The absorber material used in the control rods is silver-indium-cadmium alloy which is essentially "black" to thermal neutrons and has sufficient additional resonance absorption to significantly increase its worth. The alloy is in the form of extruded rods which are sealed in stainless steel tubes to prevent the rods from coming in direct contact with the coolant. In construction, the silver-indium-cadmium rods are inserted into cold-worked stainless steel tubing which is then sealed at the bottom and the top by welded end plugs. Sufficient diametral and end clearance is provided to accommodate relative thermal expansions.

The bottom plugs are made bullet-nosed to reduce the hydraulic drag during reactor trip and to guide smoothly into the dashpot section of the fuel assembly guide thimbles. The upper plug is threaded for assembly to the spider and has a reduced end section to make the joint more flexible.

The spider assembly is in the form of a central hub with radial vanes containing cylindrical fingers from which the absorber rods are suspended. Handling grooves and internal grooves for connection to the drive rod assembly coupling are machined into the upper end of the hub. A coil spring inside the spider body absorbs the impact energy at the end of a trip insertion. The radial vanes are joined to the hub and the fingers are joined to the vanes by furnace brazing. A centerpost which holds the spring and its retainer is threaded into the hub within the skirt and welded to prevent loosening in service. All components of the spider assembly are made from type 304 and 308 stainless steel except for the retainer which is of 17-4 PH material and the springs which are Inconel 718 alloy or oil tempered carbon steel where the springs do not contact the coolant.

The absorber rods are fastened securely to the spider to assure trouble free service. The rods are first threaded into the spider fingers and then pinned to maintain joint tightness, after which the pins are welded in place. The end plug below the pin position is designed with a reduced section to permit flexing of the rods to correct for small operating or assembly misalignments.

The overall length is such that when the assembly is withdrawn through its full travel the tips of the absorber rods remain engaged in the guide thimbles so that alignment between rods and thimbles is always maintained. Since the rods are long and slender, they are relatively free to conform to any small misalignments with the guide thimble.

Differences between the Westinghouse and AREVA/Framatome RCCA's are:

AREVA/Framatome RCCA spiders are a one-piece casting that includes vanes and fingers made of 316L stainless steel. The other spider assembly components are made from type 304 and 308 stainless steel. The 24 control rods are attached to the spider by a nut and pin combination. The upper end plug extension shank is first pinned to the spider boss then a nut is torqued and lock welded in place to prevent rotation.

AREVA/Framatome RCCA clad material is 316L stainless steel. The cladding surfacing is ion-nitrided.

Burnable Poison Assembly

Each burnable absorber assembly consists of borosilicate or WABA burnable absorber rods attached to a hold down assembly. Conceptual burnable absorber assemblies (containing borosilicate absorber) are shown in Figure 4.2.3.2. WABA rods may be used in place of the borosilicate absorber rods.

The borosilicate absorber rods consist of borosilicate glass tubes contained within Type 304 stainless steel tubular cladding which is plugged and seal welded at the ends to encapsulate the glass. The glass is also supported along the length of its inside diameter by a thin wall tubular inner liner. The top end of the liner is open to permit the diffused helium to pass into the void volume and the liner overhangs the glass. A typical borosilicate burnable absorber rod is shown in longitudinal and transverse cross-section in Figure 4.2.3-2a.

A WABA rod (Figure 4.2.3-3) consists of annular pellets of alumina-boron carbide ($A1_20_3$-B_4C) burnable absorber material contained within two concentric Zircaloy tubes. These Zircaloy tubes, which form the inner and outer clad for the WABA rod, are plugged and welded at each end to encapsulate the annular stack of absorber material. The assembled rod is then internally pressurized to 650 psig and seal welded. The absorber stack lengths are positioned axially within the WABA rods by the use of Zircaloy bottom-end spacers. An annular plenum is provided within the rod to accommodate the helium gas released from absorber material depletion during irradiation. Further design details are given in Section 3.0 Reference 16.

WABA rods with a reduced length of burnable absorber are also used. Figures 4.2.3-3B and 4.2.3-3C show the WABA rod and assembly, respectively. The length of the absorber stack in a WABA rod is reduced from 134 inches to 132 inches and the spacer length is adjusted to keep the absorber stack centered at the core midplane at beginning of life hot full power conditions.

The burnable absorber rods are statically suspended and positioned in selected guide thimbles within the fuel assemblies. The absorber rods in each assembly are attached together at the top end of the rods to a hold down assembly by a flat, perforated retaining plate which fits within the fuel assembly top nozzle and rests on the adapter plate. The absorber rod assembly is held down and restrained against vertical motion through a spring pack which is attached to the plate and is compressed by the upper core plate when the reactor upper internals assembly is lowered into the reactor. This arrangement ensures that the absorber rods cannot be ejected from the core by flow forces. Each rod is permanently attached to the base plate by a nut which is crimped into place.

The borosilicate rod cladding is slightly cold worked Type 304 stainless steel, and the WABA rod cladding is Zircaloy-4. All other structural materials are Types 304 and 308 stainless steel except for the springs which are Inconel-718. The borosilicate glass tube provides sufficient boron content to meet the criteria discussed in Section 4.3.1.3.

Neutron Source Assembly

The purpose of the neutron source assembly is to provide a base neutron level to insure that the detectors are operational and responding to core multiplication neutrons. Since there is very little neutron activity during loading, refueling, shutdown, and approach to criticality, a neutron source is placed in the reactor to provide a neutron count of at least 0.5 counts per second on the

source range detectors attributable to core neutrons. The detectors, called source range detectors, are used primarily when the core is subcritical and during special subcritical modes of operations.

The source assembly also permits detection of changes in the core multiplication factor during core loading refueling, and approach to criticality. This can be done since the multiplication factor is related to an inverse function of the detector count rate. Therefore a change in the multiplication factor can be detected during addition of fuel assemblies while loading the core, a change in control rod positions, and changes in boron concentration.

Both primary and secondary neutron source rods are used. The primary source rod, containing a radioactive material, spontaneously emits neutrons during initial core loading and reactor startup. After the primary source rod decays beyond the desired neutron flux level, neutrons are then supplied by the secondary source rod.

The initial Sequoyah reactor core employed six source assemblies; two primary source assemblies and four secondary source assemblies. Each primary source assembly contained one primary source rod and twelve burnable poison rods. Each secondary source assembly contained a symmetrical grouping of four or six secondary source rods and zero or twenty burnable poison rods. Locations not filled with a source or burnable poison rod contained a thimble plug. Source assemblies are shown in Figures 4.2.3-4 and 4.2.3-5a&b. For subsequent reloads, primary sources are removed and secondary sources provide the necessary neutron count. The original four rod secondary source assembles have been replaced with 6 source rods per assembly.

Neutron source assemblies are employed at diametrically opposite sides of the core. The assemblies are inserted into the rod cluster control guide thimbles in fuel assemblies at selected unrodded locations.

The primary and secondary source rods both utilize the same cladding material as the absorber rods. The secondary source rods contain Sb-Be pellets stacked to a height of approximately 88 inches. The primary source rods contain capsules of Californium (Pu-Be is a possible alternate) source material and alumina spacer rods to position the source material within the cladding.

Secondary source assemblies may be composed of four single encapsulated source rodlets as shown in Figure 4.2.3-5a or six double encapsulated source rodlets as shown in Figure 4.2.3-5b. Externally, the two types of secondary sources appear no differently. In order to accommodate the double encapsulated source rodlet design, the Sb-Be pellets are of a slightly smaller diameter. This requires that two more source rodlets per assembly be used in order to achieve the same source strength as the single encapsulated secondary source. Both types have identical critical interface parameters and are completely interchangeable.

The other structural members are constructed of type 304 stainless steel except for the springs. The springs exposed to the reactor coolant are wound from an age hardened nickel base alloy for corrosion resistance and high strength. The springs, when contained within the rods when corrosion resistance is not necessary, are oil tempered carbon steel.

Thimble Plug Assembly

Fuel assemblies which do not contain either control rods, source rods, or burnable absorber rods, may be fitted with thimble plug assemblies.

The thimble plug assemblies as shown in Figure 4.2.3-6 consist of a flat base plate with short rods suspended from the bottom surface and a spring pack assembly. The twenty-four short rods, called thimble plugs, project into the upper ends of the guide thimbles. Similar short rods may also be used on the source assemblies and burnable absorber assemblies to plug the ends of all vacant fuel assembly guide thimbles. At installation in the core, the thimble plug assemblies interface with both the upper core plate and with the fuel assembly top nozzles by resting on the adaptor plate. The spring pack is compressed by the upper core plate when the upper internals assembly is lowered into place. Each thimble plug is permanently attached to the base plate by a nut which is locked to the threaded end of the plug by a small lock-pin welded to the nut or by crimping the nut.

All components in the thimble plug assembly, except for the springs, are constructed from type 304 stainless steel. The springs are wound from an age hardened nickel base alloy for corrosion resistance and high strength.

4.2.3.2.2 Control Rod Drive Mechanism (CRDM)

All parts of the control rod drive mechanism exposed to reactor coolant are made of metals which resist the corrosive action of the water. Three types of metals are used exclusively: stainless steels, Inconel-X and cobalt based alloys. Wherever magnetic flux is carried by parts exposed to the main coolant, 400 series stainless steel is used. Cobalt based alloys are used for the pins and latch tips. Inconel-X is used for the springs of latch assemblies and 304 stainless steel is used for all pressure retaining components. Hard chrome plating provides wear surfaces on the sliding parts and prevents galling between mating parts.

A rod position indicator coil stack assembly slides over the control rod drive mechanism rod travel housing. It detects the drive rod assembly position by means of 42 discrete coils that magnetically sense the entry and presence of the drive rod assembly over the normal length of the drive rod assembly travel.

Control Rod Drive Mechanism (CRDM)

Control rod drive mechanisms are located on the dome of the reactor vessel head. They are coupled to rod clusters control assemblies which have neutron absorber material over the entire length of the control rods and derive their name from this feature. The control rod drive mechanism is shown in Figure 4.2.3-7 and schematically in Figure 4.2.3-8.

The primary function of the control rod drive mechanism is to insert, withdraw, or hold rod cluster control assemblies within the core to control average core temperature and to shut down the reactor.

The control rod drive mechanism is a magnetically operated jack. A magnetic jack is an arrangement of three electro-magnets which are energized in controlled sequence by a power cycler to insert or withdraw rod cluster control assemblies in the reactor core in discrete steps.

The control rod drive mechanism consists of four separate sub-assemblies. They are the pressure vessel assembly, the coil stack assembly, the latch assembly, and the drive rod assembly.

1. The pressure vessel assembly includes a latch housing and a rod travel housing which are connected by a threaded, seal welded, maintenance joint which facilitates replacement of the latch assembly. The closure at the top of the rod travel housing is a threaded cap with a canopy seal weld. If canopy seal weld degradation is identified, a canopy clamp assembly may be installed to provide a permanent non-weld mechanism method of stopping leakage in the canopy seal weld.

   The latch housing is the lower portion of the pressure vessel and encloses the latch assembly. The rod travel housing is the upper portion of the pressure vessel and provides space for the drive rod assembly during its upward movement as the control rods are withdrawn from the core.

2. The coil stack assembly includes the coil housings, and electrical conduit and connector, and three operating coils; 1) the stationary gripper coil, 2) the moveable gripper coil, and 3) the lift coil.

   The coil stack assembly is a separate unit which is installed on the control rod drive mechanism by sliding it over the outside of the latch housing. It rests on the base of the latch housing without mechanical attachment.

   Energizing of the operation coils causes movement of the pole pieces and latches in the latch assembly.

3. The latch assembly includes the guide tube, stationary pole pieces, moveable pole pieces, and two sets of latches; 1) the moveable gripper latch, and 2) the stationary gripper latch.

   The latches engage grooves in the drive rod assembly. The moveable gripper latches are moved up or down in 5/8 inch steps by the lift pole to raise or lower the drive rod assembly. The stationary gripper latches hold the drive rod assembly while the moveable gripper latches are repositioned for the next 5/8 inch step.

4, The drive rod assembly includes a flexible coupling, a drive rod, a disconnect button, a disconnect rod assembly, and a locking button.

   The drive rod is machined with grooves on a 5/8 inch pitch which receive the latches during holding or moving of the drive rod assembly. The flexible coupling is attached to the drive rod and produces the means for coupling to the rod cluster control assembly.

   The disconnect button, disconnect rod assembly, and locking button provide positive locking of the coupling to the rod cluster control assembly and permits remote disconnection of the drive rod assembly.

The control rod drive mechanism is a trip design. Tripping can occur during any part of the power cycler sequencing if power to the coils is interrupted.

The control rod drive mechanism is treaded and seal welded on a head adaptor on top of the reactor vessel head and is coupled to the rod cluster control assembly directly below.

The mechanism is capable of handling a 360 pound load, including the drive rod assembly weight, at a maximum rate of 45 inches/minute. Withdrawal of the rod cluster control assembly is accomplished by magnetic forces while insertion is by gravity.

The mechanism internals are designed to operate in 650°F reactor coolant. The pressure vessel assembly is designed to contain reactor coolant at 650°F and 2500 psia. The three operating coils are designed to operate at 392°F with forced air cooling required to maintain that temperature.

The control rod drive mechanism shown schematically in Figure 4.2.3-8 withdraws and inserts its control rod as electrical pulses are received by the operator coils. An ON or OFF sequence, repeated by silicon controlled rectifiers in the power programmer, causes either withdrawal of insertion of the control rod. Position of the drive rod assembly is measured by 42 discrete coils mounted on the rod position indicator coil stack assembly surrounding the rod travel housing. Each coil magnetically senses the entry and presence of the top of the ferro-magnetic drive rod assembly as it moves through the coil center line.

During plant operation the stationary gripper coil of the control rod drive mechanism holds the control rod withdrawn from the core in a static position until the movable gripper coil is energized.

Rod Cluster Control Assembly Withdrawal

The control rod is withdrawn by repetition of the following sequence of events:

1. Movable Gripper Coil - ON

   The latch locking plunger raises and swings the movable gripper latches into the drive rod assembly groove. A 1/16 inch axial clearance exists between the latch teeth and the drive rod.

2. Stationary Gripper Coil - OFF

   The force of gravity, acting upon the drive rod assembly and attached control rod, causes the stationary gripper latches and plunger to move downward 1/16 inch until the load of the drive assembly with attached control rod is transferred to the moveable gripper latches. The plunger continues to move downward and swings the stationary gripper latches out of the drive rod assembly groove.

3. Lift Coil - ON

   The 5/8 inch gap between the moveable gripper pole and the lift pole closes and the drive rod assembly with attached control rod raises one step length (5/8 inch).

4. Stationary Gripper Coil - ON

   The plunger raises and closes the gap below the stationary gripper pole. The three links, pinned to the plunger, swing and the stationary gripper latches into a drive rod assembly groove. The latches contact the drive rod assembly and lift it (and the attached control rod) 1/16 inch. The 1/16 inch vertical drive rod assembly movement transfers the drive rod assembly load from the movable gripper latches to the stationary gripper latches.

5. Movable Gripper Coil - OFF

   The latch locking plunger separates from the movable gripper pole under the force of a spring and gravity. Three links, pinned to the plunger, swing the three movable gripper latches out of the drive rod assembly groove.

6. Lift Coil - OFF

   The gap between the movable gripper pole and lift pole opens. The movable gripper latches drop 5/8 inch to a position adjacent to a drive rod assembly groove.

7. Repeat Step 1

   The sequence described above (1 through 6) is termed as one step or one cycle. The control rod moves 5/8 inch for each step or cycle. The sequence is repeated at a rate of up to 72 steps per minute and the drive rod assembly (which has a 5/8 inch groove pitch) is raised 72 grooves per minute. The control rod is thus withdrawn at a rate up to 45 inches per minute.

<u>Rod Cluster Control Assembly Insertion</u>

The sequence for control rod insertion is similar to that for control rod withdrawal, except the timing of lift coil ON and OFF is changed to permit lowering the control rod.

1. Lift Coil - ON

   The 5/8 inch gap between the movable gripper and lift pole closes. The movable gripper latches are raised to a position adjacent to a drive rod assembly groove.

2. Movable Gripper Coil - ON

   The latch locking plunger raises and swings the movable a gripper latches into a drive rod assembly groove. A 1/16 inch axial clearance exists between the latch teeth and the drive rod assembly.

3. Stationary Gripper Coil - OFF

   The force of gravity, acting upon the drive rod assembly and attached control rod, causes the stationary gripper latches and plunger to move downward 1/16 inch until the load of the drive rod assembly and attached control rod is transferred to the movable gripper latches. The plunger continues to move downward and swings the stationary gripper latches out of the drive rod assembly groove.

4. Lift Coil - OFF

   The force of gravity separates the movable gripper pole from the lift pole and the drive rod assembly and attached control rod drop down 5/8 inch.

5. Stationary Gripper - ON

   The plunger raises and closes the gap below the stationary gripper pole. The three links, pinned to the plunger, swing the three stationary gripper latches into a drive rod assembly groove. The latches contact the drive rod assembly and lift it (and the attached control rod) 1/16 inch. The 1/16 inch vertical drive rod assembly movement transfers the drive rod assembly load from the movable gripper latches to the stationary gripper latches.

6. Movable Gripper Coil - OFF

   The latch locking plunger separates from the movable gripper pole under the force of a spring and gravity. Three links, pinned to the plunger, swing the three movable gripper latches out of the drive rod assembly groove.

7. Repeat Step 1

   The sequence is repeated, as for control rod withdrawal, up to 72 steps per minute which gives a control rod insertion rate of 45 inches per minute.

<u>Holding and Tripping of the Control Rods</u>

During most of the plant operating time, the control rod drive mechanisms hold the control rods withdrawn from the core in a static position. In the holding mode, only one coil, the stationary gripper coil, is energized on each mechanism. The drive rod assembly and attached control rod hang suspended from the three latches.

If power to the stationary gripper coil is cut off, the combined weight of the drive rod assembly and the rod cluster control assembly is sufficient to move latches out of the drive rod assembly groove. The control rod falls by gravity into the core. The trip occurs as the magnetic field, holding the stationary gripper plunger half against the stationary gripper pole, collapses and the stationary gripper plunger half is forced down by the weight acting upon the latches. After the half is forced down by the weight acting upon the latches. After the drive rod assembly is released by the mechanism, it falls, freely until the control rods enter the buffer section of their thimble tubes.

4.2.3.3 Design Evaluation

4.2.3.3.1 Reactivity Control Components

The components are analyzed for loads corresponding to normal, upset, emergency and faulted conditions. The analysis performed depends on the mode of operation under consideration.

The scope of the analysis requires many different techniques and methods, both static and dynamic.

Some of the loads that considered on each component where applicable are as follows:

1. Control Rod Scram (equivalent static load)

2. Differential Pressure

3. Spring Preloads

4. Coolant Flow Forces (static)

5. Temperature Gradients

6. Difference in thermal expansion
   a. Due to temperature differences
   b. Due to expansion of different materials

7. Interference between components

8. Vibration (mechanically or hydraulically induced)

9. Loading conditions and stress limits as listed in Table 5.2-2

10. Pump Overspeed

11. Seismic Loads (Safe shutdown earthquake and 1/2 safe shutdown earthquake).

The main objective of the analysis is to satisfy allowable stress limits, to assure an adequate design margin, and to establish deformation limits which are concerned primarily with the functioning of the components. The stress limits are established not only to assure that peak stresses will not reach unacceptable values, but also limit the amplitude of the oscillatory stress component in consideration of fatigue characteristics of the materials. Standard methods of strength of materials are used to establish the stresses and deflections of these components. The dynamic behavior of the reactivity control components has been studied using experimental test data (D-Loop, Reference 10) and experience from operating reactors. The AREVA/Framatome RCCA design is similar enough to the Westinghouse design that the above analysts still applies.

Sufficient diametral and end clearances have been provided in the neutron absorber, burnable poison, and source rods to accommodate the relative thermal expansions between the enclosed material and the surrounding clad and end plugs. There is no warping induced in the

rods although the clearance offered by the guide thimble would permit a postulated warpage to occur without restraint on the rods. Bending is not considered in the analysis of the rods except for that associated with possible misalignment of the rod in the guide tube and flow induced vibration, which was performed for the AREVA/Frametome supplied rods. The radial and axial temperature profiles have been determined by considering gap conductance, thermal expansion, and neutron and/or gamma heating of the contained material as well as gamma heating of the clad. The maximum neutron absorber material temperature was found to be below the metting temperature of the absorber. Rod, guide thimble, and dashpot flow analysis performed indicates that the flow is sufficient to prevent coolant boiling and maintain clad temperatures at which the clad material has adequate strength to resist coolant operating pressures and rod internal pressures.

