely by sliding. In other words, none of the impact energy is dissipated by the noise from the impact, from local plastic deformation in the cask at the location of impact, or from the potential tipping action of the cask.
- The missile impact and high wind, which applies a steady drag force on the cask, are assumed to act synergistically to maximize the movement of the cask.
- The cask is assumed to be freestanding on a concrete surface. The interface friction coefficient is assumed to be .53 as endorsed in this FSAR.
- The dynamic effect of the impact is represented by the force-time curve developed in the

Bechtel topical report “Design of Structures for Missile Impact” [3.II.21], also used in the main report in this FSAR.

The analysis for sliding under the above assumptions reduces to solving Newton's equation of motion of the form:

$$m \frac{d^2x}{dt^2} = F(t) + F_{dp} - \mu mg$$

where

m : mass of the cask,

t : time coordinate with its origin set at the instant when the sum of the missile impact force and wind drag force overcomes the static friction force,

x : displacement as a function of time coordinate t ,

$F(t)$: missile impact force as a function of time (from [3.II.22]),

F_{dp} : drag force from high wind,

μ : interface friction, endorsed by the NRC is 0.53 for freestanding cask on a reinforced concrete pad .

g : acceleration due to gravity.

The above second-order differential equation is solved numerically for the HI-STORM 100S Version E and Version E1 overpack and the HI-TRAC Version MS transfer cask, and the calculated sliding displacements are summarized in Table 3.II.4.10 per [3.II.24] and [3.II.23].

The maximum sliding computed for a site's large missile impact case sets the minimum inter-cask gap and the distance to the pad's edge at the ISFSI.

No generic limits for sliding are established for the HI-TRAC Version MS. Therefore, the sliding result for the HI-TRAC VERSION MS transfer cask in Table 3.II.4.10 is strictly informational.

b. Small and Intermediate Missiles

The small and intermediate missiles (Table 2.2.5) are analyzed to determine the extent to which they will penetrate the HI-STORM 100S Version E and Version E1 overpack or the HI-TRAC Version MS and cause potential damage to the MPC Enclosure Vessel. Classical energy balance methods are used to compute the depth of penetration at the following impact locations:

- on the HI-STORM 100 Version E and Version E1 outer shell
- on the HI-STORM 100 Version E lid top plate and 100S Common Lid top plate
- on the HI-TRAC Version MS outer shell
- on the top surface of the MPC upper lid

The MPC upper lid is analyzed for a direct missile impact because, when the MPC is placed inside the HI-TRAC Version MS, the MPC lid is theoretically accessible to a vertically downward directed small or intermediate missile.

The following assumptions are made in the analysis:

- The intermediate missile and the small missile are assumed to be unyielding, and hence the entire initial kinetic energy is assumed to be absorbed by local yielding and denting of the cask surface.
- No credit is taken for the missile resistance offered by the HI-TRAC's water jacket shell. It is assumed a priori that the small and intermediate missiles will penetrate the water jacket shell with no energy loss. Therefore, in the analysis 100% of the missile impact energy is applied directly to the HI-TRAC Version MS main outer shell. At trunnion locations, trunnion block has better penetration resistance than the lead it replaces, hence, HI-TRAC MS with trunnion option has better missile resistance and is not explicitly evaluated.
- For missile strikes on the side and top lid of the overpack, the analysis credits the structural resistance in compression offered by the concrete material that backs the outer shell and the lid.
- The resistance from the concrete is conservatively assumed to act over an area equal to the target area of impact. In other words, no diffusion of the load is assumed to occur through the concrete.

The analyses documented in [3.II.23] and [3.II.24] shows that the depth of penetration of the small missile is less than the thinnest section of material on the exterior surface of the HI-STORM 100S Version E or Version E1 or the HI-TRAC Version MS. Therefore, the small missile will dent, but not penetrate, the cask. Likewise, the 1-inch missile cannot enter the air inlet/outlet vents in the HI-STORM 100S Version E and Version E1 overpack. The penetration results for the small and intermediate missile are summarized in Table 3.II.4.11 per [3.II.24] and [3.II.23].

For the intermediate missile, the analyses documented in [3.II.24] and [3.II.23] show that there will be no penetration through the concrete surrounding the inner shell of the storage overpack or penetration of the top lid. Likewise, the intermediate missile will not penetrate the lead surrounding the HI-TRAC Version MS inner shell. At trunnion locations, trunnion block offers better penetration resistance than the lead it replaces. Therefore, there will be no impairment to the Confinement Boundary due to tornado-borne missile strikes. Furthermore, since the HI-STORM 100S Version E and Version E1 and HI-TRAC Version MS inner shells are not compromised by the missile strike, there will be no permanent deformation of the inner shells and ready retrievability of the MPC will be assured.

(ii) Loading Case M-2; Vertical Free fall of Loaded cask:

Since the lifting devices and the cask appurtenances (lifting attachments on the cask) are designed to meet the sing-failure proof criteria as per section 2.II.2.7, the vertical free fall of the HI-STORM cask and the horizontal fall of the HI-TRAC is not credible. If the lifting devices fail to meet the single failure proof criteria as per section 2.II.2.7, the postulated drops shall be addressed as part of the 10CFR72.212

evaluations. Such site-specific evaluation (if warranted) shall use the identical structural (finite element) models or evaluation methodologies as discussed in the following.

(iii) Loading Case M-3; Non-Mechanistic Tip-Over:

As discussed in Section 2.II.2.2, the non-mechanistic tip-over event applies to a loaded HI-STORM Version E and Version E1 module that is not anchored (or otherwise constrained from overturning on the ISFSI pad). The cask tip-over is not postulated as an outcome of any environmental phenomenon or accident condition. The cask tip-over is a non-mechanistic event, which is analyzed to comply with the guidance in NUREG-1536 [2.1.5]. The objective of the analysis is to demonstrate that the plastic deformation in the fuel basket is limited to the value at which the criticality safety is maintained, retrieval of the fuel by normal means is assured, and that there is no significant loss of radiation shielding in the storage system.

The tip over event is an artificial construct wherein the HI-STORM 100S Version E or Version E1 overpack is assumed to be perched on its edge with its C.G. directly over the pivot point A (Figure 3.II.4.6)). In this orientation, the overpack begins its downward rotation with zero initial velocity. Towards the end of the tip-over, the overpack is horizontal with its downward velocity ranging from zero at the pivot point (point A) to a maximum at the farthest point of impact. The angular velocity at the instant of impact defines the downward velocity distribution along the contact line.

In the following, an explicit expression for calculating the angular velocity of the cask at the instant when it impacts on the ISFSI pad is derived. Referring to Figure 3.II.4.6, let r be the length AC where C is the cask centroid. Therefore,

$$r = \left(\frac{d^2}{4} + h^2 \right)^{1/2}$$

The mass moment of inertia of the HI-STORM Version E and Version E1 system, considered as a rigid body, can be written about an axis through point A, as

$$I_A = I_c + \frac{W}{g} r^2$$

where I_c is the mass moment of inertia about a parallel axis through the cask centroid C, and W is the weight of the cask ($W = Mg$).

Let $\theta_1(t)$ be the rotation angle between a vertical line and the line AC. The equation of motion for rotation of the cask around point A, during the time interval prior to contact with the ISFSI pad, is

$$I_A \frac{d^2 \theta_1}{dt^2} = Mgr \sin \theta_1$$

This equation can be rewritten in the form

$$\frac{I_A}{2} \frac{d(\dot{\theta}_1)^2}{d\theta_1} = Mgr \sin \theta_1$$

which can be integrated over the limits $\theta_1 = 0$ to $\theta_1 = \theta_{2f}$ (Figure 3.II.4.6). The final angular velocity $\dot{\theta}_1$ at the time instant just prior to contact with the ISFSI pad is given by the expression

$$\dot{\theta}_1(t_B) = \sqrt{\frac{2Mgr}{I_A} (1 - \cos \theta_{2f})}$$

where, from Figure 3.II.2,

$$\theta_{2f} = \cos^{-1}\left(\frac{d}{2r}\right)$$

This equation establishes the initial conditions for the final phase of the tip-over analysis; namely, the portion of the motion when the cask is decelerated by the resistive force at the ISFSI pad interface. Using the data germane to HI-STORM Version E and Version E1 (Table 3.4.11) and the above equations, the angular velocity of impact is calculated as:

$$\dot{\theta}_1(t_B) = 1.48 \text{ rad/sec.}$$

Table 3.II.4.13 summarizes the stress results per [3.II.26], along with the corresponding material allowable stress.

In addition to the above analyses, an additional tipover analysis is performed for the HI-STORM Version E storage cask with loaded MPC containing MPC-32M CBS basket using the same methodology as described above for the tipover analysis containing MPC-32M basket. The LS-DYNA model is constructed according to the dimensions specified in the licensing drawings included in Section 1.5. The bounding target foundation properties per Table 2.II.0.1 are utilized. The details of the finite element model, input data and results are archived in the calculation package [3.II.26]. The following conclusions demonstrate that all safety criteria are satisfied for the cask system with MPC-32M CBS basket design.

- i. The lateral deflection of the most heavily loaded basket panel in the active fuel region complies with the deflection criterion in Table 2.II.2.4.
- ii. The CBS remain attached to the basket maintaining their physical integrity.
- iii. The plastic strains in the MPC enclosure vessel remain below the allowable material plastic strain limit.
- iv. The cask closure lid does not dislodge after the tipover event, i.e., the closure lid bolts remain in-tact.

v. The shielding capacity of overpack is not compromised by the tip-over accident and there is no gross plastic deformation in the overpack to affect the retrievability of the MPC.

Tipover analyses are performed for the HI-STORM 100S Version E1 storage cask and 100S common lid with loaded MPC containing MPC-32M CBS and MPC-68M CBS baskets and using the same methodology as described above for the HI-STORM 100S Version E tipover analysis containing MPC-32M basket. The LS-DYNA model is constructed according to the dimensions specified in the licensing drawings included in Section 1.5. The bounding target foundation properties per Table 2.II.0.1 are utilized. The details of the finite element model, input data and results are archived in the calculation package [3.II.26]. Based on the results in [3.II.26] all safety criteria listed above are satisfied. Tipover analyses are only performed with MPC-32M CBS and MPC-68M CBS Metamic-HT baskets as they are more prone to deflections due to reduced support from basket shims and the extended fuel basket panels outside the active fuel region. Comparative tipover evaluations of the other fuel basket variants, as permitted in Table 1.II.2.2, are presented in [3.II.26] and [3.A.7]. Structural qualification of HI-STORM 100S common lid under tipover is also presented in [3.II.26].

(iv) Loading Case M-5; Design Basis Earthquake: This loading case and corresponding acceptance criteria is defined in Paragraph 2.II.2.2.

For a “low intensity” Design Basis earthquake, the two inequalities in Paragraph 2.II.2.2(c) provide the acceptance criteria.

In this section, the combination of vertical and horizontal ZPA of the earthquake that would cause incipient loss of kinematic stability is derived using static equilibrium. The resulting inequality defines the threshold of the so-called low intensity earthquake for which the HI-STORM 100S Version E and Version E1 system is qualified without a dynamic analysis.

For the purpose of performing a conservative analysis to determine the maximum ZPA that will not cause incipient tipping and relative sliding, the HI-STORM 100S VERSION E and Version E1 System is considered as a rigid body subject to a net horizontal quasi-static inertia force and a vertical quasi-static inertia force. This is consistent with the approach used in previously licensed HI-STORM dockets. The vertical seismic load is conservatively assumed to act in the most unfavorable direction (upwards) at the same instant. The vertical seismic load is assumed to be equal to or less than the net horizontal load with ϵ being the ratio of vertical component to one of the horizontal components.

i. Prevention against edging of the cask:

For use in calculations, define D_{BASE} as the HI-STORM support span, and H_{CG} as the height of the centroid of HI-STORM 100S VERSION E and Version E1 System.

$D_{BASE} = 132.5"$ (conservatively used per HI-STORM dwg. specified in Section 1.II.5)

$H_{CG} = 112.9"$ (Based on Table 3.II.2.5)

An overturning stability limit is achieved by using the value of H_{CG} (call it H) from the above. Because the HI-STORM 100S Version E and Version E1 System is a radially symmetric structure, the two horizontal seismic accelerations can be combined vectorially and applied as an overturning force at the C.G. of the cask. The net overturning static moment per [3.II.3] is

$$W G_H \cdot H$$

where W is the total system weight and G_H is the resultant zero period acceleration seismic loading (vectorial sum of two orthogonal seismic loads) so that $W G_H$ is the inertia load due to the resultant horizontal acceleration. The overturning moment is balanced by a vertical reaction force, acting at the outermost contact patch radial location $r = D_{BASE}/2$. The resistive moment is minimized when the vertical zero period acceleration G_V tends to reduce the apparent weight of the cask. At that instant, the moment that resists "incipient tipping" per [3.II.3] is:

$$W (1 - G_V) r$$

Performing a static moment balance and eliminating W results in the following inequality to ensure a "no-overturning condition per [3.II.3]:

$$G_H + \frac{r}{H} G_V \leq \frac{r}{H}$$

Using the values of r and H for the HI-STORM 100S VERSION E and Version E1 ($r = 66.25"$, $H = 108.66"$), representative combinations of G_H and G_V that satisfy the limiting equality relation are computed and tabulated below (G_V is kept as 2/3 of horizontal response per [3.II.28]):

Acceptable Net Horizontal G-Level (HI-STORM100S Version E and Version E1), G_H	Acceptable Vertical G-Level, G_V
0.422	0.281

Using the same methodology in this section, the maximum allowable horizontal and vertical ZPAs to maintain a minimum safety factor of 1.1 against tipping are calculated and presented in [3.II.23] for the tallest HI-STORM 100S Version E1.

ii. Prevention of sliding of the cask:

Using static force equilibrium equations, as defined in section 2.II.2.2, the following inequality must be met to prevent sliding of the cask.

$$W \cdot G_H \leq \mu \cdot W \cdot (1-G_V)$$

$$\text{Or } G_H \leq (1-G_V) \cdot \mu$$

All variables in the above equation are defined earlier.

μ = limiting value of the friction coefficient at the HI-STORM/ISFSI pad interface is assumed to be equal to 0.53 (the NRC-approved value in Docket No. 72-1014).

As seen above, this relative sliding between the cask and the concrete pad is independent of its weight and the center of gravity.

Using the representative combinations of G_H and G_V that satisfy the limiting equality relation are computed and tabulated below (G_V is kept as 2/3 of horizontal response per [3.II.28]):

Acceptable Net Horizontal G-Level (HI-STORM100S Version E and Version E1), G_H	Acceptable Vertical G-Level, G_V
0.391	0.261

For earthquakes with ZPA stronger than the ones defined above, it is necessary to perform a time-history dynamic analysis. The HI-STORM 100S Version E and Version E1 Systems plus their contents may be assumed as a 6 degree-of-freedom body subject to a seismic event consisting of three orthogonal statistically independent acceleration time-histories. The input seismic acceleration time histories shall meet the relevant requirements specified in the SRP 3.7.1 [3.II.13]. The analysis shall include the soil-structure-interaction (SSI) effects as applicable and follow the methodology from NUREG/CR-6865 [3.II.30]. The comprehensive 3D time-history analysis will be addressed as part of the 10CFR 72.212 evaluation based on the site subgrade and seismic conditions.

Under a seismic event, a small clearance between the MPC and the HI-STORM inner shell may lead to a high localized strain in the region of the shell where impacts from rattling of the canister occur. The extent of local strain from these impacts is minimized by locating the guide tube in the vertical direction such that its impact footprint is aligned with the surface of the closure lid which has been shimmed to close the crevice between the lid and the shell. Thus the impact between the guide tubes and the MPC lid will occur at a location where the maximum damage to the MPC shell will be local denting in the region where it is buttressed by the edge of a (thick) MPC lid. Therefore, a through-wall damage of the MPC shell is not credible. Furthermore, the force of impact will evidently be greater in the non-mechanistic tip-over case. Therefore, the seismic impact case is designated as non-governing for the guide tube/MPC impact scenario.

(v) MPC Reflood analysis

This loading event is not treated in this FSAR; it was first considered in the HI-STORM 100S (docket # 72-1032) FSAR where a complete summary of a conservatively constructed thermal transient analysis for a whole array of different fuel rod types is provided (reference is made to

sub-paragraph 3.4.4.1.11 in the HI-STORM 100 FSAR [3.II.3]). A summary of the analysis outline excerpted from the above is provided below for completeness.

[

PROPRIETARY INFORMATION WITHHELD PER 10CFR2.390

]

(vi) Moving Floodwater

The object of the analysis is to determine the maximum floodwater velocity that a loaded HI-STORM Version E and Version E1 overpack on the ISFSI pad can withstand before tipping over or sliding. The kinematic stability analysis consists of writing static equilibrium equations for tipping and sliding.

The flood condition subjects the HI-STORM overpack to external pressure, together with a horizontal load due to water velocity. Because the HI-STORM Version E and Version E1 storage overpack is equipped with ventilation openings, the hydrostatic pressure from flood submergence does not affect the overpack.

The water velocity associated with flood produces a horizontal drag force, which may act to cause sliding or tip-over. In accordance with the provisions of ANSI/ANS 57.9, the acceptable upper bound flood velocity, V , must provide a minimum factor of safety of 1.1 against overturning and sliding.

The overturning horizontal force, F , due to hydraulic drag, is given by the classical formula:

$$F = C_d A V^* \quad [\text{Equation 1}]$$

where:

$$V^* = \text{velocity head} = \frac{\rho V^2}{2g} \quad (\rho \text{ is water weight density, and } g \text{ is acceleration due to gravity}).$$

A = projected area of the HI-STORM overpack cylinder perpendicular to the fluid velocity vector, equal to D times h , where h is the height of the floodwater.

C_d = drag coefficient

The value of C_d for flow past a cylinder at Reynolds number above $5E+05$ is given as 0.5 in the literature [3.II.19]

The drag force tending to cause HI-STORM 100S's sliding is opposed by the friction force, which is given by

$$F_f = \mu W^* \quad [\text{Equation 2}]$$

where:

μ = limiting value of the friction coefficient at the HI-STORM 100S/ISFSI pad interface is assumed to be equal to 0.53 (the NRC-approved value in this FSAR).

W^* = apparent (buoyant) weight of HI-STORM 100S with an empty MPC.

i. Sliding Factor of Safety

The factor of safety against sliding, β_1 , is given by

$$\beta_1 = \frac{F_f}{F} = \frac{\mu W^*}{C_d A V^*} = \frac{2g\mu W^*}{C_d(Dh)\rho V^2} \quad [\text{Equation 3}]$$

The factor of safety, β_1 , must be greater than 1.1. For $g = 32.2 \text{ ft/sec}^2$, $C_d = 0.5$, and $\rho = 62.4 \text{ lbf/ft}^3$, the maximum value of V as a function of the floodwater height h is given by

$$V = \sqrt{\frac{1.876\mu W^*}{Dh}} \quad [\text{Equation 4}]$$

ii. Overturning Factor of Safety

For determining the margin of safety against overturning, β_2 , the cask is assumed to pivot about a

fixed point located at the outer edge of the contact circle at the interface between HI-STORM 100S and the ISFSI. The overturning moment due to the hydraulic force F_T is balanced by a restoring moment from the buoyant weight acting at radius $D/2$.

Overturning moment, $M_o = Fh/2$ where F is given by Equation 1 above.

Restoring moment, $M_r = W^* D/2$ [Equation 5]

For stability against tipping $M_o \leq M_r$

or $Fh \leq W^*D$

Hence the factor of safety against overturning is

$$\beta_2 = \frac{W^*D}{Fh} = \frac{W^*D}{C_d A V^* h} = \frac{2gW^*}{C_d h^2 \rho V^2} \quad [\text{Equation 6}]$$

β_2 must be greater than 1.1. For $g = 32.2 \text{ ft/sec}^2$, $C_d = 0.5$, and $\rho = 62.4 \text{ lbf/ft}^3$, the maximum value of V as a function of the floodwater height h is given by

$$V = \frac{\sqrt{1.876W^*}}{h} \quad [\text{Equation 7}]$$

The smaller of the value of V from Equations 4 and 7 defines the maximum permissible flood velocity for the site. Because the height and weight of the overpack can be variable, the numerical value of V shall vary. The calculation of V for the case of the overpack illustrated in the Licensing drawing with minimum density concrete (171 pcf) and the MPC with only one fuel assembly (i.e., the minimum weight cask) is computed as follows:

From Tables 3.II.2.6 and the drawings in Section 1.5, the diameter and maximum height of the overpack are

$$D = 132.5 \text{ in} = 11.04 \text{ ft}$$

$$h = 214.5 \text{ in} = 17.87 \text{ ft}$$

From Tables 3.II.2.6, the minimum weight of the HI-STORM 100S Version E or Version E1 overpack with an empty MPC is

$$W = 275,000 \text{ lbf}$$

Finally, assuming that $W^* = 0.87W$, the acceptable upper bound flood velocity is determined from Equation 4 as

$$V = \sqrt{\frac{1.876(0.53)(0.87 \times 275,000)}{(11.04)(17.87)}} = 34.7 \text{ ft/sec}$$

Using the same methodology, the maximum acceptable flood water velocity is determined to be 33.97ft/sec for tallest HI-STORM 100S Version E1 cask (h = 224in) with HI-STORM 100S Common Lid.

3.II.4.5 Cold

A discussion of the resistance to failure due to brittle fracture is provided in the newly created Supplement 14.II (to align this FSAR with the latest NRC guidance).

The value of the ambient temperature has two principal effects on the HI-STORM 100 system, namely:

- i. The steady-state temperature of all material points in the cask system will go up or down by the amount of change in the ambient temperature.
- ii. As the ambient temperature drops, the absolute temperature of the contained helium will drop accordingly, producing a proportional reduction in the internal pressure in accordance with the Ideal Gas Law.

In other words, the temperature *gradients* in the system under steady-state conditions will remain the same regardless of the value of the ambient temperature. The internal pressure, on the other hand, will decline with the lowering of the ambient temperature. Since the stresses under normal storage condition arise principally from pressure and thermal gradients, it follows that the stress field in the MPC under the limiting cold ambient condition (–40 degree F) would be smaller than the "heat" condition of storage, treated in the preceding subsection. Additionally, the allowable stress limits tend to increase as the component temperatures decrease.

Therefore, the stress margins computed in the foregoing subsection can be conservatively assumed to apply to the "cold" condition as well.

Finally, as discussed below, the system is engineered to withstand “cold” temperatures (–40 degrees F) without impairment of its storage function.

Unlike the MPC, the HI-STORM storage overpack is an open structure; it contains no pressure. Its stress field is unaffected by the ambient temperature, unless low temperatures produce brittle fracture due to the small stresses which develop from self-weight of the structure and from the minute difference in the thermal expansion coefficients in the constituent parts of the equipment (steel and concrete). To prevent brittle fracture, all structural steel material in the HI-STORM overpack is qualified by impact testing pursuant to the ASME Code.

The structural material used in the MPC (Alloy X) is recognized in the ASME Codes to be completely immune from brittle fracture.

The material property used to determine whether a flaw in the Metamic HT basket panel would propagate under the most adverse dynamic stress scenario is the Charpy impact strength, C_r . Aluminum is among the small group of metals that maintains its impact strength under extreme cold conditions. The conservative crack propagation analysis, documented in [3.II.25], shows that there exists large safety factor against crack propagation in the HI-STORM Version E and Version E1 Metamic HT fuel baskets due to the non-mechanistic tipover event. Note that the maximum stress intensity (28.1 ksi) used in this conservative analysis is significantly higher than the stresses induced in the MPC-32M (and 32M CBS) basket from the HI-STORM Version E or Version E1 tipover analysis. Since Metamic's fracture resistance at low temperatures remains robust in the manner of aluminum, brittle fracture under "cold" condition is not a credible failure mode for the Metamic HT fuel basket.

As no liquids are included in the HI-STORM storage overpack design, loads due to expansion of freezing liquids are not considered. The HI-TRAC Version MS transfer cask utilizes demineralized water in the water jacket. However, the specified lowest service temperature for the HI-TRAC Version MS is 0 degrees F and a 25% ethylene glycol solution is required for ambient temperatures in the range of 0 degrees F to 32 degrees F. Therefore, loads due to expansion of freezing liquids are not considered.

Finally, under a postulated loading of an MPC from a HI-TRAC Version MS transfer cask into a cold HI-STORM storage overpack, it must be demonstrated that sufficient clearances are available to preclude interference when the "hot" MPC is inserted into a "cold" storage overpack. To this end, a bounding analysis for free thermal expansions has been performed in Chapter 4, wherein the MPC shell is postulated at its maximum design basis temperature and the thermal expansion of the overpack is ignored. As shown in Section 4.II.4 the engineered radial clearance is sufficient to preclude jamming of the MPC upon insertion into a cold HI-STORM storage overpack.

3.II.4.6 Structural Integrity of Damaged Fuel Containers (DFCs) and Damaged Fuel Isolators (DFIs)

The Damaged Fuel Container (DFC) is used to store fuel that is physically impaired such that it cannot be handled by normal means. The DFC, as shown in Figure 2.II.1-4, is equipped with a handle welded to a square cellular box with a perforated baseplate structurally capable of supporting the weight of the fuel while permitting water (but not particulates) to pass through. All load bearing members of the DFC are designed to meet Level A service limit when holding a spent fuel assembly. Because the DFC is always handled under water, there are no radiation release-related issues associated with it. The Damaged Fuel Isolator (DFI), as shown in Figure 2.II.1-5, is used to confine a fuel assembly which can be handled by its own lifting appurtenance. The DFI serves to provide a confinement for the coarse particulates but not for gaseous matter. The sole design requirement for the DFI is that it is sized to envelope the fuel assembly and yet provides adequate clearance with the storage cell to permit insertion and removal of the fuel by the available force in the Fuel Handling Bridge.

3.II.4.7 Service Life of HI-STORM 100 Version E and Version E1 and HI-TRAC VW Version MS³

The term of the 10CFR72, Subpart L C of C, granted by the NRC is 20 years; therefore, the License Life (see Glossary) of all components is 20 years. Nonetheless, the HI-STORM Version E and Version E1 storage overpack and the HI-TRAC Version MS transfer cask are engineered for 60 years of design life, while satisfying the conservative design requirements defined in Chapter 2, including the regulatory requirements of 10CFR72. In addition, the storage overpack and HI-TRAC Version MS are designed, fabricated, and inspected under the comprehensive Quality Assurance Program approved by the USNRC and in accordance with the applicable requirements of the ACI and ASME Codes. This assures high design margins, high quality fabrication, and verification of compliance through rigorous inspection and testing, as described in Chapter 9 and the licensing drawings in Section 1.II.5. Technical Specifications defined in Chapter 12 assure that the integrity of the cask and the contained MPC are maintained throughout the components' design life. The design life of a component, as defined in the Glossary, is the minimum duration for which the equipment or system is engineered to perform its intended function if operated and maintained in accordance with the FSAR. The design life is essentially the lower bound value of the service life, which is the expected functioning life of the component or system. Therefore, component longevity should be: licensed life < design life < service life. (The licensed life, enunciated by the USNRC, is the most pessimistic estimate of a component's life span). For purposes of further discussion, we principally focus on the service life of the HI-STORM 100 system components that, as stated earlier, is the reasonable expectation of equipment's functioning life span.

The service life of the storage overpack and HI-TRAC Version MS transfer cask is further discussed in the following.

3.II.4.7.1 Storage Overpack

The principal design considerations that bear on the adequacy of the storage overpack for the service life are addressed as follows:

Exposure to Environmental Effects

All exposed surfaces of the HI-STORM 100S overpack are made from ferritic steels that are readily painted. Concrete, which serves strictly as a shielding material, is completely encased in steel. Therefore, the potential of environmental vagaries such as spalling of concrete, are ruled out for HI-STORM Version E and Version E1. Under normal storage conditions, the bulk temperature of the HI-STORM Version E and Version E1 storage overpack will, because of its large thermal inertia, change very gradually with time. Therefore, material degradation from rapid thermal ramping conditions is not credible for the HI-STORM Version E and Version E1 storage overpack. Similarly, corrosion of structural steel embedded in the concrete structures due to salinity in the environment at coastal sites is not a concern for HI-STORM Version E and Version E1 because it contains no rebars. As discussed in Appendix 1.D, the aggregates, cement and water used in the

3 Sub-sections 3.II.4.7 and 3.II.4.8 have been adopted from the HI-STORM 100S FSAR [3.II.3]

storage cask concrete are carefully controlled to provide high durability and resistance to temperature effects. The configuration of the storage overpack assures resistance to freeze-thaw degradation. In addition, the storage overpack is specifically designed for a full range of enveloping design basis natural phenomena that could occur over the 60-year design life of the storage overpack as defined in Subsection 2.2.3. Supplement 14.II provides further discussions on chemical and galvanic reactions, material compatibility and operating environments.

Material Degradation

As discussed in Supplement 14.II, the relatively low neutron flux to which the storage overpack is subjected cannot produce measurable degradation of the cask's material properties and impair its intended safety function. Exposed carbon steel components are coated to prevent corrosion. The controlled environment of the ISFSI storage pad mitigates damage due to direct exposure to corrosive chemicals that may be present in other industrial applications.

Maintenance and Inspection Provisions

The requirements for periodic inspection and maintenance of the storage overpack throughout the 60-year design life are defined in Chapter 9. These requirements include provisions for routine inspection of the storage overpack exterior and periodic visual verification that the ventilation flow paths of the storage overpack are free and clear of debris. ISFSIs located in areas subject to atmospheric conditions that may degrade the storage cask or canister should be evaluated by the licensee on a site-specific basis to determine the frequency for such inspections to assure long-term performance. In addition, the HI-STORM 100 system is designed for easy retrieval of the MPC from the storage overpack should it become necessary to perform more detailed inspections and repairs on the storage overpack.

The above findings are consistent with those of the NRC's Waste Confidence Decision Review [3.II.22], which concluded that dry storage systems designed, fabricated, inspected, and operated in accordance with such requirements are adequate for a 100-year service life while satisfying the requirements of 10CFR72.

3.II.4.7.2 Transfer Cask

The principal design considerations that bear on the adequacy of the HI-TRAC Version MS transfer cask for the service life are addressed as follows:

Exposure to Environmental Effects

All transfer cask materials that come in contact with the spent fuel pool are coated to facilitate decontamination. The HI-TRAC Version MS is designed for repeated normal condition handling operations with high factor of safety to assure structural integrity. The resulting cyclic loading produces stresses that are well below the endurance limit of the cask's materials, and therefore, will not lead to a fatigue failure in the transfer cask. All other off-normal or postulated accident conditions are infrequent or one-time occurrences that do not contribute significantly to fatigue. In

addition, the transfer cask utilizes materials that are not susceptible to brittle fracture during the lowest temperature permitted for loading, as discussed in Supplement 14.II.

Supplement 14.II provides further discussions on chemical and galvanic reactions, material compatibility and operating environments.

Material Degradation

As discussed in Supplement 14.II, all transfer cask materials that are susceptible to corrosion are coated. The controlled environment in which the HI-TRAC Version MS is used mitigates damage due to direct exposure to corrosive chemicals that may be present in other industrial applications. The infrequent use and relatively low neutron flux to which the HI-TRAC Version MS materials are subjected do not result in radiation embrittlement or degradation of the HI-TRAC's shielding materials that could impair the HI-TRAC's intended safety function. The HI-TRAC Version MS transfer cask materials are selected for durability and wear resistance for their deployment.

Maintenance and Inspection Provisions

The requirements for periodic inspection and maintenance of the HI-TRAC Version MS transfer cask throughout the 60-year design life are defined in Chapter 9. These requirements include provisions for routine inspection of the HI-TRAC Version MS transfer cask for damage prior to each use, including an annual inspection of the lifting attachments. Precautions are taken during lid handling operations to protect the sealing surfaces of the bottom lid. The leak tightness of the liquid neutron shield is verified periodically. The water jacket pressure rupture discs and other fittings used can be easily removed.

3.II.4.8 MPC Service Life

The term of the 10CFR72, Subpart L C of C, granted by the NRC (i.e., licensed life) is 20 years. Nonetheless, the HI-STORM 100 MPCs are designed for 60 years of design life pursuant to the regulatory requirements of 10CFR72. Additional assurance of the integrity of the MPC and the contained SNF assemblies throughout the 60-year life of the MPC Enclosure Vessel is provided through the following:

- Design, fabrication, and inspection invoke the pertinent requirements of the ASME Code, as applicable, assures high inherent design margins in operating modes.
- Fabrication and inspection performed in accordance with the comprehensive Quality Assurance program assures competent compliance with the fabrication requirements.
- Use of materials with known characteristics, verified through rigorous inspection and testing, assures component compliance with design requirements.
- Use of welding procedures in full compliance with Section III of the ASME Code ensures high-quality weld joints.

Technical Specifications, as defined in Chapter 12.II, have been developed and imposed on the MPC that assure that the integrity of the MPC and the contained SNF assemblies is maintained throughout the 60-year design life of the MPC.

The principal design considerations bearing on the adequacy of the MPC for the service life are summarized below.

Corrosion

All MPC Confinement Boundary materials are fabricated from corrosion-resistant stainless steel. The corrosion-resistant characteristics of such materials for dry SNF storage canister applications, as well as the protection offered by these materials against other material degradation effects, are well established in the nuclear industry. The Fuel basket is made of Metamic HT whose anodized surfaces provide an inert surface to the MPVC's aqueous environment during Part 50 operations. The moisture in the MPC is removed to eliminate all oxidizing liquids and gases and the MPC cavity is backfilled with dry inert helium at the time of closure to maintain an atmosphere in the MPC that provides corrosion protection for the SNF cladding throughout the dry storage period. The preservation of this non-corrosive atmosphere is assured by the inherent seal-worthiness of the MPC Confinement Boundary integrity (there are no gasketed joints in the MPC).

Structural Fatigue

The passive non-cyclic nature of dry storage conditions does not subject the MPC to conditions that might lead to structural fatigue failure. Ambient temperature and insolation cycling during normal dry storage conditions and the resulting fluctuations in MPC thermal gradients and internal pressure are the only mechanism for fatigue. These low-stress, high-cycle conditions cannot lead to a fatigue failure of the MPC that is made from stainless alloy stock (endurance limit well in excess of 20,000 psi). All other off-normal or postulated accident conditions are infrequent or one-time occurrences, which cannot produce fatigue failures. Finally, the MPC uses materials that are not susceptible to brittle fracture at low temperatures.

Maintenance of Helium Atmosphere

The inert helium atmosphere in the MPC provides a non-oxidizing environment for the SNF cladding to assure its integrity during long-term storage. The preservation of the helium atmosphere in the MPC is assured by the robust design of the MPC Confinement Boundary described in Chapter 7. Maintaining an inert environment in the MPC mitigates conditions that might otherwise lead to SNF cladding failures. The required mass quantity of helium backfilled into the canister at the time of closure and the associated fabrication and closure requirements for the canister are specifically set down to assure that an inert helium atmosphere is maintained in the canister throughout the 60-year design life.

Allowable Fuel Cladding Temperatures

The helium atmosphere in the MPC promotes heat removal and thus reduces SNF cladding temperatures during dry storage. In addition, the SNF decay heat will substantially attenuate over a 60-year dry storage period. Maintaining the fuel cladding temperatures below allowable levels during long-term dry storage mitigates the damage mechanism that might otherwise lead to SNF cladding failures. The allowable long-term SNF cladding temperatures used for thermal acceptance of the MPC design are conservatively determined, as discussed in Chapter 4.II.

Neutron Absorber Boron Depletion

The effectiveness of the fixed borated neutron absorbing material used in the MPC fuel basket design requires that sufficient concentrations of boron be present to assure criticality safety during worst case design basis conditions over the 60-year design life of the MPC. Information on the characteristics of the borated neutron absorbing material used in the MPC fuel basket is provided in Subsection 1.2.1 and Chapter 8. The relatively low neutron flux, to which this borated material is subjected and will continue to decay over time, does not result in significant depletion of the material's available boron to perform its intended safety function. In addition, the boron content of the material used in the criticality safety analysis is conservatively based on the minimum specified boron areal density (rather than the nominal), which is further reduced by 10% for analysis purposes. Analysis discussed in Section 6.II.3 demonstrates that the boron depletion in the neutron absorber material is negligible over a 60-year duration. Thus, sufficient levels of boron are present in the fuel basket neutron absorbing material to maintain criticality safety functions over the 60-year design life of the MPC.

The above findings are consistent with those of the NRC's Waste Confidence Decision Review, which concluded that dry storage systems designed, fabricated, inspected, and operated in the manner of the requirements set down in this document are adequate for a 100-year service life, while satisfying the requirements of 10CFR72.

3.II.4.9 Design and Service Life

The discussion in the preceding sections seeks to provide the logical underpinnings for setting the design life of the storage overpacks, the HI-TRAC Version MS transfer cask, and the MPCs as sixty years. Design life, as stated earlier, is a lower bound value for the expected performance life of a component (service life). If operated and maintained in accordance with this Safety Analysis Report, Holtec International expects the service life of HI-STORM Version E and Version E1 casks to substantially exceed their design life values.

Table 3.II.4.1: Threaded Anchor Location (TAL) Data

Component	Size of tapped hole	Number of tapped holes	Minimum thread engagement (in.)	Comment
MPC lid	1.75 inch; 5 UNC	4	3.0	The tapped holes are in Alloy X material of the Lid
HI-TRAC Version MS	2.25 inch; 4.5 UNC	8	2.25	The tapped holes are in the low alloy steel forging of the HI-TRAC top flange
HI-STORM Version E and Version E1	3.25 inch; 4 UNC	4	4.0	The tapped holes are in anchor block forgings which are strength welded to the radial connectors.

3.II.5 Fuel Rods

The regulations governing spent fuel storage cask approval and fabrication (10 CFR 72.236) require that a storage cask system “will reasonably maintain confinement of radioactive material under normal, off-normal, and credible accident conditions” (§72.236(l)). Although the cladding of intact fuel rods does provide a barrier against the release of radioactive fission products, the confinement evaluation for the HI-STORM 100 system (Chapter 7) takes no credit for fuel cladding integrity in satisfying the regulatory confinement requirement.

As described in chapter 7, the Confinement Boundary in the HI-STORM 100S system consists of the MPC Enclosure Vessel. The Enclosure Vessel is designed and, to the extent practicable, manufactured in accordance with the most stringent ASME B&PV Code (Section III, Subsection NB). As required by NB, all materials are 100% UT inspected and all butt welds are subjected to 100% volumetric inspection. The field closure features redundant barriers (the MPC lid and port cover plates are the primary barriers, the closure ring is the secondary barrier). Furthermore, MPC design, welding, testing and inspection requirements meet the guidance of ISG-18 such that leakage from the Confinement Boundary is non-credible under the postulated normal and off-normal conditions. It is therefore concluded that since the MPC confinement vessel remains intact, and the design bases temperatures and pressure are not exceeded, leakage from the MPC Confinement Boundary is not credible. Confinement for accident conditions is also addressed in Chapter 7, which concludes that there is no mechanistic failure mode that could result in a breach of the Confinement Boundary, and escape of radioactive materials to the environment.

Since fuel rod cladding is not considered in the design criteria for the confinement of radioactive material under normal, off-normal, or accident conditions of storage, no specific analysis or test results are required to demonstrate cladding integrity.

3.II.6 Supplemental Data

3.II.6.1 Calculation Packages

In addition to the calculations presented in this supplement, supporting calculation packages have been prepared to document other information pertinent to the analyses. Supporting calculation packages back up the summary results reported herein. The Calculation Packages are referenced in this supplement and are maintained as proprietary documents in Holtec's Configuration Control system.

3.II.6.2 Computer Programs

Three computer programs, all in long-term use in the safety analysis of HI-STORM/HI-STAR systems, have been utilized to perform structural and mechanical analyses documented in this FSAR. These codes are ANSYS, LS-DYNA and Visual Nastran.

i. ANSYS Mechanical [3.II.7]

ANSYS is the original (and commonly used) name for ANSYS Mechanical general-purpose finite element analysis software. ANSYS Mechanical is the VERSION of ANSYS commonly used for structural applications. It is a self-contained analysis tool incorporating pre-processing (geometry creation, meshing), solver, and post processing modules in a unified graphical user interface. ANSYS Mechanical is a general-purpose finite element modeling package for numerically solving a wide variety of mechanical problems. These problems include: static/dynamic structural analysis (both linear and non-linear), heat transfer and fluid problems, as well as acoustic and electro-magnetic problems.

ANSYS Mechanical has been independently QA validated by Holtec International and used for structural analysis of casks, fuel racks, pressure vessels, and a wide variety of SSCs, for over twenty-five years.

ii. LS-DYNA [3.II.5]

LS-DYNA is a general-purpose finite element code for analyzing the large deformation static and dynamic response of structures including structures coupled to fluids. The main solution methodology is based on explicit time integration and is therefore well suited for the examination of the response to shock loading. A contact-impact algorithm allows difficult contact problems to be easily treated. Spatial discretization is achieved by the use of four node tetrahedron and eight node solid elements, two node beam elements, three and four node shell elements, eight node solid shell elements, truss elements, membrane elements, discrete elements, and rigid bodies. A variety of element formulations are available for each element type. Adaptive re-meshing is available for shell elements. LS-DYNA currently contains approximately one hundred constitutive models and ten equations-of-state to cover a wide range of material behavior.

In this safety analysis report, LS-DYNA is used to analyze all loading conditions that involve

short-time dynamic effects.

LS-DYNA is maintained in a QA-validated status in Holtec's Configuration Control system.

iii. Visual Nastran (now renamed SYMWISE) [3.II.6]

Visual Nastran is used for rigid body motion simulation of the cask components, where a simplified analysis is appropriate. Visual Nastran is a kinematics simulation code that includes large orientation change capability, simulation of impacts, and representation of contact and friction behavior. Visual Nastran Desktop (VN) performs time history dynamic analysis of freestanding structures using the acceleration time-histories in the three orthogonal directions as the input. It provides a complete articulation of the dynamic response of the rigid body, including sliding, precession, and tipping (and combinations thereof). Visual Nastran is maintained in a QA-validated status by Holtec International.

All three computer codes have been benchmarked and QA-validated to establish their veracity.

The compliance matrix below provides the necessary information to document their validation status, and the measures employed pursuant to ISG-21 and Holtec's QA program, to ensure error-free solutions.

ISG-21 and QA Compliance Matrix for Computer Codes				
	Item	ANSYS	LS-DYNA	Visual Nastran
1.	Benchmark and QA-validation are documented in Holtec Report No.(s) (Proprietary Reports)	HI-2012627	HI-961519	HI-2022896
2.	Computer Program Type (Public or Private Domain)	Public Domain	Public Domain	Public Domain
3.	Does Holtec maintain a system evaluating error notices if any are issued by the Code provider to evaluate their effect on the safety analyses carried out using the Code, including Part 21 notification? (Yes/No)	Yes	Yes	Yes
4.	Is the use of the Code restricted to personnel qualified under the Company's personnel qualification program? (Yes/No)	Yes	Yes	Yes
5.	Has benchmarking been performed against sample problems with known independently obtained numerical solutions (Yes/No)	Yes	Yes	Yes
6.	Have element types used in the safety analyses herein also employed in the benchmarking effort? (Yes/No)	Yes	Yes	N/A
7.	Are the element types used in this FSAR also used in other Holtec dockets that support other CoCs? (Yes/No)	Yes	Yes	N/A
8.	Is each update of the Code vetted for backwards consistency with prior updates? (Yes/No)	Yes	Yes	Yes
9.	Is the use of the Code limited to the range of parameters specified in the User Manual provided by the Code Developer? (Yes/No)	Yes	Yes	Yes
10.	Are the element aspect ratios, where applicable, used in the simulation model within the limit recommended by the Code Developer or Holtec's successful experience in other safety analyses? (Yes/No)	Yes	Yes	N/A
11.	Are element sizes used in the simulation models consistent with past successful analyses in safety significant applications? (Yes/No)	Yes	Yes	N/A
12.	Was every computer run in this chapter free of an error warning (i.e., in hidden warnings in the Code that indicate a possible error in the solution)? (Yes/No)	Yes	Yes	N/A
13.	If the answer to the above is No, then is the annotated warning discussed in the discussion of the result in this report?	N/A	N/A	N/A

3.II.7 Compliance with the Structural Requirements in Part 72

Supporting information to provide reasonable assurance with respect to the adequacy of the HI-STORM 100 system with the “Version E” and “Version E1” overpack to store spent nuclear fuel in accordance with the stipulations of 10CFR72 is presented throughout this supplement. The following statements are applicable to an affirmative structural safety evaluation:

- The design and structural analysis of the system is in complete compliance with the provisions of 10CFR72.
- The HI-STORM 100 system structures, systems, and components (SSC) that are important to safety (ITS) are identified in the licensing drawings in Section 1.II.5.
- The requirements of 10CFR72.24 with regard to information pertinent to structural evaluation is provided in Chapters 2.II, 3.II, and 12.II.
- Technical Specifications pertaining to the structures of the HI-STORM 100 system with “Version E” and “Version E1” overpack, HI-TRAC Version MS transfer cask and MPC-32M have been provided in Chapter 13 herein pursuant to the requirements of 10CFR72.26.
- A series of analyses to demonstrate compliance with the requirements of 10CFR72.122(b) and (c), and 10CFR72.24(c)(3) have been performed which show that SSCs in the storage system designated as ITS possess an adequate margin of safety with respect to all load combinations applicable to normal, off-normal, accident, and natural phenomenon events. In particular, the following information is provided:
 - i. Information on the applicable loadings for the fuel basket, enclosure vessel, and the HI-STORM Version E/HI-STORM Version E1/HI-TRAC Version MS overpacks for normal, off-normal, accident, and natural phenomenon events is provided in Subsection 3.II.1.2
 - ii. Stress limits applicable to the Code materials are found in Section 3.3 of the main report.
 - iii. The stress and displacement response of the cask components under the applicable loads have been computed by analysis and reported in Subsections 3.II.4.3 and 3.II.4.4. The reference stress analysis models are also provided to serve as the platform for future safety analyses.
- The structural design and fabrication details of the fuel baskets whose safety function in the storage system is to maintain nuclear criticality safety, are provided in the drawings in Section 1.II.5. The structural factors of safety, summarized in Section 3.II.4 for all credible load combinations under normal, off-normal,

accident, and natural phenomenon events demonstrate that the acceptance criteria are satisfied in all cases. In particular, the maximum lateral deflection in the fuel basket panels under accident events has been determined to be within the limit used in the criticality analysis (see Subsection 3.II.4.4). Thus, the requirement of 10CFR72.124(a), with respect to structural margins of safety for SSCs important to nuclear criticality safety are fully satisfied.

- Structural margins of safety during handling, packaging, and transfer operations, under the provisions of 10CFR Part 72.236(b), imply that the lifting and handling devices be engineered to comply with the stipulations of ANSI N14.6 and NUREG-0612, as applicable. The requirements of the governing standards for handling operations are discussed in Subsection 2.II.2.7. Factors of safety for all ITS appurtenances under lifting and handling operations are summarized in tables in Subsection 3.II.4.3, which show that adequate structural margins exist in all cases.
- Consistent with the provisions of 10CFR72.236(i), the Confinement Boundary for the HI-STORM 100 system has been engineered to maintain confinement of radioactive materials under normal, off-normal, and postulated accident conditions. This assertion of confinement integrity is made on the strength of the following information provided in this FSAR.
 - i. The MPC Enclosure Vessel which constitutes the Confinement Boundary is designed and fabricated in accordance with Section III, Subsection NB (Class 1 nuclear components) of the ASME Code to the maximum extent practicable.
 - ii. The primary lid of the MPC Enclosure Vessel is welded using a strength groove weld and is subjected to multiple liquid penetrant examinations and pressure testing to establish a maximum confidence in weld joint integrity.
 - iii. The closure system of the MPC Enclosure Vessel consists of *two* independent isolation barriers.
 - iv. The Confinement Boundary is constructed from stainless steel alloys with a proven history of material integrity under the environmental conditions of an ISFSI.
 - v. The load combinations for normal, off-normal, accident, and natural phenomena events have been compiled and applied on the MPC Enclosure Vessel (Confinement Boundary) in Section 3.4 which show that the factor of safety (with respect to the appropriate limits) is greater than one in all cases. Design Basis natural phenomena events such as tornado-borne missiles (large, intermediate, or small) have also been analyzed to evaluate their potential for reaching and breaching the Confinement Boundary in Subsection 3.II.4.4. Analyses show that the integrity of the Confinement

Boundary is preserved under all design basis projectile impact scenarios.

- The information on structural design included in this FSAR complies with the requirements of 10CFR72.120 and 10CFR72.122.
- The structural design features in the HI-STORM 100 system are in compliance with the specific requirements of 10CFR72.236(e), (f), (g), (h), (i), (j), (k), and (m).

SUPPLEMENT 3.III

STRUCTURAL EVALUATION OF THE MPC-68M AND MPC-68MCBS

3.III.0 OVERVIEW

In this supplement, the structural adequacy of the MPC-68M and MPC-68MCBS design variant is evaluated pursuant to the guidelines of NUREG-1536.

The organization of technical information in this supplement mirrors the format and content of Chapter 3 except that it only contains material directly pertinent to the MPC-68M and MPC-68MCBS.

The MPC-68M consists of a stainless steel (Alloy X) Enclosure Vessel, which is identical to that of the MPC-68, a BWR fuel basket made from Metamic-HT, and aluminum basket shims. In the CBS design variant of the MPC-68M, the aluminum baskets shims are bolted to basket panel extensions at the periphery of the basket. Section 1.III.2 contains a complete description of the MPC-68M components. Descriptions in this supplement regarding MPC-68M also apply to the MPC-68MCBS, unless otherwise noted.

The applicable codes, standards, and practices governing the structural analysis of the MPC-68M as well as the design criteria, are presented in Supplement 2.III. Throughout this supplement, the term “*safety factor*” is defined as the *ratio of the allowable stress (load) or displacement for the applicable load combination to the maximum computed stress (load) or displacement*. Where applicable, bounding safety factors are computed using values that bound the calculated results.

3.III.1 STRUCTURAL DESIGN

3.III.1.1 Discussion

A general discussion of the structural features of the MPC is provided in Subsection 3.1.1, and in general it applies to the MPC-68M with one notable exception. The MPC-68M fuel basket is qualified using a deflection-based acceptance criterion (see Subsection 2.III.0.1) as opposed to a stress-based criterion. The drawings of the MPC-68M fuel basket and MPC Enclosure Vessel are provided in Section 1.5.

3.III.1.2 Design Criteria

Same as in Subsection 3.1.2, including all of its paragraphs, except as modified in Subsection 2.III.0.1 for the MPC-68M fuel basket.

3.III.2 WEIGHTS AND CENTERS OF GRAVITY

Since the weight density of Metamic-HT is significantly less than that of Alloy X, the MPC-68M weighs less than the MPCs listed in Table 3.2.1. The bounding weights for the MPC-68M are provided in Table 3.III.1.

The center of gravity (CG) height of the empty MPC-68M, and various other configurations involving the MPC-68M, is provided in Table 3.III.2.

3.III.3 MECHANICAL PROPERTIES OF MATERIALS

The strength properties of Metamic-HT have been characterized through a comprehensive test program, and Minimum Guaranteed Values suitable for structural design are provided in Supplement 1.III.

The fuel basket shims are made of an aluminum alloy (ASTM B221 2219-T851). Representative mechanical properties for the fuel basket shims are tabulated in Table 3.III.3. Strictly speaking, the shim is not a structural material because it does not withstand any tensile loads and is located in a confined space which would prevent its uncontrolled deformation under load. The simulation of the shim in the basket's structural model, however, utilizes its mechanical properties of which only the Yield Strength has a meaningful (but secondary) role. Accordingly, in this FSAR, the nominal value of the Yield Strength specified in Table 3.III.3 herein, is set down as a "critical characteristic" for the shim material. The minimum value of the Yield Strength reported in the material supplier's CoC must be at least 90% of the nominal value in the above referenced table to ensure that the non-mechanistic tip-over analysis will not have to be revisited. The simulation of the shim in the MPC-68MCBS basket's structural model utilizes a bilinear material model to capture plastic deformation. Since only extremely small plastic deformation is observed, only the Yield Strength has a meaningful (but secondary) role.

The mechanical properties for all other materials of construction are the same as in Section 3.3 (including all subsections and tables).

3.III.4 GENERAL STANDARDS FOR CASKS

3.III.4.1 Chemical and Galvanic Reactions

The materials used in the HI-STORM 100 System are examined in Subsection 3.4.1 to establish that they do not participate in any chemical or galvanic reactions when exposed to the various environments during all normal operating conditions and off-normal and accident events. The only new materials that are introduced in the MPC-68M are Metamic-HT (for the fuel basket) and aluminum (for the basket shims). The environmental compatibility of these materials is examined below.

The MPC-68M is principally constructed of stainless steel shell, aluminum basket shims, and Metamic-HT. Borated aluminum and stainless steel have been used in close proximity in wet storage for over 30 years. Many spent fuel pools at nuclear plants contain fuel racks, which are fabricated from Metamic (classic) and stainless steel materials. Not one case of chemical or galvanic degradation has been found in such fuel racks. This experience provides a sound basis to conclude that chemical and galvanic corrosion of these materials will be negligible. For further protection, both Metamic-HT and aluminum basket shims are installed in the anodized state in the MPC.