The Westinghouse designed wet annular burnable absorber (WABA) is used in reload cores. Reference 16 verifies that the WABA design meets burnable poison design criteria.

Analysis on the cluster control assembly spider indicates the spider is structurally adequate to withstand the various operating loads including the higher loads which occur during the control rod drive mechanism stepping action and rod drop.

The materials selected are considered to be the best available from the standpoint of resistance to irradiation damage and compatibility to the rector environment. The materials selected partially dictated the reactor environment (e.g., $C1^-$ control in the coolant). The current design type reactivity controls have been in service for as much as six years with no apparent degradation of construction materials.

At high fluences the austenitic materials increase in strength with a corresponding decreased ductility (as measured by tensile tests) but energy absorption (as measured by impact tests) remain quite high. Corrosion of the materials exposed to the coolant is quite low and proper control of $C1^-$ and O_2 in the coolant will prevent occurrence of stress corrosion. All of the austenitic stainless steel base materials used are processed and fabricated to preclude sensitization. Although the control rod spiders are fabricated by furnace brazing, the procedure used for the Westinghouse spider vanes requires that the pieces be rapidly cooled so that the time-at-temperature is minimized. The time that is spent by the control rod spiders in the sensitization range, 800 - 1500°F, is not more than 0.2 hours, as a maximum, during fabrication to preclude sensitization. The 17-4 PH parts for Westinghouse are all aged at highest standard aging temperature of 1100°F to avoid stress corrosion problems exhibited by aging at lower temperatures.

Analysis of the rod cluster control assemblies show that if the control rod drive mechanism pressure housing ruptures the rod cluster control assembly will be ejected from the core by the pressure differential of the operating pressure and ambient pressure across the drive rod assembly. The ejection is also predicted on the failure of control rod drive mechanism to retain the drive rod/rod cluster control assembly position. It should be pointed out that a control rod drive mechanism pressure housing rupture will cause the ejection of only one rod cluster control assembly with the other assemblies remaining in the core. Analysis for the Westinghouse spider vanes showed that a pressure drop in excess of 4000 psi must occur across a two-fingered vane to break the vane/spider body joint. Since the greatest pressure of the primary system coolant is only 2250 psi, a pressure drop in excess of 4000 psi could not be expected to occur. Thus, the ejection of the neutron absorber rods is not possible.

Ejection of a burnable poison or thimble plug assembly is conceivable based on the postulation on that the hold down bar fails and the base plate and burnable poison rods are severely deformed. In the unlikely event that failure of the hold down bar occurs, the upward displacement of the burnable poison assembly only permits the base plate to contact the upper core plate. In the case of the thimble plug assembly, the thimble plugs will partially remain in the fuel assembly guide thimbles thus maintaining a majority of the desired flow impedance. Further displacement of complete ejection would necessitate the square base plate and burnable poison rods be forced, thus plastically deformed, to fit up through a smaller diameter hole. It is expected that this condition requires a substantially higher force or pressure drop than that of the hold down bar failure.

Westinghouse experience with control rods, burnable poison rods, and source rods are discussed in Reference 2.

The mechanical design of the reactivity control components provides for the protection of the active elements to prevent the loss of control capability and functional failure of critical components. The components have been reviewed for potential failure and consequences of a functional failure of critical parts. The results of the Westinghouse review are summarized below.

1. The basic absorbing material is sealed from contact with the primary coolant and the fuel assembly and guidance surfaces by a high quality stainless steel clad. Potential loss of absorber mass or reduction in reactivity control material due to mechanical or chemical erosion or wear is therefore reliably prevented.

2. A breach of the cladding for any postulated reason does not result in serious consequences. The absorber material, silver-indium-cadmium, is relatively inert and would still remain remote from high coolant velocity regions. Rapid loss of material resulting in significant loss of reactivity control material would not occur.

3. The individually clad absorber rods are doubly secured to the retaining spider finger by the threaded joint and a welded lock pin. No failure of this joint has ever been experienced in functional testing or in years of actual service in operating plants such as San Onofre, Connecticut Yankee, Zorita, Beznau No. 1, Robert Emmett Ginna, etc.

   It should also be noted that in several instances of control rod jamming caused by foreign particles, the individual rods at the site of the jam have borne the full capacity of the control rod drive mechanism and higher impact loads to dislodge the jam without failure. The guide tube card/guide thimble arrangement is such that large loads are required to buckle individual control rods. The conclusion to be drawn from this experience is that this joint is extremely insensitive to potential mechanical damage. A failure of the joint would result in the insertion of the individual rod into the core. This results in reduced reactivity which is a fall safe condition. Further information is given in Reference 2.

4. The spider finger braze joint by which the individual rods are fastened to the vanes has also experienced the service described above and been subjected to the same jam freeing procedures also without failure. A failure of this joint would also result in insertion of the individual rod into the core.

5. The radial vanes are attached to the spider body again by a brazed joint. The joints are designed to a theoretical strength in excess of that of the components joined.

   It is a feature of the design that the guidance of the rod cluster control assembly is accomplished by the inner fingers of these vanes. They are therefore the most susceptible to mechanical damage. Since these vanes carry two rods, failure of the van-to-hub joint such as the isolated incidents at Connecticut-Yankee does not prevent the free insertion of the rod pair (Reference 2). Neither does such a failure interfere with the continuous free operation of the drive line, also as experienced at Connecticut-Yankee (Reference 2).

   Failure of the vans-to-hub joint of a single rod vane could potentially result in failure of the separated vane and rod to insert. This could occur only at withdrawal elevations where the spider is above the continuous guidance section of the guide tube (in the upper internals). A rotation of the disconnected vane could cause it to hang on one of the guide cards in the intermediate guide tube. Such an occurrence would be evident from the failure of the rod cluster control assembly to insert below a certain elevation but with free motion above this point.

   This possibility is considered extremely remote because the single rod vanes are subjected to only vertical loads and very light lateral reactions from the rods. The lateral loads are light even during a seismic event because the guide tube/guide thimble arrangement allows very limited lateral motion. The consequences of such a failure are not considered critical since only one drive line of the reactivity control system would be involved. This condition is readily observed and can be cleared at shutdown.

6. The spider hub being of single unit cylindrical construction is very rugged and of extremely low potential for damage. It is difficult to postulate any condition to cause failure. Should some unforeseen event cause fracture of the hub above the vanes, the lower portion with the vanes and rods attached would insert by gravity into the core causing reactivity decrease. The rod could then not be removed by the drive line, again a fail safe condition. Fracture below the vanes cannot be postulated since all loads, including scram impact, are taken above the vane elevation.

7. The rod cluster control rods are provided a clear channel for insertion by the guide thimbles of the fuel assemblies. All fuel rod failures are protected against by providing this physical barrier between the fuel rod and the intended insertion channel. Distortion of the fuel rods by bending cannot apply sufficient force to damage or significantly distort the guide thimble. Fuel rod distortion by swelling, though precluded by design, would be terminated by fracture before contact with the guide thimble occurs. If such were not the case, it would be expected that a force reaction at the point of contact would cause a slight deflection of the guide thimble. The radius of curvature of the deflected shape of the guide thimbles would be sufficiently large to have a negligible influence on rod cluster control assembly insertion.

   The Westinghouse designed enhanced performance RCCA (EPRCCA) may be used in place of the standard RCCA in reload cores. Reference 21 verifies that EPRCC design meets rod cluster control assembly design criteria.

   Framatome experience with control rods is discussed in References 23, 24, and 25.

Burnable Absorber Assemblies

The burnable absorber assemblies are static temporary reactivity control elements. The axial position is assured by the hold down assembly which bears against the upper core plate. Their lateral position is maintained by the guide thimbles of the fuel assemblies.

The individual rods are shouldered against the underside of the retainer plate and securely fastened at the top by a threaded nut which is then crimped or locked in place by a welded pin. The square dimension of the retainer plate is larger than the diameter of the flow holes through the core plate. Failure of the hold down bar or spring pack therefore does not result in ejection of the burnable poison rods from the core.

The only incident that could potentially result in ejection of the burnable absorber rods is a multiple fracture of the retainer plate. This not considered credible because of the light loads borne by this component. During normal operation the loads borne by the plate are approximately 5 lb/rod or a total of 100 lb. distributed at the points of attachment. Even a multiple fracture of the retainer plate would result in jamming of the plate segments against the upper core plate, again preventing ejection. Excessive reactivity increase due to burnable absorber ejection is therefore prevented.

The guide thimbles of the fuel assembly afford the same protection from damage due to fuel rod failures as that described for the rod cluster control assembly rods.

The Westinghouse designed wet annular burnable absorber (WABA) is used in reload cores. Reference 16 verifies that the WABA design meets burnable absorber design criteria.

Rods have performed very well in actual service with no failures observed through full life of one fuel cycle.

4.2.3.3.2 Control Rod Drive Mechanism (CRDM) Material Selection

All pressure retaining materials comply with Section III of the ASME Pressure vessel code, and will be fabricated from austenitic (304) stainless steel.

Magnetic pole pieces are fabricated from 410 stainless steel. All non-magnetic parts, except pins and springs, are fabricated from 304 stainless steel. Haynes 25 is used to fabricate link pins. Springs are made from Inconel-X. Latch arm tips are clad with Stellite 6 to provide improved wearability. Hard chrome plate and Stellite 6 are used selectively for bearing and wear surfaces.

At the start of the development program, a survey was made to determine whether a material better than 410 stainless steel was available for the magnetic pole pieces. Ideal material requirements are as follows:

1. High magnetic saturation value

2. High permeability

3. Low coercive force

4. High resistivity

5. High curie temperature

6. Corrosion resistant

7. High impact strength

8. Non-oriented

9. High machinability

10. Resistance to radiation damage

After a comprehensive material trade-off study was made it was decided that the 410 stainless steel was satisfactory for this application.

The cast coil housings require a magnetic material. Both low-carbon cast steel and ductile iron have been successfully tested for this application. The choice, made on the basis of cost, indicates ductile iron will be specified on the control rod drive mechanism. The finished housings are zinc plated to provide corrosion resistance.

Coils are wound on bobbins of molded Dow Corning 302 material, with double glass-insulated copper wire. Coils are then vacuum impregnated with silicon varnish. A wrapping of mica sheet is secured to the coil outer surface. The result is a well-insulated coil capable of sustained operation at 200 degrees centigrade.

The drive rod assembly utilizes a 410 stainless steel drive rod. The coupling is machined from 403 stainless steel. Other parts are 304 stainless steel with the exception of the springs which are Inconel-X and the locking button which is Haynes 25.

Radiation Damage

As required by the equipment specification, the control rod drive mechanisms are designed to meet a radiation requirement of 10 RADS/HR. Materials have been selected to meet this requirement.

The above radiation level which amounts to 1.753×10^6 RADS in twenty years will not limit control rod drive mechanism life. Control rod drive mechanisms at Yankee Rowe which have been in operation since 1960 have not experienced problems due to radiation.

Positioning Requirements

The mechanism has a step length of 5/8 inches which determines the positioning capabilities of the control rod drive mechanism. (Note: Positioning requirements are determined by reactor physics).

Evaluation of Materials Adequacy

The ability of the pressure vessel assembly components to perform throughout the design lifetime as defined in the equipment specification is confirmed by the stress analysis report required by the ASME Boiler and Pressure Vessel Code, Section III. Internal components subjected to wear will withstand a minimum of 2,500,000 steps without refurbishment as confirmed by life tests.

Results of Dimensional and Tolerance Analysis

With respect to the control rod drive mechanism systems as a whole, critical clearances are present in the following areas:

1. Latch assembly (Diametral clearances)

2. Latch arm-drive rod clearances

3. Coil stack assembly-thermal clearances

4. Coil fit in coil housing

The following write-up defines clearances that are designed to provide reliable operation in the control rod drive mechanism in these four critical areas. These clearances have been proven by life tests and actual field performance at operating plants.

1. Latch Assembly - Thermal Clearances

The magnetic jack has several clearances when parts made of 410 stainless steel fit over parts made from 304 stainless steel. Differential thermal expansion is therefore important. Minimum clearances of these parts at 68°F is 0.011 inches. At the maximum design temperature of 650°F minimum clearance is 0.0045 inches and at the maximum expected operating temperatures of 550°F is 0.0057 inches.

2. Latch Arm - Drive Rod Clearances

The control rod drive mechanism incorporates a load transfer action. The movable or stationary gripper latch is not under load during engagement, as previously explained, due to load transfer action.

Figure 4.2.3-9 shows latch clearance variation with the drive rod as a result of minimum and maximum temperatures. Figure 4.2.3-10 shows clearance variations over the design temperature range.

3. Coil Stack Assembly - Thermal Clearances

The assembly clearance of the coil stack assembly over the latch housing was selected so that the assembly could be removed under all anticipated conditions of thermal expansion.

At 70°F the inside diameter of the coil stack is 7.428/7.438 inches. The outside diameter of the latch housing is 7.39/7.38 inches.

Thermal expansion of the mechanism due to operating temperature of the control rod drive mechanism results in minimum inside diameter of the coil stack being 7.440 inches at 222°F and the maximum latch housing diameter being 7.426 inches at 650°F.

Under the extreme tolerance conditions listed above it is necessary to allow time for a 70°F coil housing to heat during a replacement operation.

Four similar type coil stack assemblies were removed from four hot control drive mechanism mounted on 11.035 inch centers on a 550°F test loop, allowed to cool, and then replaced without incident as a test to prove the preceding.

4. Coil Fit in Coil Housing

Control rod drive mechanism and coil housing clearances are selected so that coil heat up results in a close to tight fit. This is done to facilitate thermal transfer and coil cooling in a hot control rod drive mechanism.

4.2.3.4 Tests, Verification and Inspection

4.2.3.4.1 Reactivity Control Components

Tests and inspections are performed on each reactivity control component to verify the mechanical characteristics. In the case of the rod cluster control assembly, prototype testing has been conducted and both manufacturing test/inspections and functional testing at the plant site are performed.

During the component manufacturing phase, the following requirements apply to the reactivity control components to assure the proper functioning during reactor operation:

1. All materials are procured to specifications to attain the desired standard of quality.

2. A spider from each braze lot is proof tested by applying a 5000 pound load to the spider body, so that approximately 310 lbs is applied to each vane. This proof load provides a bending moment at the spider body approximately equivalent to 1.4 times the load caused by the acceleration imposed by the CRDM.

3. All clad/end plug welds are checked for integrity by visual inspection, X-ray, and are helium leak checked. All the seal welds in the neutron absorber rods, burnable poison rods and source rods are checked in this manner.

4. To assure proper fitup with the fuel assembly, the rod cluster control, burnable poison and source assemblies are installed in the fuel assembly and checked for binding in the dry condition.

The rod cluster assemblies are functionally tested, following initial core loading but prior to critically to demonstrate reliable operation of the assemblies. Each assembly is operated one time at no flow/cold conditions and one time at full flow/hot conditions. The assemblies are also trip tested at full flow/hot conditions. Those assemblies whose trip times fall outside a certain tolerance will be tested an additional 3 times at full flow/hot conditions. Thus each assembly is adequately tested to verify that the assemblies are properly functioning.

4.2.3.4.2 Control Rod Drive Mechanisms

Quality assurance procedures during production of control rod drive mechanisms include material selection, process control, mechanism component tests during production and hydrotests.

After all manufacturing procedures had been developed; several prototype control rod drive mechanisms and drive rod assemblies were life tested with the entire drive line under environmental conditions of temperature, pressure and flow. All acceptance tests were of duration equal to or greater than service required for the plant operation. All drive rod assemblies tested in this manner have shown minimal wear damage.

These tests include verification that the trip time achieved by the control rod drive mechanisms meet the design requirement for trip time from start of rod cluster control assembly motion to dashpot entry: This trip time requirement will be confirmed for each control rod drive mechanism prior to initial reactor operation and at periodic intervals after initial reactor operation. In addition, a Technical Specification has been set to ensure that the trip time requirement is met.

It is expected that all control rod drive mechanisms will meet specified operating requirements for the duration of plant life with normal refurbishment. However, a Technical Specification pertaining to an inoperable rod cluster control assembly has been set.

In order to demonstrate proper operation of the control rod drive mechanism and to ensure acceptable core power distributions during operation partial rod cluster control assembly movement checks are performed on the rod cluster control assemblies during reactor critical operation. (Refer to Plant Technical Specifications). In addition, drop tests of the rod cluster control assemblies are performed after each refueling shutdown to demonstrate continued ability to meet trip time requirements.

To confirm the mechanical adequacy of the fuel assembly and rod cluster control assembly, functional test programs have been conducted on a full scale control rod. The prototype assembly was tested under simulated conditions of reactor temperature, pressure, and flow for approximately 1000 hours. The prototype mechanism accumulated about 3,000,000 steps and 600 trips. At the end of the test the control rod drive mechanism was still operating satisfactorily.

Actual experience on the Ginna, Mihama No. 1, Point Beach No. 1 and H. B. Robinson plants indicates excellent performance of control rod drive mechanisms.

All units are production tested prior to shipment to confirm ability of control rod drive mechanisms to meet design specification-operational requirements.

4.2.3.5 Instrumentation Applications

Instrumentation for determining reactor coolant average temperature (T_{avg}) is provided to create demand signals for moving groups of rod cluster control assemblies to provide load follow (determined as a function of turbine impulse pressure) during normal operation and to counteract operational transients. The hot and cold leg resistance temperature detectors (RTD's) are described in Section 7.2. The location of the RTD's in each loop is shown on the flow diagrams in Chapter 5. The Reactor Control System which controls the reactor coolant average temperature by regulation of control rod bank position is described in Chapter 7.

Rod Position indication instrumentation is provided to sense the actual position of each drive rod assembly (i.e., control rod) so that the actual position of the individual rod may be displayed to the operator. Signals are also supplied by this system as input to the rod deviation comparator. The rod position indication system is described in Chapter 7.

The reactor makeup control system, whose functions are to permit adjustment of the reactor coolant boron concentration for reactivity control (as well to maintain the desired operating fluid inventory in the volume control tank), consists of a group of instruments arranged to provide a manually preselected makeup composition that is borated or diluted as required to the charging pump suction header or the volume control tank. This system, as well as other systems including boron sampling provisions that are part of the Chemical and Volume Control System, are described in Section 9.3.

4.3 NUCLEAR DESIGN

4.3.1 Design Bases

This section describes the design bases and functional requirements used in the nuclear design of the fuel and reactivity control system and relates these design bases to the General Design Criteria (GDC) presented in 10 CFR 50, Appendix A. Where applicable, supplemental criteria such as the Final Acceptance Criteria for Emergency Core Cooling Systems are addressed. Before discussing the nuclear design bases it is appropriate to briefly review the four major categories ascribed to conditions of plant operation.

The full spectrum of plant conditions is divided into four categories, in accordance with the anticipated frequency of occurrence and risk to the public:

1. Condition I - Normal Operation
2. Condition II - Incidents of Moderate Frequency
3. Condition III - Infrequent Faults
4. Condition IV - Limiting Faults

In general the Condition I occurrences are accommodated with margin between any plant parameter and the value of that parameter which would require either automatic or manual protective action. Condition II incidents are accommodated with, at most, a shutdown of the reactor with the plant capable of returning to operation after corrective action. Fuel damage (Fuel damage as used here is defined as penetration of the fission product barrier, i.e., the fuel rod clad) is not expected during Condition I and Condition II events. It is not possible, however, to preclude a very small number of rod failures. These are within the capability of the CVCS and are consistent with the plant design basis.

Condition III incidents will not cause more than a small fraction of the fuel elements in the reactor to be damaged, although sufficient fuel element damage might occur to preclude immediate resumption of operation. The release of radioactive material due to Condition III incidents should not be sufficient to interrupt or restrict public use of these areas beyond the exclusion radius. Furthermore, a Condition III incident will not by itself generate a Condition IV fault or result in a consequential loss of function of the reactor coolant system or reactor containment barriers.

Condition IV occurrences are faults that are not expected to occur but are defined as limiting faults which must be designed against. Condition IV faults shall not cause a release of radioactive material that exceeds the limits of 10 CFR 100.