Furthermore, galvanic corrosion is not an applicable corrosion mechanism during long-term storage since the interior of the MPC during normal operation is both inerted with helium and essentially devoid of any moisture while the MPC shell surfaces are expected to be practically free from condensation and gross environmental contaminants. The cleanliness requirements and inspections during fabrication and fuel loading operations also ensure that the MPC has minimal surface debris and impurities.

Tests on Metamic-HT

Extensive tests [1.III] have been conducted to establish material properties of Metamic-HT including its corrosion-resistance characteristics. The Metamic-HT specimens were used for corrosion testing in demineralized water and in 2000 ppm boric acid solution. The tests concluded that the Metamic-HT panels will sustain no discernible degradation due to corrosion when subjected to the severe thermal and aqueous environment that exists around a fuel basket during fuel loading or unloading conditions.

Aluminum Alloy

Aluminum alloy used in the fuel basket shims are hard anodized to achieve the desired emissivity specified in Supplement 4.III. The anodizing is an electrolytic passivation process used to increase the thickness of the natural oxide layer on the surface of metal parts. Anodizing increases corrosion resistance and wear resistance of the material surface. There is no mechanistic process for the basket shims with hard anodized surface to react with borated water or demineralized water during fuel loading operation. Under the long-term storage condition, the basket shims are exposed to dry and inert helium with no potential for reaction.

Finally, to ensure safe fuel loading operation, the operating procedure described in Chapter 8 provides for the monitoring of hydrogen gas in the area around the MPC lid prior to and during welding or cutting activities. Although the aluminum surfaces (Metamic-HT fuel basket and aluminum basket shims) are anodized, there is still a potential for generation of hydrogen in minute amounts when immersed in spent fuel pool water for an extended period. Accordingly, as a defense-in-depth measure, the lid welding procedure requires purging the space below the MPC lid prior to and during welding or cutting operation to eliminate any potential for formation of any combustible mixture of hydrogen and oxygen. Following the completion of the MPC lid welding and hydrostatic testing, the MPC-68M is drained and dried. After the completion of the drying

operation, there is no credible mechanism for any combustible gases to be generated within the MPC-68M.

3.III.4.2 Positive Closure

Same as in Subsection 3.4.2.

3.III.4.3 Lifting Attachment Points

The structural analyses of the lifting attachment points in Subsection 3.4.3 (including all paragraphs) are bounding for the MPC-68M for the following reasons:

- i. the MPC-68M does not require any changes to the HI-STORM overpacks or the HI-TRAC transfer casks for loading operations or long-term storage;
- ii. the MPC-68M utilizes the same MPC Enclosure Vessel design as all MPCs;
- iii. the fully loaded weight of the MPC-68M (Table 3.III.1) is less than bounding MPC weight analyzed in Chapter 3 (Table 3.2.1).

3.III.4.4 Heat

The thermal evaluation of the MPC-68M is reported in Supplement 4.III.

3.III.4.4.1 Summary of Pressures and Temperatures

The design pressures and design temperatures listed in Tables 2.2.1 and 2.2.3, respectively, are applicable to the MPC-68M. Temperature limits of MPC-68M fuel basket and basket shim materials are specified in Table 4.III.2.

3.III.4.4.2 Differential Thermal Expansion

The material presented in Supplement 4.III demonstrates that a physical interference between discrete components of the MPC-68M (e.g., fuel basket and enclosure vessel) will not develop due to differential thermal expansion during any operating condition.

3.III.4.4.3 Stress Calculations

The majority of the stress calculations reported in Paragraph 3.4.4.3 are unaffected by or bound the addition of the MPC-68M to the HI-STORM 100 System for the following reasons:

- i. the MPC-68M does not require any changes to the HI-STORM overpacks or the HI-TRAC transfer casks for loading operations or long-term storage;

- ii. the MPC-68M utilizes the same MPC Enclosure Vessel design as all MPCs;
- iii. the fully loaded weight of the MPC-68M (Table 3.III.1) is less than the bounding MPC weight analyzed in Chapter 3 (Table 3.2.1);

Therefore, the stress calculations reported in Paragraph 3.4.4.3 are not repeated here unless material, geometry, or load changes warrant new analysis or discussion. In other words, unless a new analysis is presented in this subsection, the results in Paragraph 3.4.4.3 for the HI-STORM 100 System are also valid for the MPC-68M either inside the HI-STORM overpack or the HI-TRAC transfer cask.

3.III.4.4.3.1 Analysis of Load Cases F.3.b and F.3.c (Table 3.1.3)

During a non-mechanistic tip-over event, the fuel assemblies exert a lateral force on the fuel basket panels as the overpack impacts the ground and decelerates. The lateral force causes the fuel basket panels to deflect potentially affecting the spacing between stored fuel assemblies. To maintain the fuel in a subcritical configuration, a deflection limit for the fuel basket panels is set in Subsection 2.III.0.1, which is supported by the criticality safety analysis in Supplement 6.III. Here a finite element analysis is performed using ANSYS to demonstrate that the maximum lateral deflection in the fuel basket panels under a bounding deceleration of 60g is less than the limit specified in Section 2.III.0.1. The 60g input deceleration is bounding because it exceeds the design basis deceleration limit of 45g for the non-mechanistic tip over of the HI-STORM storage overpack (see Subsection 3.III.4.10) and for the horizontal drop of the HI-TRAC transfer cask (see Subsection 3.4.9), and is equal to the design basis lateral deceleration limit of 60g for the HI-STAR transport cask [1.1.3] for future considerations. The analysis methodology presented in this subsection is identical to the methodology used in [2.III.6.2] to qualify the F-37 fuel basket.

As shown in Figure 3.III.1, a representative slice of the MPC-68M fuel basket, consisting of a smaller end section and a full section, is modeled in detail including the contained fuel assemblies and supporting basket shims. The fuel basket panels are modeled with SOLSH190 solid shell elements. The basket shims and each fuel assembly are modeled with SOLID45 solid elements. The mass density assigned to the fuel assemblies corresponds to the maximum BWR fuel assembly weight per Table 2.1.22, except at the 16 cell locations along the basket perimeter where Damaged Fuel Containers are permitted. At these 16 locations, the mass density corresponds to the maximum weight of a BWR fuel assembly plus DFC per Table 2.1.22. Standard contact pairs using CONTA173/TARGE170 elements are defined at the interfaces of fuel assembly/basket panel, shim/basket panel, and between stacked basket panels including all the intersecting slot locations. At the perimeter corners, the intersecting basket panels are bonded together in the finite element model, and the strength properties of the corner most elements are then adjusted depending on whether there is a full length weld at that location. At corner locations that are not welded full length (see licensing drawing in Section 1.5), the elastic modulus of the corner elements is reduced to 1% of the MGv in Table 1.III.2 to effectively eliminate the joint's shear and moment carrying capacity. The fuel basket material model is implemented with true stress-true strain multi-linear isotropic hardening plasticity model. An elastic material model is used for the basket shims since

no plastic deformation is expected. To accommodate large plastic deformation in the fuel basket panels, sufficiently small element sizes (< 0.40 in) are used and 9 integration points through the thickness are specified. A sensitivity study was performed in [2.III.6.2] to confirm that the panel stresses and displacements obtained using solid shell elements are converged and comparable to those obtained using 5 solid elements through the thickness of the panel.

The FEA model of the MPC-68MCBS fuel basket is similar to that of the MPC-68M except for the following notable changes:

- i. The solid basket shims and each fuel assembly are modeled with SOLID185 solid elements. Hollow basket shims are modeled with SOLSH190 solid shell elements. SOLID185 is a general-purpose 3D solid element for material non-linearities and includes all the SOLID45 element formulations.
- ii. The simulation of the shim in the MPC-68MCBS basket's structural model utilizes a bilinear material model to capture plastic deformation. Only small plastic deformation is observed, therefore, only the Yield Strength has a meaningful (but secondary) role.
- iii. All bonded contacts and material modifications associated with welds are eliminated as the MPC-68MCBS fuel basket replaces loose basket shims with continuous basket shims (CBS) bolted to basket panel extensions on the basket periphery. Bolts are not explicitly modeled; however, shim/basket panels at bolted locations are bonded to replicate a bolted joint. Bolt holes in the Continuous Basket Shims and basket panel extensions are sized so that shims can slide up against basket panels without subjecting bolts to shear loads.
- iv. At the eight perimeter corners, the intersecting basket panels are bonded together in the finite element model to model shim and bolts at these locations. Bolts at these perimeter corners are qualified using strength of material formulations.

The 60g deceleration is applied to the model with the basket in the so-called 0° orientation (see Figure 3.III.5). This orientation is chosen for analysis because it maximizes the lateral load on a single basket panel, which in turn maximizes the lateral deflection of the panel. In the 0° orientation, the amplified weight of each stored fuel assembly (during the 60g impact event) bears entirely on one basket panel. Conversely, in the 45° orientation, the amplified weight of each stored fuel assembly is equally supported by two basket panels. The difference in loading between these two basket orientations is pictorially shown in Figure 3.III.5, where “m” denotes the fuel assembly mass, “a” denotes the maximum lateral deceleration, and “d” denotes the enveloping size of the fuel assembly. For comparison purposes, the pressure loads on the basket panels are defined as “p” and “q”, respectively, for the 0° and 45° orientations. From the figure, the pressure load p that develops in the 0° orientation is 41% greater than the pressure load q that develops in the 45° orientation. Hence, the lateral deflection of a basket panel is much greater for the 0° orientation (which is why it is chosen for detailed analysis). It is also noted that the 90° corners where the basket panels intersect do not provide any additional moment resistance because of the slotted joint construction (see Figure 1.III.1); therefore, the 45° orientation (or any other orientation between

0° and 45°) does not give rise to any prying loads at the cell corners. Finally, to ensure that the analysis for the 0° orientation is conservative and bounds all other basket orientations, the analysis is performed based on a lateral impact deceleration of 60g even though, according to the results presented in Section 3.III.4.10, the maximum impact deceleration due to the non-mechanistic tip over event (measured at the top of the overpack lid) is less than 45g.

The stress and strain distributions in the MPC-68M fuel basket panels at 60g are shown in Figures 3.III.2 and 3.III.3, respectively. The stress and strain distributions in the MPC-68MCBS fuel basket panels at 60g are shown in Figures 3.III.7 and 3.III.8, respectively. These figures show that the state of stress in the fuel basket panels is primarily elastic. The fuel basket displacements are plotted in Figures 3.III.4 and 3.III.9. Tables 3.III.4 and 3.III.5 compare the maximum lateral displacement in a fuel basket panel (relative to its end supports) with the deflection limit specified in Subsection 2.III.0.1.

Per the licensing drawing, the nominal width of fuel basket panels in the vertical direction may be increased or decreased provided that the length of the panel slots is increased or decreased proportionally. This means that the fixed-height fuel basket may be assembled using more (or fewer) panels than the number depicted on the licensing drawing. The results of the ANSYS static analysis for the fuel basket presented herein are valid for any panel width since (a) the lateral load on the fuel basket per unit (vertical) length remains the same and (b) the length of the slots measured as a percentage of the panel width remains the same.

Finally, to evaluate the potential for crack propagation and growth for the MPC-68M fuel basket under the non-mechanistic tipover event, a bounding crack propagation analysis is carried out in Attachment D of [1.III.A.3]. The analysis demonstrates that a through-thickness linear flaw measuring 1/32 inch in length (i.e., maximum undetectable flaw size per inspection criteria) remains stable under the most severe accident loading conditions.

3.III.4.4.3.2 Elastic Stability and Yielding of the MPC-68M Fuel Basket under Compression Loads (Load Case F3 in Table 3.1.3)

Under certain conditions, the fuel basket plates may be under direct compressive load. Although the finite element simulations can predict the onset of an instability and post-instability behavior, the computation in this subsection uses (the more conservative) classical instability formulations to demonstrate that an elastic instability of the basket plates is not credible.

A solution for the stability of the fuel basket plate is obtained using the classical formula for buckling of a wide bar [3.III.1]. Material properties are selected corresponding to a metal temperature of 375°C, which bounds the computed metal temperatures anywhere in the fuel basket (see Table 4.III.3). The critical buckling stress for a pin-ended bar is:

$$\sigma_{cr} = \left(\pi \right)^2 \frac{E}{12(1-\nu^2)} \left(\frac{h}{a} \right)^2$$

where h is the plate thickness, a is the unsupported plate length, E is the Young's Modulus of Metamic-HT at 375°C, ν is Poisson's Ratio (use 0.3 for this calculation)

From the drawings in Section 1.5, h = 0.40 in, a = 6.05 in, and E = 6,125 ksi (Table 1.III.2). Then, the classical critical buckling stress is computed as 24.199 ksi, which exceeds the yield strength of the material (9.425 ksi) at 375°C. This demonstrates that basket plate instability by elastic buckling is not possible.

3.III.4.5 Cold

Same as in Subsection 3.4.5.

3.III.4.6 HI-STORM 100 Kinematic Stability under Flood Condition (Load Case A in Table 3.1.1)

The stability evaluation of the HI-STORM 100 overpack under flood conditions in Subsection 3.4.6 bounds the scenario of a loaded MPC-68M inside a HI-STORM overpack. The previous analysis is bounding because it uses as input the empty weight of the HI-STORM overpack (i.e., no MPC inside) combined with the maximum CG height from Table 3.2.3.

3.III.4.7 Seismic Event and Explosion

Since there are no physical changes to the HI-STORM overpacks and the MPC-68M reduces the CG height of the loaded HI-STORM overpacks, relative to those analyzed in Chapter 3, the seismic event and explosion analyses presented in Subsection 3.4.7 (including all paragraphs) bound the scenario of a loaded MPC-68M inside a HI-STORM overpack.

3.III.4.8 Tornado Wind and Missile Impact (Load Case B in Table 3.1.1 and Load Case 04 in Table 3.1.5)

The results for the post-impact response of the HI-STORM 100 overpack in Subsection 3.4.8 for the combination of tornado missile plus either steady tornado wind or instantaneous tornado pressure drop bound the results for a loaded MPC-68M inside a HI-STORM overpack. The results are bounding because they are calculated assuming a lower bound weight for the loaded HI-STORM and an upper bound CG height (as compared to a loaded MPC-68M inside a HI-STORM).

In addition, since the MPC-68M does not require any physical changes to the HI-STORM overpacks or the HI-TRAC transfer casks for MPC loading, the missile penetration analyses presented in Subsection 3.4.8 remain valid.

3.III.4.9 HI-TRAC Drop Events

The HI-TRAC drop analyses presented in Subsection 3.4.9 (including all paragraphs) are valid for a loaded MPC-68M inside a HI-TRAC for the following reasons:

- i. the MPC-68M does not require any changes to the HI-TRAC transfer casks for MPC loading;
- ii. the MPC and its contents are modeled as a solid body (i.e., no explicit modeling of MPC fuel basket);
- iii. the difference in weight between a fully loaded MPC-68M and the MPC analyzed in Subsection 3.4.9 is less than 5% of the total drop weight.

3.III.4.10 HI-STORM 100 Non-Mechanistic Tip-over and Vertical Drop Event (Load Cases 02.a and 02.c in Table 3.1.5)

Pursuant to the provision in NUREG-1536, a non-mechanistic tip-over of a loaded MPC-68M inside a HI-STORM overpack on to the ISFSI pad is considered in this supplement. Calculations are also performed to determine the maximum vertical carry height limit such that the deceleration sustained by a vertical free fall of a HI-STORM overpack carrying a loaded MPC-68M onto the ISFSI pad is less than design basis deceleration limit specified in Table 3.1.2.

The tip-over analysis performed in Appendix 3.A is based on the HI-STORM 100 geometry and a bounding weight. Since the MPC-68M has a slightly higher center of gravity and weighs less than the MPC modeled in Appendix 3.A, it is not a foregone conclusion that the maximum rigid body deceleration level is, in fact, reduced if a HI-STORM 100, with a loaded MPC-68M inside, suffers a non-mechanistic tip-over onto the identical target. In what follows, we present a summary of the analysis undertaken to demonstrate conclusively that the result for maximum deceleration level is less than design basis deceleration limit specified in Table 3.1.2 when the MPC-68M is stored inside the HI-STORM 100 overpack. The analysis employs the methodology previously established in Subsection 3.4.10 for analyzing the HI-STORM 100S overpack.

Appendix 3.A presents a result for the angular velocity of the cylindrical body representing a HI-STORM 100 just prior to impact with the defined target. The result is expressed in Subsection 3.A.6 in terms of the cask geometry, and the ratio of the mass divided by the mass moment of inertia about the corner point that serves as the rotation origin. Since the mass moment of inertia is also linearly related to the mass, the angular velocity at the instant just prior to target contact is independent of the cask mass. Subsequent to target impact, we investigate post-impact response by considering the cask as a cylinder rotating into a target that provides a resistance force that varies linearly with distance from the rotation point. We measure “time” as starting at the instant of impact, and develop a one-degree-of freedom equation for the post-impact response (for the rotation angle into the target) as:

$$\ddot{\theta} + \omega^2 \theta = 0$$

where

$$\omega^2 = \frac{kL^3}{3I_A}$$

The initial conditions at time zero are: the initial angle is zero and the initial angular velocity is equal to the rigid body angular velocity acquired by the tip-over from the center-of-gravity over corner position. In the above relation, L is the length of the overpack, I is the mass moment of inertia defined in Appendix 3.A, and k is a “spring constant” associated with the target resistance. If we solve for the maximum angular acceleration subsequent to time zero, we obtain the result in terms of the initial angular velocity as:

$$\ddot{\theta}_{\max} = \omega \dot{\theta}_0$$

If we form the maximum linear acceleration at the top of the overpack lid, we can finally relate the decelerations of the HI-STORM 100 configuration analyzed in Appendix 3.A and the HI-STORM 100/MPC-68M configuration solely in terms of their geometry properties and their mass ratio. The value of “k”, the target spring rate is the same for both overpacks so it does not appear in the relationship between the two decelerations. After substituting the appropriate geometry and calculated masses, we determine that the ratio of maximum rigid body decelerations at the top surface of the lids is:

$$A_{\text{HI-STORM 100-68M}}/A_{\text{HI-STORM 100}} = 1.01$$

The fact that the calculated ratio is only marginally above 1.0 indicates that the MPC-68M has a minor effect on the non-mechanistic tip-over analysis performed in Appendix 3.A. The maximum rigid body deceleration for the HI-STORM 100/MPC-68M configuration is determined by scaling the calculated result from Appendix 3.A as follows:

$$A_{\text{HI-STORM 100-68M}} = 1.01 \times A_{\text{HI-STORM 100}} = 1.01 \times 42.98g = 43.42g$$

This demonstrates that when the MPC-68M is stored inside the HI-STORM 100 overpack the result for maximum deceleration level is less than the design basis deceleration limit specified in Table 3.1.2. Based on the comparative evaluations in Subsection 3.4.10, the HI-STORM 100 overpack is the limiting overpack for the non-mechanistic tip-over event. Therefore, when the MPC-68M is inside the HI-STORM 100S or the HI-STORM 100S Version B overpack, the maximum rigid body deceleration at the top surface of the lid is less than the deceleration above.

Next we demonstrate that the deceleration sustained by a vertical free fall of a HI-STORM overpack carrying a loaded MPC-68M onto the ISFSI pad is less than the design basis deceleration limit specified in Table 3.1.2. According to Appendix 3.A, analysis of a single mass impacting a

spring with a given initial velocity shows that the maximum deceleration “a_M” of the mass is related to the dropped weight “w” and the drop height “h” as follows:

$$a_M \sim \frac{\sqrt{h}}{\sqrt{w}}$$

In other words for a fixed drop height, as the dropped weight decreases, the maximum deceleration of the mass increases. Since the MPC-68M weighs less than the MPC analyzed in Appendix 3.A, the maximum deceleration calculated in Appendix 3.A is not bounding. From the above relationship, the maximum deceleration for the HI-STORM 100/MPC-68M configuration is determined as:

$$a_{100-68M} = \sqrt{\frac{w_{100}}{w_{100-68M}}} a_{100}$$

where $w_{100-68M}$ is the weight of a HI-STORM 100 carrying a loaded MPC-68M, w_{100} is the weight of a loaded HI-STORM 100 overpack as analyzed in Appendix 3.A, and a_{100} is the maximum deceleration of the HI-STORM 100 calculated in Appendix 3.A for an 11” vertical drop. The above equation yields the following result:

$$a_{100-68M} = 44.39g$$

Although the result is higher than the maximum deceleration calculated in Appendix 3.A, it is still less than the design basis vertical deceleration limit specified in Table 3.1.2. Therefore, the previously established lift height limit of 11 inches for a loaded HI-STORM overpack is also applicable to HI-STORM overpacks carrying the MPC-68M. Note that depending on site-specific conditions, a lower lift height limit may be required. See Section 2.2.3.1.

Finally, Subsection 3.4.10 provides the results of a simple elastic strength of materials calculation, which demonstrates that the cylindrical storage overpack will not permanently deform to the extent that the MPC cannot be removed by normal means after a tip-over event. Those results are valid for the MPC-68M since:

- i. there are no changes to the HI-STORM overpack stemming from the MPC-68M;
- ii. the external dimensions of the MPC-68M are the same as all other MPC types;
- iii. the results are calculated using upper bound impact decelerations.

3.III.4.11 Storage Overpack and HI-TRAC Transfer Cask Service Life

Same as in Subsection 3.4.11 (including all paragraphs).

3.III.4.12 MPC Service Life

Same as in Subsection 3.4.12 and with the following supplementary information provided herein.

3.III.4.12.1 Metamic-HT Considerations

Metamic-HT has been extensively tested as indicated in Supplement 1.III. Testing has included extensive tests for creep, irradiation and corrosion to ensure long-term fuel basket performance under normal conditions of storage. The Metamic-HT is also not susceptible to structural fatigue and brittle fracture under long term conditions of storage. Corrosion is discussed further in Subsection 3.III.4.1. Creep and boron depletion are further discussed below.

i) Fuel Basket Creep

The Metamic sourcebook contains data on the testing to determine the creep characteristics of the Metamic-HT under both unirradiated and irradiated conditions. A creep equation to estimate a bounding estimate of total creep as a function of stress and temperature is also provided. The creep equation developed from this test provides a conservative prediction of accumulated creep strain by direct comparison to measured creep in unirradiated and irradiated coupons.

The creep equation for Metamic-HT that bounds *all* measured data (tests run for 20,000 hours) is of the classical exponential form in stress and temperature [1.III.3], which is written symbolically as $\varepsilon = f(\sigma, T)$.

Creep in the MPC-68M fuel basket will not be a reactivity modifier because the basket is arrayed in the vertical orientation. The lateral loading of the fuel basket walls is insignificant and hence no mechanistic means for the basket panels to undergo lateral deformation from creep exists, even if the panel material were susceptible to creep.

The creep effect would tend to shorten the fuel basket under the self-weight of the basket. An illustrative calculation of the cumulative reduction of the basket length is presented below to demonstrate the insignificant role of creep in the MPC-68M fuel basket.

The in-plane compressive stress, σ , at height x in the basket panel is given by

$$\sigma = \rho(H-x) \quad (3.III.1)$$

where:

ρ = weight density of Metamic-HT

H = height of the fuel basket

Using the above stress equation, the total creep shrinkage, δ , is given by

$$\delta = \int_0^H f(\sigma, T) dx \quad (3.III.2)$$

where:

T = panel's metal temperature (conservatively assumed to be 375°C for a period of 60 years)

H = height of the basket (conservatively assumed to be 200 inches)

Using the creep equation (provided in [1.III.3]) and performing the above integration numerically yields $\delta = 0.138$ inch. In other words, the computed shrinkage of the basket is less than 0.069% of its original length. Therefore, it is concluded that for the vertical storage configuration the creep effects of the MPC-68M fuel basket are insignificant due to absence of any meaningful loads on the panels. Therefore, creep in the Metamic-HT fuel basket is not a matter of safety concern.

ii) Fuel Basket Boron Depletion

The similarities between Metamic-HT and Metamic (classic) neutron absorbers and their exposure to the same long-term conditions of storage in the HI-STORM 100 system provide a logical basis to expect negligible neutron absorber boron depletion in Metamic-HT. However, to assure criticality safety during worst case design basis conditions over the 40-year design life, the analysis discussed in Subsection 6.III demonstrates that the boron depletion in the Metamic-HT is negligible over a 50-year duration. Thus, sufficient levels of boron are present in the fuel basket to maintain criticality safety over the 40-year design life of the MPC.

3.III.4.12.2 Basket Shim Considerations:

i) Basket Shim Creep

Like the fuel basket, the basket shims are not subject to any significant loading during storage. The ability of the basket shims (made of a creep resistant aluminum alloy) has been evaluated and qualified in Docket No. 71-9325 [2.III.6.2] for transport applications where the stress level (in horizontal configuration) is significant. Therefore, in light of the minuscule stress levels from self-weight in long-term storage, creep is ruled out as a viable concern for the basket shims.

ii) Basket Shim Corrosion

Basket shim corrosion is discussed in Subsection 3.III.4.1.

3.III.4.13 Design and Service Life

Same as in Subsection 3.4.13.

3.III.5 FUEL RODS

Same as in Section 3.5.

3.III.6 SUPPLEMENTAL DATA

3.III.6.1 Additional Codes and Standards Referenced in HI-STORM 100 System Design and Fabrication

Same as in Subsection 3.6.1.

3.III.6.2 Computer Programs

ANSYS 11.0, which is a public domain finite element code, has been utilized to perform structural analyses of MPC-68M documented in this supplement.

ANSYS 17.1, which is a public domain finite element code, has been utilized to perform structural analyses of MPC-68MCBS documented in this supplement.

3.III.6.3 Appendices Included in Supplement 3.III

None.

3.III.6.4 Calculation Packages

A calculation package containing the structural calculations supporting Supplement 3.III has been prepared, reviewed, and archived according to Holtec International's quality assurance program (see Chapter 13).

3.III.7 COMPLIANCE WITH NUREG-1536

The material in this supplement for the MPC-68M provides the same information as previously provided for the other MPC types in Chapter 3. Therefore, to the extent applicable, the information provided is in compliance with NUREG-1536.

HI-TRAC 125D Transfer Cask w/ Top Lid, Pool Lid, and fully loaded MPC-68M (water jacket filled)	96.9
HI-TRAC 100D Transfer Cask w/ Top Lid, Pool Lid, and fully loaded MPC-68M (water jacket filled)	94.3
HI-TRAC 100G Transfer Cask w/ Top Lid, Pool Lid, and fully loaded MPC-68M (water jacket filled)	107.7

Notes:

1. The datum used for calculations involving the HI-STORM is the bottom of the overpack baseplate. The datum used for calculations involving the HI-TRAC is the bottom of the pool lid.
2. The datum used for calculations involving only the MPC is the bottom of the MPC baseplate.
3. The CG height of the HI-STORM overpack is calculated based on standard density concrete (i.e., 166 pcf dry) in the radial cavity. At higher densities, the CG height is slightly lower, which makes the HI-STORM overpack less prone to tipping.
4. The MPC-68MCBS is very similar to MPC-68M in construction. There is only negligible deviation in CG height.