The core design power distribution limits related to fuel integrity are met for Condition I occurrences through conservative design and maintained by the action of the Control System. The requirements for Condition II occurrences are met by providing an adequate protection system which monitors reactor parameters. The Control and Protection Systems are described in Chapter 7 and the consequences of Condition II, III and IV occurrences are given in Chapter 15.

4.3.1.1 Fuel Burnup

Basis

The fuel rod design basis is described in Section 4.2. The nuclear design basis is to install sufficient reactivity in the fuel to attain a region discharge burnup of 48000 MWD/MTU. The above along with the Design Basis 4.3.1.3, Control of Power Distribution, satisfies GDC-10.

Discussion

Fuel burnup is a measure of fuel depletion which represents the integrated energy output of the fuel (MWD/MTU) and is a convenient means for quantifying fuel exposure criteria. The core design lifetime or design discharge burnup is achieved by installing sufficient initial excess reactivity in each fuel region and by following a fuel replacement program (such as that described in Subsection 4.3.2) that meets safety related criteria in each cycle of operation.

Initial excess reactivity installed in the fuel, although not a design basis, must be sufficient to maintain core criticality at full power operating conditions throughout cycle life with equilibrium xenon, samarium, and other fission products present. The end of design cycle life is defined to occur when the chemical shim concentration is essentially zero with control rods present to the degree desired for operational requirements (e.g., the controlling bank at the "bite" position or full out). In terms of chemical shim boron concentration this represents approximately 10 ppm with no control rod insertion.

A limitation on initial installed excess reactivity is not required other than as is quantified in terms of other Design Bases such as core Negative Reactivity Feedback and Shutdown Margin discussed below.

4.3.1.2 Negative Reactivity Feedbacks (Reactivity Coefficient)

Basis

The fuel temperature coefficient will be negative and the moderator temperature coefficient of reactivity will be non-positive for power operating conditions, thereby providing negative reactivity feedback characteristics. The design basis meets GDC-11.

Discussion

When compensation for a rapid increase in reactivity is considered, there are two major effects. These are the resonance absorption effects (Doppler) associated with changing fuel temperature and the spectrum effect resulting from changing moderator density. These basic physics characteristics are often identified by reactivity coefficients. The use of slightly enriched uranium ensures that the Doppler coefficient of reactivity is negative. This coefficient provides the most rapid reactivity compensation. The core is also designed to have an overall negative moderator temperature coefficient or reactivity so that the average coolant temperature or void content provides another, slower compensatory effect. The negative moderator temperature coefficient

can be achieved through use of fixed burnable absorbers, Integral Fuel Burnable Absorber (IFBA) and/or control rods, which decreases the concentration of soluble boron while maintaining reactivity control.

Restrictions on burnable absorber content (quantity and distribution) are not applied as a design basis other than as it relates to accomplishment of a non-positive moderator temperature coefficient at power operating conditions as discussed in Section 4.3.2.

4.3.1.3 <u>Control of Power Distribution</u>

Basis

The nuclear design basis is that, with at least a 95 percent confidence level:

1. Under normal operating conditions, at full power, the fuel will not be operated at a linear power greater than the HFP average linear power multiplied by the factor F_Q^{RTP} * K(z), including an allowance of 0.7 percent for calorimetric error and not including a power spike factor due to densification. F_Q^{RTP} is the maximum heat flux hot channel factor, $F_Q(z)$, at 100 percent power. K(z) is the normalized $F_Q(z)$ as a function of core height.

2. Under abnormal conditions including the maximum overpower condition, the fuel peak power will not cause melting as defined in Paragraph 4.4.1.2.

3. The fuel will not operate with a power distribution that violates the departure from nucleate boiling (DNB) design basis (i.e., the DNBR will not be less than the safety analysis limits, as discussed in Subsection 4.4.1) under Condition I and II events including the maximum overpower condition.

4. Fuel management is such as to produce rod powers and burnups consistent with the assumptions in the fuel rod mechanical integrity analysis of Section 4.2.

The above basis meets GDC-10.

Discussion

Calculations of extreme power shapes which effect fuel design limits are performed with proven methods and verified frequently with measurements from operating reactors. The conditions under which limiting power shapes are assumed to occur are conservatively chosen with regard to any permissible operating state.

Even though there is good agreement between calculated peak power and measurements, a nuclear uncertainty margin is applied to the calculated peak local power. Such a margin is provided both for the analyses of normal operating states and for anticipated transients.

4.3.1.4 Maximum Controlled Reactivity Insertion Rate

Basis

The maximum reactivity insertion rate due to withdrawal of Rod Cluster Control Assemblies or by boron dilution is limited. This limit, expressed as a maximum reactivity change rate (75 pcm/sec where 1 pcm = $10^{-5}\ \Delta\rho$) is set such that peak heat generation rate and DNBR do not exceed the maximum allowable at overpower conditions. This satisfies GDC-25.

The maximum reactivity worth of control rods and the maximum rates of reactivity insertion employing control rods are limited so that a Rod Withdrawal or Rod Ejection accident will not cause rupture of the coolant pressure boundary or disruption of the core internals to a degree which would impair core cooling capacity (see Chapter 15).

Following any Condition IV event (Rod Ejection, Steamline Break etc.) the reactor can be brought to the shutdown condition and the core will maintain coolable geometry. This satisfies GDC-28.

Discussion

Reactivity insertion associated with an accidental withdrawal of a control bank (or banks) is limited by the maximum rod speed (or travel rate) and by the worth of the bank(s). For this reactor the maximum control rod speed is 45 inches per minute and the maximum rate of reactivity change considering two control banks moving is less than 75 pcm/sec.

4.3.1.5 Shutdown Margins

Basis

Minimum shutdown margin (SDM) is required by the SQN Technical Specifications. The amount of SDM is specified in the SQN Core Operating Limits Report (COLR) and is required in all operating modes, hot shutdown and cold shutdown conditions.

In all analyses involving reactor trip, the single, highest worth Rod Cluster Control Assembly is postulated to remain untripped in its full-out position (stuck rod criterion). This satisfies GDC-26.

Discussion

Two independent reactivity control systems are provided: control rods and soluble boron in the coolant. The control rod system can compensate for the reactivity effects of the fuel and water temperature changes accompanying power level changes over the range from full-load to no-load. In addition, the control rod system provides the minimum shutdown margin under Condition I events and is capable of making the core subcritical rapidly enough to prevent exceeding acceptable fuel damage limits assuming that the highest worth control rod is stuck out upon trip.

The boron system can compensate for all xenon burnout reactivity changes and will maintain the reactor in the cold shutdown condition. Thus, backup and emergency shutdown provisions are provided by a mechanical and a chemical shim control system which satisfies GDC-26.

Basis

When fuel assemblies are in the pressure vessel and the vessel head is not in place, k_{eff} will be maintained at or below 0.95 with control rods and soluble boron.

Discussion

ANSI Standard N18.2 specifies a k_{eff} not to exceed 0.95 in spent fuel storage racks and transfer equipment flooded with pure water and a k_{eff} not to exceed 0.98 in normally dry new fuel storage racks assuming optimum moderation. No criterion is given for the refueling operation, however a 5 percent margin, which is consistent with spent fuel storage and transfer and the new fuel storage, is adequate for the controlled and continuously monitored operations involved.

The boron concentration required to meet the refueling shutdown criteria is specified in the SQN Technical Specifications. Verification that this shutdown criteria is met, including uncertainties, is achieved using standard design methods such as the ARK or PHOENIX-P and TURTLE or ANC codes. The subcriticality of the core is continuously monitored as described in the SQN Tech Specs.

4.3.1.6 Stability

Basis

The core will be inherently stable to power oscillations of the fundamental mode. This satisfies GDC-12.

Spatial power oscillations within the core, with a constant core power output, should they occur can be reliably and readily detected and suppressed.

Oscillations of the total power output of the core, from whatever cause, are readily detected by the loop temperature sensors and by the nuclear instrumentation. The core is protected by these systems and a reactor trip would occur if power unacceptably increased, preserving the design margins to fuel design limits. The stability of the turbine/steam generator/core systems and the reactor control system is such that total core power oscillations are not normally possible. The redundancy of the protection circuits ensures an extremely low probability of exceeding design power levels.

The core is designed so that diametral and azimuthal oscillations due to spatial xenon effects are self-damping and no operator action or control action is required to suppress them. The stability to diametral oscillations is so great that this excitation is highly improbable. Convergent azimuthal oscillations can be excited by prohibited motion of individual control rods. Such oscillations are readily observable and alarmed, using the excore long ion chambers. Indications are also continuously available from incore thermocouples and loop temperature measurements. Moveable incore detectors can be activated to provide more detailed information. In all cores, these horizontal plane oscillations are self-damping by virtue of reactivity feedback effects designed into the core.

However, axial xenon spatial power oscillations may occur late in core life. The control bank and excore detectors are provided for control and monitoring of axial power distributions.

Assurance that fuel design limits are not exceeded is provided by reactor Overpower ΔT and Overtemperature ΔT trip functions which use the measured axial power imbalance as an input.

4.3.1.7 Anticipated Transients Without Trip

The effects of anticipated transients with failure to trip are not considered in the Design Bases of the plant. Analysis has shown that the likelihood of such a hypothetical event is negligibly small. Furthermore, analysis of the consequences of a hypothetical failure to trip following anticipated transients has shown that no significant core damage would result and system peak pressures would be limited to such that the primary stress anywhere in the system boundary is less than the "emergency conditions" defined in the ASME Nuclear Power Plant Components Code, Section III, acceptable values and no failure of the Reactor Coolant System would result. (Reference 1).

4.3.2 Description

4.3.2.1 Nuclear Design Description

The reactor core consists of a specified number of fuel rods which are held in bundles by spacer grids and top and bottom fittings. The fuel rods are constructed of cylindrical Zircaloy tubes containing UO_2 fuel pellets. The bundles, known as fuel assemblies, are arranged in a pattern which approximates a right circular cylinder.

Each fuel assembly contains a 17 x 17 rod array composed of 264 fuel rods, 24 rod cluster control (RCC) thimbles and an incore instrumentation thimble. Figure 4.2.1-1 shows a cross sectional view of a 17 x 17 fuel assembly and the related RCC locations. Further details of the fuel assembly are given in Subsection 4.2.1.

Fuel assemblies of three different enrichments were used in the initial core loading to establish a favorable radial power distribution. Figure 4.3.2-1 shows the fuel loading pattern used in the first core. Two regions consisting of the two lower enrichments are interspersed so as to form a checkerboard pattern in the central portion of the core. The third region is arranged around the periphery of the core and contains the highest enrichment. The enrichments for the first core are shown in Table 4.3.2-1.

Reload cores will normally operate approximately 16.5 months at full power operation, accumulating approximately 17,500 MWD/MTU per cycle. The exact reloading pattern, initial and final positions of assemblies, and the number of fresh assemblies and their placement are dependent on the energy requirements for the next cycle and burnup and power histories of the previous cycles.

The core average enrichment is determined by the amount of fissionable material required to provide the desired core lifetime and energy requirements. The physics of the burnout process is such that operation of the reactor depletes the amount of fuel available due to the absorption of neutrons by the U-235 atoms and their subsequent fission. In addition, the fission process

results in the formation of fission products, some of which readily absorb neutrons. These effects, depletion and the buildup of fission products, are partially offset by the buildup of plutonium from the non-fission absorption of neutrons in U-238, as shown in Figure 4.3.2-2 for a typical 17 x 17 fuel assembly. Therefore, at the beginning of any cycle a reactivity reserve equal to the depletion of the fissionable fuel and the buildup of fission product poisons over the specified cycle life must be "built" into the reactor. This excess reactivity is controlled by removable neutron absorbing material in the form of boron dissolved in the primary coolant, integral fuel burnable absorbers and burnable poison rods.

The concentration of boric acid in the primary coolant is varied to provide control and to compensate for long term reactivity requirements. The concentration of the soluble neutron absorber is controlled by means of the Chemical Volume and Control System (CVCS) to compensate for reactivity changes due to fuel burnup, fission product poisoning including xenon and samarium, burnable absorber depletion, and the cold-to-operating moderator temperature change. Rapid transient reactivity requirements and safety shutdown requirements are met with control rods.

As the boron concentration is increased, the moderator temperature coefficient becomes less negative. The use of a soluble absorber alone would result in a positive moderator coefficient at BOL for the first cycle. Therefore, burnable absorbers are used in the first core to sufficiently reduce the soluble boron concentration to ensure that the moderator temperature coefficient is negative at power operating conditions. During operation the absorber content in these rods is depleted, thus adding positive reactivity to offset some of the negative reactivity from fuel depletion and fission product buildup. The depletion rate of the burnable absorber rods is not critical since chemical shim is always available and flexible enough to cover any possible deviations in the expected burnable absorber depletion rate. Figure 4.3.2-3 is a graph of a typical core depletion with and without burnable absorber rods. Note that even at end-of-life conditions some residual absorber remains in the fixed burnable absorbers, resulting in a net decrease in the first cycle lifetime.

In addition to reactivity control, the burnable absorber rods are strategically located to provide a favorable radial power distribution. Figure 4.3.2-4 shows the burnable absorber distribution within a fuel assembly for the several burnable absorber patterns used in a 17 x 17 array. The initial core burnable absorber loading pattern is shown in Figure 4.3.2-5.

Tables 4.3.2-1 through 4.3.2-3 contain a summary of the reactor core design parameters for the first fuel cycle, including reactivity coefficients, delayed neutron fraction and neutron lifetimes. Sufficient information is included to permit an independent calculation of the nuclear performance characteristics of the core.

4.3.2.2 Power Distributions

The accuracy of power distribution calculations has been confirmed through approximately one thousand flux maps during some twenty years of operation under conditions very similar to those expected for Sequoyah. Details of this confirmation are given in Reference 2 and in Subparagraph 4.3.2.2.6.

4.3.2.2.1 Definitions

Power distributions are quantified in terms of hot channel factors. These factors are a measure of the peak pellet power within the reactor core and the total energy produced in a coolant channel, relative to the total reactor power output, and are expressed in terms of quantities related to the nuclear or thermal design namely:

Power density is the thermal power produced per unit volume of the core (kw/liter).

Linear power density is the thermal power produced per unit length of active fuel (kw/ft). Since fuel assembly geometry is standardized, this is the unit of power density most commonly used. For all practical purposes it differs from kw/liter by a constant factor which includes geometry and the fraction of the total thermal power which is generated in the fuel rod.

Average linear power density is the total thermal power produced in the fuel rods divided by the total active fuel length of all rods in the core.

Local heat flux is the heat flux at the surface of the cladding (BTU-ft^{-2} - hr^{-1}). For nominal rod parameters this differs from linear power density by a constant factor.

Rod power or rod integral power is the length integrated linear power density in one rod (kw).

Average rod power is the total thermal power produced in the fuel rods divided by the number of fuel rods (assuming all rods have equal length).

The hot channel factors used in the discussion of power distributions in this section are defined as follows:

F_Q, Heat Flux Hot Channel Factor, is defined as the maximum local heat flux on the surface of a fuel rod divided by the average fuel rod heat flux, allowing for manufacturing tolerances on fuel pellets and rods and including fuel densification effects.

F^N_Q, Nuclear Heat Flux Hot Channel Factor, is defined as the maximum local fuel rod linear power density divided by the average fuel rod linear power density, assuming nominal fuel pellet and rod parameters.

F^E_Q, Engineering Heat Flux Hot Channel Factor, is the allowance on heat flux required for manufacturing tolerances. The engineering factor allows for local variations in enrichment, pellet density and diameter, surface area of the fuel rod and eccentricity of the gap between pellet and clad.

Statistically combined the net effect is a factor of 1.03 to be applied to fuel rod surface heat flux.

$F^N_{\Delta H}$, Nuclear Enthalpy Rise Hot Channel Factor, is defined as the ratio of the integral of linear power along the rod with the highest integrated power to the average rod power.

Manufacturing tolerances, hot channel power distribution and surrounding channel power distributions are explicitly treated in the calculation of DNB ratio described in Section 4.4.

It is convenient for the purposes of discussion to define subfactors of F_Q, however, design limits are set in terms of the total peaking factor.

F_Q = Total peaking factor or heat flux hot channel factor

$$= \frac{\text{Maximum kw/ft}}{\text{Average kw/ft}}$$

without densification effects

$$F_Q = F^N_Q \times F^E_Q$$

$$= F^N_{XY} \times F^N_Z \times F^N_U \times F^E_Q$$

where

F^N_Q and F^E_Q are defined above.

F^U_N = the measurement uncertainty associated with a full core flux map with moveable detectors

F^N_{XY} = ratio of peak power density to average power density in the horizontal plane of peak local power.

F^N_Z = ratio of the power per unit core height in the horizontal plane of peak local power to the average value of power per unit core height. If the plane of peak local power coincides with the plane of maximum power per unit core height then F^N_z is the core average axial peaking factor.

To include the allowances made for densification effects, which are height dependent, the following quantities are defined.

S(Z) = the allowance made for densification effects at height Z in the core. See Subparagraph 4.3.2.2.5.

P(Z) = ratio of the power per unit core height in the horizontal plane at height Z to the average value of power per unit core height.

$F^N_{XY}(Z)$ = ratio of peak power density to average power density in horizontal plane of height Z.

Then

F_Q = Total peaking factor

$$= \frac{\text{Maximum Kw/ft}}{\text{Average Kw/ft}}$$

Including densification allowance

$$F_Q = \max\left[F_{XY}^N(Z) \text{ x } P(Z)\right] \text{x } S(Z) \text{ x } F_U^N \text{ x} F_Q^E$$

4.3.2.2.2 Radial Power Distributions

The power shape in horizontal sections of the core at full power is a function of the fuel assembly and burnable poison loading patterns, the control rod pattern and the fuel burnup distribution. Thus, at any time in the cycle any horizontal section of the core can be characterized as unrodded or with group D control rods. These two situations combined with burnup effects determine the radial power shapes which can exist in the core at full power. The effect on radial power shapes of power level, xenon, samarium and moderator density effects are considered also but these are quite small. The effect of non-uniform flow distribution is negligible. While radial power distributions in various planes of the core are often illustrated, the core radial enthalpy rise distribution as determined by the integral of power up each channel is of greater interest. Figures 4.3.2-6 through 4.3.2-11 show representative radial power distributions for one eighth (1/8) of the core for representative operating conditions. These conditions are 1) Hot Full Power (HFP) at Beginning-of-Life (BOL), unrodded, no xenon, 2) HFP at BOL, unrodded, equilibrium xenon, 3) HFP at BOL, Bank D, equilibrium xenon, 4) HFP at Middle-of-Life, unrodded, equilibrium xenon, and 5) HFP at End-of-Life (EOL), unrodded, equilibrium xenon.

Since the position of the hot channel varies from time to time, a single reference radial design power distribution is selected for DNB calculations. This reference power distribution is conservatively chosen to concentrate power in one area of the core, minimizing the benefits of flow redistribution. Assembly powers are normalized to core average power.

4.3.2.2.3 Assembly Power Distributions

For the purpose of illustration, assembly power distributions from the BOL and EOL conditions corresponding to Figures 4.3.2-7 and 4.3.2-11, respectively, are given for the same assembly in Figures 4.3.2-12 and 4.3.2-13, respectively.

Since the detailed power distribution surrounding the hot channel varies from time to time, a conservatively flat assembly power distribution is assumed in the DNB analysis, described in Section 4.4, with the rod of maximum integrated power artificially raised to the design value of $F^N_{\Delta H}$. Care is taken in the nuclear design of all fuel cycles and all operating conditions to ensure that a flatter assembly power distribution does not occur with limiting values of $F^N_{\Delta H}$.

4.3.2.2.4 Axial Power Distributions

The shape of the power profile in the axial or vertical direction is largely under the control of the operator through the manual operation of the control rods or automatic motion of the rods in response to CVCS operation. Nuclear effects which cause variations in the axial power shape include moderator density, Doppler effect on resonance absorption, spatial distribution of xenon and burnup. Automatically controlled variations in total power output and full length rod motion are also important in determining the axial power shape at any time. Signals are available to the operator from the excore ion chambers which are long ion chambers outside the reactor vessel

running parallel to the axis of the core. Separate signals are taken from the top and bottom halves of the chambers. The difference between top and bottom signals from each of four pairs of detectors is displayed on the control panel and called the Flux Imbalance ΔI. Calculations of the core average peaking factor for many plants and measurements from operating plants under many operating situations are associated with either ΔI or axial offset in such a way that an upper bound can be place on the peaking factor. For these correlations axial offset is defined as

$$\text{axial offset} = \frac{\Phi t - \Phi b}{\Phi t + \Phi b}$$

and Φt and Φb are the top and bottom detector readings.

Representative axial power shapes from Reference 3 for BOL, MOL, and EOL conditions are shown in Figures 4.3.2-14 through 4.3.2-16. These figures cover a wide range of axial offset, including values not permitted at full power.

The radial power distribution shown in Figure 4.3.2-8 involving the partial insertion of control rods represent a synthesis of power shapes from the rodded and unrodded planes. The applicability of the separability assumption upon which this procedure is based is ensured through extensive three-dimensional calculations of possible rodded conditions. As an example, Figure 4.3.2-17 compares the axial power distribution for several assemblies at different distances from inserted control rods with the core average axial distribution.

The only significant difference from the average occurs in the low power peripheral assemblies, thus, confirming the validity of the separability assumption.

4.3.2.2.5 Local Power Peaking

Fuel densification, which has been observed to occur under irradiation in several operating reactors, causes the fuel pellets to shrink both axially and radially. The pellet shrinkage combined with random hang-up of fuel pellets results in gaps in the fuel column when the pellets below the hung-up pellet settle in the fuel rod. The gaps vary in length and location in the fuel rod. Because of decreased neutron absorption in the vicinity of the gap, power peaking occurs in the adjacent fuel rods resulting in an increased power peaking factor. A quantitative measure of this local power peaking is given by the power spike factor, S(Z), where Z is the axial location in the core.

The method used to compute the power spike factor is described in Reference 4 and is summarized in Figure 4.3.2-18. The information flow outlined in Figure 4.3.2-18 is as follows:

1. The probability that an axial gap of a certain size will occur at a given location in the core is determined from fuel performance data.

2. The magnitude of the power spike caused by a single axial gap of a certain size is determined from nuclear calculations as shown in Figure 4.3.2-19. This curve is valid for uranium fuel enrichments up to 5.0 w/o (Reference 29).

3. For each axial interval to be analyzed, axial gap occurrence probabilities and the single event power spikes are entered into the DRAW computer code. The code produces a curve of power spike vs. probability of exceeding power spike for each elevation in the core. The power census for a core is then statistically combined with the power spike probability curve to obtain a power spike penalty for the core such that less than one rod will exceed F_Q at a 95-percent confidence level.

The power spike factor due to densification is assumed to be a local perturbation. Thus, densification effects F_Q but not $F_{\Delta H}$. The magnitude of the increased power peaking which increases from no effect at the bottom of the core to a few percent at the top of the core is shown in Figure 4.3.2-20. This curve is applicable for fuel pellets that have a density of at least 93.5 percent (geometric).

For fuel produced by a process other than those for which Reference 3 is applicable, specifications will be followed to ensure that the effects of densification will be no greater than has been allowed in the design. The specifications for quantifying the extent of densification will be based on the NRC report on fuel densification (Reference 4).

Results reported in Reference 5 show that the power spike penalty should not be included in determining the predicted F_Q.

4.3.2.2.6 Limiting Power Distribution

According to the ANSI classification of plant conditions (see Section 15.0), Condition I occurrences are those which are frequently or regularly expected in the course of power operation, maintenance, or maneuvering of the plant. As such, Condition I occurrences are accommodated with margin between any plant parameter and the value of that parameter which would require either automatic or manual protective action. Inasmuch as Condition I occurrences frequently or regularly occur, they must be considered from the point of view of effecting the consequences of fault conditions (Condition II, III and IV). In this regard, analysis of each fault condition described is generally based on a conservative set of initial conditions corresponding to the most adverse set of conditions which can occur during Condition I operation.

The list of steady state and shutdown conditions, permissible deviations (such as one coolant loop out of service) and operational transients is given in Section 15.1. Implicit in the definition of normal operation is proper and timely action by the reactor operator. That is, the operator follows recommended operating procedures for maintaining appropriate power distributions and takes any necessary remedial actions when alerted to do so by the plant instrumentation. Thus, as stated above, the worst or limiting power distribution which can occur during normal operation is to be considered as the starting point for analysis of ANSI Conditions II, III and IV events.

Improper procedural actions or errors by the operator are assumed in the design as occurrences of moderate frequency (ANSI Condition II). Some of the consequences which might result are listed in Section 15.2. Therefore, the limiting power shapes which result from such Condition II events, are those power shapes which deviate from the normal operating condition at the recommended axial offset band, e.g. due to lack of proper action by the operator during a xenon

transient following a change in power level brought about by control rod motion. Power shapes which fall in this category are used for determination of the reactor protection system setpoints so as to maintain margin to overpower or DNB limits.

The means for maintaining power distributions within the required hot channel factor limits are described in the SQN Technical Specifications. A complete discussion of power distribution control in Westinghouse PWRs is included in Reference 6. Reference 30 describes the axial offset control strategy used at SQN. Detailed information on the design constraints on local power density in a Westinghouse PWR, on the defined operating procedures and on the measures taken to preclude exceeding design limits is presented in the Westinghouse Topical Report on peaking factors (Reference 7). The following paragraphs summarize these reports and describe the calculations used to establish the upper bound on peaking factors.

The calculations used to establish the upper bound on peaking factors, F_Q and $F_{\Delta H}$, include all of the nuclear effects which influence the radial and/or axial power distributions throughout core life for various modes of operation including load follow, reduced power operation, and axial xenon transients.

Radial power distributions are calculated for the full power condition, and fuel and moderator temperature feedback effects are included for the average enthalpy plane of the reactor. The steady state nuclear design calculations are done for normal flow with the same mass flow in each channel and flow redistribution effects neglected. The effect of flow redistribution is calculated explicitly where it is important in the DNB analysis of accidents. The effect of xenon on radial power distribution is small (compare Figures 4.3.2-6 and 4.3.2-7), but is included as part of the normal design process. Radial power distributions are relatively fixed and easily bounded with upper limits.

The core average axial profile, however, can experience significant changes which can rapidly occur as a result of rod motion and load changes and more slowly due to xenon distribution. For the study of points of closest approach to axial power distribution limits, several thousand cases are examined. Since the properties of the nuclear design dictate what axial shapes can occur, boundaries on the limits of interest can be set in terms of the parameters which are readily observed on the plant. Specifically, the nuclear design parameters which are significant to the axial power distribution analysis are:

1. core power level
2. core height
3. coolant temperature and flow
4. coolant temperature program as a function of reactor power
5. fuel cycle lifetimes
6. rod bank worths
7. rod bank overlaps

Normal operation of the plant assumes compliance with the following conditions:

1. Control rods in a single bank move together with no individual rod insertion differing by more than 12 steps (indicated) from the bank demand position;

2. Control banks are sequenced with overlapping banks;

3. The control bank insertion limits are not violated.

4. Axial power distribution procedures, which are given in terms of flux imbalance control and control bank position are observed.

The axial power distribution procedures referred to above are part of the required operating procedures which are followed in normal operation. Briefly they require control of the axial offset at all power levels within a permissible operating band. This minimizes xenon transient effects on the axial power distribution.

Calculations are performed for normal operation of the reactor, including load following maneuvers. Beginning, middle, and end of cycle conditions are included in the calculations. Different histories of operation are assumed prior to calculating the effect of load follow transients on the axial power distribution. These different histories assume base loaded operation and extensive load following. For a given plant and fuel cycle, a finite number of maneuvers are studied to determine the general behavior of the local power density as a function of core elevation.

These cases represent many possible reactor states in the life of one fuel cycle, and they have been chosen as sufficiently definitive of the cycle by comparison with much more exhaustive studies performed on some 20 or 30 different, but typical, plant and fuel cycle combinations. The cases are described in detail in Reference 7 and 30, and they are considered to be necessary and sufficient to generate a local power density limit which, when increased by 5 percent for conservatism, will not be exceeded with a 95-percent confidence level. Many of the points do not approach the limiting envelope. However, they are part of the time histories which lead to the hundreds of shapes which do define the envelope. They also serve as a check that the reactor studied is typical of those more exhaustively studied.

Thus, it is not possible to single out any transient or steady-state condition which defines the most limiting case. It is not even possible to separate out a small number which form an adequate analysis. The process of generating a myriad of shapes is essential to the philosophy that leads to the required level of confidence. A maneuver which provides a limiting case for one reactor fuel cycle (defined as approaching the line of Figure 4.3.2-21) is not necessarily a limiting case for another reactor or fuel cycle with different control bank worths, enrichments, burnup, coefficients, etc. Each shape depends on the detailed history of operation up to that time and on the manner in which the operator conditioned xenon in the days immediately prior to the time at which the power distribution is calculated.

The calculated points are synthesized from axial calculations combined with radial factors appropriate for rodded and unrodded planes in the first cycle. In these calculations, the effects on the unrodded radial peak of xenon redistribution that occurs following the withdrawal of a control bank (or banks) from a rodded region is obtained from two-dimensional X-Y calculations. A 1.03 factor to be applied on the unrodded radial peak was obtained from calculations in which xenon distribution was preconditioned by the presence of control rods and then allowed to redistribute for several hours. A detailed discussion of this effect may be found in Reference 7. The calculated values have been increased by a factor of 1.05 for conservatism and a factor of 1.03 for the engineering factor F^E_Q.

The envelope drawn over the calculated max (F_Q(X, Y, Z) x Power) points in Figure 4.3.2-21 represents an upper bound envelope on local power density versus elevation in the core. It should be emphasized that this envelope is a conservative representation of the bounding values of local power density. Expected values are considerably smaller and, in fact, less conservative bounding values may be justified with additional analysis or surveillance requirements. For example, Figure 4.3.2-21 bounds both BOL and EOL conditions but without consideration of radial power distribution flattening with burnup, i.e., both BOL and EOL points presume the same radial peaking factor. Inclusion of the burnup flattening effect would reduce the local power densities corresponding to EOL conditions which may be limiting at the higher core elevations.

Finally, as previously discussed, this upper bound envelope is based on procedures of load follow which require operation within an allowed axial offset range. These procedures are detailed in the SQN Technical Specifications and are followed by relying only upon excore surveillance supplemented by the normal monthly full core map requirement and by computer-based alarms on deviation from the allowed flux imbalance band.

Allowing for fuel densification effects the average linear power is 5.43 kw/ft at 3411 MW(th) and 5.50 kw/ft at 3455 MW(th). When K(z) = 1, the conservative upper bound of the normalized local power density, including uncertainty allowances is F_Q^{RTP} which allows safe operation at 102 percent of 3411 MW(th) and 100.7% of 3455 MW(th).

To determine reactor protection system setpoints, with respect to power distributions, three categories of events are considered, namely rod control equipment malfunctions, operator errors of commission, and operator errors of omission. In evaluating these three categories of events, the core is assumed to be operating within the four constraints described above.

The first category comprises uncontrolled rod withdrawal (with rods moving in the normal bank sequence) for full length banks. Also included are motions of the full-length banks below their insertion limits, which could be caused, for example, by uncontrolled dilution or primary coolant cooldown. Power distributions were calculated throughout these occurrences, assuming short term corrective action. That is, no transient xenon effects were considered to result from the malfunction. The event was assumed to occur from typical normal operating situations, which include normal xenon transients. It was further assumed in determining the power distributions that the total core power level would be limited by reactor trip to below 116.5 percent of 3455 MWt. Since the study is to determine protection limits with respect to power and axial offset, no credit was taken for trip setpoint reduction due to flux imbalance. Results are given in Figure 4.3.2-22 in units of kw/ft. The peak power density which can occur in such events, assuming reactor trip at or below 116.5 percent of 3455 MWt, is less than that required for center-line melt, including uncertainties and densification effects.

The second category, also appearing in Figure 4.3.2-22, assumes that the operator mispositions the full-length rod bank in violation of the insertion limits and creates short-term conditions not included in normal operating conditions.

The third category assumes that the operator fails to take action to correct a flux imbalance violation. The results shown on Figure 4.3.2-23 are F_Q multiplied by 3479 MWt, which includes an allowance for calorimetric error. The peak linear power does not exceed 18 kw/ft,

including the above factors, provided the assumed error in operation does not continue for a period which is long compared to the xenon time constant. The calculation results shown on Figure 4.3.2-23 which are greater than 18 kw/ft result from transients which would proceed without operator intervention for greater than 0.25 hour and would result in violation of the control rod insertion limits in the Technical Specifications. Since the peak kw/ft is below the above limit, no flux imbalance penalties are required for overpower protection. It should be noted that a reactor overpower accident is not assumed to occur coincident with an independent operator error. Additional detailed discussion of these analyses is presented in Reference 7 and 30.

Analyses of possible operating power shapes show that the appropriate hot channel factors F_Q and $F^N_{\Delta H}$ for peak local power density and for DNB analysis at full power are the values given in Table 4.3.2-2 and addressed in the SQN Technical Specifications.

The maximum allowable F_Q can be increased with decreasing power, as shown in the SQN Technical Specifications. Increasing $F^N_{\Delta H}$ with decreasing power is permitted by the DNB protection setpoints and allows radial power shape changes with rod insertion to the insertion limits, as described in Section 4.4.3. The allowance for increased $F^N_{\Delta H}$ permitted is $F^N_{\Delta H} = F^{RTP}_{\Delta H}\ (1 + PF_{\Delta H}(1\text{-}P))$ where $F^{RTP}_{\Delta H}$ and $PF_{\Delta H}$ are set by the Core Operating Limits Report. This becomes a design basis criterion which is used for establishing acceptable control rod patterns and control bank sequencing. Likewise, fuel loading patterns for each cycle are selected with consideration of this design criterion. The worst values of $F^N_{\Delta H}$ for possible rod configurations occurring in normal operation are used in verifying that this criterion is met. Typical radial factors and radial power distributions are shown in Figure 4.3.2-6 through 4.3.2-11. The worst values generally occur when the rods are assumed to be at their insertion limits. Maintenance of axial offset control establishes rod positions which are above the allowed rod insertion limits, thus providing increasing margin to the $F_{\Delta H}$ criterion. Section 3.2 of Reference 8 discusses the determination of $F_{\Delta H}$. These limits are taken as input to the thermal hydraulic design basis, as described in Section 4.4.3.2.1.

When a situation is possible in normal operation which could result in local power densities in excess of those assumed as the precondition for a subsequent hypothetical accident, but which would not itself cause fuel failure, administrative controls and alarms are provided for returning the core to a safe condition. These alarms are described in detail in Chapter 7.0.

4.3.2.2.7 Experimental Verification of Power Distribution Analysis

This subject is discussed in depth in Reference 2. A summary of this report is given here.

In a measurement of peak local power density, F_Q with the moveable detector system described in Subsection 7.7.1 and 4.4.5, the following uncertainties have to be considered.

1. Reproducibility of the measured signal

2. Errors in the calculated relationship between detector current and local flux

3. Errors in the calculated relationship between detector flux and peak rod power some distance from the measurement thimble.

The appropriate allowance for (1) above has been quantified by repetitive measurements made with several inter-calibrated detectors by using the common thimble features of the incore detector system. This system allows more than one detector to access any thimble. Errors in category (2) above are quantified to the extent possible, by using the fluxes measured at one thimble to predict fluxes at another location which is also measured. Local power distribution predictions are verified in critical experiments on arrays of rods with simulated guide thimbles, control rods, burnable poisons, etc. These critical experiments provide quantification of errors of types (2) and (3) above.

Reference 2 describes critical experiments performed at the Westinghouse Reactor Evaluation Center and measurement taken on two Westinghouse plants with incore systems of the same type as used in the plant described herein. The report concludes that the uncertainty associated with the peak nuclear heat flux factor, F_Q is 4.5 percent at the 95 percent confidence level with only 5 percent of the measurements greater than the inferred value. This is the equivalent of a 1.645 sigma limit on a normal distribution and is the uncertainty to be associated with a full core flux map with moveable detectors reduced with a reasonable set of input data incorporating the influence of burnup on the radial power distribution. The uncertainty is usually rounded up to 5 percent.

In comparing measured power distributions (or detector currents) with the calculations for the same operating conditions it is not possible to isolate the detector reproducibility. Thus a comparison between measured and predicted power distributions has to include some measurement error. Such a comparison is given in Figure 4.3.2-24 for one of the maps used in Reference 2. Since the first publication of the report, hundreds of maps have been taken on these and other reactors. The results confirm the adequacy of the 5 percent uncertainty allowance on F_Q.

A similar analysis for the uncertainty in $F_{\Delta H}$ (rod integral power) measurements results in an allowance of 3.65 percent of the equivalent of a 1.645 sigma confidence level. For historical reasons an 8 percent uncertainty factor is allowed in the nuclear design basis; that is, the predicted rod integrals at full power must not exceed the design $F_{\Delta H}$ less 8 percent.

A recent measurement in the second cycle of a 121 assembly, 12-foot core is compared with a simplified one dimensional core average axial calculation in Figure 4.3.2-25. This calculation does not give explicit representation to the fuel grids.

The accumulated data on power distributions in actual operation is basically of three types:

1. Much of the data is obtained in steady state operation at constant power in the normal operating configuration;

2. Data with unusual values of axial offset are obtained as part of the excore detector calibration exercise;

3. Special tests have been performed in load follow and other transient xenon conditions which have yielded useful information on power distributions.

These data are presented in detail in Reference 6. Figure 4.3.2-26 contains a summary of measured values of F_Q as a function of axial offset for five plants from that report.

4.3.2.2.8 Testing

A very extensive series of physics tests is performed on first cores. These tests and the criteria for satisfactory results are described in detail in Chapter 14. Since not all limiting situations can be created at beginning of life, the main purpose of the tests is to provide a check on the calculational methods used in the predictions for the conditions of the test. Tests performed at the beginning of each reload cycle are limited to verification of the selected safety-related parameters of the reload design.

4.3.2.2.9 Monitoring Instrumentation

The adequacy of instrument numbers, spatial deployment, required correlations between readings and peaking factors, calibration and errors are described in Reference 2, 6 and 8. The relevant conclusions are summarized in Sections 4.3.2.2.7 and 4.4.5.

Provided the limitations given in Subparagraph 4.3.2.2.6 on rod insertion and flux imbalance are observed, the excore detector system provides adequate online monitoring of power distributions. Further details of specific limits on the observed rod positions and flux are given in the SQN Technical Specifications, with a discussion of their bases.

Limits for alarms, reactor trip, etc. are given in the Technical Specification. Descriptions of the systems provided are given in Section 7.7.

4.3.2.3 Reactivity Coefficients

The kinetic characteristics of the reactor core determine the response of the core to changing plant conditions or to operator adjustments made during normal operation, as well as the core response during abnormal or accidental transients. These kinetic characteristics are quantified in reactivity coefficients. The reactivity coefficients reflect the changes in the neutron multiplication due to varying plant conditions such as power, moderator or fuel temperatures, or less significantly due to a change in pressure or void conditions. Since reactivity coefficients change during the life of the core, ranges of coefficients are employed in transient analysis to determine the response of the plant throughout life. The results of such simulations and the reactivity coefficients used are presented in Chapter 15. The reactivity coefficients are calculated on a core wise basis by radial and axial diffusion theory methods. The effect of radial and axial power distribution on core average reactivity coefficients is implicit in those calculations and is not significant under normal operating conditions. For example, a skewed xenon distribution which results in changing axial off-set by 5 percent changes the moderator and Doppler temperature coefficients by less than 0.01 pcm/°F and 0.03 pcm/°F, respectively. An artificially skewed xenon distribution which results in changing the radial $F^N_{\Delta H}$ by 3 percent changes the moderator and Doppler temperature coefficients by less than 0.03 pcm/°F and

0.001 pcm/°F, respectively. The spatial effects are accentuated in some transient conditions, for example, in the postulated rupture of the main steam line and rupture of a rod cluster control assembly mechanism housing as described in Sections 15.4.2.1 and 15.4.6.

The analytical methods and calculational models used in calculating the reactivity coefficients are given in Subsection 4.3.3. These models have been confirmed through extensive testing of more than thirty cores similar to Sequoyah; results of these tests are discussed in Subsection 4.3.3.

Quantitative information for calculated reactivity coefficients, including fuel-Doppler coefficient, moderator coefficients (density, temperature, pressure, void) and power coefficient is given in the following sections.