CHAPTER 4¹ THERMAL EVALUATION

4.0 OVERVIEW

The HI-STORM System is designed for long-term storage of spent nuclear fuel (SNF) in a vertical orientation. An array of HI-STORM Systems laid out in a rectilinear pattern will be stored on a concrete ISFSI pad in an open environment. In this section, compliance of the HI-STORM thermal performance to 10CFR72 requirements for outdoor storage at an ISFSI is established. The analysis considers passive rejection of decay heat from the stored SNF assemblies to the environment under normal, off-normal, and accident conditions of storage. Effects of incident solar radiation (insolation) and partial radiation blockage due to the presence of neighboring casks at an ISFSI site are included in the analyses. Finally, the thermal margins of safety for long-term storage of both moderate burnup (up to 45,000 MWD/MTU) and high burnup spent nuclear fuel (greater than 45,000 MWD/MTU) in the HI-STORM 100 system are quantified. Safe thermal performance during on-site loading, unloading and transfer operations utilizing the HI-TRAC transfer cask is also demonstrated.

The HI-STORM thermal evaluation follows the guidelines of NUREG-1536 [4.4.1] and ISG-11 [4.1.4] to demonstrate thermal compliance of the HI-STORM system. These guidelines provide specific limits on the permissible maximum cladding temperature in the stored commercial spent fuel (CSF)² and other confinement boundary components, and on the maximum permissible pressure in the confinement space under certain operating scenarios. Specifically, the requirements are:

1. The fuel cladding temperature for long-term storage shall be limited to 752°F (400°C).
2. The fuel cladding temperature for short-term operations shall be limited to 752°F (400°C) for high burnup fuel and 1058°F (570°C) for moderate burnup fuel.
3. The fuel cladding temperature should be maintained below 1058°F (570°C) for accident and off-normal event conditions.
4. The maximum internal pressure of the MPC should remain within its design pressures for normal, off-normal, and accident conditions.

-
- 1 This chapter has been prepared in the format and section organization set forth in Regulatory Guide 3.61. However, the material content of this chapter also fulfills the requirements of NUREG-1536. Pagination and numbering of sections, figures, and tables are consistent with the convention set down in Chapter 1, Section 1.0, herein. Finally, all terms-of-art used in this chapter are consistent with the terminology of the glossary.
 - 2 Defined as nuclear fuel that is used to produce energy in a commercial nuclear reactor (See glossary).

REPORT HI-2002444	4-1	

5. The cask materials should be maintained within their minimum and maximum temperature criteria for normal, off-normal, and accident conditions.
6. For fuel assemblies proposed for storage, the cask system should ensure a very low probability of cladding breach during long-term storage.
7. The HI-STORM System should be passively cooled.
8. The thermal performance of the cask shall be in compliance with the design criteria specified in FSAR Chapters 1 and 2 for normal, off-normal, and accident conditions.

As demonstrated in this chapter, the HI-STORM System is designed to comply with all of the criteria listed above. Sections 4.1 through 4.3 describe thermal analyses and input data that are common to all conditions. All thermal analyses to evaluate normal conditions of storage in a HI-STORM storage module are described in Section 4.4. All thermal analyses to evaluate normal handling and on-site transfer in a HI-TRAC transfer cask are described in Section 4.5. All thermal analyses to evaluate off-normal and accident conditions are described in Section 4.6. This FSAR chapter is in full compliance with ISG-11 and with NUREG-1536 guidelines, subject to the exceptions and clarifications discussed in Chapter 1, Table 1.0.2.

The HI-STORM thermal evaluations for CSF are grouped in two categories of fuel assemblies. The two groups are classified as Low Heat Emitting (LHE) fuel assemblies and Design Basis (DB) fuel assemblies. The LHE group of fuel assemblies are characterized by low burnup, long cooling time, and short active fuel lengths. Consequently, their heat loads are dwarfed by the DB group of fuel assemblies. All Dresden-1 (6x6 and 8x8 and a thorium rod canister constituted as part of an 8x8 fuel assembly), Quad+, Humboldt Bay (7x7 and 6x6), Indian Point, Haddam Neck and all stainless-steel clad fuel assemblies are classified as LHE fuel. The low heat emitting characteristics of these fuel assemblies render them non-governing for thermal evaluation. The HI-STORM System temperatures for MPCs loaded with LHE fuel are bounded by design basis evaluations reported in this chapter.

The HI-STORM System is evaluated for two fuel storage scenarios. In one scenario, designated as uniform loading, every basket cell is assumed to be occupied with fuel producing heat at the maximum rate. As discussed in Chapter 2, this storage specification is extremely conservative, and virtually impossible to realize in actual practice. A less unrealistic, yet conservative idealization of storage scenario, designated as regionalized loading, involves defining two discrete regions within the basket. The two regions are designated as Region 1 (inner region) and Region 2 (outer region). Regionalized storage is designed to recognize storage of fuel assemblies having wide disparity in heat emission rates. For further discussion of regionalized storage, Section 2.1 of Chapter 2 should be consulted.

HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-2	

The HI-STORM System is designed for one reference storage condition defined in Table 4.0.1. This condition establishes the required helium backfill pressures computed later in this chapter (See Subsection 4.4.5.1). Having defined the helium backfill pressures an array of analyses are performed to evaluate the range of storage configurations specified in Chapter 2 and results reported in Section 4.4.

4.1 DISCUSSION

The HI-STORM FSAR seeks to establish complete compliance with the provisions of ISG-11 [4.1.4]. For this purpose the HI-STORM normal storage fuel cladding temperatures are required to meet the 752°F (400°C) temperature limit for all CSF (See Section 4.3). Additionally, when the MPCs are deployed for storing High Burnup Fuel (HBF) further restrictions during certain fuel loading activities (vacuum drying) are set forth to preclude fuel temperatures from exceeding the normal temperature limits. To ensure explicit compliance, a specific term “short term operations” is defined in Chapter 2 to cover all fuel loading activities. ISG-11 fuel cladding temperature limits are applied for short-term operations (see Table 4.3.1).

Potential thermally challenging states for the spent fuel arise if the fuel drying process utilizes the pressure reduction process (i.e., vacuum drying). The short-term evolutions that may be thermally limiting and warrant analysis are:

- i. Vacuum Drying
- ii. Loaded MPC in HI-TRAC in the Vertical Orientation

The threshold MPC heat generation rate at which the HI-STORM peak cladding temperature reaches a steady state equilibrium value approaching the normal storage peak clad temperature limit is computed in this chapter. Likewise, the MPC heat generation rates that produce the steady state equilibrium temperature approaching the normal storage peak clad temperature limit for the MPC in HI-TRAC are computed in this chapter. These computed heat generation rates directly bear upon the compliance of the system with ISG-11 [4.1.4] and are, accordingly, adopted in the system Technical Specifications for high burnup fuel (HBF).

The aboveground HI-STORM system consists of a sealed MPC situated inside a vertically-oriented, ventilated storage overpack. Air inlet and outlet ducts that allow for air cooling of the stored MPC are located at the bottom and top, respectively, of the cylindrical overpack. The SNF assemblies reside inside the MPC, which is sealed with a welded lid to form the confinement boundary. The MPC contains a stainless-steel honeycomb fuel basket structure with square-shaped compartments of appropriate dimensions to allow insertion of the fuel assemblies prior to welding of the MPC lid and closure ring. Each fuel basket panel, with the exception of exterior panels on the MPC-68 and MPC-32, is equipped with a thermal neutron absorber panel sandwiched between an Alloy X steel sheathing plate and the fuel basket panel, along the entire length of the active fuel region. The MPC is backfilled with helium up to the design-basis initial fill level (Table 1.2.2). This provides a stable, inert environment for long-term storage of the SNF. Heat is rejected from the SNF in the HI-STORM System to the environment by passive heat transport mechanisms only.

The helium backfill gas plays an important role in the MPC’s thermal performance. The helium fills all the spaces between solid components and provides an improved conduction medium (compared to air) for dissipating decay heat in the MPC. Within the MPC the pressurized helium environment sustains a closed loop thermosiphon action, removing SNF heat by an upward flow of helium through the storage cells. This MPC internal convection heat dissipation mechanism is illustrated in Figure 4.1.1. On the outside of the MPC a ducted overpack construction with a

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-4	

vertical annulus facilitates an upward flow of air by buoyancy forces. The annulus ventilation flow cools the hot MPC surfaces and safely transports heat to the outside environment. The annulus ventilation cooling mechanism is illustrated in Figure 4.1.2. To ensure that the helium gas is retained and is not diluted by lower conductivity air, the MPC confinement boundary is designed and fabricated in accordance with the ASME B&PV Code Section III, Subsection NB as an all-seal-welded pressure vessel with redundant closures. It is demonstrated in Section 11.1.3 that the failure of one field-welded pressure boundary seal will not result in a breach of the pressure boundary. The helium gas is therefore assumed to be retained in an undiluted state, and may be credited in the thermal analyses.

An important thermal design criterion imposed on the HI-STORM System is to limit the maximum fuel cladding temperature to within design basis limits (Table 4.3.1) for long-term storage of design basis SNF assemblies. An equally important requirement is to minimize temperature gradients in the MPC so as to minimize thermal stresses. In order to meet these design objectives, the MPC baskets are designed to possess certain distinctive characteristics, which are summarized in the following.

The MPC design minimizes resistance to heat transfer within the basket and basket periphery regions. This is ensured by an uninterrupted panel-to-panel connectivity realized in the all-welded honeycomb basket structure. The MPC design incorporates top and bottom plenums with interconnected downcomer paths. MPCs with extruded aluminum shims maintain the same paths through the annulus gap in the shims. The top plenum is formed by the gap between the bottom of the MPC lid and the top of the honeycomb fuel basket, and by elongated semicircular holes in each basket cell wall. The bottom plenum is formed by large elongated semicircular holes at the base of all cell walls. The MPC basket is designed to eliminate structural discontinuities (i.e., gaps) which introduce added thermal resistances to heat flow. Consequently, temperature gradients are minimized in the design, which results in lower thermal stresses within the basket. Low thermal stresses are also ensured by an MPC design that permits unrestrained axial and radial growth of the basket. The possibility of stresses due to restraint on basket periphery thermal growth is eliminated by providing adequate basket-to-canister shell gaps to allow for basket thermal growth during all operational modes.

The MPCs design maximum decay heat loads for storage of zircaloy clad fuel are listed in Table 4.0.1. Storage of stainless steel clad fuel is permitted for a low decay heat limit set forth in Chapter 2 (Tables 2.1.17 through 2.1.24). Storage of zircaloy clad fuel with stainless steel clad fuel in an MPC is permitted. In this scenario, the zircaloy clad fuel must meet the lower decay heat limits for stainless steel clad fuel. The axial heat distribution in each fuel assembly is conservatively assumed to be non-uniformly distributed with peaking in the active fuel mid-height region (See axial burnup Table 2.1.11).

The HI-STORM System (i.e., HI-STORM overpack, HI-TRAC transfer cask and MPC) is evaluated under normal storage (HI-STORM overpack), during off-normal and accident events and during short term operations in a HI-TRAC. Results of HI-STORM thermal analysis during normal (long-term) storage are obtained and reported in Section 4.4. Results of off-normal and

accident events are reported in Section 4.6. Results of HI-TRAC short term operations (fuel loading, vacuum drying) are reported in Section 4.5.

4.2 SUMMARY OF THERMAL PROPERTIES OF MATERIALS

Materials present in the MPCs include stainless steels (Alloy X), aluminum alloy (2219), neutron absorber (Boral or METAMIC) and helium. Materials present in the HI-STORM storage overpack include carbon steels and concrete. Materials present in the HI-TRAC transfer cask include carbon steel, lead, Holtite-A neutron shield, paints (See Appendix 1.C) and demineralized water. In Table 4.2.1, a summary of references used to obtain cask material properties for performing all thermal analyses is presented.

Individual thermal conductivities of the alloys that comprise the Alloy X materials and the bounding Alloy X thermal conductivity are reported in Appendix 1.A of this report. Tables 4.2.2 and 4.2.3 provide numerical thermal conductivity data of materials at several representative temperatures. The currently approved neutron absorber materials, (Boral™ and Metamic™) are both made of aluminum powder and boron carbide powder. Although their manufacturing processes differ, from a thermal standpoint, their ability to conduct heat is virtually identical. Therefore, the values of conductivity of the original neutron absorber (Boral) continue to be used in the thermal calculations.

For the HI-STORM overpack, the emissivity/absorptivity of painted surfaces is particularly important. Recognizing the considerable variations in reported values for thermal conductivity and emissivity, the values that are conservative with respect to both authoritative references and values used in analyses on previously licensed cask dockets have been selected. Specific discussions of the conservatism of the selected values are included in the following paragraphs.

As specified in Table 4.2.1, the concrete thermal conductivity is taken from Marks' Standard Handbook for Mechanical Engineers, which is conservative compared to a variety of recognized concrete codes and references. Neville, in his book "Properties of Concrete" (4th Edition, 1996), gives concrete conductivity values as high as 2.1 Btu/(hr×ft×°F). For concrete with siliceous aggregates, the type to be used in HI-STORM overpacks, Neville reports conductivities of at least 1.2 Btu/(hr×ft×°F). Data from Loudon and Stacey, extracted from Neville, reports conductivities of 0.980 to 1.310 Btu/(hr×ft×°F) for normal weight concrete protected from the weather. ACI-207.1R provides thermal conductivity values for seventeen structures (mostly dams) at temperatures from 50-150°F. Every thermal conductivity value reported in ACI-207.1R is greater than the value used in the HI-STORM thermal analyses. Additionally, the NRC has previously approved analyses that use higher conductivity values than those applied in the HI-STORM thermal analysis. For example, thermal calculations for the NRC approved Vectra NUHOMS cask system (June 1996, Rev. 4A) used thermal conductivities as high as 1.17 Btu/(hr×ft×°F) at 100°F. Based on these considerations, the concrete thermal conductivity value chosen for HI-STORM thermal analyses is considered to be conservative.

Holtite-A is a composite material consisting of approximately 37 wt% epoxy polymer, 1 wt% B₄C and 62 wt% aluminum trihydrate. While polymers are generally characterized by a low conductivity (0.05 to 0.2 Btu/ft-hr-°F), the addition of fillers in substantial amounts can raise the mixture conductivity by up to a factor of ten. The thermal conductivity of epoxy filled resins with

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-9	

alumina is reported in the technical literature³ as approximately 0.5 Btu/ft-hr-°F and higher. A conservatively postulated conductivity of 0.3 Btu/ft-hr-°F is used in the thermal models for the neutron shield region⁴ (in the HI-TRAC transfer cask). As the thermal inertia of the neutron shield is not credited in the analyses, the density and heat capacity properties are not reported herein.

Surface emissivity data for key materials of construction are provided in Table 4.2.4. The emissivity properties of painted external surfaces are generally excellent. Kern [4.2.5] reports an emissivity range of 0.8 to 0.98 for a wide variety of paints. In the HI-STORM thermal analysis, an emissivity of 0.85⁵ is applied to painted surfaces. The HI-TRAC 100G utilizes paint with an emissivity of 0.91. A conservative solar absorptivity coefficient of 1.0 is applied to all exposed overpack surfaces.

In Table 4.2.5, the heat capacity and density of the MPC, overpack and CSF materials are presented. These properties are used in performing transient (i.e., hypothetical fire accident condition) analyses. The temperature-dependent values of the viscosities of helium and air are provided in Table 4.2.6.

The heat transfer coefficient for exposed surfaces is calculated by accounting for both natural convection and thermal radiation heat transfer. The natural convection coefficient depends upon the product of Grashof (Gr) and Prandtl (Pr) numbers. Following the approach developed by Jakob and Hawkins [4.2.9], the product $Gr \times Pr$ is expressed as $L^3 \Delta T Z$, where L is height of the overpack, ΔT is overpack surface temperature differential and Z is a parameter based on air properties, which are known functions of temperature, evaluated at the average film temperature. The temperature-dependent values of Z are provided in Table 4.2.7.

³ “Principles of Polymer Systems”, F. Rodriguez, Hemisphere Publishing Company (Chapter 10).

⁴ The thermal conductivity value used in the thermal models for the neutron shield region is confirmed to be bounded by the Holtite-A test data [4.2.13] with a margin.

⁵ This is conservative with respect to prior cask industry practice, which has historically utilized higher emissivities [4.2.16].

4.3 SPECIFICATIONS FOR COMPONENTS

HI-STORM System materials and components designated as “Important to Safety” (i.e., required to be maintained within their safe operating temperature ranges to ensure their intended function) which warrant special attention are summarized in Table 4.3.1. The neutron shielding ability of Holtite-A neutron shield material used in the HI-TRAC transfer cask is ensured by demonstrating that the material exposure temperatures are maintained below the maximum allowable limit. Long-term integrity of SNF is ensured by the HI-STORM System thermal evaluation which demonstrates that fuel cladding temperatures are maintained below design basis limits. Neutron absorber materials used in MPC baskets for criticality control (made from B₄C and aluminum) are stable in excess of temperatures specified in Table 2.2.3¹. Accordingly this temperature is conservatively adopted as the short-term temperature limit for neutron absorber materials. The overpack concrete, the primary function of which is shielding, will maintain its structural, thermal and shielding properties provided that American Concrete Institute (ACI) guidance on temperature limits (see Appendix 1.D) is followed.

Compliance to 10CFR72 requires, in part, identification and evaluation of short-term off-normal and severe hypothetical accident conditions. The inherent mechanical characteristics of cask materials and components ensure that no significant functional degradation is possible due to exposure to short-term temperature excursions outside the normal long-term temperature limits. For evaluation of HI-STORM System thermal performance, material temperature limits for long-term normal, short-term operations, and off-normal and accident conditions are provided in Table 4.3.1. In Table 4.3.1, ISG-11 [4.1.4] temperature limits are adopted for Commercial Spent Fuel (CSF). These limits are applicable to all fuel types, burnup levels and cladding materials approved by the NRC for power generation.

4.3.1 Evaluation of Moderate Burnup Fuel

It is recognized that hydrides present in irradiated fuel rods (predominantly circumferentially oriented) dissolve at cladding temperatures above 400°C [4.3.1]. Upon cooling below a threshold temperature (T_p), the hydrides precipitate and reorient to an undesirable (radial) direction if cladding stresses at the hydride precipitation temperature T_p are excessive. For moderate burnup fuel, T_p is conservatively estimated as 350°C [4.3.1]. In a recent study, PNNL has evaluated a number of bounding fuel rods for reorientation under hydride precipitation temperatures for MBF [4.3.1]. The study concludes that hydride reorientation is not credible during short-term operations involving low to moderate burnup fuel (up to 45 GWD/MTU). Accordingly, the higher ISG-11 temperature limit is justified for moderate burnup fuel and is adopted in the HI-STORM FSAR for short-term operations for MBF fueled MPCs (see Table 4.3.1).

¹ B₄C is a refractory material that is unaffected by high temperature (on the order of 1000°F) and aluminum is solid at temperatures up to 1080°F [4.2.19].

4.4 THERMAL EVALUATION FOR NORMAL CONDITIONS OF STORAGE

The HI-STORM System (i.e., HI-STORM overpack, HI-TRAC transfer cask and MPC) thermal evaluation is performed in accordance with the guidelines of NUREG-1536 [4.4.1] and ISG-11 [4.1.4]. To ensure a high level of confidence in the thermal evaluation, 3-Dimensional models of the MPC, HI-STORM overpack and HI-TRAC transfer cask are constructed to evaluate fuel integrity under normal (long-term storage), off-normal and accident conditions and in the HI-TRAC transfer cask under short-term operation and hypothetical accidents. The thermal models incorporate an array of conservatisms to ensure robustly bounding thermal solutions. The principal features of these models are described in this section for HI-STORM and Section 4.5 for HI-TRAC. Thermal analysis results for the long-term storage scenarios are obtained and reported in this section.

4.4.1 Overview of the Thermal Model

The MPC basket design consists of four distinct geometries to hold 24 or 32 PWR, or 68 BWR fuel assemblies. The basket is a matrix of interconnected square compartments designed to hold the fuel assemblies in a vertical position under long term storage conditions. The basket is a honeycomb structure of stainless steel (Alloy X) plates with full-length edge-welded intersections to form an integral basket configuration. All individual cell walls, except outer periphery cell walls in the MPC-68 and MPC-32, are provided with neutron absorber plates sandwiched between the box wall and a stainless steel sheathing plate over the full length of the active fuel region. The neutron absorber plates used in all MPCs are made of an aluminum-based, boron carbide-containing material to provide criticality control, while maximizing heat conduction capabilities.

Thermal analysis of the HI-STORM System is performed for an array of limiting heat load scenarios defined in Chapter 2 for uniform and regionalized fuel loading (wherein each fuel assembly in a region is assumed to be generating heat at the maximum permissible rate). While the assumption of limiting heat generation in each storage cell imputes a certain symmetry to the cask thermal problem, it grossly overstates the total heat duty of the system in most cases because it is unlikely that any basket would be loaded with fuel emitting heat at their limiting values (see for example a fuel loading scenario discussed in Section 2.1). The principal attributes of the thermal model are described in the following:

- i. While the rate of heat conduction through metals is a relatively weak function of temperature, radiation heat exchange is a highly nonlinear function of surface temperatures.
- ii. Heat generation in the MPC is axially non-uniform due to non-uniform axial burnup profiles in the fuel assemblies.
- iii. Inasmuch as the transfer of heat occurs from inside the basket region to the outside, the temperature field in the MPC is spatially distributed with the maximum values reached in the central core region.

4.4.1.1 Description of the 3-D Thermal Model

i. Introduction

The interior of the MPC is a 3-D array of square shaped cells inside an irregularly shaped basket outline confined inside the cylindrical space of the MPC cavity. To ensure an adequate representation of these features, a 3-D geometric model of the MPC is constructed using the FLUENT CFD code pre-processor [4.1.2]. Other than representing the composite cell walls (made up of Alloy X panels, neutron absorber panels and Alloy X sheathing) by a homogeneous panel with equivalent orthotropic (thru-thickness and parallel plates direction) thermal conductivities, the 3-D model requires no idealizations of the fuel basket structure. Further, since it is impractical to model every fuel rod in every stored fuel assembly explicitly, the cross section bounded by the inside of the storage cell (inside of the fuel channel in the case of BWR MPCs), which surrounds the assemblage of fuel rods and the interstitial helium gas (also called the “rodded region”), is replaced with an “equivalent” square homogeneous section characterized by an effective thermal conductivity. Homogenization of the storage cell cross-section is illustrated in Figure 4.4.1. As the effective conductivity of the rodded region includes radiation heat transfer the conductivities will be a strong function of temperature because radiation heat transfer (a major component of the heat transport between the fuel rods and the surrounding basket cell metal) rises as the fourth power of absolute temperature. Therefore, in effect, the effective conductivity of the equivalent square section (depending on the coincident temperature) will be different throughout the basket. For thermal-hydraulic simulation, each fuel assembly in its storage cell is represented by an equivalent porous medium. For BWR fuel, the presence of the fuel channel divides the storage cell space into two distinct axial flow regions, namely, the in-channel (rodded) region and the square prismatic annulus region (in the case of PWR fuel this modeling complication does not exist).

ii. Details of the 3-D Model

The 3-D model implemented to analyze the HI-STORM system has the following key attributes:

- a. As mentioned above, the composite walls in the fuel basket consisting of the Alloy X structural panels, the aluminum-based neutron absorber, and the Alloy X sheathing, are represented by an orthotropic homogeneous panel of equivalent thermal conductivity in the three principal directions. The in-plane and thru-thickness thermal conductivities of the composite wall are computed using a standard procedure for such shapes with certain conservatisms, as described below.

During fabrication, a uniform normal pressure is applied to each “Box Wall - Neutron Absorber - Sheathing” sandwich in the assembly fixture during welding of the sheathing periphery on the box wall. This ensures adequate surface-to-surface contact between the neutron absorber and the adjacent Alloy X surfaces. The mean coefficient of linear expansion of the neutron absorber is higher than the thermal expansion coefficients of the basket and sheathing materials. Consequently, basket heat-up from the stored SNF will further ensure a tight fit of the neutron absorber plate in the sheathing-to-box pocket.

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-18	

Nevertheless the possible presence of small microscopic gaps due to less than perfect surface-to-surface contact requires consideration of an interfacial contact resistance between the neutron absorber and box-sheathing surfaces. In the thermal analysis a 2 mil neutron absorber to pocket gap has been used. This is conservative as the sandwich is engineered to ensure an essentially no-gap fitup and assembly of the neutron-absorber panels. Furthermore, no credit is taken for radiative heat exchange across the neutron absorber to sheathing or neutron absorber to box wall gaps.

The heat conduction properties of the composite “Box Wall - Neutron Absorber - Sheathing” sandwich panels in the two principal basket cross sectional directions (i.e., thru-thickness and parallel plates direction) are unequal. In the thru-thickness direction, heat is transported across layers of sheathing, helium-gap, neutron absorber and box wall resistances that are essentially in series. Heat conduction in the parallel plates direction, in contrast, is through an array of essentially parallel resistances comprised of these several layers listed above. In this manner the composite walls of the fuel basket storage cells are replaced with a solid wall of equivalent through thickness and parallel plates direction conductivities. Table 4.4.1 provides the values of the conductivities as a function of temperature for the different MPC types.

- b. In the case of a BWR CSF, the fuel bundle and the small surrounding spaces inside the fuel “channel” are replaced by an equivalent porous media having the flow impedance properties computed using a conservatively articulated 3-D CFD model [4.4.2]. The space between the BWR fuel channel and the storage cell is represented as an open flow annulus. The fuel channel is also explicitly modeled. The porous medium within the channel space is also referred to as the “rodded region”. The fuel assembly is assumed to be positioned coaxially with respect to its storage cell. The 3-D model of an MPC-68 storage cell occupied with channeled BWR fuel is shown in Figure 4.4.4.

In the case of the PWR CSF, the porous medium extends to the entire cross-section of the storage cell. As described in [4.4.2], the CFD model for both the BWR and PWR case is prepared for the Design Basis fuel in comprehensive detail, which includes grid straps, BWR water rods and PWR guide and instrument tubes (assumed to be plugged for conservatism).

- c. Every MPC fuel storage cell is assumed to be occupied by design basis PWR or BWR fuel assemblies specified in Chapter 2 (Table 2.1.5). The in-plane thermal conductivity of the design basis fuel assemblies are obtained using ANSYS [4.1.1] finite element models of an array of fuel rods enclosed by a square box. Radiation heat transfer from solid surfaces (cladding and box walls) are enabled in these models. Using these models the effective conduction-radiation conductivities are obtained and reported in Table 4.4.2. For heat transfer in the axial direction an area weighted mean of cladding and helium conductivities are computed (see Table 4.4.2). Axial conduction heat transfer in the fuel pellets and radiation heat dissipation in the axial direction are conservatively ignored. Thus, the thermal conductivity of the rodded region, like the porous media simulation for helium flow, is represented by a 3-D continuum having effective planar and axial conductivities.