4.3.2.3.1 Fuel Temperature (Doppler) Coefficient

The fuel temperature (Doppler) coefficient is defined as the change in reactivity per degree change in effective fuel temperature and is primarily a measure of the Doppler broadening of U-238 and Pu-240 resonance absorption peaks. Doppler broadening of other isotopes such as U-236, Np-237 etc. are also considered but their contributions to the Doppler effect is small. Lead test assemblies with fuel pellets made from highly enriched reprocessed uranium blended down with natural uranium have elevated U-236 concentrations, which are evaluated by the BAW-2328 Report of July 1998. An increase in fuel temperature increases the effective resonance absorption cross sections of the fuel and produces a corresponding reduction in reactivity.

The fuel temperature coefficient is calculated by performing two-group X-Y calculations using an updated version of the TURTLE code (Reference 9), the PALADON code (Reference 10), or the ANC code (Reference 31). The moderator temperature is held constant and the power level is varied. Spatial variation of fuel temperature is taken into account by calculating the effective fuel temperature as a function of power density as discussed in Paragraph 4.3.3.1.

A typical Doppler temperature coefficient is shown in Figure 4.3.2-27 as a function of the effective fuel temperature (at Beginning-of-life and End-of-Life conditions). The effective fuel temperature is lower than the volume averaged fuel temperature since the neutron flux distribution is non-uniform through the pellet and gives preferential weight to the surface temperature. The Doppler-only contribution to the power coefficient, defined later, is shown in Figure 4.3.2-28 as a function of relative core power. The integral of the differential curve on Figure 4.3.2-28 is the Doppler contribution to the power defect and is shown in Figure 4.3.2-29 as a function of relative power. The Doppler coefficient becomes more negative as a function of life as the Pu-240 content increases, thus increasing the Pu-240 resonance absorption but less negative as the fuel temperature changes with burnup as described in Paragraph 4.3.3.1. The upper and lower limits of Doppler coefficient used in accident analyses are given in Chapter 15.

4.3.2.3.2 Moderator Coefficients

The moderator coefficient is a measure of the change in reactivity due to a change in specific coolant parameters such as density, temperature, pressure or void. The coefficients so obtained are moderator density, temperature, pressure and void coefficients.

Moderator Density and Temperature Coefficients

The moderator temperature coefficient is defined as the change in reactivity per degree change in the moderator temperature. Generally, the effect of the changes in moderator density as well as the temperature are considered together. A decrease in moderator density means less moderation which results in a negative moderator temperature coefficient. An increase in coolant temperature, keeping the density constant, leads to a hardened neutron spectrum and results in an increase in resonance absorption in U-238, Pu-240 and other isotopes. The hardened spectrum also causes a decrease in the fission to capture ratio in U-235 and Pu-239. Both of these effects make the moderator temperature coefficient more negative. Since water density changes more rapidly with temperature as temperature increases, the moderator temperature coefficient becomes more negative with increasing temperature.

The soluble boron used in the reactor as a means of reactivity control also has an effect on moderator density coefficient since the soluble boron poison density as well as the water density is decreased when the coolant temperature rises. An increase in the soluble poison concentration introduces a positive component in the moderator coefficient. If the concentration of soluble poison is large enough, the net value of the coefficient may be positive. With the burnable poison rods present, however, the initial hot boron concentration is sufficiently low that the moderator temperature coefficient is negative at operating temperatures. The effect of control rods is to make the moderator coefficient more negative by reducing the required soluble boron concentration and by increasing the "leakage" of the core.

With burnup, the moderator coefficient becomes more negative primarily as a result of boric acid dilution but also to a significant extent from the effects of the buildup of plutonium and fission products.

The moderator coefficient is calculated for the various plant conditions discussed above by performing two-group X-Y calculations, varying the moderator temperature (and density) by about ± 5°F about each of the mean temperatures. The moderator coefficient is shown as a function of core temperature and boron concentration for a typical unrodded and rodded core in Figures 4.3.2-30 through 4.3.2-32. The temperature range covered is from cold (68°F) to about 600°F. The contribution due to Doppler coefficient (because of change in moderator temperature) has been subtracted from these results. Figure 4.3.2-33 shows the hot, full power moderator temperature coefficient plotted as a function of first cycle lifetime for the just critical boron concentration condition based on the design boron letdown condition.

The moderator coefficients presented here are calculated on a core wise basis, since they are used to describe the core behavior in normal and accident situations when the moderator temperature changes can be considered to affect the whole core.

Moderator Pressure Coefficient

The moderator pressure coefficient relates the change in moderator density, resulting from a reactor coolant pressure change, to the corresponding effect on neutron production. This coefficient is of much less significance in comparison with the moderator temperature coefficient. A change of 50 psi in pressure has approximately the same effect on reactivity (in magnitude but opposite in sign) as a half-degree change in moderator temperature. This

coefficient can be determined from the moderator temperature coefficient by relating change in pressure to the corresponding change in density. The moderator pressure coefficient is negative over a portion of the moderator temperature range at beginning of life (-0.004 pcm/psi, BOL) but is always positive at operating conditions and becomes more positive during life (+ 0.3 pcm/psi, EOL).

Moderator Void Coefficient

The moderator void coefficient relates the change in neutron multiplication to the presence of voids in the moderator. In a PWR this coefficient is not very significant because of the low void content in the coolant. The core void content is less than one-half of one percent and is due to local or statistical boiling. The void coefficient varies from 50 pcm/percent void at BOL and at low temperatures to -250 pcm/percent void at EOL and at operating temperatures. The negative void coefficient at operating temperature becomes more negative with fuel burnup.

4.3.2.3.3 Power Coefficient

The combined effect of moderator temperature and fuel temperature change as the core power level changes is called the total power coefficient and is expressed in terms of reactivity change per percent power change. The power coefficient at BOL and EOL conditions is given in Figure 4.3.2-34.

It becomes more negative with burnup, reflecting the combined effect of moderator and fuel temperature coefficients with burnup. The power defect (integral reactivity effect) at BOL and EOL is given in Figure 4.3.2-35.

4.3.2.3.4 Comparison of Calculated and Experimental Reactivity Coefficients

Subsection 4.3.3 describes the comparison of calculated and experimental reactivity coefficients in detail. Based on the data presented there, the accuracy of the current analytical model is:

± 0.2 percent $\Delta\rho$ for Doppler and power defect
± 2 pcm/°F for the moderator coefficient

Experimental evaluation of the calculated coefficients are done during the physics startup tests described in Chapter 14.

4.3.2.3.5 Reactivity Coefficients Used in Transient Analysis

Table 4.3.2-2 gives the representative ranges for the reactivity coefficients used in transient analysis. The exact values of the coefficient used in the analysis depend on whether the transient of interest is examined at the beginning or end of life, whether most negative or the most positive (least negative) coefficients are appropriate, and whether spatial nonuniformity must be considered in the analysis. Conservative values of coefficients, considering various aspects of analysis are used in the transient analysis. This is described in Chapter 15.

The values listed in Table 4.3.2-2 and illustrated in Figures 4.3.2-27 through 4.3.2-35 are typical best estimate values calculated for a first cycle. The coefficients appropriate for use in subsequent cycles depends on the core's operating history, the number and enrichment of fresh

fuel assemblies, the loading pattern of burned and fresh fuel, the number and location of any burnable absorbers, etc. The need for a reevaluation of any accident in a subsequent cycle is contingent upon whether or not the coefficients for that cycle fall within the identified range used in the analysis presented in Chapter 15. Control rod requirements are given in Table 4.3.2-3 for the core described and for a hypothetical equilibrium cycle since these are markedly different. These latter numbers are provided for information only since refueling specifications for subsequent cycles have not been established.

4.3.2.4 Control Requirements

To ensure the shutdown margin stated in the SQN Technical Specifications under conditions where a cooldown to ambient temperature is required, concentrated soluble boron is added to the coolant. Boron concentrations for several core conditions are listed in Table 4.3.2-2. For all core conditions, including refueling, the boron concentration is well below the solubility limit. The rod cluster control assemblies are employed to bring the reactor to the hot shutdown condition. The minimum required shutdown margin is given in the SQN Technical Specifications.

The ability to accomplish the shutdown for hot conditions is demonstrated in Table 4.3.2-3 comparing the difference between the Rod Cluster Control Assembly reactivity available with an allowance for the worst stuck rod with that required for control and protection purposes. The shutdown margin includes an allowance of 7 percent for analytic uncertainties (Reference 34). The largest reactivity control requirement appears at the end-of-life (EOL) when the moderator temperature coefficient reaches its peak negative value as reflected in the larger power defect.

The control rods are required to provide sufficient reactivity to account for the power defect from full power to zero power and to provide the required shutdown margin. The reactivity addition resulting from power reduction consists of contributions from Doppler, moderator temperature, flux redistribution, and reduction in void content, as discussed below.

4.3.2.4.1 Doppler

The Doppler effect arises from the broadening of U-238 and Pu-240 resonance peaks with an increase in effective pellet temperature. This effect is most noticeable over the range of zero power to full power due to the large pellet temperature increase with power generation.

4.3.2.4.2 Variable Average Moderator Temperature

When the core is shutdown to the hot zero power condition, the average moderator temperature changes from the equilibrium full load value determined by the steam generator and turbine characteristics (steam pressure, heat transfer, tube fouling, etc.) to the equilibrium no load value, which is based on the steam generator shell side design pressure. The design change in temperature is conservatively increased by 4°F to account for the control dead band and measurement errors.

Since the moderator coefficient is negative, there is a reactivity addition with power reduction. The moderator coefficient becomes more negative as the fuel depletes because the boron concentration is reduced. This effect is the major contributor to the increased requirement at end of life.

4.3.2.4.3 Redistribution

During full power operation, the coolant density decreases with core height, and this, together with partial insertion of control rods, results in less fuel depletion near the top of the core. Under steady state conditions, the relative power distribution will be slightly asymmetric towards the bottom of the core. On the other hand, at hot zero power conditions, the coolant density is uniform up the core, and there is no flattening due to Doppler. The result will be a flux distribution which at zero power can be skewed toward the top of the core. The reactivity insertion due to the skewed distribution is calculated with an allowance for the most adverse effects of xenon distribution.

4.3.2.4.4 Void Content

A small void content in the core is due to nucleate boiling at full power. The void collapse coincident with power reduction makes a small reactivity contribution.

4.3.2.4.5 Rod Insertion Allowance

At full power, the control bank is operated within a prescribed band of travel to compensate for small periodic changes in boron concentration, changes in temperature and very small changes in the xenon concentration not compensated for by a change in boron concentration. When the control bank reaches either limit of this band, a change in boron concentration is required to compensate for additional reactivity changes. Since the insertion limit is set by a rod travel limit, a conservatively high calculation of the inserted worth is made which exceeds the normally inserted reactivity.

4.3.2.4.6 Burnup

Excess reactivity of 10 percent $\Delta\rho$ to 25 percent $\Delta\rho$ (hot) is installed at the beginning of each cycle to provide sufficient reactivity to compensate for fuel depletion and fission products throughout the cycle. This reactivity is controlled by the addition of soluble boron to the coolant and by burnable poisons. The soluble boron concentration for several core configurations, the unit boron worth, and burnable absorber worth are given in Tables 4.3.2-1 and 4.3.2-2. Since the excess reactivity for burnup is controlled by soluble boron and/or burnable absorbers, it is not included in control rod requirements.

4.3.2.4.7 Xenon and Samarium Poisoning

Changes in xenon and samarium concentrations in the core occur at a sufficiently slow rate, even following rapid power level changes, that the resulting reactivity change is controlled by changing the soluble boron concentration.

4.3.2.4.8 pH Effects

Changes in reactivity due to a change in coolant pH, if any, are sufficiently small in magnitude and occur slowly enough to be controlled by the boron system. Further details are available in Reference 11.

4.3.2.5 Control

Core reactivity is controlled by means of a chemical poison dissolved in the coolant, Rod Cluster Control Assemblies, and burnable absorbers as described below.

4.3.2.5.1 Chemical Poison

Boron in solution as boric acid is used to control relatively slow reactivity changes associated with:

1. The moderator temperature defect in going from cold shutdown at ambient temperature to the hot operating temperature at zero power

2. The transient xenon and samarium poisoning, such as that following power changes or changes in Rod Cluster Control Assembly position

3. The excess reactivity required to compensate for the effects of fissile inventory depletion and buildup of long-life fission products

4. The burnable absorbers depletion

The boron concentrations for various core conditions are presented in Table 4.3.2-2.

4.3.2.5.2 Rod Cluster Control Assemblies

The number of Rod Cluster Control Assemblies is shown in Table 4.3.2-1. The Rod Cluster Control Assemblies are used for shutdown and control purposes to offset fast reactivity changes associated with:

1. The required shutdown margin in the hot zero power, stuck rod condition

2. The reactivity compensation as a result of an increase in power above hot zero power (power defect, including Doppler, and moderator reactivity changes)

3. Unprogrammed fluctuations in boron concentration, coolant temperatures, or xenon concentration (with rods not exceeding the allowable rod insertion limits)

4. Reactivity ramp rates resulting from load changes.

The allowed full length control bank reactivity insertion is limited at full power to maintain shutdown capability. As the power level is reduced, control rod reactivity requirements are also reduced and more rod insertion is allowed. The control bank position is monitored and the operator is notified by an alarm if the limit is approached. The determination of the insertion limit uses conservative xenon distributions and axial power shapes. In addition, the Rod Cluster Control Assembly withdrawal pattern determined from these analyses is used in determining power distribution factors and in determining the maximum worth of an inserted Rod Cluster Control Assembly ejection accident. For further discussion, refer to the Technical Specifications on Rod Insertion Limits.

Power distribution, Rod Ejection and Rod Misalignment analyses are based on the arrangement of the shutdown and control groups of the Rod Cluster Control Assemblies shown in Figure 4.3.2-36. All shutdown Rod Cluster Control Assemblies are withdrawn before withdrawal of the control banks is initiated. In going from zero to 100 percent power, control banks B, C and D are withdrawn sequentially. The limits of rod positions and further discussion on the basis for rod insertion limits are provided in the SQN Technical Specifications.

To accommodate the use of mixed oxide fuels in future reloads, four additional control rod drive mechanisms were included in the original design, identical to the other full length drive mechanisms, increasing the total number of full length drive mechanisms from 53 to 57. These additional drive mechanisms are located at postings E-5, E-11, L-5, and L-11. To provide additional shut down margin for a proposed tritium production core, rod cluster control assemblies were relocated to the four spare locations. The drive rod and rod cluster control assemblies were removed from the mechanisms located at positions D-2, P-4, B-12, and M-14.

Since no control rods are presently connected to the spare drive mechanisms there are no nuclear effects associated with these drives. For the spare guide tubes, a cover or plug on the top of each guide tube limits the flow past the upper support plate via the spare guide tubes.

4.3.2.5.3 Burnable Absorbers

The burnable absorbers provide partial control of the excess reactivity available during the cycle. In doing so, the absorbers prevent the moderator temperature coefficient from being positive at normal operating conditions. They perform this function by reducing the requirement for soluble poison in the moderator at the beginning of the first fuel cycle as previously described. The first cycle fixed burnable absorber rod pattern in the core together with the number of rods per assembly is shown in Figure 4.3.2-5, while the arrangements within an assembly are displayed in Figure 4.3.2-4. The reactivity worth of these rods is shown in Table 4.3.2-1. The boron in the rods is depleted with burnup but at a sufficiently slow rate so that the resulting critical concentration of the soluble boron is such that the moderator temperature coefficient remains negative at all times for power operating conditions.

4.3.2.5.4 Peak Xenon Startup

Compensation for the peak xenon buildup is accomplished using the boron control system. Startup from the peak xenon condition is accomplished with a combination of rod motion and boron dilution. The boron dilution may be made at any time, including during the shutdown period, provided the shutdown margin is maintained.

4.3.2.5.5 Load Follow Control and Xenon Control

During load follow maneuvers, power changes are accomplished using control rod motion and dilution or boration by the boron system as required. Control rod motion is limited by the control rod insertion

limits on full length rods as provided in the Technical Specifications and discussed in Subparagraphs 4.3.2.5.2. The power distribution is maintained within acceptable limits through the location of the full-length rod bank. Reactivity changes due to the changing xenon concentration can be controlled by rod motion and/or changes in the soluble boron concentration.

4.3.2.5.6 Burnup

Control of the excess reactivity for burnup is accomplished using soluble boron and/or burnable absorbers. The boron concentration must be limited during operating conditions to ensure that the moderator temperature coefficient is negative. Sufficient burnable absorbers are installed at the beginning of a cycle to give the desired cycle lifetime without exceeding the boron concentration limit. The practical minimum boron concentration is 10 ppm.

4.3.2.6 Control Rod Patterns And Reactivity Worth

The full length Rod Cluster Control Assemblies are designated by function as the control groups and the shutdown groups. The terms "group" and "bank" are used synonymously throughout this report to describe a particular grouping of control assemblies. The Rod Cluster Control Assembly Pattern is displayed in Figure 4.3.2-36 and was changed to provide additional shut down margin for a proposed tritium production core. The control banks are labeled A, B, C and D and the shutdown banks are labeled SA, SB, SC and SD. Each bank, although operated and controlled as a unit, is comprised of two sub-groups. The axial position of the Rod Cluster Control Assemblies may be manually or automatically controlled. The Rod Cluster Control Assemblies are all dropped into the core following actuation of reactor trip signals.

Two criteria have been employed for selection of the control groups. First the total reactivity worth must be adequate to meet the requirements specified in Table 4.3.2-3. Second, in view of the fact that these rods may be partially inserted at power operation, the total power peaking factor should be low enough to ensure that the power capability requirements are met. Analyses indicate that the first requirement can be met either by a single group or by two or more banks whose total worth equals at least the required amount. The axial power shape would be more peaked following movement of a single group of rods worth three to four percent $\Delta\rho$; therefore, four banks (described as A, B, C, and D in Figure 4.3.2-36) have been selected.

The position of control banks for criticality under any reactor condition is determined by the concentration of boron in the coolant. On an approach to criticality, boron is adjusted to ensure that criticality will be achieved with control rods above the insertion limit set by shutdown and other considerations (See the Technical Specifications). Early in the cycle there may also be a withdrawal limit at low power to maintain a negative moderator temperature coefficient. Usual practice is to adjust boron to ensure that the rod position lies within the so-called maneuvering band.

Ejected Rod worths are given in Subsection 15.4.6 for several different conditions.

Allowable deviations due to misaligned control rods are addressed in the SQN Technical Specifications.

A representative calculation for two banks of control rods simultaneously withdrawn (Rod Withdrawal accident) is given in Figure 4.3.2-37.

Calculation of control rod reactivity worth versus time following reactor trip involves both control rod velocity and differential reactivity worth. The rod position versus time of travel after rod release is given in Figure 4.3.2-38. For nuclear design purposes, the reactivity worth versus rod position is calculated by a series of steady-state calculations at various control and rod positions, assuming all rods out of the core as the initial position in order to minimize the initial reactivity insertion rate. To be conservative, the rod of the highest worth is assumed stuck out of the core, and the flux distribution (and thus reactivity importance) is assumed to be skewed to the bottom of the core. The results of the calculations is shown in Figure 4.3.2-39.

The shutdown groups provide additional negative reactivity to ensure an adequate shutdown margin. Shutdown margin is defined as the amount by which the core would be subcritical at hot shutdown if all rod cluster control assemblies are tripped, but assuming that the highest worth assembly remains fully withdrawn and no changes in xenon or boron take place. The loss of control rod worth due to the material irradiation is negligible, since only bank D may be in the core under normal operating conditions (near full power).

The values given in Table 4.3.2-3 show that the available reactivity in withdrawn rod cluster control assemblies provides the design bases minimum shutdown margin, allowing for the highest worth cluster to be at its fully withdrawn position. An allowance for the uncertainty in the calculated worth of N-1 rods is made before determination of the shutdown margin.

4.3.2.7 Criticality of Fuel Assemblies

Criticality of fuel assemblies outside of the reactor is precluded by adequate design of fuel transfer and fuel storage facilities and by administrative controls. This section identifies those criteria important to criticality safety analyses.

New Fuel Storage

New fuel is normally stored dry in the new fuel storage vault. The infinite array reactivity of the new fuel racks was calculated (Reference 33) by using the AMPX system of codes for cross-section generation and KENO-IV for reactivity determination. The fuel is assumed to be fresh and unirradiated with an enrichment of 5.0 weight percent of U-235 for standard fuel. This analysis is still valid for the VANTAGE 5H (V5H) fuel, since the design differences between standard and V5H fuel do not affect this analysis. Similarly, other fuel designs would be acceptable if design differences are small. Mechanical uncertainties and biases due to mechanical tolerances during construction were treated by using either the "worst case" conditions or by performing sensitivity studies to determine their effort.