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-19	

- d. The internals of the MPC, including the basket cross section, bottom mouse holes, top plenum, and circumferentially irregular downcomer are modeled explicitly. For simplicity, the mouse holes are modeled as rectangular openings with understated flow area.
- e. The inlet and outlet vents in the HI-STORM overpack are modeled explicitly to incorporate any effects of non-axisymmetry of inlet air passages on the system's thermal performance.
- f. The air flow in the HI-STORM/MPC annulus is simulated by a $k-\omega$ turbulence model with the transitional option enabled.

The 3-D model described above is illustrated in the cross section for the MPC-68 in Figure 4.4.3. A closeup of the fuel cell spaces which explicitly include the channel-to-cell gap in the 3-D model is shown in Figure 4.4.4. The principal 3-D modeling conservatisms are listed below:

- 1) The storage cell spaces are loaded with design basis fuel having the highest axial flow resistance (See Table 2.1.5).
- 2) Each storage cell is generating heat at its limiting value under uniform or regionalized storage scenarios as defined in Chapter 2, Section 2.1.
- 3) Axial dissipation of heat by the fuel pellets is neglected.
- 4) Axial dissipation of heat by radiation in the fuel bundle is neglected.
- 5) The fuel assembly channel length for BWR fuel is overstated.
- 6) The most severe environmental factors for long-term normal storage - ambient temperature of 80°F and 10CFR71 insolation levels - were coincidentally imposed on the system.
- 7) The absorptivity of the external surfaces of the HI-STORM is conservatively assumed to be unity.
- 8) To understate MPC internal convection heat transfer, the helium pressure is understated.
- 9) No credit is taken for contact between fuel assemblies and the MPC basket wall or between the MPC basket and the basket supports or between the MPC basket wall and the basket shims.
- 10) Heat dissipation by fuel basket peripheral supports is neglected.
- 11) Fuel basket and MPC shell emissivities are understated (see Table 4.2.4).
- 12) The $k-\omega$ model used for simulating the HI-STORM annulus flow yields uniformly conservative results [4.1.6].

The effect of crud resistance on fuel cladding surfaces has been evaluated and found to be negligible. The evaluation assumes a thick crud layer (130 μm) with a bounding low conductivity (conductivity of helium). The crud resistance increases the clad temperature by a very small amount ($\sim 0.1^\circ\text{F}$). Accordingly this effect is neglected in the thermal evaluations.

REPORT HI-2002444	4-20	

4.4.1.2 Fuel Assembly 3-Zone Flow Resistance Model

The HI-STORM System is evaluated for storage of bounding PWR (W-17x17) and BWR (GE-10x10) fuel assemblies. During fuel storage helium enters the MPC fuel cells from the bottom plenum and flows upwards through the open spaces in the fuel storage cells and exits in the top plenum. Because of the low flow velocities the helium flow in the fuel storage cells and MPC spaces is in the deep laminar regime ($Re < 100$). The bottom and top plenums are essentially open spaces engineered in the fuel basket ends to facilitate helium circulation. In the case of BWR fuel storage, a channel enveloping the fuel bundle divides the flow in two parallel paths. One flow path is through the in-channel or rodded region of the storage cell and the other flow path is in the square annulus area outside the channel. In the global thermal modeling of the HI-STORM System the following approach is adopted:

- (i) In BWR fueled MPCs an explicit channel-to-cell gap is modeled.
- (ii) The fuel assembly enclosed in a square envelope (fuel channel for BWR fuel or fuel storage cell for PWR fuel) is replaced by porous media with equivalent flow resistance.

The above modeling approach is illustrated in Figure 4.4.4.

In the FLUENT program, porous media flow resistance is modeled as follows:

$$\Delta P = D\mu VL \quad (\text{Eq. 1})$$

where ΔP is the hydraulic pressure loss, D is the flow resistance coefficient, μ is the fluid viscosity, V is the superficial fluid velocity and L is the porous media length. In the HI-STORM thermal models the fuel storage cell length between the bottom and top plenums¹² is replaced by porous media. As discussed below the porous media length is partitioned in three zones with discrete flow resistances.

To characterize the flow resistance of fuel assemblies inside square envelopes (fuel channel for BWR fuel or fuel storage cell for PWR fuel) 3D models of W-17x17 and GE-10x10 fuel assemblies are constructed using the FLUENT CFD program. These models are embedded with several pessimistic assumptions to overstate flow resistance. These are:

- (a) Water rods (BWR fuel) and guide tubes (PWR fuel) are assumed to be completely blocked
- (b) Fuel rods assumed to be full length
- (c) Channel length (BWR fuel) overstated
- (d) Bounding grid thickness used
- (e) Bottom fittings resistance overstated
- (f) Bottom nozzle lateral flow holes (BWR fuel) assumed to be blocked

¹² These are the mousehole openings at the ends of the fuel basket to facilitate helium circulation. The mouseholes are explicitly included in the 3D thermal models with an understated flow area.

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-21	

Using the 3D fuel assembly models flow solutions under an impressed pressure differential between the two extremities of the fuel storage cell are computed at reference conditions (7 atmosphere absolute pressure and 450°F temperature). The results of the 3D flow solutions are post-processed as described next and equivalent porous media flow resistances obtained.

Because of the narrow flow passages in the bare rods and gridded regions of the fuel assembly the flow resistance of the fueled length to axial helium flow is greater than the flow resistance from the fuel assembly ends (bottom nozzle, top fitting, handle etc.). This physical fact is duly recognized by defining three distinct axial zones as follows:

Zone 1: Length below the active fuel region

Zone 2: Active fuel region

Zone 3: Length above the active fuel region

In the 3-Zone flow resistance modeling, the flow resistance of each zone is characterized by post-processing the 3D fuel flow model solutions. For this purpose two approaches to flow resistance characterization are adopted. The first approach is the pressure drop method. This method is suitable when a zone is characterized by irregular geometries and the objective is to obtain a lumped resistance to duplicate the pressure drop. The second method is the shear stress method, which is suitable for flow zones characterized by regular geometries. For the 3-Zone flow resistance modeling the pressure drop method is adopted for the inactive regions (Zone 1 and Zone 3). The flow resistance coefficients are computed by post-processing the fuel assemblies 3D model flow solutions as follows:

Step 1: Obtain the helium volumetric flow Q under the impressed pressure differential.

Step 2: Compute helium superficial velocity, $V = Q/A$ where A is the square envelope cross-sectional area.

Step 3: Obtain the individual Zone 1 and Zone 3 lengths (L_1 and L_3) and pressure drops (ΔP_1 and ΔP_3) from the FLUENT solutions.

Step 4: Compute Zone 1 and Zone 3 resistance coefficients D_1 and D_3 using Eq. 1, V , L_1 , L_3 , ΔP_1 and ΔP_3 from above steps.

The shear stress method is suitable for the active fuel region (Zone 2) as this region is characterized by an ordered array of entities (rods and grids). This method uses area averaged wall shear stresses post-processed from the active region (Zone 2) of the fuel assembly. Using hydraulic flow principles the wall shear stresses are mapped to flow resistance coefficients. To account for geometric discontinuities the active fuel region is sliced in a suitable number of constant geometry (bare rods and grids) sub-regions. Based on the fuel bundle layout, a total of 17 slices are identified for GE-10x10 fuel and 20 slices for W-17x17 fuel. In each sub-region an area averaged shear stress over all wetted surfaces (fuel rods, non-fuel rods, square envelope and grids) is post-processed and flow resistance coefficients of each slice are computed. The flow resistance of Zone 2 is obtained by computing the length-weighted average of the slice resistance coefficients.

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-22	

4.4.3 Test Model

The HI-STORM thermal analysis is performed on the FLUENT [4.1.2] Computational Fluid Dynamics (CFD) program. To ensure a high degree of confidence in the HI-STORM thermal evaluations, the FLUENT code is benchmarked using data from tests conducted with casks loaded with irradiated SNF ([4.1.3], [4.1.7]). The benchmark work is archived in QA validated Holtec reports ([4.1.5], [4.1.6]). These evaluations show that the FLUENT solutions are conservative in all cases. In view of these considerations, additional experimental verification of the thermal design is not necessary.

4.4.4 Maximum and Minimum Temperatures

4.4.4.1 Maximum Temperatures

The 3-D model from the previous subsection is used to determine temperature distributions under long-term normal storage conditions for an array of cases covering PWR and BWR fuel storage in uniform and regionalized loading configurations. For this purpose one bounding MPC design in each of the two fuel classes – MPC-68 for BWR and MPC-32 for PWR – are analyzed and results obtained and summarized in this subsection. For a bounding evaluation the MPCs are assumed to be emplaced in a limiting overpack (HI-STORM 100S Version B).

The HI-STORM 100S Version B is the limiting overpack by virtue of the inlet and outlet vents design. Compared to two other overpack designs (i.e., HI-STORM 100 and HI-STORM 100S), the HI-STORM 100S Version B has smaller inlet and outlet vents. Thus Version B vent airflow resistances are bounding. Also, the HI-STORM 100S Version B is the shortest of the overpacks. This reduces the chimney height which minimizes the driving head for air flow. Because the HI-STORM 100S Version B will have the least cooling air flow, it will yield bounding results.

The Type IS variant of HI-STORM 100S Version B features a 360° outlet vents, which enhance the air flow and thereby improve cooling of the MPC. Analyses documented in a companion report [4.5.1] demonstrate that PCT, component temperatures and MPC cavity pressures for the HI-STORM 100S Version B (non-Type IS) either bound those for the HI-STORM 100S Version B Type IS system or, as in the case of the overpack lid components, are slightly higher with large margins-to-limits under normal, off-normal and hypothetical accident conditions of storage.

A cross-reference of HI-STORM thermal analyses is provided in Table 4.4.5. Under regionalized loading, an array of runs covering a range of regionalized storage configurations specified in Chapter 2 ($X=0.5$ to $X=3$) are analyzed. The results are graphed in Figures 4.4.6 and 4.4.7 for PWR and BWR fuel storage respectively. Based on this array of runs the fuel storage condition corresponding to $X = 0.5$ is determined to be limiting for both PWR and BWR MPCs. Accordingly HI-STORM MPC and overpack temperatures are reported for this storage condition in Tables 4.4.6 and 4.4.7.

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-23	

Damaged fuel is canisterized in damaged fuel containers (DFCs) before long-term storage. Each MPC type has designated locations for placement of DFCs, as described in Chapter 2. Particularly, the DFCs are placed for storage in basket peripheral locations. The presence of DFCs impedes helium flow through it. However, since the DFCs are placed in the cold peripheral locations, they do not control the peak cladding temperature. Moreover, as a substantial fraction of basket cells are occupied by intact fuel, the overall effect of DFC fuel storage on the heat dissipation from the basket is small. To account for its impact, a heat load penalty described in Tables 4.4.3 and 4.4.4 is placed on the DFC locations under both uniform and regionalized heat load patterns.

It should be noted that the 3-D FLUENT cask model incorporates the effective conductivity of the fuel assembly submodel. Therefore the FLUENT models report the peak temperature in the fuel storage cells. Thus, as the fuel assembly models include the fuel pellets, the FLUENT calculated peak temperatures are actually peak pellet centerline temperatures which bound the peak cladding temperatures with a margin.

MPCs that utilize extruded aluminum shims exhibit improved thermal performance to those of other basket support designs since they facilitate heat dissipation due to its higher thermal conductivity. The computed temperatures for MPCs with extruded shims [4.5.1] are therefore lower than those presented in Tables 4.4.6 and 4.4.7. In addition, as shown in Table 4.4.13, the MPC internal pressures with the extruded aluminum shims is less than the pressures exhibited in Table 4.4.9 for the corresponding MPC type. As such, the thermal performance of MPCs with extruded shims is bounded by the thermal analysis performed below.

The following observations can be derived by inspecting the temperature field obtained from the thermal models:

- The fuel cladding temperatures are below the regulatory limit (ISG-11 [4.1.4]) under all storage scenarios (uniform and regionalized) in all MPCs.
- The maximum temperature of the basket structural materials are within their design limits.
- The maximum temperature of the neutron absorbers are below their design limits.
- The maximum temperatures of the MPC pressure boundary materials are below their design limits.
- The maximum temperatures of concrete is within the guidance of the governing ACI Code (see Table 4.3.1).

The above observations lead us to conclude that the temperature field in the HI-STORM System with a loaded MPC containing heat emitting SNF complies with all regulatory temperature limits. In other words, the thermal environment in the HI-STORM System is in compliance with Chapter 2 Design Criteria.

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-24	

As discussed in Chapter 1, the HI-STORM 100S and HI-STORM 100S Version B have an optional configuration with cylindrical guides. The optional stainless steel guide tubes are much shorter than the channels and the total surface area of the tubular guides is smaller than that of the channels. This reduces friction loss in the air flow and improves the natural convection heat dissipation by air through the annular gap between MPC and HI-STORM. Therefore, the HI-STORM 100S and HI-STORM 100S Version B with the optional cylindrical guide configuration complies with all regulatory temperature limits.

4.4.4.2 Minimum Temperatures

In Table 2.2.2 of this report, the minimum ambient temperature condition for the HI-STORM storage overpack and MPC is specified to be -40°F. If, conservatively, a zero decay heat load with no solar input is applied to the stored fuel assemblies, then every component of the system at steady state would be at a temperature of -40°F. Low service temperature (-40°F) evaluation of the HI-STORM is provided in Chapter 3. All HI-STORM storage overpack and MPC materials of construction will satisfactorily perform their intended function in the storage mode at this minimum temperature condition.

4.4.4.3 Effects of Elevation

The reduced ambient pressure at site elevations significantly above the sea level will act to reduce the ventilation air mass flow, resulting in a net elevation of the peak cladding temperature. However, the ambient temperature (i.e., temperature of the feed air entering the overpack) also drops with the increase in elevation. Because the peak cladding temperature also depends on the feed air temperature (the effect is one-for-one within a small range, i.e., 1°F drop in the feed air temperature results in ~1°F drop in the peak cladding temperature), the adverse ambient pressure effect of increased elevation is partially offset by the ambient air temperature decrease. The table below illustrates the variation of air pressure and corresponding ambient temperature as a function of elevation.

Elevation (ft)	Pressure (psia)	Ambient Temperature Reduction versus Sea Level
Sea Level (0)	14.70	0°F
2000	13.66	7.1°F
4000	12.69	14.3°F

A survey of the elevation of nuclear plants in the U.S. shows that nuclear plants are situated near about sea level or elevated slightly (~1000 ft). The effect of the elevation on peak fuel cladding temperatures is evaluated by performing calculations for a HI-STORM 100 System situated at an elevation of 1500 feet. At this elevation the ambient temperature would decrease by approximately 5°F (See Table above). The peak cladding temperatures are calculated for a bounding configuration (non-uniform storage at $X = 0.5$), and conservatively assuming no reduction in ambient temperature using the 3D model described in Subsection 4.4.1.1 and compared to the sea level conditions. The results are given in the following table.

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-25	

MPC Design	PCT at Sea Level	PCT at 1500 feet
MPC-32 PWR	711.4°F	723.8°F
MPC-68 BWR	697.1°F	718.2°F

These results show that the PCT, including the effects of site elevation, continues to be well below the regulatory cladding temperature limit of 752°F. In light of the above evaluation, it is not necessary to place any ISFSI elevation constraints for HI-STORM deployment at elevations up to 1500 feet. If, however, an ISFSI is sited at an elevation greater than 1500 feet, the effect of altitude on the PCT shall be quantified as part of the 10 CFR 72.212 evaluation for the site using the site ambient conditions.

4.4.5 Maximum Internal Pressure

4.4.5.1 MPC Helium Backfill Pressure

For design basis heat load, the helium backfill shall be sufficient to produce the required operating pressure of 7 atmospheres (absolute) during normal storage at reference conditions (See Table 4.0.1). Thermal analyses performed on the different MPC designs indicate that this operating pressure requires a certain helium backfill pressure specified at a reference temperature (70°F). The minimum backfill pressure to attain this operating pressure for each MPC type is provided in Table 4.4.11. An upper limit on the helium backfill pressure corresponds to the design pressure of the MPC vessel (Table 2.2.1). The upper limit on the backfill pressure is also reported in Table 4.4.11. To bound the minimum and maximum backfill pressures listed in Table 4.4.11 with margin, a helium backfill specification is set forth in Table 4.4.12. These values support the technical specification of the system for the design basis heat load of the MPC.

In addition the technical specifications allow for using a wider range on the backfill pressure if the heat load of the MPC is less than 28.74 kW. The minimum of this range corresponds to an operating pressure of 5 atm. The heat loads for this condition are provided in Table 2.1.31. If the MPC is loaded such that Table 2.1.31 is satisfied, the lower pressure range in the technical specifications may be used.

It is conservative to backfill the MPC to the higher pressure range regardless of MPC heat load.

Two methods are available for ensuring that the appropriate quantity of helium has been placed in an MPC:

- i. By pressure measurement
- ii. By measurement of helium backfill volume (in standard cubic feet)

The direct pressure measurement approach is more convenient if FHD is used to dry the MPC cavity. In this case, a certain quantity of helium is already in the MPC. Because the helium is mixed inside the MPC during the FHD operation, the temperature of the helium gas at the exit of the MPC, along with the pressure provides a reliable means to compute the inventory of helium.

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-26	

A shortfall or excess of helium is adjusted by a calculated raising or lowering of the MPC pressure such that the MPC backfill pressure is within the specifications.

When vacuum drying is used to dry the MPC cavity it is more convenient to fill the MPC by introducing a known quantity of helium by measuring the quantity of helium introduced using a calibrated mass flow meter or other measuring apparatus. The required quantity of helium is computed by the product of net free volume and helium specific volume at the reference temperature (70°F) and a target pressure that lies in the mid-range of the specifications.

The net free volume of the MPC is obtained by subtracting B from A, where

A = MPC cavity volume in the absence of fuel and any DFC and/or NFH as computed from nominal design dimensions.

B = Total volume of the fuel and any DFC and/or NFH as computed from nominal design dimensions

4.4.5.2 MPC Pressure Calculations

The MPC pressure calculations are performed using the reference conditions in Table 4.0.1 since this condition always results in the highest pressure in the MPC and bounds the allowed pressure range for the lower MPC heat load as described above.

During normal storage, the gas temperature within the MPC rises to its maximum operating basis temperature. The gas pressure inside the MPC will also increase with rising temperature to its maximum operating pressure. The pressure rise is determined using the ideal gas law.

Table 4.4.8 presents a summary of the minimum MPC free volumes determined for each MPC type (MPC-24, MPC-68, MPC-32, and MPC-24E). The MPC maximum gas pressure is computed for a postulated release of fission product gases from fuel rods into this free space. For these scenarios, the amounts of each of the release gas constituents in the MPC cavity are summed and the resulting total pressures determined from the ideal gas law. Based on fission gases release fractions in NUREG-1536 [4.4.1] and the net free volume and initial fill gas pressure of the fuel rods, maximum gas pressures with 1% (normal), 10% (off-normal) and 100% (accident condition) rod rupture are calculated and provided in Table 4.4.9. The maximum computed gas pressures reported in Table 4.4.9 are all below the MPC internal design pressures for normal, off-normal and accident conditions specified in Table 2.2.1.

Evaluation of Non-Fuel Hardware

The inclusion of PWR non-fuel hardware (BPRA control elements and thimble plugs) to the PWR baskets influences the MPC internal pressure through two distinct effects. The presence of non-fuel hardware increases the effective basket conductivity, thus enhancing heat dissipation and lowering fuel temperatures as well as the temperature of the gas filling the space between fuel

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-27	

rods. The gas volume displaced by the mass of non-fuel hardware lowers the cavity free volume. These two effects, namely, temperature lowering and free volume reduction, have opposing influence on the MPC cavity pressure. The first effect lowers gas pressure while the second effect raises it. In the HI-STORM thermal analysis, the computed temperature field (with non-fuel hardware excluded) has been determined to provide a conservatively bounding temperature field for the PWR baskets (MPC-24, MPC-24E, and MPC-32). The MPC cavity free space is computed based on volume displacement by the heaviest fuel (bounding weight) with non-fuel hardware included. This approach ensures conservative bounding pressures.

During in-core irradiation of BPRAs, neutron capture by the B-10 isotope in the neutron absorbing material produces helium. Two different forms of the neutron absorbing material are used in BPRAs: Borosilicate glass and B₄C in a refractory solid matrix (Al₂O₃). Borosilicate glass (primarily a constituent of Westinghouse BPRAs) is used in the shape of hollow pyrex glass tubes sealed within steel rods and supported on the inside by a thin-walled steel liner. To accommodate helium diffusion from the glass rod into the rod internal space, a relatively high void volume (~40%) is engineered in this type of rod design. The rod internal pressure is thus designed to remain below reactor operation conditions (2,300 psia and approximately 600°F coolant temperature). The B₄C- Al₂O₃ neutron absorber material is principally used in B&W and CE fuel BPRA designs. The relatively low temperature of the poison material in BPRA rods (relative to fuel pellets) favor the entrapment of helium atoms in the solid matrix.

Several BPRA designs are used in PWR fuel that differ in the number, diameter, and length of poison rods. The older Westinghouse fuel (W-14x14 and W-15x15) has used 6, 12, 16, and 20 rods per assembly BPRAs and the later (W-17x17) fuel uses up to 24 rods per BPRA. The BPRA rods in the older fuel are much larger than the later fuel and, therefore, the B-10 isotope inventory in the 20-rod BPRAs bounds the newer W-17x17 fuel. Based on bounding BPRA rods internal pressure, a large hypothetical quantity of helium (7.2 g-moles/BPRA) is assumed to be available for release into the MPC cavity from each fuel assembly in the PWR baskets. The MPC cavity pressures (including helium from BPRAs) are summarized in Table 4.4.9.

4.4.6 Engineered Clearances to Eliminate Thermal Interferences

Thermal stress in a structural component is the resultant sum of two factors, namely: (i) restraint of free end expansion and (ii) non-uniform temperature distribution. To minimize thermal stresses in load bearing members, the HI-STORM System is engineered with adequate gaps to permit free thermal expansion of the fuel basket and MPC in axial and radial directions. In this subsection, differential thermal expansion calculations are performed to demonstrate that engineered gaps in the HI-STORM System are adequate to accommodate thermal expansion of the fuel basket and MPC.

The HI-STORM System is engineered with gaps for the fuel basket and MPC to expand thermally without restraint of free end expansion. Differential thermal expansion of the following gaps are evaluated:

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-28	

- a. Fuel Basket-to-MPC Radial Gap
- b. Fuel Basket to MPC Axial Gap
- c. MPC-to-Overpack Radial Gap
- d. MPC-to-Overpack Axial Gap

To demonstrate that the fuel basket and MPC are free to expand without restraint, it is required to show that differential thermal expansion from fuel heatup is less than the as-built gaps that exist in the HI-STORM System. For this purpose a suitably bounding temperature profile ($T(r)$) for the fuel basket is established in Figure 4.4.5 wherein the center temperature (T_C) is set at the limit (752°F) for fuel cladding (conservatively bounding assumption) and the basket periphery (TP) conservatively postulated at an upperbound of 610°F (see Table 4.4.6 for the maximum fuel and basket periphery temperatures). To maximize the fuel basket differential thermal expansion, the basket periphery-to-MPC shell temperature difference is conservatively maximized ($\Delta T = 175^\circ\text{F}$). From the bounding temperature profile $T(r)$ and ΔT , the mean fuel basket temperature ($T1$) and MPC shell temperature ($T2$) are computed as follows:

$$T1 = \frac{\int_0^1 rT(r)dr}{\int_0^1 rdr} = 676^\circ\text{F}$$

$$T2 = TP - \Delta T = 425^\circ\text{F}$$

The differential radial growth of the fuel basket ($Y1$) from an initial reference temperature ($To = 70^\circ\text{F}$) is computed as:

$$Y1 = R \times [A1 \times (T1 - To) - A2 \times (T2 - To)]$$

where:

R = Basket radius (conservatively assumed to be the MPC radius)

$A1, A2$ = Coefficients of thermal expansion for fuel basket and MPC shell at $T1$ and $T2$ respectively for Alloy X (Chapter 1 and Table 3.3.1)

For computing the relative axial growth of the fuel basket in the MPC, bounding temperatures for the fuel basket (T_C) and MPC shell temperature $T2$ utilized above are adopted. The differential expansion is computed by a formula similar to the one for radial growth after replacing R with basket height (H), which is conservatively assumed to be that of the MPC cavity.

For computing the radial and axial MPC-to-overpack differential expansions, the MPC shell is postulated at its design temperature (Chapter 2, Table 2.2.3) and thermal expansion of the overpack is ignored. Even with the conservative computation of the differential expansions in the manner of the foregoing, it is evident from the data presented in Table 4.4.10 that the differential expansions are a fraction of the nominal cold gaps presented on the corresponding drawings in Section 1.5.

REPORT HI-2002444	4-29	

4.4.7 Evaluation of System Performance for Normal Conditions of Storage

The HI-STORM System thermal analysis is based on a detailed and complete heat transfer model that conservatively accounts for all modes of heat transfer in various portions of the MPC and overpack. The thermal model incorporates conservative features that render the results for long-term storage to be extremely conservative.

Temperature distribution results obtained from this highly conservative thermal model show that the maximum fuel cladding temperature limits are met with adequate margins. Expected margins during normal storage will be much greater due to the conservative assumptions incorporated in the analysis. The long-term impact of decay heat induced temperature levels on the HI-STORM System structural and neutron shielding materials is considered to be negligible. The maximum local MPC basket temperature level is below the recommended limits for structural materials in terms of susceptibility to stress, corrosion and creep-induced degradation. Furthermore, stresses induced due to imposed temperature gradients are within Code limits (See Structural Evaluation Chapter 3). Therefore, it is concluded that the HI-STORM System thermal design is in compliance with 10CFR72 requirements.

4.5 THERMAL EVALUATION OF SHORT TERM OPERATIONS

Prior to placement in a HI-STORM overpack, an MPC must be loaded with fuel, outfitted with closures, dewatered, dried, backfilled with helium and transported to the HI-STORM module. In the unlikely event that the fuel needs to be returned to the spent fuel pool, these steps must be performed in reverse. Finally, if required, transfer of a loaded MPC between HI-STORM overpacks or between a HI-STAR transport overpack and a HI-STORM storage overpack must be carried out in an assuredly safe manner. All of the above operations, henceforth referred to as “short term operations”, are short duration events that would likely occur no more than once or twice for an individual MPC.

The device central to all of the above operations is the HI-TRAC transfer cask that, as stated in Chapter 1, is available in two anatomically similar weight ratings (100- and 125-ton). Three different versions of the 100 ton HI-TRAC (HI-TRAC 100, HI-TRAC 100D, HI-TRAC 100G) and two different versions of the 125 ton HI-TRAC (HI-TRAC 125, HI-TRAC 125D) are available for use during fuel transfer operations. The HI-TRAC transfer cask is a short-term host for the MPC; therefore it is necessary to establish that, during all thermally challenging operation events involving either the 100-ton or 125-ton versions of the HI-TRAC, the permissible temperature limits presented in Section 4.3 are not exceeded. The following discrete thermal scenarios, all of short duration, involving the HI-TRAC transfer cask, have been identified as warranting thermal analysis.

- i. Post-Loading Wet Transfer Operations
- ii. MPC Cavity Vacuum Drying
- iii. Normal Onsite Transport in a Vertical Orientation
- iv. MPC Cooldown and Reflood for Unloading Operations

Onsite transport of the MPC occurs with the HI-TRAC in the vertical orientation, which preserves the thermosiphon action within the MPC. To avoid excessive temperatures, transport with the HI-TRAC in the horizontal condition is generally not permitted. However, it is recognized that an occasional downending of a HI-TRAC may become necessary to clear an obstruction such as a low egress bay door opening. In such a case the operational imperative for HI-TRAC downending must be ascertained and the permissible duration of horizontal configuration must be established on a site-specific basis and compliance with the thermal limits of ISG-11 [4.1.4] must be demonstrated as a part of the site-specific safety evaluation.

The fuel handling operations listed above place a certain level of constraint on the dissipation of heat from the MPC relative to the normal storage condition. Consequently, for some scenarios, it is necessary to provide additional cooling when decay heat loads are such that short-term cladding temperature limits would be exceeded. For such situations, the Supplemental Cooling System (SCS) is required to provide additional cooling during short term operations. The SCS is required by the CoC for any MPC when the MPC heat load is such that short-term cladding temperature limits would be exceeded. The specific design of an SCS must accord with site-specific needs and resources, including the availability of plant utilities. However, a set of specifications to ensure

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-47	

that the performance objectives of the SCS are satisfied by plant-specific designs are set forth in Appendix 2.C.

4.5.1 HI-TRAC Thermal Model

The HI-TRAC transfer cask is used to load and unload the HI-STORM concrete storage overpack, including onsite transport of the MPCs from the loading facility to an ISFSI pad. Section views of the HI-TRAC have been presented in Chapter 1. Within a loaded HI-TRAC, heat generated in the MPC is transported from the contained fuel assemblies to the MPC in the manner described in Section 4.4. From the outer surface of the MPC to the ambient air, heat is transported by a combination of conduction, thermal radiation and natural convection. For evaluation of the thermal state of a loaded canister during all short-term operations, the three dimensional (3D) thermal model of the MPC described in Section 4.4 is utilized.

All FLUENT thermal analyses to establish margins of safety are carried out for the MPC model that yields the highest peak cladding temperature and MPC cavity pressure under the long term storage condition as discussed in Section 4.4. The above criterion identifies MPC-32 under regionalized fuel loading with $X = 0.5$ and $X=3$ as the governing cases.

Two HI-TRAC transfer cask designs, namely, the 125-ton and the 100-ton versions, are developed for onsite handling and transport, as discussed in Chapter 1. The two designs are principally different in terms of lead thickness and the thickness and number of the heat dissipating ribs (radial connectors) in the water jacket region. The aggregate heat dissipation by the ribs is defined by the product of the number of radial ribs, N and thickness, t_r . The numerical model developed for HI-TRAC thermal characterization conservatively accounts for these differences by applying the higher lead thickness and constructing the water jacket region having the lowest product of N and t_r . In this manner, the HI-TRAC thru-wall resistance to heat transfer is overestimated, yielding higher MPC internal and fuel cladding temperatures.

Transport of heat within HI-TRAC occurs through multiple concentric layers of air, steel and shielding materials. A small gap exists between the outer surface of the MPC and the inner surface of the HI-TRAC overpack. Heat is transported across this gap by the parallel mechanisms of natural convection, conduction and thermal radiation. Assuming that the MPC is centered and does not contact the transfer cask walls conservatively minimizes heat transport across this gap. Heat is transported through the cylindrical wall of the HI-TRAC transfer cask by conduction through successive layers of steel, lead, and steel. A water jacket, which provides neutron shielding for the HI-TRAC transfer cask, surrounds the cylindrical steel wall. The water jacket is essentially an array of carbon steel radial ribs with welded, connecting enclosure plates. Heat is dissipated by conduction and natural convection in the water cavities and by conduction in the radial ribs. Heat is passively rejected to the ambient from the outer surface of the HI-TRAC transfer cask by natural convection and thermal radiation.

The HI-TRAC transfer cask thermal analysis is based on a 3D FLUENT model that incorporates several conservative features, namely:

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-48	

- i. A constant solar flux is assumed with maximum permissible heat load and asymptotic steady state conditions to yield the most adverse temperature field in the cask. A theoretically bounding solar absorptivity of 1.0 is applied to all exposed surfaces.
- ii. Air motion in the HI-TRAC annulus is explicitly modeled. The MPC is assumed to be concentrically aligned with the cask cavity and the annulus is filled with air.
- iii. Although the HI-TRAC transfer cask baseplate is in contact with supporting surfaces, for conservatism, an insulated boundary condition is applied to the HI-TRAC baseplate.
- iv. The HI-TRAC transfer cask fluid columns in the water jacket and the open air volume above the MPC are conservatively assumed to remain in the laminar flow regime.
- v. The annular gap between the HI-TRAC transfer cask and MPC shrinks under heat up to operating temperatures. The enhancement of heat transfer due to the gap reduction is conservatively neglected.
- vi. Buoyancy driven motion of air above the MPC is included in the thermal model.
- vii. Radiation heat transfer is simulated by the more robust Discrete Ordinates (DO) model deployed in the HI-STAR 180 (Docket 71-9325) and HI-STORM FW (72-1032) in lieu of the DTRM model.
- viii. The rodged zone, which contains the spent fuel assemblies, is modeled as a homogeneous porous media using the flow resistance properties based on extensive CFD simulations [4.4.2] performed in the HI-STORM 100 docket and used in subsequent safety evaluations in both HI-STORM 100(Docket 72-1014) and HI-STORM FW dockets (Docket 72-1032). A recent experimental work by the Sandia National Laboratory (SNL), however, indicates that the axial flow resistance in the PWR fuel may be somewhat greater [4.5.1]. Although the SNL experimental data is not yet published by the NRC as of this writing (March, 2014), in the interest of conservatism, the higher flow resistance, $1 \times 10^6 \text{ m}^{-2}$ for all three zones of fuel assembly, indicated by their work has been used in all of the thermal simulations for HI-TRAC [4.5.1].
- ix. The HI-TRAC external surfaces are modeled as surfaces with convection, radiative heat exchange with air and a constant maximum incident solar heat flux load. Insolation on cylindrical surfaces is conservatively based on 12-hour levels prescribed in 10CFR71 averaged on a 24-hour basis. It is considered appropriate to use the 24-hour averaged insolation level due to the large thermal inertia of HI-TRAC which precludes it from reaching a steady-state thermal condition during a twelve-hour period.

The computational fluid dynamics model of the HI-TRAC transfer cask captures all essential details of the cask body including the radial ribs, lead, steel shells and the water jacket. Figures 4.5.1 show the discretization of the cask and its enclosed MPC for FLUENT implementation.

REPORT HI-2002444	4-49	

4.5.2 Time-to-Boil for a Water-Filled MPC

Fuel loading operations are conducted with the HI-TRAC transfer cask and its contents submerged in pool water. Under these conditions, the HI-TRAC system is essentially at the pool water temperature. When the HI-TRAC transfer cask and the loaded MPC under water-flooded conditions is removed from the pool and staged in an ambient air environment, the water, MPC, and HI-TRAC transfer cask metal absorb the decay heat emitted by the fuel assemblies. This results in a slow temperature rise of the HI-TRAC system with time, starting from an initial (pool water) temperature. The rate of temperature rise is limited by the thermal inertia of the HI-TRAC system. Environmental factors (e.g., wetting of the external surface of the HI-TRAC) may be used to influence the rate of change of the system's temperature. However, the calculated time-to-boil clock is not affected by the use of these environmental factors.

The available time before the water in the MPC would reach boiling is computed under a conservative set of assumptions summarized below:

- i. Heat loss by natural convection and radiation from the exposed HI-TRAC surfaces to ambient air is neglected (i.e., an adiabatic heat-up calculation is performed).
- ii. The smaller of the two (i.e., 100-ton and 125-ton) HI-TRAC transfer cask metal mass is credited in the analysis. The 100-ton design has a significantly smaller quantity of metal mass, which will result in a higher rate of temperature rise.
- iii. The water mass in the MPC cavity is understated.

Table 4.5.2 summarizes the lower bound weights and thermal inertias of the constituent components in the loaded HI-TRAC 100 transfer cask. The rate of temperature rise of the HI-TRAC transfer cask and contents during an adiabatic heat-up is governed by the following equation:

$$\frac{dT}{dt} = \frac{Q}{C}$$

Where:

- Q = Coincident fuel decay heat in the canister (Btu/hr)
 C = Thermal inertia of a loaded HI-TRAC (Btu/°F) (See Table 4.5.2)
 T = Temperature of the HI-TRAC system (°F)
 t = time (hr)¹

Therefore, the time-to-boil (τ) is determined as follows:

¹ Time clock begins when the lid is placed on the MPC, or immediately following measurement of the temperature of the water in the MPC cavity.

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-50	

$$\tau = \frac{(T_{\text{boil}} - T_{\text{initial}})}{(dT/dt)}$$

Where:

T_{boil} = Boiling temperature of water (set equal to 212°F at the water surface in the MPC cavity)

T_{initial} = Initial temperature of the water in the MPC cavity (°F)

The time-to-boil clock starts when the lid is placed on the MPC while the HI-TRAC is in the spent fuel pool, and is terminated when MPC draining is completed (see Section 8.1.5). The time-to-boil clock may also be terminated by removing the MPC lid, while the loaded HI-TRAC is still in the spent fuel pool. Following placement of the lid on the MPC, the initial temperature of the water in the MPC shall be set as equal to the pool water temperature. After removal of the MPC from the spent fuel pool, measurement of the actual temperature of the water in the MPC may be performed at any point. This measured temperature may be used as an updated initial temperature that may be used to calculate an updated time-to-boil. All calculations of the time-to-boil for a loaded canister shall be made using the above formula. Table 4.5.3 provides a summary of τ at several representative heat loads and initial MPC cavity water temperatures.

An alternate method using the FLUENT thermal model described in Section 4.5.1 can be adopted to evaluate the time for water within the MPC to boil using site-specific conditions. Principal modeling steps and acceptance criteria are defined in Table 4.5.10a.

As set forth in the HI-STORM operating procedures, in the unlikely event that the maximum allowable time provided in Table 4.5.3 is found to be insufficient to complete wet transfer operations, a forced water circulation shall be initiated and maintained to remove the decay heat from the MPC cavity. In this case, relatively cooler water will enter via the MPC lid drain port connection and heated water will exit from the vent port. At the conclusion of forced water circulation, the temperature of the water in the MPC shall be measured and used to calculate an updated time-to-boil. The minimum water flow rate required to maintain the MPC cavity water temperature below boiling with an adequate subcooling margin is determined as follows:

$$M_w = \frac{Q}{C_{pw} (T_{\text{max}} - T_{\text{in}})}$$

where:

M_w = minimum water flow rate (lb/hr)

C_{pw} = water heat capacity (Btu/lb-°F)

T_{max} = maximum MPC cavity water mass temperature (must be less than 212°F)

T_{in} = MPC water inlet temperature

Q = Coincident fuel decay heat in the canister (Btu/hr)

For example, the MPC cavity water temperature limited to 150°F, MPC water inlet temperature at 125°F and design basis maximum heat load (36.9 kW, approximately 125,908 Btu/hr), the water flow rate computes as 5038 lb/hr (10.1 gpm).

4.5.3 MPC Temperatures During Moisture Removal Operations

4.5.3.1 Vacuum Drying Operation

The initial loading of SNF in the MPC requires that the water within the MPC be drained, fuel dried and the water replaced with helium. Vacuum drying of fuel is conducted by evacuating the MPC after completion of MPC draining operation. For MPCs containing Moderate Burnup Fuel (MBF) assemblies only, this operation may be carried out using the vacuum drying method up to the threshold heat loads defined in Table 4.5.1. In this Table Q1 is the threshold heat load for vacuum drying operations without time limits. The requirements and limits for moisture removal are provided in LCO 3.1.1 of the HI-STORM 100 CoC and are specific to the amendment to which the HI-STORM 100 System is being loaded. To minimize fuel temperatures during vacuum drying operations the HI-TRAC annulus must be water filled.

At heat loads greater than the threshold heat load defined above, the peak cladding temperature cannot be maintained below the ISG-11, Revision 3 limit of 570°C for MBF under a vacuum condition of infinite duration. Under this scenario, cycles of vacuum drying resulting in heatup followed with cooling by helium are performed until drying criteria is achieved. Similarly, vacuum drying of MPCs containing one or more High Burnup Fuel (HBF) assemblies is also permitted under time limits. The peak cladding temperature for drying HBF must be maintained below ISG-11 Rev 3 limit of 400°C. It must be noted that the permissible time for heatup/cooldown cycles is a function of canister specific heat loads. At lower heat loads the duration of vacuum drying cycles is higher. The thermal model defined below must be used for heatup/cooldown cycles for site-specific canister heat load maps. It must be ensured per ISG-11 Rev 3 that the repeated thermal cycling is limited to less than 10 cycles, with cladding temperature variations less than 65°C (117°F) each cycle. Fuel drying may also be conducted by using forced helium drying (FHD) process as discussed in Section 4.5.3.2.

A 3-D FLUENT thermal model of the MPC is constructed in the same manner as described in Section 4.4. The principal input to this model is the effective conductivity of fuel under vacuum drying operations. To reasonably bound vacuum drying operations the effective conductivity of fuel is computed assuming the MPC is filled with water vapor at a very low pressure (1 torr) for the entire duration of vacuum drying¹⁸. The methodology for computing the effective conductivity is given in Section 4.4.1. To ensure a conservative evaluation the thermal model is incorporated with the following assumptions:

- i. Threshold heat load Q1, defined in Table 4.5.1, is assumed and steady-state condition reached under Q1 results in vacuum drying of only MBF without time limits.

¹⁸ This is conservative as the MPC pressure is progressively lowered below ambient pressure to facilitate moisture removal. Near the end of the vacuum drying operation the pressure is substantially lowered to approximately 1 torr to facilitate the 30-minute 3-torr vacuum rebound test followed by backfilling of the MPC with helium.

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-52	

- ii. The external surface of the MPC shell is postulated to vary linearly from 100°C (212°F) normal boiling temperature of water at the top to 111°C (231°F) elevated pressure boiling temperature at the bottom to account for the hydrostatic head.
- iii. The bottom surface of the MPC is insulated.
- iv. MPC internal convection heat transfer is suppressed.
- v. Top surface of the MPC is in communicative contact with air (Table 2.2.2). Natural convection and radiation cooling from the MPC top is included in the thermal model.

The principle objective of the vacuum drying analysis is to ensure that fuel temperatures are below ISG-11, Rev. 3 temperature limits (See Table 4.3.1). Under threshold heat load Q1 the results and margins are tabulated in Table 4.5.5. The results show that ISG-11, Rev. 3 limits are met with ample margins.

4.5.3.2 Forced Helium Dehydration

To dry the MPC cavity using a Forced Helium Dehydration (FHD) system, a conventional, closed loop dehumidification system consisting of a condenser, a demister, a compressor, and a pre-heater is utilized to extract moisture from the MPC cavity through repeated displacement of its contained helium, accompanied by vigorous flow turbulence. A vapor pressure of 3 torr or less is assured by verifying that the helium temperature exiting the demister is maintained at or below the psychrometric threshold of 21°F for a minimum of 30 minutes. See Appendix 2.B for detailed discussion of the design criteria and operation of the FHD system.

The FHD system provides concurrent fuel cooling during the moisture removal process through forced convective heat transfer. The attendant forced convection-aided heat transfer occurring during operation of the FHD system ensures that the fuel cladding temperature will remain below the applicable peak cladding temperature limit for normal conditions of storage, which is well below the high burnup cladding temperature limit 752°F (400°C) for all combinations of SNF type, burnup, decay heat, and cooling time. Because the FHD operation induces a state of forced convection heat transfer in the MPC, (in contrast to the quiescent mode of natural convection in long term storage), it is readily concluded that the peak fuel cladding temperature under the latter condition will be greater than that during the FHD operation phase. In the event that the FHD system malfunctions, the forced convection state will degenerate to natural convection, which corresponds to the conditions of normal onsite transport. As a result, the peak fuel cladding temperatures will approximate the values reached during normal onsite transport as described elsewhere in this chapter.

In the event of a FHD malfunction, the MPC cavity must be filled with helium to achieve an MPC cavity pressure of 72 psig, as described in Chapter 11. A thermal analysis is performed to demonstrate that the fuel is under a safe condition in the event of FHD malfunction. The licensing basis thermal model with most limiting decay heat i.e. maximum decay heat load with X=3 (Table 2.1.30), is adopted for thermal analysis. Since this cask operation is performed inside a building, no solar insolation is applied on the cask external surfaces. The predicted steady state temperature results for this scenario are summarized in Table 4.5.10. The results demonstrate that the fuel

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-53	

cladding and all other component temperatures are well below their off-normal temperature limits specified in Table 2.2.3 of the FSAR. Therefore, the fuel and MPC are in a safe condition when the MPC pressure is maintained at least at 72 psig in the event of FHD malfunction.

4.5.4 Cask Cooldown and Reflood Analysis During Fuel Unloading Operation

NUREG-1536 requires an evaluation of cask cooldown and reflood procedures to support fuel unloading from a dry condition. Two options are available for cask cooldown: Direct Water Quenching and Helium Cooldown followed by Direct Water Quenching. It is not mandatory to perform helium cooldown prior to quenching but some users may choose to perform helium cooldown for high heat load MPCs.

4.5.4.1 Option 1: Direct Water Quenching

Past industry experience generally supports cooldown of cask internals and fuel from hot storage conditions by direct water quenching. Direct MPC cooldown is effectuated by introducing water through the lid drain line. From the drain line, water enters the MPC cavity near the MPC baseplate. Steam produced during the direct quenching process will be vented from the MPC cavity through the lid vent port. To maximize venting capacity, both vent port RVOA connections must remain open for the duration of the fuel unloading operations. As direct water quenching of hot fuel results in steam generation, it is necessary to limit the rate of water addition to avoid MPC overpressurization. For example, steam flow calculations using bounding assumptions (100% steam production and MPC at design pressure) show that the MPC is adequately protected up to a reflood rate of 3715 lb/hr. Limiting the water reflood rate to this amount or less would prevent exceeding the MPC design pressure.

During direct reflood operations the fuel cladding is subject to high temperature gradients and concomitant thermal stresses. The integrity of fuel under direct quenching is evaluated in a generic manner in the HI-STORM FW SAR (Docket No. 72-1032, Ref. [4.5.2]). To define a bounding scenario at time $t = 0$ sec, a uniformly bounding temperature throughout the entire fuel rod is set at 752°F (400°C), which is the temperature limit of fuel cladding. At time $t = 0.1$ sec, a reasonably bounding 80°F quench water temperature is assigned to the lower half of the fuel rod to simulate a thermal shock with a large step change in the cladding temperature. The resulting transient stress and strain distributions in the fuel rod are evaluated with finite element ANSYS models. The results show that the maximum stress and strain values remain within the elastic range and remain well within failure strain limit (a factor of 6 against failure strain). This safety analysis documented in Section 3.4.4.1.11 of the HI-STORM FW FSAR provides the assurance that the MPC reflood event will not cause a breach of fuel cladding.

4.5.4.2 Option 2: Helium Cooldown followed by Direct Water Quenching

Under a closed-loop forced helium circulation condition, the helium gas is cooled, via an external chiller. The chilled helium is then introduced into the MPC cavity from connections at the top of the MPC lid. The helium gas enters the MPC basket and moves through the fuel basket cells, removing heat from the fuel assemblies and MPC internals. The heated helium gas exits the MPC

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-54	

from the lid connection to the helium recirculation and cooling system. Because of the turbulence and mixing of the helium contents in the MPC cavity by the forced circulation, the MPC exiting temperature is a reliable measure of the thermal condition inside the MPC cavity. The objective of the cooldown system is to lower the bulk helium temperature in the MPC cavity to below the normal boiling temperature of water (212°F). For this purpose, the rate of helium circulation shall be sufficient to ensure that the helium exit gas temperature is below this threshold limit with a margin.

An example calculation for the required helium circulation rate is provided below to limit the helium temperature to 200°F. The calculation assumes no heat loss from the MPC boundaries and a conservatively bounding heat load (38 kW (1.3x10⁵ Btu/hr)). Under these assumptions, the MPC helium is heated adiabatically by the MPC decay heat from a given inlet temperature (T₁) to a temperature (T₂). The required circulation rate to limit T₂ to 200°F is computed as follows:

$$m = \frac{Q_d}{C_p(T_2 - T_1)}$$

where:

Q_d = Design maximum decay heat load (Btu/hr)

m = Minimum helium circulation rate (lb/hr)

C_p = Heat capacity of helium (1.24 Btu/lb-°F (Table 4.2.5))

T₁ = Helium supply temperature (assumed 15°F in this example)

Substituting the values for the parameters in the equation above, m is computed as 567 lb/hr.

4.5.5 Maximum Temperatures under Onsite Transport Conditions

4.5.5.1 HI-TRAC Transport outside a Building

The requirements of utilizing SCS system in the onsite transfer operation are listed in Table 4.5.4. Condition 3 of Table 4.5.4 mandates the use of SCS for an MPC containing one or more HBF above the threshold heat load. This will assure that cladding temperature limits are met for HBF at heat loads higher than threshold heat load. See Appendix 2.C for the SCS requirements.

A 3-D FLUENT thermal model of an MPC inside a HI-TRAC transfer cask was constructed as described in Subsection 4.5.1 to evaluate temperature distributions under onsite transport. In the normal onsite transport mode, the annular region between the canister and the cask has air and the cask is subject to heat input from insolation. The ambient temperature when HI-TRAC is placed in the outdoor environment corresponds to the maximum outdoor ambient temperature specified in Table 2.2.2 under short term operations. Even though the duration of onsite transport is typically short enough to preclude the MPC and HI-TRAC from reaching steady-state, a steady-state thermal analysis is conservatively performed. The results summarized herein are when steady state conditions have been reached.

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-55	

The safety analysis of the onsite transport scenario requires the computation of the margins of safety with respect to the peak fuel cladding temperature of moderate and high burnup fuel¹⁹, MPC internal pressure, fuel basket metal temperature, hydraulic pressure in the water jacket and the temperature of the HI-TRAC body parts.

The water in the water jacket surrounding the HI-TRAC transfer cask body provides necessary neutron shielding. During normal handling and onsite transport operations this shielding water is contained within the water jacket at an elevated pressure. The water jacket is equipped with two pressure relief devices to prevent overpressure.

The steady state analyses are first performed for the design basis heat load under the two extreme allowable regionalized storage scenarios ($Q = 36.9$ kW, $X = 0.5$ and $Q = 30.17$ kW, $X = 3$ in MPC-32), which are the maximum permissible heat load allowed to be stored in HI-STORM system defined in Subsection 2.1.9.1. The computed fuel temperatures in this scenario remain below the cladding temperature limit of moderate burnup fuel, but exceed the temperature limit of high burnup fuel (Table 4.3.1). For both regionalized storage scenarios, the MPC internal pressure, fuel basket and the HI-TRAC parts temperatures are presented in Table 4.5.6, and their corresponding allowable limits show positive margins of safety. As these are bounding steady state temperatures, the results support onsite transport of fuel in the HI-TRAC without the aid of any supplemental cooling for MPC containing only moderate fuel burnup and cooling times up to the maximum design basis heat load of the HI-STORM System.

The steady state analyses are then performed for the threshold heat load which requires SCS for MPC containing HBF, which is defined in Table 4.5.4. In this scenario, the heat generation rate in the MPC is reduced to 90% of maximum design basis rate. Under the two extreme allowable regionalized storage scenarios ($Q = 33.21$ kW, $X = 0.5$ and $Q = 27.15$ kW, $X = 3$ in MPC-32), the computed fuel temperatures remain below the cladding temperature limits of high and moderate burnup fuel (Table 4.3.1). The MPC components, fuel basket and the HI-TRAC parts temperatures are presented in Table 4.5.7, and their corresponding allowable limits show positive margins of safety. Therefore, the results support onsite transport of fuel in the HI-TRAC without the aid of any supplemental cooling for any fuel burnup and cooling times up to 90% of maximum design basis heat load[†] of the HI-STORM System.

4.5.5.2 Evaluation of HI-TRAC inside a Building

When HI-TRAC is located inside the fuel loading building, the ambient air temperature inside a building may be higher than the outdoor environment evaluated in Subsection 4.5.5.1. Since ambient air temperature may be higher inside the building, a maximum indoor air temperature specified in Table 2.2.2 under short term operations is used in the analysis. Since the cask is inside a building, no solar insolation is applied to the cask. A steady state analysis is performed for the 90% of design basis heat load under the regionalized storage scenario ($Q = 27.15$ kW, $X = 3$ in MPC-32), which results in the lowest PCT safety margin for high burnup fuel. The peak cladding, fuel basket and the HI-TRAC parts temperatures are presented in Table 4.5.8. The predicted

¹⁹ The cladding temperature limit for the high burn up fuel is more restrictive (See Table 4.3.1).

[†] The individual storage cell heat loads are also restricted to 90% of their design maximum heat loads.

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-56	

component temperatures are below their corresponding temperatures for outdoor environment presented in Table 4.5.7. Therefore, the normal on-site transfer of a HI-TRAC outside the building and with solar insolation as evaluated in Subsection 4.5.5.1 is the limiting thermal condition.

4.5.5.3 Evaluation of SCS Failure

Table 4.5.4 mandates the use of the SCS for MPC containing one or more HBF above the threshold heat load to ensure fuel remains below the short-term operation temperature limits mandated by ISG-11, Rev. 3. If the SCS fails during operation, an accident condition defined in Section 11.2, the thermal state of the fuel would asymptotically approach steady state maximum conditions corresponding to the coincident thermal payload in the HI-TRAC transfer cask. The results of steady state analysis are provided in Table 4.5.6 for the design basis heat load. It is shown that the fuel remains well below its accident limit (Table 4.3.1).