The calculation method and cross-section values were verified by comparison with a set of critical experiments analyzed by the same method. This benchmarking data was sufficiently diverse to establish that the method bias and uncertainty will apply to rack conditions which include strong neutron absorbers, large water gaps, low moderator densities, and dry storage.

The results of these experiments yielded a method bias of 0.0083 Δk. The most conservative k_{eff} under normal conditions was calculated using full density water as 0.9416, meeting the criticality criteria to maintain k_{eff} at or below 0.95. This k_{eff} included the method bias and 95/95 uncertainties in the method bias and the maximum k_{eff}. In addition, this most conservative case combined the effects of worst-case mechanical tolerances, material thickness tolerances, and conservatively accounting for enrichment variability (with enrichment assumed to be 5.05 wt%).

A low density, optimum moderation case has been determined to be the worst-case accident scenario for these new fuel storage racks. The model used in the full density case was used to model the low density case. A water density of 0.060 gm/cm3 was also used in this analysis. The result was a k_{eff} of 0.9660, including all biases and uncertainties, meeting the criticality criteria for accident conditions to maintain k_{eff} at or below 0.98.

For other accident conditions, the double contingency principle of ANSI N16.1-1975 is applied. In applying this principle, one is not required to assume two independent, unlikely, concurrent events to preclude criticality. For all other accident conditions, the absence of a moderator in the new fuel storage racks is a realistic initial condition.

Thus, for normal operations, using the method described above including all the biases and uncertainties mentioned, the k_{eff} of the new fuel storage racks is determined to be <0.95. This meets the criteria stated in Section 4.3.1.5.

<u>Spent Fuel Storage - Wet</u>

Each storage cell has an internal envelope dimension of 8.75-inches square with 0.060-inch thick stainless steel walls. A single Boral absorber panel is positioned between the walls of adjacent cells within the modules.

Peripheral cells with a 0.0235-inch stainless steel sheathing on the outside supporting the Boral panel. The fuel storage cells are located on a nominal lattice spacing of 8.97 ± 0.04 inches. The Boral absorber has a thickness of 0.102 ± 0.005 inch and a nominal B-10 areal density of 0.0324 g/cm^2 (0.030 g B-10/cm^2 minimum). The design basis fuel assembly is a 17 x 17 Westinghouse Vantage-5H assembly containing UO_2 at a maximum initial enrichment of 4.95 ± 0.05 wt% U-235 by weight. (If fuel assemblies with natural UO_2 blankets are used, the design basis enrichment is that of the central enriched zone.)

The spent fuel racks have been analyzed in accordance with the Holtec International methodology contained in Holtec Report HI - 992349 (Ref. 38). This methodology ensures that the spent fuel rack multiplication factor, k_{eff} is less than or equal to 0.95, as recommended by the NRC guidance contained in NRC Letter to All Power Reactor Licensees from B.K. Grimes, "OT Position for Review and Acceptance of Spent Fuel Storage and Handling Applications," April 14, 1978 and USNRC Internal Memorandum from L. Kopp, "Guidance On The Regulatory Requirements For Criticality Analysis Of Fuel Storage At Light-Water Reactor Power Plants," August 19, 1998 (Refs. 39 & 40). The codes, methods, and techniques contained in the methodology are used to satisfy the k_{eff} criterion. The spent fuel storage racks are analyzed to allow storage of Westinghouse 17 X 17 V5H fuel assemblies and other fuel assemblies, with enrichments up to 4.95%±0.05% w/o U-235 utilizing credit for checkerboard configurations, burnup, integral fuel burnable absorbers, gadolinia absorbers, cooling time, and soluble boron, to ensure that k_{eff} is maintained ≤ 0.95, including uncertainties, tolerances, and accident

conditions. In addition, the spent fuel pool k_{eff} is maintained < 1.0 including uncertainties and tolerances on a 95/95 basis without any soluble boron. Calculations have been performed to evaluate the reactivity of fuel used at SQN. The results show that Westinghouse 17 X 17 exhibits higher reactivity, thereby bounding all fuel utilized and stored in the spent fuel pool at SQN.

In the high density Spent Fuel Storage Rack design (Refs. 38 and 41), the spent fuel storage pool is divided into three separate and distinct regions which, for the purpose of criticality considerations, are considered as separate pools. Region 1 is designed to accommodate new fuel with a maximum enrichment of 4.95 $\pm$ 0.05 wt% U-235, or spent fuel regardless of the discharge fuel burnup in a 1-in-4 checkerboard arrangement of 1 fresh assembly with 3 spent fuel assemblies with specified enrichment, burnup and cooling times. Region 2 is designed to accommodate fuel which have 4.95 $\pm$ 0.05 wt% initial enrichment burned to at least 30.27 MWD/KgU (assembly average), or fuel of other enrichment with a burnup yielding an equivalent reactivity in the fuel racks. Region 3 is designed to accommodate fuel of 4.95 $\pm$ 0.05 wt% initial enrichment or fuel assemblies of any lower reactivity in a 2-out-of-4 checkerboard arrangement with water-filled cells.

The water in the spent fuel storage pool normally contains soluble boron, which results in large subcriticality margins under actual operating conditions. However, the NRC guidelines, based upon the accident condition in which all soluble poison is assumed to have been lost, specify that the limiting k_{eff} of < 1.0 be evaluated in the absence of soluble boron. Hence, the design of all regions is based on the use of unborated water, which maintains each region in a subcritical condition during normal operation with the regions fully loaded. The double contingency principle discussed in ANSI N-16.1-1975 (Ref. 42) and the April 1978 NRC letter allows credit for soluble boron under other abnormal or accident conditions, since only a single accident need be considered at one time. For example, the most severe accident scenario is associated with the accidental mishandling of a fresh fuel assembly face adjacent to a fresh fuel assembly of Region 3. This could potentially increase the criticality of Region 3. To mitigate these postulated criticality related accidents, boron is dissolved in the pool water. The soluble boron concentration required to maintain $k_{eff} \leq 0.95$ under normal conditions is 300 ppm and 700 ppm under the most severe postulated fuel mis-location accident. Safe operation of the spent fuel storage racks may therefore be achieved by controlling the location of each assembly in accordance with Technical Specifications. During fuel movement boron concentration is periodically verified to be within limit.

Most accident conditions do not result in an increase in the reactivity of any one of the three regions. Examples of these accident conditions are the loss of cooling and the dropping of a fuel assembly on the top of the rack. However, accidents can be postulated that could increase the reactivity. This increase in reactivity is unacceptable with unborated water in the storage pool. Thus, for these accident occurrences, the presence of soluble boron in the storage pool prevents criticality in all regions. The most limiting postulated accident with respect to the storage configurations assumed in the spent fuel rack criticality analysis is the misplacement of a nominal 4.95$\pm$0.05 wt% U-235 fuel assembly into an empty storage cell location in the Region 3 checkerboard storage arrangement. The amount of soluble boron required to maintain k_{eff} less than or equal to 0.95 due to this fuel misload accident is 700 ppm (Ref. 38).

A spent fuel boron dilution analysis was performed to ensure that sufficient time is available to detect and mitigate dilution of the spent fuel pool prior to exceeding the k_{eff} design basis limit of 0.95 (Ref. 43). The spent fuel pool boron dilution analysis concluded that an inadvertent or unplanned event that would result in a dilution of the spent fuel pool boron concentration from 2000 ppm to 700 ppm is not a credible event.

The concentration of dissolved boron in the spent fuel storage pool satisfies Criterion 2 of the NRC Policy Statement.

The spent fuel storage pool boron concentration is required to be $\geq$ 2000 ppm. The specified concentration of dissolved boron in the spent fuel storage pool preserves the assumptions used in the analyses of the potential critical accident scenarios as described in Reference 44. This concentration of dissolved boron is the minimum required concentration for fuel assembly storage and movement within the spent fuel storage pool.

4.3.2.8 Stability

4.3.2.8.1 Introduction

The stability of the PWR cores against xenon-induced spatial oscillations and the control of such transients are discussed extensively in References 6, 12, 13 and 14. A summary of these reports is given in the following discussion, and the design bases are given in Paragraph 4.3.1.6.

In a large reactor core, xenon-induced oscillations can take place with no corresponding change in the total power of the core. The oscillation may be caused by a power shift in the core which rapidly occurs by comparison with the xenon-iodine time constants. Such a power shift occurs in the axial direction when a plant load change is made by control rod motion and results in a change in the moderator density and fuel temperature distributions. Such a power shift could occur in the diametral plane of the core as a result of abnormal control action.

Due to the negative power coefficient of reactivity, PWR cores are inherently stable to oscillations in total power. Protection against total power instabilities is provided by the Control and Protection System as described in Section 7.7. Hence, the discussion on the core stability is limited here to xenon-induced spatial oscillations.

4.3.2.8.2 Stability Index

Power distributions, either in the axial direction or in the X-Y plane, can undergo oscillations due to perturbations introduced in the equilibrium distributions without changing the total core power. The xenon-induced oscillations are essentially limited to the first flux overtones in the current PWR's, and the stability of the core against xenon-induced oscillations can be determined in terms of the eigenvalues of the first flux overtones. Writing the eigenvalue ζ of the first flux harmonic as

$$\zeta = b + ic, \qquad (4.3\text{-}1)$$

then b is defined as the stability index and T = 2 π/c as the oscillation period of the first harmonic. The time-dependence of the first harmonic $\delta\Phi$ in the power distribution can now be represented as

$$\delta\Phi(t) = A\, e^{\zeta t} = a e^{bt} \cos ct. \qquad (4.3\text{-}2)$$

where A and a are constants. The stability index can also be obtained approximately by:

$$b = \frac{1}{T} \, 1n \, \frac{A_{n+1}}{A_n} \qquad (4.3 - 3)$$

where A_n, A_n+1 are the successive peak amplitudes of the oscillation and T is the time period between the successive peaks.

4.3.2.8.3 Prediction Of The Core Stability

The stability of the core described herein (i.e., with 17 x 17 fuel assemblies) against xenon-induced spatial oscillations is expected to be equal to or better than that of earlier designs. The prediction is based on a comparison of the parameters which are significant in determining the stability of the core against the xenon-induced oscillations, namely (1) the overall core size is unchanged and spatial power distributions will be similar, (2) the moderator temperature coefficient is expected to be similar to or slightly more negative, and (3) the Doppler coefficient of reactivity is expected to be equal to or slightly more negative at full power.

Analysis of both the axial and X-Y xenon transient tests, discussed in Subparagraph 4.3.2.8.5, shows that the calculational model is adequate for the prediction of core stability.

4.3.2.8.4 Stability Measurements

1. Axial Measurements

   Two axial xenon transient tests conducted in a PWR with a core height of 12 feet and 121 fuel assemblies is reported in Reference 15, and are briefly discussed here. The tests were performed at approximately 10 percent and 50 percent of cycle life.

   Both a free-running oscillation test and a controlled test were performed during the first test. The second test at mid-cycle consisted of a free-running oscillation test only. In each of the free-running oscillation tests, a perturbation was introduced to the equilibrium power distribution through an impulse motion of the Control Bank D and the subsequent oscillation was monitored to measure the stability index and the oscillation period. In the controlled test conducted early in the cycle, the part-length (P/L) rods were used to follow the oscillations to maintain an axial off-set (AO) within the prescribed limits. The AO of power was obtained from the excore ion chamber readings (which had been calibrated against the incore flux maps) as a function of time for both free-running tests as shown in Figure 4.3.2-41.

   The total core power was maintained constant during these spatial xenon tests, and the stability index and the oscillation period were obtained from a least-square fit of the AO data in the form of Equation (4.3-2). The AO of power is the quantity that properly represents the axial stability in the sense that it essentially eliminates any contribution from even order harmonics including the fundamental mode. The conclusions of the tests are:

   a. The core was stable against induced axial xenon transients both at the core average burnups of 1550 MWD/MTU and 7700 MWD/MTU. The measured stability indices are -0.041 hr^{-1} for the first test (Curve 1 of Figure 4.3.2-41) and -0.014 hr^{-1} for the second test (Curve 2 of Figure 4.3.2-41). The corresponding oscillation periods are 32.4 hrs. and 27.2 hrs., respectively.

b. The reactor core becomes less stable as fuel burnup progresses and the axial stability index was essentially zero at 12,000 MWD/MTU.

2. Measurements in the X-Y Plane

Two X-Y xenon oscillation tests were performed at a PWR plant with a core height of 12 feet and 157 fuel assemblies. The first test was conducted at a core average burnup of 1540 MWD/MTU and the second at a core average burnup of 12,900 MWD/MTU. Both of the X-Y xenon tests show that the core was stable in the X-Y plane at both burnups. The second test shows that the core became more stable as the fuel burnup increased and all Westinghouse PWR's with 121 and 157 assemblies are expected to be stable throughout their burnup cycles. The results of these tests are applicable to the 193 assembly SQN cores as discussed in Section 4.3.2.8.3.

In each of the two X-Y tests, a perturbation was introduced to the equilibrium power distribution through an impulse motion of one RCC unit located along the diagonal axis. Following the perturbation, the uncontrolled oscillation was monitored using the moveable detector and thermocouple system and the excore power range detectors. The quadrant tilt difference (QTD) is the quantity that properly represents the diametral oscillation in the X-Y plane of the reactor core in that the differences of the quadrant average powers over two symmetrically opposite quadrants essentially eliminates the contribution to the oscillation from the azimuthal mode. The QTD data were fitted in the form of Equation (4.3-2) through a least-square method. A stability index of -0.076 hr^{-1} with a period of 29.6 hours was obtained from the thermocouple data shown in Figure 4.3.2-42.

It was observed in the second X-Y xenon test that the PWR core with 157 fuel assemblies had become more stable due to an increased fuel depletion and the stability index was not determined.

4.3.2.8.5 <u>Comparison of Calculations With Measurements</u>

The analysis of the axial xenon transient tests was performed in an axial slab geometry using a flux synthesis technique. The direct simulation of the AO data was carried out using the PANDA (Reference 16) code. The analysis of the X-Y xenon transient tests was performed in an X-Y geometry using a modified TURTLE (Reference 9) code. Both the PANDA and TURTLE codes solve the two-group time-dependent neutron diffusion equation with time-dependent xenon and iodine concentrations. The fuel temperature and moderator density feedback is limited to a steady-state model. All the X-Y calculations were performed in an average enthalpy plane.

The basic nuclear cross-sections used in this study were generated from a unit cell depletion program which has evolved from the codes LEOPARD (Reference 17) and CINDER (Reference 18). The detailed experimental data during the tests including the reactor power level, enthalpy rise and the impulse motion of the control rod assembly, as well as the plant follow burnup data were closely simulated in the study.

The results of the stability calculation for the axial tests are compared with the experimental data in Table 4.3.2-4. The calculations show conservative results for both of the axial tests with a margin of approximately -0.01 hr^{-1} in the stability index.

An analytical simulation of the first X-Y xenon oscillation test shows a calculated stability index of -0.081 hr^{-1}, in good agreement with the measured value of -0.076 hr^{-1}. As indicated earlier, the second X-Y xenon test showed that the core had become more stable compared to the first test and no evaluation of the stability index was attempted. This increase in the core stability in the X-Y plane due to increased fuel burnup is due mainly to the increased magnitude of the negative moderator temperature coefficient.

Previous studies of the physics of xenon oscillations, including three-dimensional analysis, are reported in the series of topical reports, References 12, 13 and 14. A more detailed description of the experimental results and analysis of the axial and X-Y xenon transient tests is presented in Reference 15 and Section 1 of Reference 19.

4.3.2.8.6 Stability Control and Protection

The excore detector system is utilized to provide indications of xenon-induced spatial oscillations. The readings from the excore detectors are available to the operator and also form part of the protection system.

1. Axial Power Distribution

   For maintenance of proper axial power distributions, the operator is instructed to maintain an axial offset within a prescribed operating band, based on the excore detector readings. Should the axial off-set be permitted to move far enough outside this band, the protection limit will be reached and the power will be automatically reduced.

   Twelve-foot pressurized water reactor cores become less stable to axial xenon oscillations as fuel burnup progresses. However, free xenon oscillations are not allowed to occur, except for special tests. The full-length control rod banks are sufficient to dampen and control any axial xenon oscillations present. Should the axial offset be inadvertently permitted to move far enough outside the control band due to an axial xenon oscillation, or any other reason, the protection limit on axial offset will be reached and the power will be automatically reduced.

2. Radial Power Distribution

   The core described herein is calculated to be stable against X-Y xenon induced oscillations at all times in life.

   The X-Y stability of large PWR's has been further verified as part of the startup physics test program for PWR cores with 193 fuel assemblies. The measured X-Y stability of the PWR cores with 157 and 193 assemblies was in good agreement with the calculated stability, as discussed in Subparagraphs 4.3.2.8.4 and 4.3.2.8.5. In the unlikely event that X-Y oscillations occur, back-up actions are possible and would be implemented, if necessary, to increase the natural stability of the core. This is based on the fact that several actions could be taken to make the moderator temperature coefficient more negative, which will increase the stability of the core in the X-Y plane.

Provisions for protection against non-symmetric perturbations in the X-Y power distribution that could result from equipment malfunctions are made in the protection system design. This includes control rod drop, rod misalignment and asymmetric loss of coolant flow.

A more detailed discussion of the power distribution control in PWR cores is presented in Reference 6 and 7.

4.3.2.9 Vessel Irradiation

A brief review of the methods and analyses used in determination of neutron and gamma flux attenuation between the core and the pressure vessel is given below. A more complete discussion on the pressure vessel irradiation and surveillance program is given in Paragraph 5.4.3.7.

The materials that serve to attenuate neutrons originating in the core and gamma rays from both the core and structural components consist of the core baffle, core barrel, neutron panels, and associated water annuli, all of which are within the region between the core and the pressure vessel.

In general, few group neutron diffusion theory codes are used to determine flux and fission power density distributions within the active core and the accuracy of these analyses is verified by in-core measurements on operating reactors. Region and rod-wise power sharing information from the core calculations is then used as source information in two-dimensional S_n transport calculations which compute the flux distributions throughout the reactor.

The neutron flux distribution and spectrum in the various structural components vary significantly from the core to the pressure vessel. Representative values of the neutron flux distribution and spectrum are presented in Table 4.3.2-5. The values listed are based on time-averaged equilibrium cycle reactor core parameters and power distributions, and thus, are suitable for long term nvt projections and for correlation with radiation damage estimates.

As discussed in Paragraph 5.4.3.7, the irradiation surveillance program utilizes actual test samples to verify the accuracy of the calculated fluxes at the vessel.

4.3.3 Analytical Methods

Calculations required in nuclear design consist of three distinct types, which are performed in sequence:

1. determination of effective fuel temperatures
2. generation of macroscopic few-group parameters
3. space-dependent, few-group diffusion calculations

These calculations are carried out by computer codes which can be executed individually. However, at Westinghouse most of the codes required have been linked to form a automated design sequence which minimizes design time, avoids errors in transcription of data, and standardizes the design methods.

4.3.3.1 Fuel Temperature (Doppler) Calculations

Temperatures radially vary within the fuel rod, depending on the heat generation rate in the pellet, the conductivity of the materials in the pellet, gap, and clad, and the temperature of the coolant.

The fuel temperatures for use in most nuclear design Doppler calculations are obtained from a simplified version of the Westinghouse fuel rod design model described in Subparagraph 4.2.1.3.1 which considers the effect of radial variation of pellet conductivity, expansion-coefficient and heat generation rate, elastic deflection of the clad, and a gap conductance which depends on the initial fill gas, the hot open gap dimension, and the fraction of the pellet over which the gap is closed and the evolution of helium gas from the IFBA, if present. The fraction of the gap assumed closed represents an empirical adjustment used to produce good agreement with observed reactivity data at BOL. Further gap closure occurs with burnup and accounts for the decrease in Doppler defect with burnup which has been observed in operating plants.

For detailed calculations of the Doppler coefficient, such as for use in xenon stability calculations, a more sophisticated temperature model is used which accounts for the effects of fuel swelling, fission gas release, and plastic clad deformation.

Radial power distributions in the pellet as a function of burnup are obtained from LASER (Reference 20) calculations.

The effective U-238 temperature for resonance absorption is obtained from the radial temperature distribution by applying a radially dependent weighting function. The weighting function was determined from REPAD (Reference 21) Monte Carlo calculations of resonance escape probabilities in several steady state and transient temperature distributions. In each case a flat pellet temperature was determined which produced the same resonance escape probability as the actual distribution. The weighting function was empirically determined from these results.

The effective Pu-240 temperature for resonance absorption is determined by a convolution of the radial distribution of Pu-240 number densities from LASER burnup calculations and the radial weighting function. The resulting temperature is burnup dependent, but the difference between U-238 and Pu-240 temperatures, in terms of reactivity effects, is small.

The effective pellet temperature for pellet dimensional change is that value which produces the same outer pellet radius in a virgin pellet as that obtained from the temperature model. The effective clad temperature for dimensional change is its average value.

The temperature calculational model has been validated by plant Doppler defect data as shown in Table 4.3.2-6 and Doppler coefficient data as shown in Figure 4.3.2-43. Stability index measurements also provide a sensitive measure of the Doppler coefficient near full power (See Paragraph 4.3.2.8). It can be seen that Doppler defect data is typically within 0.2 percent $\Delta\rho$ of prediction.

4.3.3.2 Macroscopic Group Constants

Macroscopic few-group constants and consistent microscopic cross sections (needed for feedback and microscopic depletion calculations) are generated for fuel cells by ARK or PHOENIX-P.

ARK (Reference 22) is a point model cell-homogenization, neutron spectrum, isotopic depletion program which evolved from the codes LEOPARD (Reference 17) and CINDER (Reference 18). Normally a simplified approximation of the main fuel chains is used; however, where needed, a complete solution for significant isotopes in the fuel chains, from Th-232 to Cm-244, is available (Reference 23). Microscopic fast and thermal cross section data are taken for the most part from the ENDF/B library (Reference 24) with a few exceptions where other data provide better agreement with experimental data. Group constants for control rods are calculated in a linked version of the HAMMER (Reference 25) and AIM (Reference 26) codes to provide an improved treatment of self shielding in the broad resonance structure of these isotopes at epithermal energies relative to that available in LEOPARD. Until the advent of PHOENIX-P, ARK was the basis for all reactivity calculations, depletion rates, and reactivity feedback models.

Validation of the cross section method is based on analysis of critical experiments as shown in Table 4.3.2-7, isotopic data as shown in Table 4.3.2-8, plant critical boron (C_B) values at HZP, BOL, as shown in Table 4.3.2-9 and at HFP as a function of burnup as shown in Figures 4.3.2-44 through 4.3.2-46. Control rod worth measurements are shown in Table 4.3.2-10.

Confirmatory critical experiments on burnable absorbers are described in Reference 27.

PHOENIX (Reference 35) is a two-dimensional, multigroup neutron transport theory code for calculating lattice physics parameters for LWR core modeling. PHOENIX-P is an adaptation of PHOENIX for PWR lattice physics analyses. Its cross section library was established from the CSRL-V 227 group ENDF/B-V (Reference 36) cross section library. Geometric capabilities include the ability to model different types of pin cell and assembly configurations present in Westinghouse PWRs. It includes the capability for cell lattice modeling on an assembly level. It provides homogenized, two-group cross sections for nodal calculations and feedback models. It is also used in a special geometry to generate appropriately weighted constants for the baffle/reflector regions. Validation of PHOENIX-P is discussed in Reference 37.

4.3.3.3 Spatial Few-Group Diffusion Calculations

Spatial few-group diffusion calculations primarily consist of two-group X-Y calculations using an updated version of the TURTLE code, two group X-Y nodal calculations using PALADON or ANC, two-group axial calculations using APOLLO, an advanced version of the PANDA code, and three dimensional calculations using THURTLE (Reference 28), a three-dimensional version of TURTLE, PALADON, or ANC.

Discrete X-Y calculations (1 mesh per cell) or nodal calculations are performed to determine critical boron concentrations and power distributions in the X-Y plane. An axial average in the X-Y plane is obtained by synthesis from unrodded and rodded planes or by three dimensional nodal calculations. The moderator temperature coefficient is evaluated by varying the inlet temperature in the same X-Y calculations used for power distribution and reactivity predictions.

Validation of TURTLE and THURTLE reactivity calculations is associated with the validation of the group constants themselves, as discussed in Paragraph 4.3.3.2. Validation of the Doppler calculations is associated with the fuel temperature validation discussed in Paragraph 4.3.3.1. Validation of the moderator coefficient calculations is obtained by comparison with plant measurements at hot zero power conditions as shown in Table 4.3.2-11.

THURTLE is primarily used in evaluating three-dimensional effects such as xenon redistribution. In addition, THURTLE is used to validate one- and two-dimensional results from APOLLO and TURTLE.

PALADON is used in two-dimensional and three-dimensional performance of safety analysis calculations, critical boron concentrations, control rod worths, reactivity coefficients, etc. PALADON calculations are normalized to TURTLE results whenever necessary.

ANC is used in two-dimensional and three-dimensional performance of safety analysis calculations, critical boron concentrations, X-Y power and burnup distributions, control rod worths, reactivity coefficients, etc. Validation of ANC results is discussed in reference 31.

APOLLO utilizes the burnup-dependent macroscopic cross sections generated by ARK or PHOENIX-P. The cross sections are collapsed from three-dimensional calculations using power volume weighting. The APOLLO model is used as an axial model. APOLLO is utilized to determine differential rod worths, axial power shapes during steady state and transient xenon conditions, burnup distributions, and control rod operational limits, etc.

Validation of the spatial codes for calculating power distributions involves the use of incore and excore detectors and is discussed in Subparagraph 4.3.2.2.7.

Based on comparison with measured data it is estimated that the accuracy of current analytical methods is:

± 0.2 percent $\Delta\rho$ for Doppler defect

± 2 x 10^{-5} $\Delta\rho$/°F for moderator coefficient

± 50 ppm for critical boron concentration with depletion

± 3 percent for power distributions

± 0.2 percent $\Delta\rho$ for rod bank worth

± 4 pcm/step for differential rod worth

± 0.5 pcm/ppm for boron worth

± 0.1 percent $\Delta\rho$ for moderator defect

Diameter of Instrument Guide Thimbles, in.	0.450 I.D. x 0.4820 O.D.
Burnable Absorber Rods	
Number	1400
Material	Borosilicate Glass
Outside Diameter, in.	0.381
Inner Tube, O.D., in.	0.1815
Clad Material	Stainless Steel
Inner Tube Material	Stainless Steel
Boron Loading (w/o B_2O_3 in glass rod)	12.5
Weight of Boron-10 per foot of rod, lb/ft	.000419
Initial Reactivity Worth, %$\Delta\rho$	7.63 (hot), ~5.5 (cold) 7.4 (hot, 1167 ppm) 4.1 (cold, 2000 ppm) 6.7 (cold, 0 ppm)
Excess Reactivity	
Maximum Fuel Assembly K (Cold, Clean, Unborated Water)	1.39
Maximum Core Reactivity (Cold, Zero Power, Beginning of Cycle)	1.222

TABLE 4.3.2-1 (Sheet 2)

REACTOR CORE DESCRIPTION
(First Cycle)

Fuel Rods	
Number	50,952
Outside Diameter, in.	0.374
Diameter Gap, in.	0.0065
Clad Thickness, in.	0.0225
Clad Material	Zircaloy-4
Fuel Pellets	
Material	UO_2 Sintered
Density (percent of Theoretical)	95
Fuel Enrichments w/o	
Region 1	2.10
Region 2	2.60
Region 3	3.10
Diameter, in.	0.3225
Length, in.	0.530
Mass of UO_2 per Foot of Fuel Rod, lb/ft	0.364
Rod Cluster Control Assemblies	
Neutron Absorber	Ag-In-Cd
Composition	80%, 15%, 5%
Diameter, in.	0.341
Density, lbs/in.^{3}	0.367
Cladding Material	Type 304, Cold Worked Stainless Steel
Clad Thickness, in.	0.0185
Number of Clusters, Full length	53
Number of Absorber Rods per Cluster	24
Full Length Assembly Weight (dry), lb.	147.0

TABLE 4.3.2-2

NUCLEAR DESIGN PARAMETERS
(First Cycle)

Core Average Linear Power, kw/ft, including densification effects	5.44
Total Heat Flux Hot Channel Factor, F_Q	2.237
Nuclear Enthalpy Rise Hot Channel Factor, $F^N_{\Delta H}$	1.55
Reactivity Coefficients	
Doppler Coefficient:	See Figures 4.3.2-27 and 4.3.2-28
Moderator Temperature Coefficient at Operating Conditions, pcm/°F[(a)]	0 to -40.0
Boron Coefficient in Primary Coolant, pcm/ppm[(a)]	-16 to -8
Rodded Moderator Density Coefficient at Operating Conditions, Δk/gm/cc	$\leq$ +0.43
Delayed Neutron Fraction and Lifetime	
β_{eff} BOL, (EOL)	0.0075, (0.0044)
ℓ^* , BOL, (EOL), μ sec	19.4 (18.1)
Control Rod Worths	
Rod Requirements	See Table 4.3.2-3
Maximum Bank Worth, pcm	< 2000
Maximum Ejected Rod Worth	See Chapter 15
Boron Concentrations (Beginning of Cycle	
Refueling	2000
k_{eff} = 0.95, Cold, Rod Cluster Control Assemblies In	1333
Zero Power, K_{eff} = 0.99, Cold, Rod Cluster Control Assemblies Out	1458
Zero Power, k_{eff} = 0.99, Hot, Rod Cluster Control Assemblies Out	1356
Full Power, No Xenon, k_{eff} = 1.0, Hot Rod Cluster Control Assemblies Out	1154
Full Power, Equilibrium Xenon, k_{eff} = 1.0, Hot, Rod Cluster Control Assemblies Out	869
Reduction With Fuel Burnup	
First Cycle, ppm/GWD/MTU[(b)]	See Figure 4.3.2-3
Reload Cycle, ppm/GWD/MTU	~100

(a) Note: 1 pcm = (percent mille) 10^{-5} $\Delta\rho$ where $\Delta\rho$ is calculated from two statepoint values of k_{eff} by 1n (k_2/k_1).

(b) Gigawatt Day (GWD) = 1000 Megawatt Day (1000 MWD). During the first cycle, the fixed burnable absorbers significantly reduce the boron depletion rate compared to reload cycles. The values quoted are representative of averages only.

TABLE 4.3.2-3

REACTIVITY REQUIREMENTS FOR ROD CLUSTER CONTROL ASSEMBLIES

Reactivity Effects, percent $\Delta\rho$	End of Life Typical Cycle
1. Control requirements	
Fuel temperature (Doppler), %$\Delta\rho$	1.10
Moderator temperature, %$\Delta\rho$	1.03
Void, %$\Delta\rho$	0.05
Redistribution, %$\Delta\rho$	0.95
Rod Insertion Allowance, %$\Delta\rho$	0.58
2. Total Control, %$\Delta\rho$	3.71
3. Estimated Rod Cluster Control Assembly Worth (53 Rods)*	
a. All full length assemblies inserted, %$\Delta\rho$	7.17
b. All but one (highest worth) assemblies inserted, %$\Delta\rho$	6.25
4. Estimated Rod Cluster Control Assembly credit with 7 percent adjustment to accommodate uncertainties (3b - 7 percent), %$\Delta\rho$	5.81
5. Shutdown margin available (4-2), %$\Delta\rho$	2.10[a]

[a] The design basis minimum shutdown is 1.6%.

*Unit 1 is permitted to operate with 52 control rod assemblies (with no control rod assembly installed in core location H-8) during U1C24 and U1C25.

*Unit 2 is permitted to operate with 52 Control Rod Assemblies (with no Control Rod Assembly installed in core location H-8) during Unit 2 Cycle 24 (U2C24) and U2C25.

4.4 THERMAL AND HYDRAULIC DESIGN

4.4.1 Design Bases

The overall objective of the thermal and hydraulic design of the reactor core is to provide adequate heat transfer which is compatible with the heat generation distribution in the core such that heat removal by the Reactor Coolant System or the Emergency Core Cooling System (when applicable) assures that the following performance and safety criteria requirements are met:

1. Fuel damage (fuel damage as used here is defined as penetration of the fission product barrier: the fuel rod clad) is not expected during normal operation and operational transients (Condition I) or any transient conditions arising from faults of moderate frequency (Condition II). It is not possible, however, to preclude a very small number of rod failures. These will be within the capability of the plant cleanup system and are consistent with the plant design bases.

2. The reactor can be brought to a safe state following a Condition III event with only a small fraction of fuel rods damaged[1] although sufficient fuel damage might occur to preclude resumption of operation without considerable outage time.

3. The reactor can be brought to a safe state and the core can be kept subcritical with acceptable heat transfer geometry following transients arising from Condition IV events.

In order to satisfy the above criteria the following design bases have been established for the thermal and hydraulic design of the reactor core.

4.4.1.1 Departure from Nucleate Boiling Design Basis

Basis

There will be at least a 95% probability that departure from nucleate boiling (DNB) will not occur on the limiting fuel rods during normal operation and operational transients and any transient conditions arising from faults of moderate frequency (Condition I and II events) at 95% confidence level. Historically, this criterion has been conservatively met by adhering to the following thermal design basis: there must be at least a 95% probability that the minimum departure from nucleate boiling ratio (DNBR) of the limiting power rod during Condition I and II events is greater than or equal to the safety analysis DNBR limit. The design limit DNBR is set at 1.22 for the typical cell and 1.21 for the thimble cell. Plant specific margin to accommodate rod bow and other DNB penalties and allowance for flexibility in the design, operation, and analysis of the plant is provided by performing the safety analyses to a safety analysis DNBR limit value of 1.38.

Discussion

Historically, this DNBR limit has been 1.30 for Westinghouse applications. In this application, the WRB-1 correlation (Reference 86) is employed. With the significant improvement in the accuracy of the critical heat flux prediction by using the WRB-1 correlation instead of previous DNB correlations, a DNBR limit of 1.17 is applicable for the 17x17 Standard fuel assembly (Reference 86) and for the VANTAGE 5H fuel assembly (Reference 87).

The design method used to meet the DNB design basis is the MINI-Revised Thermal Design Procedure (Reference 94) which is a conservative application of the Revised Thermal Design Procedure (Reference 95). In the MINI-RTDP method, uncertainties in the nuclear peaking factors and fuel fabrication parameters are combined statistically with the THINC-IV and Transient Code UTILIZE DNB correlation uncertainties to define the DNBR design limit such that there is at least a 95 percent probability (with 95 percent confidence) that DNB will not occur when the calculated minimum DNBR is equal to or greater than the design limit. The uncertainties included in the MINI-RTDP method are for the nuclear enthalpy hot-channel factor F(N, H); the enthalpy rise engineering hot-channel factor, F(E, H); and the THINC-IV and transient codes. Since the uncertainties in these parameters are considered in determining the design DNBR value, the plant safety analyses are performed using input values without uncertainties for these parameters. For this application, the DNBR design limit value is 1.22 for the typical cell and 1.21 for the thimble.

In addition to the considerations above, a specific plant allowance has been considered in the present analysis. In particular, a DNBR limit value of 1.38 has been used in the safety analyses for the plant. The difference between the DNBR value used in the safety analyses and the design DNBR value (1.38 vs. 1.21) provides plant specific DNB margin to offset the rod bow penalty and other DNB penalties that may occur. This DNB margin may also be used for flexibility in the design, operation or analysis of the plant.

For conditions outside the range of parameters for the WRB-1 correlation (refer to Section 4.4.2.3.1), the W-3 correlation is used with a DNBR correlation limit of 1.30 for pressure equal to or greater than 1000 psia. For low pressure applications (500-1000 psia), the W-3 DNBR correlation limit is 1.45 (Reference 96).

By preventing departure from nucleate boiling, adequate heat transfer is assured between the fuel clad and the reactor coolant, thereby preventing clad damage as a result of inadequate cooling. Maximum fuel rod surface temperature is not a design basis as it will be within a few degrees of coolant temperature during operation in the nucleate boiling region. Limits provided by the nuclear control and protection systems are such that this design basis will be met for transients associated with Condition II events including overpower transients. There is an additional large DNBR margin at rated power operation and during normal operating transients.

4.4.1.2 Fuel Temperature Design Basis

Basis

During modes of operation associated with Condition I and Condition II events, the maximum fuel temperature shall be less than the melting temperature of UO_2. The UO_2 melting temperature for at least 95% of the peak kW/ft fuel rods will not be exceeded at the 95% confidence level. The melting temperature of UO_2 is taken as 5080°F (Reference 1) unirradiated and reducing 58°F per 10,000 MWD/MTU. By precluding UO_2 melting, the fuel geometry is preserved and possible adverse effects of molten UO_2 on the cladding are eliminated. To preclude center melting and as a basis for overpower protection system setpoints, a calculated centerline fuel temperature of 4700°F has been selected as the overpower limit. This provides sufficient margin for uncertainties in the thermal evaluations as described in Subparagraph 4.4.2.10.1.

Discussion

Fuel rod thermal evaluations are performed at rated power, maximum overpower and during transients at various burnups. These analyses assure that this design basis as well as the fuel integrity design bases given in Section 4.2 are met. They also provide input for the evaluation of Condition III and IV faults given in Chapter 15.

4.4.1.3 Core Flow Design Basis

Basis

A minimum of 91.0%* of the Thermal Flow Rate will pass through the fuel rod region of the core and be effective for fuel rod cooling. Coolant flow through the thimble tubes as well as the leakage from the core barrel-baffle region into the core are not considered effective for heat removal.

Discussion

Core cooling evaluations are based on the Thermal Flow Rate (minimum flow) entering the reactor vessel. A maximum of 9.0%** of this value is allotted as bypass flow. This includes RCC guide thimble cooling flow, head cooling flow, baffle leakage, and leakage to the vessel outlet nozzle.

4.4.1.4 Hydrodynamic Stability Design Bases

Basis

Modes of operation associated with Condition I and II events shall not lead to hydrodynamic instability. Hydrodynamic instability is defined in Section 4.4.3.5.

4.4.1.5 Other Considerations

The above design bases together with the fuel clad and fuel assembly design bases given in paragraph 4.2.1.1 are sufficiently comprehensive so additional limits are not required.

Fuel rod diametral gap characteristics, moderator-coolant flow velocity and distribution, and moderator void are not inherently limiting. Each of these parameters is incorporated into the thermal and hydraulic models used to ensure the above mentioned design criteria are met. For instance, the fuel rod diametral gap characteristics change with time (see Subparagraph 4.2.1.3.1) and the fuel rod integrity is evaluated on that basis. The effect of the moderator flow velocity and distribution (see Paragraph 4.4.2.3) and moderator void distribution (see Paragraph 4.4.2.5) are included in the core thermal (THINC) evaluation and thus affect the design bases.

Meeting the fuel clad integrity criteria covers possible effects of clad temperature limitations. As noted in Subparagraph 4.2.1.3.1, the fuel rod conditions change with time. A single clad temperature limit for Condition I or Condition II events is not appropriate since of necessity it would be overly conservative. A clad temperature limit is applied to the loss of coolant accident (Subsection 15.4.1), control rod ejection accident (Reference 2) and locked rotor accident (Reference 3).

---

* The minimum thermal flow rate passing through the core for Units 1 and 2 has decreased to 90.9%. This is applicable to Units 1 and 2, with or without the H-8 control rod assembly.

** The maximum bypass flow has increased to 9.1%. This is applicable to Units 1 and 2, with or without the H-8 control rod assembly.

4.4.2 Description

4.4.2.1 Summary Comparison

The design of Sequoyah Units 1 and 2 reactors with the 17 x 17 fuel rod array per assembly has the following identical thermal and hydraulic parameters as the Trojan fuel rod array reactor design:

1. Core power
2. System pressure
3. Open lattice fuel rod array

Values of each parameter are presented in Table 4.4.2-1 for all coolant loops in service and in Table 4.4.2-2 for all but one coolant loop in service. It is also noted that in this power capability evaluation, there has not been any change in the design criteria. The reactor is designed to meet the DNB design basis as well as no fuel centerline melting during normal operation, operational transients and faults of moderate frequency.

4.4.2.2 Fuel and Cladding Temperatures (Including Densification)

Consistent with the thermal-hydraulic design bases described in Subsection 4.4.1, the following discussion pertains mainly to fuel pellet temperature evaluation. A discussion of fuel clad integrity is presented in Subparagraph 4.2.1.3.1.