4.5.5.4 Evaluation of SCS for Lower Backfill Pressure Limit

As stated in Table 1.2.2, MPC is allowed to be backfilled with a lower pressure limit than that specified in Table 4.4.12, if the MPC heat load meets the threshold heat load requirement in Table 1.2.2. The analyses that support the threshold heat load scenario and lower helium backfill pressure limits are reported in the Revision 6 of HI-STORM 100 FSAR. To evaluate the requirement of SCS system (Table 4.5.4) for the threshold heat load with lower backfill pressure limit, a steady state analysis is performed for the bounding heat load scenario, i.e. MPC-32 with heat load of uniform 28.74 kW under an ambient environment outside the building. The computed fuel temperatures in this scenario remain below the cladding temperature limit of moderate burnup fuel, but exceed the temperature limit of high burnup fuel (Table 4.3.1). The fuel basket and the HI-TRAC parts temperatures are presented in Table 4.5.9, and their corresponding allowable limits show positive margins of safety. As these are bounding steady state temperatures, the results support onsite transport of fuel in the HI-TRAC without the aid of any supplemental cooling for MPC containing only moderate fuel burnup and cooling times up to the threshold heat load in Table 1.2.2.

The steady state analyses are then performed for 90% of threshold heat load[†], i.e. $Q = 25.86$ kW uniform in MPC-32, the computed fuel temperatures remain below the cladding temperature limits of high and moderate burnup fuel (Table 4.3.1). The MPC components, fuel basket and the HI-TRAC parts temperatures are presented in Table 4.5.9, and their corresponding allowable limits show positive margins of safety. Therefore, the results support onsite transport of high burnup fuel in the HI-TRAC without the aid of any supplemental cooling up to the 90% of threshold heat load[†] in Table 1.2.2.

4.5.5.5 Environmental Temperature Requirements

Short term operations involving the HI-TRAC transfer cask can be carried out on the basis of the safety evaluation herein if the reference ambient temperature (three day average around the cask)

[†] The individual storage cell heat loads are also restricted to 90% of their threshold maximum heat loads.

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-57	

is below the “Threshold Temperature” defined in Table 2.2.2 as 110 deg. F for operations inside the part 50 structural boundary and 90 deg. F outside of it. The determination of the Threshold Temperature compliance shall be made based on the best available thermal data for the site.

If the reference ambient temperature exceeds the corresponding Threshold Temperature then a site specific analysis using the methodology set down in Section 4.5 shall be performed using the actual heat load and reference ambient temperature equal to the three day average to ensure that the steady state peak fuel cladding temperature will remain below the Table 2.2.3 limit. If the peak fuel cladding temperature exceeds Table 2.2.3 limit then the use of a Supplemental Cooling System (SCS) is mandatory.

4.5.6 Maximum Internal Pressure

After fuel loading and vacuum drying, but prior to installing the MPC closure ring, the MPC is initially filled with helium. During handling and on-site transfer operations in the HI-TRAC transfer cask, the gas temperature within the MPC rises to its maximum operating temperature as determined by on the thermal analysis methodology described previously. In Table 4.5.6, the MPC internal pressure co-incident with the MPC temperature is reported and compared with the short term (off-normal) pressure limit specified in Table 2.2.1 to show compliance with design limit. The MPC gas pressure listed in Table 4.5.6 is below the MPC design internal pressure listed in Table 2.2.1.

4.6 OFF-NORMAL AND ACCIDENT EVENTS²⁰

In accordance with NUREG 1536 the HI-STORM 100 System is evaluated for the effects of off-normal and accident events. The design basis off-normal and accident events are defined in Chapter 2. For each event, the cause of the event, means of detection, consequences, and corrective actions are discussed and evaluated in Chapter 11. To support the Chapter 11 evaluations, thermal analyses of limiting off-normal and accident events are provided in the following.

To ensure a bounding evaluation for the array of fuel storage configurations permitted in Section 2.1, a limiting storage condition is evaluated in this section. The limiting storage condition is previously determined in the Section 4.5 and adopted herein for all off-normal and accident evaluations.

4.6.1 Off-Normal Events

4.6.1.1 Off-Normal Pressure

This event is defined as a combination of (a) maximum helium backfill pressure (Table 4.4.12), (b) 10% fuel rods rupture, and (c) limiting fuel storage configuration. The principal objective of the analysis is to demonstrate that the MPC off-normal design pressure (Table 2.2.1) is not exceeded. The MPC off-normal pressures are reported in Table 4.4.9. The result²¹ is confirmed to be below the off-normal design pressure (Table 2.2.1).

4.6.1.2 Off-Normal Environmental Temperature

This event is defined by a time averaged ambient temperature of 100°F for a 3-day period (Table 2.2.2). The results of this event (maximum temperatures and pressures) are provided in Table 4.6.1 and 4.6.2. The results are below the off-normal condition temperature and pressure limits (Tables 2.2.1 and 2.2.3).

4.6.1.3 Partial Blockage of Air Inlets

The HI-STORM 100 System is designed with debris screens installed on the inlet and outlet openings. These screens ensure the air passages are protected from entry and blockage by foreign objects. As required by the design criteria presented in Chapter 2, it is postulated that the HI-STORM air inlet vents are 50% blocked. The resulting decrease in flow area increases the flow resistance of the inlet ducts. The effect of the increased flow resistance on fuel temperature is analyzed for the normal ambient temperature (Table 2.2.2) and a limiting fuel storage configuration. The computed temperatures are reported in Table 4.6.1 and the corresponding MPC

²⁰ A new standalone Section 4.6 is added in CoC Amendment 3 to address thermal analysis of off-normal and accident events. The results are evaluated in Chapter 11.

²¹ Pressures relative to 1 atm absolute pressure (i.e. gauge pressures) are reported throughout this section.

internal pressure in Table 4.6.2. The results are confirmed to be below the temperature limits (Table 2.2.3) and pressure limit (Table 2.2.1) for off-normal conditions.

4.6.2 Accident Events

4.6.2.1 Fire Accidents

4.6.2.1.1 Licensing-Basis (Postulated) Fire Accident

Although the probability of a fire accident affecting a HI-STORM 100 System during storage operations is low due to the lack of combustible materials at an ISFSI, a licensing-basis fire event has been assumed and analyzed. Under the postulated fire, the outer layers of HI-TRAC or HI-STORM overpacks are heated for the duration of fire by the incident thermal radiation and forced convection heat fluxes. The amount of combustible material for the postulated fire is limited to a volume of 50 gallons.

(a) HI-STORM Fire

The fuel tank fire is conservatively assumed to surround the HI-STORM Overpack. Accordingly, all exposed overpack surfaces are heated by radiation and convection heat transfer from the fire. Based on NUREG-1536 and 10 CFR 71 guidelines [4.6.1], the following fire parameters are assumed:

1. The average emissivity coefficient must be at least 0.9. During the entire duration of the fire, the painted outer surfaces of the overpack are assumed to remain intact, with an emissivity of 0.85. It is conservative to assume that the flame emissivity is 1.0, the limiting maximum value corresponding to a perfect blackbody emitter. With a flame emissivity conservatively assumed to be 1.0 and a painted surface emissivity of 0.85, the effective emissivity coefficient is 0.85. Because the minimum required value of 0.9 is greater than the actual value of 0.85, use of an average emissivity coefficient of 0.9 is conservative.
2. The average flame temperature must be at least 1475°F (800°C). Open pool fires typically involve the entrainment of large amounts of air, resulting in lower average flame temperatures. Additionally, the same temperature is applied to all exposed cask surfaces, which is very conservative considering the size of the HI-STORM cask. It is therefore conservative to use the 1475°F (800°C) temperature.
3. The fuel source must extend horizontally at least 1 m (40 in), but may not extend more than 3 m (10 ft), beyond the external surface of the cask. Use of the minimum ring width of 1 meter yields a deeper pool for a fixed quantity of combustible fuel, thereby conservatively maximizing the fire duration.
4. The convection coefficient must be that value which may be demonstrated to exist if the cask were exposed to the fire specified. Based upon results of large pool fire thermal

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-71	

measurements [4.6.2], a conservative forced convection heat transfer coefficient of 4.5 Btu/(hr×ft²×°F) is applied to exposed overpack surfaces during the short-duration fire.

Based on the 50 gallon fuel volume, the overpack outer diameter and the 1 m fuel ring width [4.6.1], the fuel ring surrounding the overpack covers 147.6 ft² and has a depth of 0.54 in. From this depth and a constant fuel consumption rate of 0.15 in/min, the fire duration is calculated to be 3.62 minutes. The fuel consumption rate of 0.15 in/min is a lowerbound value from a Sandia National Laboratories report [4.6.2]. Use of a lowerbound fuel consumption rate conservatively maximizes the duration of the fire.

To evaluate the impact of fire heating of the HI-STORM overpack, a thermal model of the overpack cylinder was constructed using the ANSYS computer code. The initial temperature of the overpack was conservatively assumed to be the maximum temperature field during storage (Table 4.4.7). In this model the outer surface and top surface of the overpack were subjected for the duration of fire (3.62 minutes) to the fire conditions defined in this subsection. In the post-fire phase, the ambient conditions preceding the fire were restored. The transient study was conducted for a period of 5 hours, which is sufficient to allow temperatures in the overpack to reach their maximum values and begin to recede.

Due to the severity of the fire condition radiative heat flux, heat flux from incident solar radiation is negligible and is not included. Furthermore, the smoke plume from the fire would block most of the solar radiation. It is recognized that the ventilation air in contact with the inner surface of the HI-STORM Overpack with design-basis decay heat and normal ambient temperature conditions varies between 80°F at the bottom and 220°F at the top of the overpack. It is further recognized that the inlet and outlet ducts occupy a miniscule fraction of area of the cylindrical surface of the massive HI-STORM Overpack. Due to the short duration of the fire event and the relative isolation of the ventilation passages from the outside environment, the ventilation air is expected to experience little intrusion of the fire combustion products. As a result of these considerations, it is conservative to assume that the air in the HI-STORM Overpack ventilation passages is held constant at a temperature of 300°F during the entire duration of the fire event.

The thermal transient response of the storage overpack is determined using the ANSYS finite element program. Time-histories for points in the storage overpack are monitored for the duration of the fire and the subsequent post-fire equilibrium phase.

Heat input to the HI-STORM Overpack while it is subjected to the fire is from a combination of an incident radiation and convective heat fluxes to all external surfaces. This can be expressed by the following equation:

$$q_F = h_{fc} (T_A - T_S) + \sigma \varepsilon [(T_A + C)^4 - (T_S + C)^4]$$

where:

q_F = Surface Heat Input Flux (Btu/ft²-hr)

h_{fc} = Forced Convection Heat Transfer Coefficient (4.5 Btu/ft²-hr-°F)

σ = Stefan-Boltzmann Constant

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-72	

T_A = Fire Temperature (1475°F)
 C = Conversion Constant (460 (°F to °R))
 T_S = Surface Temperature (°F)
 ε = Average Emissivity (0.90 per 10 CFR 71.73)

The forced convection heat transfer coefficient is based on the results of large pool fire thermal measurements [4.6.2].

After the fire event, the ambient temperature is restored and the storage overpack cools down (post-fire temperature relaxation). Heat loss from the outer surfaces of the storage overpack is determined by the following equation:

$$q_s = h_s(T_s - T_A) + \sigma\varepsilon[(T_s + C)^4 - (T_A + C)^4]$$

where:

q_s = Surface Heat Loss Flux (W/m² (Btu/ft²-hr))
 h_s = Natural Convection Heat Transfer Coefficient (Btu/ft²-hr-°F)
 T_s = Surface Temperature (°F)
 T_A = Ambient Temperature (°F)
 σ = Stefan-Boltzmann Constant
 ε = Surface Emissivity
 C = Conversion Constant (460 (°F to °R))

In the post-fire temperature relaxation phase, h_s is obtained using literature correlations for natural convection heat transfer from heated surfaces [4.2.9].

A two-dimensional, axisymmetric model was developed for this analysis. Material thermal properties used were taken from Section 4.2. The outer surface and top surface of the overpack are exposed to the ambient conditions (fire and post-fire), and the base of the overpack is insulated. The transient study is conducted for a period of 5 hours, which is sufficient to allow temperatures in the overpack to reach their maximum values and begin to recede.

During the fire the overpack external shell temperatures are substantially elevated (~550°F). However, all concrete remains below the short term temperature limit (Table 2.2.3).

These results demonstrate that the fire accident event analyzed in a most conservative manner is determined to have a minor affect on the HI-STORM Overpack. The concrete temperatures at all locations remain below the allowable temperature limit. The temperatures of steel structures are within the allowable temperature limits.

Having evaluated the effects of the fire on the overpack, we now evaluate the effects on the MPC and contained fuel assemblies. Guidance for the evaluation of the MPC and its internals during a fire event is provided by NUREG-1536 (4.0,V,5.b), which states:

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-73	

“For a fire of very short duration (i.e., less than 10 percent of the thermal time constant of the cask body), the NRC finds it acceptable to calculate the fuel temperature increase by assuming that the cask inner wall is adiabatic. The fuel temperature increase should then be determined by dividing the decay energy released during the fire by the thermal capacity of the basket-fuel assembly combination.”

The time constant of the cask body (i.e., the overpack) can be determined using the formula:

$$\tau = \frac{c_p \times \rho \times L_c^2}{k}$$

where:

c_p = Overpack Specific Heat Capacity (Btu/lb-°F)

ρ = Overpack Density (lb/ft³)

L_c = Overpack Characteristic Length (ft)

k = Overpack Thermal Conductivity (Btu/ft-hr-°F)

The concrete contributes the majority of the overpack mass and volume, so we will use the specific heat capacity (0.156 Btu/lb-°F), density (142 lb/ft³) and thermal conductivity (1.05 Btu/ft-hr-°F) of concrete for the time constant calculation. The characteristic length of a hollow cylinder is its wall thickness. The characteristic length for the HI-STORM Overpack is therefore 29.5 in, or approximately 2.46 ft. Substituting into the equation, the overpack time constant is determined as:

$$\tau = \frac{0.156 \times 142 \times 2.46^2}{1.05} = 128 \text{ hrs}$$

One-tenth of this time constant is approximately 12.8 hours (768 minutes), substantially longer than the fire duration of 3.62 minutes, so the MPC is evaluated by considering the MPC canister as an adiabatic boundary. The fuel temperature rise is computed next.

Table 4.5.2 lists lower-bound thermal inertia values for the MPC and the contained fuel assemblies. Applying a conservative upperbound decay heat load (38 kW (1.3x10⁵ Btu/hr)) and adiabatic heating for the 3.62 minutes fire, the fuel temperature rise computes as:

$$\Delta T_{fuel} = \frac{\text{Decay heat} \times \text{Time duration}}{(\text{MPC} + \text{Fuel}) \text{ heat capacities}} = \frac{1.3 \times 10^5 \text{ Btu/hr} \times (3.62 / 60) \text{ hr}}{(2240 + 4680) \text{ Btu/}^\circ\text{F}} = 1.1^\circ\text{F}$$

This is a very small increase in fuel temperature. Consequently, the impact on the MPC internal helium pressure will be quite small. The peak temperatures of the fuel cladding, MPC fuel basket and MPC shell are summarized in Table 4.6.8. Based on a conservative analysis of the HI-STORM 100 System response to a hypothetical fire event, it is concluded that the fire event does not adversely affect the temperature of the MPC or contained fuel. We conclude that the ability of the

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-74	

HI-STORM 100 System to cool the spent nuclear fuel within design temperature limits during and after fire is not compromised.

An alternate method using the FLUENT thermal model described in Section 4.4 can be adopted to evaluate HI-STORM site-specific fire accident event similar to that described in Section 4.6 of HI-STORM FW FSAR. Principal modeling steps and acceptance criteria are defined in Table 4.6.10.

(b) HI-TRAC Fire

During the handling of the HI-TRAC transfer cask, the transporter fuel tank capacity must be limited to a 50 gallons. The duration of the 50-gallon fire under the conservatively postulated spill defined in the HI-STORM fire evaluation computes as 4.775 minutes. To demonstrate the fuel cladding and MPC pressure boundary integrity under exposure to this fire duration event during a fire accident analysis of the loaded 100-ton HI-TRAC is performed. In this analysis, the contents of the HI-TRAC are conservatively postulated to undergo a transient heat-up as a lumped mass from the decay heat input and heat input from the short duration fire. This analysis, because of the lower mass of the 100-ton HI-TRAC, bounds the effects for the 125-ton HI-TRAC. Using understated thermal inertia of the HI-TRAC and design maximum heat load (36.9 kW) the temperature rise rate computes as 5.553°F/min. Therefore, the temperature rise computed as the product of this rate and the fire duration reported above is 26.5°F. In this manner the maximum cladding temperature obtained by adding the temperature rise to the initial condition (See Table 4.5.6 for design basis heat load with X=3) computes as 811°F. The maximum fire temperature computed in the conservative manner above remains below the 1058°F accident temperature limit (Table 4.3.1) by substantial margins.

The elevated temperatures as a result of the fire accident will cause the pressure in the water jacket to increase and the overpressure relief valves to vent steam to the atmosphere. Based on the fire heat input to the water jacket, 11% of the water in the water jacket is boiled off. However, it is conservatively assumed, for dose calculations, that all the water in the water jacket is lost. In the 125-ton HI-TRAC and HI-TRAC 100G, which use Holtite in the lids for neutron shielding, the elevated fire temperatures would cause the Holtite to exceed its design accident temperature limits. This condition is conservatively addressed by ignoring neutron shield in the accident dose calculations.

Due to the increased temperatures of the MPC during fire accident the internal MPC pressure increases. The fire accident pressure is computed assuming the MPC cavity temperature rises by the fire accident temperature rise computed in this section. The result is tabulated in Table 4.6.2. The fire accident MPC pressure is substantially below the accident pressure limit (Table 2.2.1).

An alternate method using the FLUENT thermal model described in Section 4.5 can be adopted to evaluate HI-TRAC site-specific fire accident event. Principal modeling steps and acceptance criteria are defined in Table 4.6.11.

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-75	

4.6.2.1.2 Site-Specific Postulated Fire Accident

All fire accident scenarios other than licensing-basis fire described above (from 50 gallons of combustible liquid) shall be considered as site-specific fire accidents. In such cases, a site-specific fire analysis must be performed using NRC endorsed acceptance criteria.

The following acceptance criteria apply to site-specific fire accidents:

- i. The peak cladding temperature during and after a fire accident shall not exceed the ISG-11 [4.1.4] permissible limit (see Table 2.2.3).
- ii. The steel structure of the overpack shall remain structurally stable i.e., the maximum temperature shall be less than 1475°F at the instant of its most heated state.
- iii. The confinement boundary shall continue to serve its design function. Confinement integrity is confirmed if the pressure in the MPC remains below the accident condition pressure limit (200 psig, Table 2.2.1); otherwise, an Enclosure Vessel failure analysis will be required.
- iv. The concrete temperature limit shall remain below its temperature limit specified in Table 2.2.3.

4.6.2.2 Jacket Water Loss

In this subsection, the fuel cladding and MPC boundary integrity is evaluated for a postulated loss of water from the HI-TRAC water jacket. The HI-TRAC is equipped with an array of water compartments filled with water. For a bounding analysis, all water compartments are assumed to lose their water and be replaced with air. Heat dissipation by natural convection and radiation in the air space is included in the thermal model. The HI-TRAC is assumed to have the maximum thermal payload (design heat load) and assumed to have reached steady state (maximum) temperatures. Under these assumed set of adverse conditions, the maximum temperatures are computed using the 3D HI-TRAC thermal model constructed in Section 4.5 with the water in water jacket spaces replaced with air. The computed results are tabulated in Table 4.6.3 for the design basis heat load. The results of jacket water loss evaluation confirm that the cladding, MPC and HI-TRAC component temperatures are below the limits prescribed in Chapter 2 (Table 2.2.3). The co-incident MPC pressure is also computed and compared with the MPC accident design pressure (Table 2.2.1). The result (Table 4.6.2) is confirmed to be below the limit.

4.6.2.3 Extreme Environmental Temperatures

To evaluate the effect of extreme weather conditions, an extreme ambient temperature (Table 2.2.2) is postulated to persist for a 3-day period. For a conservatively bounding evaluation the extreme temperature is assumed to last for a sufficient duration to allow the HI-STORM 100 System to reach steady state conditions. Because of the large mass of the HI-STORM 100 System,

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-76	

with its corresponding large thermal inertia and the limited duration for the extreme temperature, this assumption is conservative. Starting from a baseline condition evaluated in Section 4.4 (normal ambient temperature and limiting fuel storage configuration) the temperatures of the HI-STORM 100 System are conservatively assumed to rise by the difference between the extreme and normal ambient temperatures (45°F). The HI-STORM extreme ambient temperatures computed in this manner are reported in Table 4.6.4. The co-incident MPC pressure is also computed (Table 4.6.2) and compared with the accident design pressure (Table 2.2.1). The result is confirmed to be below the accident limit.

4.6.2.4 100% Blockage of Air Inlets

This event is defined as a complete blockage of all four bottom inlets. The immediate consequence of a complete blockage of the air inlets is that the normal circulation of air for cooling the MPC is stopped. An amount of heat will continue to be removed by localized air circulation patterns in the overpack annulus and outlet ducts, and the MPC will continue to radiate heat to the relatively cooler storage overpack. As the temperatures of the MPC and its contents rise, the rate of heat rejection will increase correspondingly. Under this condition, the temperatures of the overpack, the MPC and the stored fuel assemblies will rise as a function of time.

As a result of the considerable inertia of the storage overpack, a significant temperature rise is possible if the inlets are substantially blocked for extended durations. This accident condition is, however, a short duration event that is identified and corrected through scheduled periodic surveillance. Nevertheless, this event is conservatively analyzed assuming a substantial duration of blockage. The event is analyzed using the FLUENT CFD code. For MPC heat load up to the full design basis, the HI-STORM thermal model is the same 3-Dimensional model constructed for normal storage conditions (see Section 4.4) except for the bottom inlet ducts, which are assumed to be impervious to air. Using this model, a transient thermal solution of the HI-STORM 100 System starting from normal storage conditions is obtained. The results of the blocked ducts transient analysis that support the required action completion times for clearing the inlets are presented in Table 4.6.5 and confirmed to be below the accident temperature limits (Table 2.2.3). The co-incident MPC pressure is also computed and compared with the accident design pressure (Table 2.2.1). The result (Table 4.6.2) is confirmed to be below the limit.

For MPC heat loads which meet the values in Table 2.1.31, the results of the transient analysis that support the required action completion times for clearing the inlets are presented in Table 4.6.7 and confirm all temperatures are below the accident temperature limits (Table 2.2.3).

30-Day 100% Vent Blockage Accident

As noted above, the fuel and component temperatures rise due to complete blockage of HI-STORM vents. This temperature rise is small for casks where heat loads are much lower than design basis heat loads. A threshold heat load is defined for all MPCs in Table 4.6.8a at or below which fuel and component temperatures remain below their respective 30-day accident temperature limits (Table 2.2.3) under steady state conditions. A steady state evaluation of a complete vent blockage at threshold heat loads is performed for both MPC-32 and MPC-68. Steady

HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-77	

state temperature and MPC cavity pressure results are presented in Table 4.6.9. The results demonstrate that the fuel and component temperatures remain below their respective 30-day accident temperature limits defined in the Design Criteria Chapter 2 with robust margins. MPC cavity pressure is also below the accident design limit with robust margins. Thermal performance of MPC-68 bounds all types of MPC-68 and MPC-24. Therefore, the threshold total decay heat for MPC-68 is also adopted for all other variants of MPC-68 and MPC-24 canisters. To identify and clear any blockages mandatory surveillance is defined in Chapter 11.

Since the mandatory surveillance frequency for MPCs at or below threshold decay heat is substantial, the following evaluations are performed to demonstrate that the MPCs are safe at off-normal and accident conditions. Thermal off-normal and design basis events or accident conditions defined in Chapter 4 of the FSAR are concurrently evaluated with the 100% vent blockage event at threshold heat load:

(a) Pressure (fuel rod rupture): There is no credible event to cause fuel rods to rupture during a 100% vent blockage event because of the following reasons:

- The computed PCT under 100% vent blockage accident condition (Table 4.6.9) is below the ISG-11 Rev 3 long-term normal temperature limit, and
- there is no credible loading on the fuel assemblies to cause fuel rods to rupture during a 100% vent blockage event.

Accordingly, the computed cavity pressures under 30-day vent blockage event evaluated herein is not affected.

(b) Off-Normal Ambient Temperatures: This event is defined in Section 4.6.1.2 as an ambient temperature of 100°F for a 3-day period. The results of off-normal environmental temperatures coincident with 100% vent blockage event are summarized in Table 4.6.12. Component temperatures are obtained by adding the off-normal-to-normal ambient temperature difference of 20°F (11.1°C) to temperatures computed for MPCs at threshold decay heat (Table 4.6.9). The results are below the off-normal limits (Table 2.2.3) with substantial margins.

(c) Partial Blockage of Air Inlets: This condition is already covered by the postulated event wherein all the HI-STORM vents are assumed blocked.

(d) Fire: During transfer operations at the ISFSI, there is a possibility of a fire accident event to occur coincident with a 100% vent blockage event. The impact of fire on the MPC and fuel temperatures is extremely small (approximately 1°F). Overpack temperatures are primarily impacted due to heat input from the fire which is considerably larger than the SNF decay heat. Therefore, as evaluated in Section 4.6.2.1(a), the overpack components and concrete temperatures remain below their respective accident temperature limits. Therefore, this accident event coincident with a 100% vent blockage event does not challenge the HI-STORM 100 System safety limits.

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-78	

(e) Extreme Environment Temperature: This event is defined in Section 4.6.2.3 as an ambient temperature of 125°F for a 3-day period. The results of extreme environmental temperatures coincident with 100% vent blockage event are summarized in Table 4.6.13. Component temperatures are obtained by adding the extreme-to-normal ambient temperature difference of 45°F (25°C) to temperatures computed for MPCs at threshold decay heat (Table 4.6.9). The results are below the accident limits (Table 2.2.3) with substantial margins.

(f) Burial under Debris: This accident event is evaluated in Section 4.6.2.5. Since the threshold decay heat is substantially lower than the maximum design basis heat load and cask initial temperatures (Table 4.6.9) are similar for 100% vent blockage event and that evaluated in Table 4.6.6, the evaluation in Section 4.6.2.5 remains bounding.

In this manner the above evaluations reasonably assure that the HI-STORM 100 system containing MPCs are safe under off-normal and accident conditions coincident with 30-day 100% blocked vents under the threshold heat load.

4.6.2.5 Burial Under Debris

Burial of the HI-STORM 100 System under debris is not a credible accident. During storage at the ISFSI there are no structures over the casks. Minimum regulatory distances from the ISFSI to the nearest ISFSI security fence precludes the close proximity of substantial amount of vegetation. There is no credible mechanism for the HI-STORM 100 System to become completely buried under debris. However, for conservatism, complete burial under debris is considered.

To demonstrate the inherent safety of the HI-STORM 100 System, a bounding analysis that considers the debris to act as a perfect insulator is considered. Under this scenario, the contents of the HI-STORM 100 System will undergo a transient heat up under adiabatic conditions. The minimum available time ($\Delta\tau$) for the fuel cladding to reach the accident limit depends on the following: (i) thermal inertia of the cask, (ii) the cask initial conditions, (iii) the spent nuclear fuel decay heat generation and (iv) the margin between the initial cladding temperature and the accident temperature limit. To obtain a lowerbound on $\Delta\tau$, the HI-STORM 100 Overpack thermal inertia (item i) is understated, the cask initial temperature (item ii) is maximized, decay heat overstated (item iii) and the cladding temperature margin (item iv) is understated. A set of conservatively postulated input parameters for items (i) through (iv) are summarized in Table 4.6.6. Using these parameters $\Delta\tau$ is computed as follows:

$$\Delta\tau = \frac{m \times c_p \times \Delta T}{Q}$$

where:

$\Delta\tau$ = Allowable burial time (hr)

m = Mass of HI-STORM System (lb)

c_p = Specific heat capacity (Btu/lb-°F)

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-79	

ΔT = Permissible temperature rise (°F)

Q = Decay heat load (Btu/hr)

Substituting the parameters in Table 4.6.6, a substantial burial time (34.6 hrs) is obtained. The co-incident MPC pressure is also computed and compared with the accident design pressure (Table 2.2.1). The result (Table 4.6.2) is confirmed to be below the limit.

PRINCIPAL SITE-SPECIFIC HI-STORM FIRE ACCIDENT MODELING STEPS

Step 1: Site Specific Conditions	<p><u>Heat Loads</u> Site Specific heat load map.</p> <p><u>Ambient Temperature</u> – Normal storage temperature defined in Chapter 2.</p> <p><u>Fire Accident</u> – Compute fire duration τ_f based on site specific fuel quantity in accordance with methodology defined in Sub-Section 4.6.2.1(a).</p>
Step 2: FLUENT Thermal Model	Incorporate HI-STORM thermal methodologies defined in Sub-Sections 4.4.1.1 and 4.4.1.2. Use the licensing basis HI-STORM thermal model presented in [4.5.1]. Apply heat loads and ambient temperature defined in Step 1 and obtain baseline initial temperature field.
Step 3: Fire Transient Solution	Apply fire parameters defined by fire temperature, fire emissivity and convection heat transfer coefficient specified in Sub-Section 4.6.2.1(a) to FLUENT Model and compute time dependent HI-STORM temperature field starting from initial temperature field obtained in Step 2 up to end of fire τ_f .
Step 4: Post-Fire Solution	Restore ambient temperature conditions as defined in Sub-Section 4.6.2.1(a) and compute time dependent temperature field under cooldown of HI-STORM cask by natural convection and radiation. Conservatively assume paint loss from all exterior surfaces. Continue solution until all component and fuel temperatures reach their maximum and begin to recede.
Step 5: Post-Process Results	Post-process FLUENT solution and evaluate compliance of maximum fuel, basket, MPC confinement boundary, HI-STORM concrete and enclosure shell temperatures to Chapter 2 accident temperature limits. Additionally, steel structure of the overpack shall remain physically stable, i.e., the maximum temperature shall be less than 1475°F at the instant of its most heated state. Compute maximum MPC pressure in accordance with Sub-Section 4.4.5 methodology and evaluate compliance with Chapter 2 accident pressure limits.

4.7 REGULATORY COMPLIANCE

4.7.1 Normal Conditions of Storage

NUREG-1536 [4.4.1] and ISG-11 [4.1.4] define several thermal acceptance criteria that must be applied to evaluations of normal conditions of storage. These items are addressed in Sections 4.1 through 4.4. Each of the pertinent criteria and the conclusion of the evaluations are summarized here.

As required by ISG-11 [4.1.4], the fuel cladding temperature at the beginning of dry cask storage is maintained below the anticipated damage-threshold temperatures for normal conditions for the licensed life of the HI-STORM System. Maximum clad temperatures for long-term storage conditions are reported in Section 4.4.

As required by NUREG-1536 (4.0,IV,3), the maximum internal pressure of the cask remains within its design pressure for normal, off-normal, and accident conditions, assuming rupture of 1 percent, 10 percent, and 100 percent of the fuel rods, respectively. Assumptions for pressure calculations include release of 100 percent of the fill gas and 30 percent of the significant radioactive gases in the fuel rods. Maximum internal pressures are reported in Sections 4.4, 4.5 and 4.6 for normal, short term operations, and off-normal & accident conditions. Design pressures are summarized in Table 2.2.1.

As required by NUREG-1536 (4.0,IV,4), all cask and fuel materials are maintained within their minimum and maximum temperature for normal and off-normal conditions in order to enable components to perform their intended safety functions. Maximum and minimum temperatures for long-term storage conditions are reported in Section 4.4. Design temperature limits are summarized in Table 2.2.3. HI-STORM System components defined as important to safety are listed in Table 2.2.6.

As required by NUREG-1536 (4.0,IV,5), the cask system ensures a very low probability of cladding breach during long-term storage. For long-term normal conditions, the maximum CSF cladding temperature is below the ISG-11 [4.1.4] limit of 400°C (752°F).

As required by NUREG-1536 (4.0,IV,7), the cask system is passively cooled. All heat rejection mechanisms described in this chapter, including conduction, natural convection, and thermal radiation, are completely passive.

As required by NUREG-1536 (4.0,IV,8), the thermal performance of the cask is within the allowable design criteria specified in FSAR Chapters 2 and 3 for normal conditions. All thermal results reported in Section 4.4 are within the design criteria allowable ranges for all normal conditions of storage.

HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4-93	

4.7.2 Short Term Operations

Evaluation of short term operations is presented in Section 4.5. This section establishes complete compliance with the provisions of ISG-11 [4.1.4]. In particular, the ISG-11 requirement to ensure that maximum cladding temperatures under all fuel loading and short term operations be below 400°C (752°F) for high burnup fuel and below 570°C (1058°F) for moderate burnup fuel is demonstrated as stated below.

Specifically as required by ISG-11, the fuel cladding temperature is maintained below the applicable limits for HBF and MBF (Table 4.3.1) during short term operations.

As required by NUREG-1536 (4.0,IV,3), the maximum internal pressure of the cask remains within its design pressure for normal and off-normal conditions, assuming rupture of 1 percent and 10 percent of the fuel rods, respectively. Assumptions for pressure calculations include release of 100 percent of the fill gas and 30 percent of the significant radioactive gases in the fuel rods.

As required by NUREG-1536 (4.0,IV, 4), all cask and fuel materials are maintained within their minimum and maximum temperature for all short term operations in order to enable components to perform their intended safety functions.

As required by NUREG-1536 (4.0,IV,8), the thermal performance of the cask is within the allowable design criteria specified in FSAR Chapters 2 and 3 for all short term operations.

SUPPLEMENT 4.I¹

THERMAL EVALUATION OF THE HI-STORM 100U SYSTEM

4.I.0 OVERVIEW

The HI-STORM 100U is an underground vertical ventilated module (VVM) with openings for air ingress and egress and internal passages for ventilation cooling of loaded MPCs. The HI-STORM 100U construction is described in Supplement 1.I and illustrated in Figures 1.I.1 through 1.I.4. The HI-STORM 100U utilize the same MPCs used in the aboveground systems. The HI-STORM 100U inlets and outlets are 360° (axisymmetric) openings provided in the lid. The overall ventilation airflow path from inlet to outlet is illustrated in Figure 1.I.4. The licensing drawing package for the HI-STORM 100U VVM is provided in Section 1.I.5. This supplement provides a thermal evaluation of the HI-STORM 100U for normal, off-normal and accident conditions. The evaluations described herein parallel those of the aboveground HI-STORM cask contained in the main body of Chapter 4 of this FSAR. To ensure readability, the section in the main body of the chapter to which each section in this supplement corresponds is clearly identified. All tables in this supplement are labeled sequentially.

4.I.1 INTRODUCTION

The information presented in this supplement is intended to serve as a complement to the information provided in the main body of Chapter 4. Thus, information in Chapter 4 that remains applicable to the HI-STORM 100U is not repeated herein. Specifically, the following information in the main body of Chapter 4 is not repeated:

1. The thermal properties of materials in Section 4.2 applicable to the HI-STORM 100U System.
2. The specifications for components in Section 4.3 applicable to the HI-STORM 100U System.
3. The descriptions of the thermal modeling of the MPC and its internals, including fuel assemblies, in Section 4.4 which are applicable in their entirety to the HI-STORM 100U.
4. The descriptions of the short-term loading operations, carried out using the HI-TRAC transfer cask, in Section 4.5 which remain applicable in their entirety to the HI-STORM 100U.

As confirmed by appropriate supporting analyses, the heat rejection capability of the HI-STORM 100U System is essentially equivalent to its aboveground counterparts for quiescent conditions (strictly speaking, slightly better, because of the larger intake and outlet passages located in the

¹ For ease of supplement review the sections are numbered in parallel with the main Chapter 4.

HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4.I-1	

VVM lid). Further, its underground configuration renders its resistance to accident events such as fire greater than that of aboveground casks.

4.I.2 THERMAL PROPERTIES OF MATERIALS¹

The material properties compiled in Section 4.2 of the FSAR provide the required information, except for the material properties of thermal insulation and soil surrounding the HI-STORM 100U VVM, which is not present in the aboveground designs. The functional performance of insulation (applied on the cylindrical surface of the divider shell) is ensured by specifying a minimum thermal resistance. The thermal resistance is defined in conventional US units as the insulation temperature gradient (°F) per unit rate of heat loss (Btu/ft²-hr). To compute insulation resistance the insulation thickness is divided by the insulation thermal conductivity. The maximum acceptable conductivity of insulating material is obtained by dividing the insulation thickness by the specified thermal resistance. For use in transient evaluations, the density and specific heat capacity of the insulation are conservatively assumed to be the same as that of air. Property data on insulation and soil is provided in Table 4.I.1.

4.I.3 SPECIFICATIONS FOR COMPONENTS²

All applicable material temperature limits in Section 4.3 of the FSAR continue to apply to the HI-STORM 100U. Temperature limits for insulation (used only in the HI-STORM 100U VVM) are specified in Table 2.I.8.

4.I.4 THERMAL EVALUATION FOR NORMAL CONDITIONS OF STORAGE³

4.I.4.1 HI-STORM 100U Thermal Model

The HI-STORM 100U underground cask, like the aboveground overpack, is a vertical storage system designed to dissipate heat by ventilation cooling. The principal cask components - container shell, closure lid, support foundation and MPC - are shown in Figure 1.I.1. Internal cask details relevant to cask operation are shown in Figure 1.I.2. The cooling passages in the HI-STORM 100U cask is shown in Figure 1.I.4. As shown in this figure the cask lid is engineered with 360° air inlet and outlet openings. During storage, air enters the inlet opening and flows downwards in the outer annulus gap between the cask container shell and the divider shell. The divider shell is insulated to avoid heating of this incoming air. Near the bottom of the cask cavity, the air U-turns and flow upwards in the inner annulus gap between the MPC and divider shell. During its upward travel, the air extracts heat from the heat generating MPC cylinder. A concomitant effect of heat removal is the monotonic heating of air in the inner annulus. Near the top of the MPC the air enters the internal flow passages in the closure lid. Heated air exits from the vents openings in the top of the closure lid. To model the ventilation cooling engineered in the

REPORT HI-2002444	4.I-2	

underground cask, a 3-D thermal model of the HI-STORM 100U VVM is constructed as described next.

In this Supplement the HI-STORM 100U System consisting of the HI-STORM100U VVM and a loaded MPC is evaluated under normal, off-normal and accident conditions and during short-term operations. The thermal evaluations use the same aboveground MPC 3-D thermal models of the bounding PWR and BWR canisters (MPC-32 and MPC-68) situated in an underground 100U VVM. These models use the same 3-Zone porous media model used in the thermal analysis for the aboveground Overpack (HI-STORM 100S¹) to represent the flow resistance of bounding BWR (GE-10x10) and PWR (W-17x17) fuel assemblies (See Chapter 4, Subsection 4.4.1.2).

The key attributes of MPC thermal model are as follows:

1. The MPC is modeled as a geometrically accurate 3D array of square shaped cells inside a cylindrical shell with bottom and top closures. The fuel basket bottom and top mouseholes are explicitly modeled as rectangular openings with understated flow area. The MPC model is identical to that described in the main body of Chapter 4.
2. The helium flow within the MPC is modeled as laminar. This is the same modeling approach used in the aboveground cask analyses.
3. The hydraulic resistance of the fuel assemblies stored within the MPC is represented in the 3D model by 3-Zone porous media flow resistances. This is the same as used in the HI-STORM aboveground modeling (See Chapter 4, Subsection 4.4.1.2).

Consistent with the aboveground HI-STORM 100S Overpack modeling a geometrically accurate 3D model of the HI-STORM 100U VVM is constructed for thermal analysis of the belowground casks. The VVM lid with its inlet and outlet vents and internal flow passages, the inner and outer annulus, the U-turn and the gas plenum above the MPC are explicitly modeled. Access to ambient air is artificially restricted in the model by erecting a vertical cylinder above the VVM. The cylinder is open at the top to allow air ingress and exit. In this manner lateral access to air is blocked and the potential for hot air mixing above the VVM is maximized.

The airflow through the cooling passages of the VVM is modeled as turbulent, using the $k-\omega$ model with transitional option as recommended in the Holtec-proprietary benchmarking report [4.1.6]. This is the same modeling approach as used in the aboveground cask analyses. The underside of the VVM foundation pad (see Figure 1.I.1) is assumed to be supported on a subgrade at 77°F. This is the same boundary condition applied to the bottom of the ISFSI pad for the aboveground cask modeling in Section 4.4. For conservatism heat dissipation from the vertical surfaces of the VVM is suppressed by the assumption of zero heat flux model boundaries. The VVM thermal models are constructed using the same modeling platform used for aboveground analysis (FLUENT version 6.2).

¹ The aboveground HI-STORM System includes a classical overpack design (HI-STORM 100) and a shortened version (HI-STORM 100S). The limiting design (HI-STORM 100S) is used in the aboveground thermal analysis.

REPORT HI-2002444	4.I-3	

4.I.4.2 Thermal Analysis

The HI-STORM 100U System design has been designed with the objective of ensuring that it meets all temperature and pressure limits set forth in Chapter 2 and Supplement 2.I. In this supplement the HI-STORM 100U System is evaluated to demonstrate compliance with these limits.

The 100U is evaluated under an array of uniform and regionalized heat loads defined in Chapter 2 as a function of regionalization parameter X. To determine the most limiting heat load configuration an array of analyses are performed for the principal storage condition – long-term normal storage and fuel temperatures computed. The results of the analysis for the bounding PWR and BWR canisters (MPC-32 and MPC-68) are summarized in Table 4.I.2. The results show the following:

- i) The fuel temperatures in the underground VVM are essentially the same as or slightly better than fuel temperatures in the aboveground storage overpack (See Table 4.4.6).
- ii) The highest fuel temperatures are reached under regionalized storage at $X = 0.5$ (same as in the case of the aboveground (HI-STORM 100S) overpack).
- iii) Higher fuel temperatures are reached in MPC-32 (same as in the case of the aboveground (HI-STORM 100S) Overpack).
- iv) Fuel storage in the MPC-32 under regionalized fuel storage at $X=0.5$ is the limiting scenario for 100U System. This scenario is co-incident with the maximum permissible MPC heat load and therefore temperatures of other sub-systems (such as fuel basket, MPC and VVM) also reach their highest values. This result is also in keeping with the HI-STORM 100S solution presented in Section 4.4 in the main body of Chapter 4. Accordingly, this condition is adopted for evaluation of normal, off-normal and accident events and short-term operations.

Table 4.I.3 presents the HI-STORM 100U maximum temperatures and pressures for the limiting fuel storage scenario defined above. The results are below the Chapter 2 and Supplement 2.I temperature and pressure limits for normal storage.

4.I.4.3 Effect of Elevation

An evaluation of the effects of elevation on thermal performance is performed for the HI-STORM 100U. The methodology described in Subsection 4.4.4.3 is applied for the HI-STORM 100U evaluation. The peak cladding temperatures are calculated for a bounding configuration (non-uniform storage at $X = 0.5$) assuming no reduction of ambient temperature with elevation and compared to the sea level conditions. The results are given in the Table 4.I.4. The results show that the PCT, including the effects of site elevation, continues to be well below the regulatory cladding temperature limit of 752°F for quiescent conditions. In light of the above evaluation, it is not necessary to place any ISFSI elevation constraints for HI-STORM deployment at elevations up to 1500 feet that have quiescent conditions. If, however, an ISFSI is sited at an elevation greater than

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4.I-4	

sea level with non-quiescent conditions, the effect of altitude on the PCT shall be quantified as part of the 10 CFR 72.212 evaluation for the site using the site ambient and wind conditions.

4.I.4.4 Wind Conditions

Non-quiescent ambient conditions defined as a horizontal wind on an isolated HI-STORM 100U module is evaluated. These evaluations conservatively assume a unidirectional wind of sufficient duration for the HI-STORM 100U System to reach the asymptotic maximum (steady-state) temperatures. This event is evaluated using the 3D thermal model mentioned in the foregoing (in Section 4.I.4.1). To properly model wind effects, a half-symmetric model is constructed and non-quiescent ambient conditions modeled as a horizontal wind blowing into the HI-STORM 100U inlet and outlet openings from one direction. Because the 100U ventilation openings are axisymmetric the maximum cladding temperature from a wind of a certain velocity is the same regardless of direction. However, under a wind condition, the fuel rod subject to the maximum cladding temperature migrates downstream from the canister's axis of symmetry. Thus, even though the spatial peak cladding temperature remains the same as the wind velocity vector is rotated, the location of the peak changes. Thus, for steady state conditions to be reached, the wind velocity vector (magnitude and direction, and sense of action) must remain constant for a long enough time to enable steady state conditions to be reached. The wind model is used to compute fuel temperatures at several wind speeds and results are tabulated in Table 4.I.7 for the case of $X=3$, which corresponds to 30.17 kW. The results show that, depending on magnitude of the wind velocity vector, the peak cladding temperature may be above or below the temperature corresponding to the quiescent condition. In particular, the 5 mph wind is identified as being in the narrow range where the peak cladding temperature plateaus to its maximum value.

In recognition of the new design embodiment of HI-STORM 100U, the design basis heat load for the system is based on the assumption that the 5 mph horizontal wind velocity vector prevails for a sufficiently long time. Further, the inlet air temperature into the plenum is assumed to be elevated by 7°K (or 12.6°F) due to intermixing from the presence of other modules in the ISFSI array. This assumption has the effect of raising the design basis inlet air temperature to 92.6°F (from the quiescent condition reference value of 80°F).

Furthermore, an inspection of the thermal results for the quiescent condition cases in Table 4.I.2 indicates that the case of $X = 0.5$ produces the largest peak cladding temperature (6°F more than other values of X). Therefore $X = 0.5$ case is used for the thermal analysis. Finally, because the MPC-32 case yields maximum value of the peak cladding temperature (see Table 4.I.2), MPC-32 is selected for computing the allowable heat load. Thus, the thermal problem posed herein assumes that:

- i. A 5 mph horizontal wind (constant speed and direction) is blowing.
- ii. The inlet air is at 92.6°F (not 80°F as assumed in the aboveground HI-STORM simulations), to factor the effect of limited mixing of the feed air with heated exhaust air streams.

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4.I-5	

- iii. The VVM contains a loaded MPC-32 with the most adverse regionalized storage condition (i.e., $X = 0.5$).
- iv. For the aboveground system, using Paragraph 2.1.9.1, the aggregate heat load and specific heat loads in Regions 1 and 2 are computed as follows:

$$\begin{aligned} Q_d &= 36.9 \text{ kW} \\ q_1 &= 0.709 \text{ kW} \\ q_2 &= 1.419 \text{ kW} \end{aligned}$$

Therefore, the thermal problem for the constant adverse wind velocity vector case is posed as follows:

Determine the penalty factor α on Q_d such that the computed peak cladding temperature is bounded by 400°C .

The penalty factor α is computed under the most punitive fuel loading scenario corresponding to $X = 0.5$ wherein the highest peak cladding temperature is reached as discussed in subsection 4.1.4.2. It therefore follows by physical reasoning that α computed in this manner is bounding under fuel loading scenarios $X = 1, 2$ and 3 defined in Chapter 2, Paragraph 2.1.9.1. As described later in this section α is conservatively adopted to penalize the maximum permissible heat loads under $X = 1, 2$ and 3 .

The following peak cladding temperatures were calculated for the above problem for the two different heat loads:

Q_d (kW)	Maximum Cladding Temperature, $^\circ\text{C}$
36.9	423.7
35.05	408.8

By examining the trend of the two cladding temperatures for Q , an approximately 1 kW additional penalty is taken to reduce the maximum allowable heat load to 33kW, which results in a temperature of approximately 390°C considering the trend in temperature change. This examination of temperature trend, including the 10 degree margin below 400°C , affirms the requirements for cladding integrity are satisfied for this design. Therefore, the penalty factor $\alpha = 33/36.9 = 0.894$.

The design basis heat load for the range of uniform and regionalized fuel storage scenarios defined in Chapter 2 Paragraph 2.1.9.1 are reduced as shown below:

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4.1-6	

X	Penalized Heat Load ($Q_r = \alpha \cdot Q$) (kW)
0.5	$\alpha \cdot 36.9 \text{ kW} = 33.0 \text{ kW}$
1	$\alpha \cdot 34 \text{ kW} = 30.4 \text{ kW}$
2	$\alpha \cdot 31.48 \text{ kW} = 28.1 \text{ kW}$
3	$\alpha \cdot 30.17 \text{ kW} = 27.0 \text{ kW}$

This reduced heat load Q_r satisfies the requirement that the peak cladding temperature meet the 400°C under the constant adverse wind velocity vector case. This reduced value of the design basis heat load is conservatively adopted in the system Technical Specification for the “100U” model only.

4.I.5 THERMAL EVALUATION OF SHORT TERM OPERATIONS

The short-term evaluations presented in Section 4.5 are applicable in their entirety for the underground VVM.

4.I.6 THERMAL EVALUATION OF OFF-NORMAL AND ACCIDENT CONDITIONS¹

4.I.6.1 Off-Normal Conditions

(a) Elevated Ambient Air Temperature

The elevated ambient air temperature off-normal condition is defined in Table 2.I.1 as an ambient temperature of 100°F. This is 20°F higher than the normal condition ambient temperature of 80°F, also defined in Table 2.I.1 and used in the analyses described in Section 4.I.4.2 above. This condition is conservatively evaluated by adding 20°F to the calculated normal condition fuel cladding and component temperatures in Table 4.I.3. Results for this off-normal condition are presented in Table 4.I.5. The results are well below the permissible short-term temperature limits for fuel cladding, concrete, and structural steels.

(b) Partial Blockage of Air Inlets

In contrast to HI-STORM 100S, which features four inlet and four outlet vents, HI-STORM 100U has 360° (radially symmetric) vents making duct blockage in HI-STORM 100U more unlikely. Nevertheless, the case of 50% blockage of the HI-STORM 100U inlet vents is postulated. The partial air inlets blockage event is defined in Table 2.I.1 as the blockage of 50% of the air inlet flow area. This event is conservatively evaluated as a blockage of sufficient duration to reach the asymptotic maximum (steady-state) temperature field. Results for this off-normal condition are presented in Table 4.I.6. The results show large margins of safety with respect to the permissible short-term temperature limits for fuel cladding, concrete, and structural steels.

¹ This section supplements Section 4.6.

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4.I-7	

4.I.6.2 Accident Conditions

(a) Fire

The fire accident is defined in Table 2.I.1 as a 1475°F fire lasting 217 seconds. This is the same intensity and duration as the fire accident evaluated in Section 4.6 of this FSAR for the aboveground overpack. The existing fire evaluation therein bounds the HI-STORM 100U fire event, for the following reasons:

1. Because the fire evaluated in Section 4.6 is an engulfing fire, the cask area exposed to the fire heat flux is maximized. The underground surfaces of the HI-STORM 100U VVM are not directly exposed to the fire heat flux, which significantly reduces the fire heat input to the VVM as compared to an aboveground overpack. The total heat input to the VVM during the fire event is therefore much lower than is evaluated in Section 4.6.
2. The openings of the inlet ducts and outlet ducts are both located near the top of the VVM. Because heated gases rise, a downward flow of combustion gases into the module cavity is not credible. The internal surfaces of the VVM cannot, therefore, be subjected to any significant temperature elevation due to fire.

The above considerations lead to the conclusion that the fire evaluation for the aboveground overpack bounds the HI-STORM 100U fire accident.

(b) Flood

The flood accident is defined in Table 2.I.1 as a deep submergence. The worst flood from a thermal perspective is a “smart flood” that just prevents all airflow with *no* MPC cooling by water. Although the HI-STORM 100U includes design features to prevent “smart flood” occurrence such a hypothetical condition is bounded by the 100% inlet ducts blocked accident evaluated in 4.I.6.2(d). As shown in the HI-STORM 100U licensing drawings, the bottom of the MPC is situated several inches below the top of the airflow cutouts in the bottom of the divider shell. Thus, even if the bottom cutouts are substantially covered by flood water the MPC baseplate heat dissipation ensures adequate cooling of the MPC and its stored fuel. This effect is significant, because the thermosiphon convective flow within the MPC is an efficient means of heat rejection to the thermal sink (wetted baseplate).

(c) Burial Under Debris

The burial under debris accident is defined in Table 2.I.1 as an adiabatic heat-up at the maximum decay heat load. The existing burial under debris evaluation in Section 4.6 bounds the HI-STORM 100U burial under debris event because the HI-STORM 100U System thermal inertia is greater than that of the aboveground systems. This results from the higher aggregate mass of the VVM as compared to the aboveground overpack. As such the existing burial under debris evaluation for the aboveground overpack bounds the HI-STORM 100U burial under debris accident.

HOLTEC INTERNATIONAL COPYRIGHTED MATERIAL		
HI-STORM 100 FSAR		Rev. 23
REPORT HI-2002444	4.I-8	

(d) 100% Blockage of Air Ducts

The 100% air ducts blockage accident is defined in Table 2.I.1 as the blockage of 100% of the air inlet duct flow area. This event is evaluated by blocking the entire inlet opening for a considerable duration (24 hours) and performing a transient calculation of VVM, MPC and cladding temperatures. The only difference between this evaluation and the evaluation described in Section 4.I.4.2 for normal storage is the blockage of the inlet vents and the inclusion of transient effects in the 3D HI-STORM 100U model. Numerical results for this accident are presented in Table 4.I.9. The results demonstrate that all fuel cladding and component temperatures remain below their respective short-term limits.

It should be noted that the increase in temperature would increase the MPC internal pressure. The calculation performed for this accident recognizes an increase in thermosiphon cooling within the MPC that would accompany from pressure increase in a conservative manner.