The thermal-hydraulic design assures that the maximum fuel temperature is below the melting point of UO_2 (melting point of 5080°F (Reference 1) unirradiated and reducing by 58°F per 10,000 MWD/MTU). To preclude center melting and as a basis for overpower protection system setpoints, a calculated centerline fuel temperature of 4700°F has been selected as the overpower limit. This provides sufficient margin for uncertainties in the thermal evaluations as described in Subparagraph 4.4.2.10.1. The temperature distribution within the fuel pellet is predominantly a function of the local power density and the UO_2 thermal conductivity.

However, the computation of radial fuel temperature distributions combines crud, oxide, clad gap and pellet conductances. The factors which influence these conductances, such as gap size (or contact pressure), internal gas pressure, gas composition, pellet density, and radial power distribution within the pellet, etc., have been combined into a semi-empirical thermal model (see Subparagraph 4.2.1.3.1) which includes a model for time dependent fuel densification as given in References 77, 85, and 91. This thermal model enables the determination of these factors and their net effects on temperature profiles. The temperature predictions have been compared to in-pile fuel temperature measurements (References 7 through 13 and 85) and melt radius data (References 14 and 15) with good results.

Effect of Fuel Densification on Fuel Rod Temperatures

Fuel densification results in fuel pellet shrinkage. This affects the fuel temperatures in the following ways:

1. Pellet radial shrinkage increases the pellet diametral gap which results in increased thermal resistance of the gap, and thus, higher fuel temperatures (see Subparagraph 4.2.1.3.1).

2. Pellet axial shrinkage may produce pellet to pellet gaps resulting in local power spikes, described in Subparagraph 4.3.2.2.1 and thus, higher total heat flux hot channel factor, F_Q, and local fuel temperature.

3. Pellet axial shrinkage will result in a fuel stack height reduction and an increase in the linear power generation rate (kW/ft) for a constant core power level. Using the methods described in Section 5.3 of Reference 6, the increase in linear power for the fuel rod specifications listed in Table 4.3.2-1 is 0.2%.

Fuel rod thermal evaluations (fuel centerline average and surface temperatures) are performed at several times in the fuel rod lifetime (with consideration of time dependent densification) to determine the maximum fuel temperatures.

4.4.2.2.1 UO_2 Thermal Conductivity

The thermal conductivity of uranium dioxide was evaluated from data reported by Howard, et. al., (Reference 16); Lucks, et. al., (Reference 17); Danial, et. al., (Reference 18); Feith (Reference 19); Vogt, et. al., (Reference 20); Nishijima, et. al., (Reference 21); Wheeler, et. al., (Reference 22); Godfrey, et. al., (Reference 23); Stora, et. al., (Reference 24); Bush (Reference 25); Asamoto, et. al., (Reference 26); Kruger (Reference 27); and Gyllander (Reference 28).

At the higher temperatures, thermal conductivity is best obtained by utilizing the integral conductivity to melt which can be determined with more certainty.

From an examination of the data, it has been concluded that the best estimate for the value of

$$\int_0^{2800c} \text{Kdt is 93 watts / cm.}$$

This conclusion is based on the integral values reported by Gyllander (Reference 28); Lyons, et. al., (Reference 29); Coplin, et. al., (References 30); Duncan (Reference 14); Bain (Reference 31); and Stora (Reference 32).

The design curve for the thermal conductivity is shown in Figure 4.4.2-3.
The section of the curve at temperatures between 0°C and 1300°C is in excellent agreement with the recommendation of the IAEA panel (Reference 33). The section of the curve above 1300°C is derived for an integral value of 93 watts/cm (References 14, 28 and 32).

Thermal conductivity for UO_2 at 95 percent theoretical density can be represented best by the following equation:

$$K = \frac{1}{11.8 + 0.0238T} + 8.775 \times 10^{-13} T^3$$

where

$$K = watts / cm^{-\circ} C$$
$$T = {}^\circ C$$

4.4.2.2.2 Radial Power Distribution in UO_2 Fuel Rods

An accurate description of the radial power distribution as a function of burnup is needed for determining the power level for incipient fuel melting and other important performance parameters such as pellet thermal expansion, fuel swelling and fission gas release rates.

This information on radial power distributions in UO_2 fuel rods is determined with the neutron transport theory code, LASER. The LASER code has been validated by comparing the code predictions on radial burnup and isotopic distributions with measured radial microdrill data (References 34 and 35). A "radial power depression factor," f, is determined using radial power distributions predicted by LASER. The factor f enters into the determination of the pellet centerline temperature, T_c, relative to the pellet surface temperature, T_s, through the expression:

$$\int_{T_s}^{T_c} k(T)\, dT = \frac{q'f}{4\pi} \qquad (4.4\text{-}2)$$

where

k(T) = the thermal conductivity for UO_2 with a uniform density distribution

q' = the linear power generation rate.

4.4.2.2.3 Gap Conductance

The temperature drop across the pellet-clad gap is a function of the gap size and the thermal conductivity of the gas in the gap. The gap conductance model is selected such that when combined with the UO_2 thermal conductivity model, the calculated fuel centerline temperatures reflect the in-pile temperature measurements. A more detailed discussion of the gap conductance model is presented in References 77, 85 and 91.

4.4.2.2.4 Surface Heat Transfer Coefficients

The fuel rod surface heat transfer coefficients during subcooled forced convection and nucleate boiling are presented in Subparagraph 4.4.2.8.1.

4.4.2.2.5 Fuel Clad Temperatures

The outer surface of the fuel rod at the hot spot operates at a temperature of approximately 660°F for steady state operation at rated power throughout core life due to the onset of nucleate boiling. Initially (beginning-of-life), this temperature is that of the clad metal outer surface.

During operation over the life of the core, the buildup of oxides and crud on the fuel rod surface causes the clad surface temperature to increase. Allowance is made in the fuel center melt evaluation for this temperature rise. Since the thermal-hydraulic design basis limits DNB, adequate heat transfer is provided between the fuel clad and the reactor coolant so that the core thermal output is not limited by considerations of the clad temperature.

4.4.2.2.6 Treatment of Peaking Factors

The total heat flux hot channel factor, F_Q, is defined by the ratio of the maximum to core average heat flux as discussed in Subparagraph 4.3.2.2.1, the design value F_Q for normal operation is 2.40, including fuel densification effects. Subparagraph 15.4.1.1.7 discusses the F_Q value used in LOCA analyses.

This results in a peak local power of 13.0 kW/ft at full power conditions. The peak linear power for determination of protection setpoints is 21.1 kW/ft. The centerline temperature at this kW/ft must be below the UO_2 melt temperature over the lifetime of the rod, including allowances for uncertainties. The fuel temperature design basis is discussed in Subsection 4.4.1.2 and results in a maximum allowable calculated centerline temperature of 4700°F. The peak linear power for prevention of centerline melt is > 21.1 kW/ft. The centerline temperature at the peak linear power resulting from overpower transients/overpower errors (assuming a maximum overpower of 116.5%) is below that required to produce melting.

4.4.2.3 Critical Heat Flux Ratio or Departure from Nucleate Boiling Ratio and Mixing Technology

The minimum DNBRs for the rated power, and anticipated transient conditions are given in Table 4.4.2-1. The minimum DNBR in the limiting flow channel will be downstream of the peak heat flux location (hot spot) due to the increased downstream enthalpy rise.

DNBRs are calculated by using the correlation and definitions described in the following Subparagraphs 4.4.2.3.1 and 4.4.2.3.2. The THINC-IV computer code (discussed in Subparagraph 4.4.3.4.1) is used to determine the flow distribution in the core and the local conditions in the hot channel for use in the DNB correlation. The use of hot channel factors is discussed in Subparagraph 4.4.3.2.1 (nuclear hot channel factors) and in Subparagraph 4.4.2.3.4 (engineering hot channel factors).

4.4.2.3.1 Departure from Nucleate Boiling Technology

The WRB-1 DNB correlation is applicable to VANTAGE 5H fuel since, from a DNB perspective, the VANTAGE 5H assembly is virtually identical to the 17x17 Inconel R-Grid design. As documented in Reference 87, the use of the WRB-1 DNB correlation with a 95/95 limit DNBR of 1.17 is applicable to the VANTAGE 5H fuel assembly.

For conditions outside the range of applicability of the WRB-1, the W-3 correlation is used.

The W-3 correlation, and several modifications of it, have been used in Westinghouse CHF calculations. The W-3 was originally developed from single tube data, (Reference 39) but was subsequently modified to apply to the 0.422 inch O.D. rod "R" grid, [Reference 42] and "L" grid, [Reference 38] as well as the 0.374 inch O.D., [Reference 84, 40] rod bundle data. These modifications to the W-3 correlation have been demonstrated to be adequate for reactor rod bundle design.

For the W-3 correlation, the 95/95 limit DNBR is 1.30 at system pressures greater than or equal to 1000 psi. For low pressure application (500-1000 psi), the 95/95 limit DNBR is 1.45 (Reference 92).

4.4.2.3.2 Definition of DNB Heat Flux Ratio (DNBR)

The DNB heat flux ratio (DNBR) as applied to typical cells (flow cells with all walls heated) and thimble cells (flow cells with heated and unheated walls) is defined as:

$$DNBR = \frac{q''_{DNB,N}}{q''_{LOC}} \qquad (4.4\text{ - }3)$$

where

$$q''_{DNB,N} = \frac{q''_{DNB,EU}}{F} \qquad (4.4\text{ - }4)$$

and q"DNB,EU is the uniform critical heat flux as predicted by the WRB-1 DNB correlation (Reference 86).

F is the flux shape factor to account for nonuniform axial heat flux distributions (Reference 44) with the "C" term modified as in Reference 39, and q_{loc}'' is the actual local heat flux.

4.4.2.3.3 Mixing Technology

The rate of heat exchange by mixing between flow channels is proportional to the difference in the local mean fluid enthalpy of the respective channels, the local fluid density and flow velocity. The proportionality is expressed by the dimensionless thermal diffusion coefficient, TDC, which is defined as:

$$TDC = \frac{w'}{\rho V a} \qquad (4.4\text{-}14)$$

where:

w' = flow exchange rate per unit length, lbm/ft-sec
p = fluid density, lbm/ft^3
V = fluid velocity, ft/sec
a = lateral flow area between channels per unit length, ft^2/ft

The application of the TDC in the THINC analysis for determining the overall mixing effect or heat exchange rate is presented in Reference 41.

Various mixing tests have been performed at Columbia University (Reference 46). This series of tests, using the "R" mixing vane grid design on 13, 26 and 32 inch grid spacing, was conducted in pressurized water loops at Reynolds numbers similar to that of a PWR core under the following single and two phase (subcooled boiling) flow conditions:

Pressure	1500 to 2400 psia
Inlet enthalpy	303 to 638 Btu/lb
Mass velocity	.954 to 3.58 x 10^6 lbm/hr ft^2
Reynolds number	1.34 to 7.45 x 10^5
Bulk outlet quality	-52.1 to -13.5%

TDC is determined by comparing the THINC code predictions with the measured subchannel exit temperature. Data for 26 inch axial grid spacing are presented in Figure 4.4.2-6 where the thermal diffusion coefficient is plotted versus the Reynolds number. TDC is found to be independent of Reynolds number, mass velocity, pressure and quality over the ranges tested. The two phase data (local, subcooled boiling) fell within the scatter of the single phase data. The effect of two-phase flow on the value of TDC has been demonstrated by Cadek (Reference 46), Rowe and Angle, (References 47 and 48) and Gonzalez - Santalo and Griffith (Reference 49). In the subcooled boiling region the values of TDC were indistinguishable from the single phase values. In the quality region, Rowe and Angle show that in the case with rod spacing similar to that in PWR reactor core geometry, the value of TDC increased with quality to a point and then decreased, but never below the single phase value. Gonzalez - Santalo and Griffith showed that the mixing coefficient increased as the void fraction increased.

The data from these tests on the "R" grid showed that a design TDC value of 0.038 (for 26 inch grid spacing) can be used in determining the effect of coolant mixing in the THINC analysis.

A mixing test program similar to the one described above was conducted at Columbia University for the 17 x 17 geometry and mixing vane grids on 26 inch spacing (Reference 50). The mean value of TDC obtained from these tests was 0.059, and all data was well above the current design value of 0.038.

Since the actual reactor grid spacing is approximately 20 inches, additional margin is available for this design, as the value of TDC increases as grid spacing decreases (Reference 46).
Zircaloy mixing vane grids are employed in the VANTAGE 5H fuel assembly. The VANTAGE 5H Zircaloy grid design is virtually identical to the 17x17 Inconel R-grid design in that the rod size, rod pitch, heated length and grid spacing are unchanged. Due to the change in grid material from Inconel to Zircaloy, the grid height and strap thickness have increased. However, the VANTAGE 5H Zircaloy grid was designed to preserve the important characteristics of the existing 17x17 type "R" mixing vane grid. Thus, the current conservative design value of TDC is applicable to the VANTAGE 5H fuel assembly design.

4.4.2.3.4 Hot Channel Factors

The total hot-channel factors for heat flux and enthalpy rise are defined as the maximum-to-core average ratios of these quantities. The heat flux hot-channel factor considers the local maximum linear heat generation rate at a point (the 'hot spot'), and the enthalpy rise hot-channel factor involves the maximum integrated value along a channel (the 'hot-channel').

Each of the total hot-channel factors considers a nuclear hot-channel factor (see Paragraph 4.4.3.2) describing the neutron power distribution and an engineering hot-channel factor, which allows for variations in flow conditions and fabrication tolerances. The engineering hot-channel factors are made up of subfactors which account for the influence of the variations of fuel pellet diameter, density, enrichment and eccentricity; inlet flow distribution; flow redistribution; and flow mixing.

Heat Flux Engineering Hot-Channel Factor, F_Q^E

The heat flux engineering hot channel factor is used to evaluate the maximum linear heat generation rate in the core. This subfactor is determined by statistically combining the

tolerances for the fuel pellet diameter, density, enrichment, eccentricity and the fuel rod diameter, and has a value of 1.033. Measured manufacturing data on recent Westinghouse 17 x 17 fuel were used to verify that this value was not exceeded for 95% of the limiting fuel rods at a 95% confidence level

Enthalpy Rise Engineering Hot-Channel Factor, $F_{\Delta H}^{E}$

The effect of variations in flow conditions and fabrication tolerances on the hot-channel enthalpy rise is directly considered in the THINC core thermal subchannel analysis (See Subparagraph 4.4.3.4.1) under any reactor operating condition. The items considered contributing to the enthalpy rise engineering hot-channel factor are discussed below:

1. Pellet diameter, density and enrichment:

   Design values employed in the THINC analysis related to the above fabrication variations are based on applicable limiting tolerances such that these design values are met for 95 percent of the limiting channels at a 95 percent confidence level. Measured manufacturing data on Westinghouse 17 x 17 fuel show the tolerances used in this evaluation are conservative. The effect of variations in pellet diameter and enrichment is employed in the THINC analysis as a direct multiplier on the hot channel enthalpy rise.

2. Inlet Flow Maldistribution:

   The consideration of inlet flow maldistribution in core thermal performances is discussed in Subparagraph 4.4.3.1.2. A design basis of 5% reduction in coolant flow to the hot assembly is used in the THINC-IV analysis.

3. Flow Redistribution

   The flow redistribution accounts for the reduction in flow in the hot channel resulting from the high flow resistance in the channel due to the local or bulk boiling. The effect of the non-uniform power distribution is inherently considered in the THINC analysis for every operating condition which is evaluated.

4. Flow Mixing:

   The subchannel mixing model incorporated in the THINC Code and used in reactor design is based on experimental data (Reference 51) discussed in Subparagraph 4.4.3.4.1. The mixing vanes incorporated in the spacer grid design induce additional flow mixing between the various flow channels in a fuel assembly as well as between adjacent assemblies. This mixing reduces the enthalpy rise in the hot channel resulting from local power peaking or unfavorable mechanical tolerances.

4.4.2.3.5 Effects of Rod Bow on DNBR

The phenomenon of fuel rod bowing, as described in Reference 88, must be accounted for in the DNBR safety analysis of Condition I and Condition II events. Applicable credits for margin

resulting from retained conservatism in the evaluation of the DNBR and/or margin obtained from the measured plant operating parameters (such as $F^N_{\Delta H}$ or core flow) -- which are less limiting than those required by the plant safety analysis -- can be used to offset the effect of rod bow.

Based on the current methodology described in References 88, 89, and 90, a rod bow DNBR penalty of < 1.5% is applicable to 17x17 Standard fuel assemblies at a burnup of 24,000 MWD/MTU. Based on the similarities between 17x17 Standard and VANTAGE 5H fuel assemblies (i.e., fuel rod diameter, fuel rod pitch and grid spacing), this penalty is also applicable to the VANTAGE 5H fuel assembly.

The maximum rod bow penalty accounted for in the design safety analysis is based on an assembly average burnup of 24,000 MWD/MTU. At burnups greater than 24,000 MWD/MTU, credit is taken for the effect of $F^N_{\Delta H}$ burndown, due to the decrease in fissionable isotopes and the buildup of fission product inventory, and no additional rod bow penalty is required.

For the safety analysis of the Sequoyah Units, sufficient DNBR margin was retained between the safety analysis DNBR limit and the design limit DNBR (see Section 4.4.1.1) to more than offset the rod bow DNBR penalty.

4.4.2.4 Flux Tilt Considerations

Significant quadrant power tilts are not anticipated during normal operation since this phenomenon is caused by some asymmetric perturbation. A dropped or misaligned RCCA could cause changes in hot channel factors; however, these events are analyzed separately in Chapter 15. This discussion will be confined to flux tilts caused by x-y xenon transients, inlet temperature mismatches, enrichment variations within tolerances and so forth.

The design value of the enthalpy rise hot channel factor $F^N_{\Delta H}$, which includes an 8% uncertainty (as discussed in Subparagraph 4.3.2.2.7), is assumed to be sufficiently conservative that flux tilts up to and including the alarm point (see SQN Technical Specifications) will not result in values of $F^N_{\Delta H}$, greater than that assumed in this submittal. The design value of F_Q^E does not include a specific allowance for quadrant flux tilts.

4.4.2.5 Void Fraction Distribution

The calculated core average and the hot subchannel maximum and average void fractions are presented in Table 4.4.2-3 for operation at full power with design hot channel factors. The void fraction distribution in the core at various radial and axial locations is presented in Reference 52. The void models used in the THINC-IV computer code are described in Subparagraph 4.4.2.8.3.

4.4.2.6 Core Coolant Flow Distribution

Assembly average coolant mass velocity and enthalpy at various radial and axial core locations are given below. Coolant enthalpy rise and flow distributions are shown for the 4 foot elevation (1/3 of core height) in Figure 4.4.2-7 and 8 foot elevation (2/3 of core height) in Figure 4.4.2-8 and at the core exit in Figure 4.4.2-9. These distributions are for the full power conditions as

given in Table 4.4.2-1 and for the radial power density distribution shown in Figure 4.3.2-7. The THINC code analysis for this case utilized a uniform core inlet enthalpy and inlet flow distribution.

4.4.2.7 Core Pressure Drops and Hydraulic Loads

4.4.2.7.1 Core Pressure Drops

The analytical model and experimental data used to calculate the pressure drops shown in Table 4.4.2-1 are described in Paragraph 4.4.2.8. The core pressure drop includes the eight grid fuel assembly, core support plate, and holddown plate pressure drops. The full power operation pressure drop values shown in Table 4.4.2-1 are the unrecoverable pressure drops across the vessel, including the inlet and outlet nozzles, and across the core. These pressure drops are based on the Best Estimate Flow (most likely value for actual plant operating conditions) as described in Subsection 5.1. Subsection 5.1 also defines and describes the Thermal Design Flow (minimum flow) which is the basis for reactor core thermal performance and the Mechanical Design Flow (maximum flow) which is used in the mechanical design of the reactor vessel internals and fuel assemblies. Since the Best Estimate Flow is that flow which is most likely to exist in an operating plant, the calculated core pressure drops in Table 4.4.2-1 are based on this best estimate flow rather than the Thermal Design Flow.

Uncertainties associated with the core pressure drop values are discussed in Subparagraph 4.4.2.10.2.

4.4.2.7.2 Hydraulic Loads

The fuel assembly hold down springs, Figure 4.2.1-2, are designed to keep the fuel assemblies resting on the lower core plate under transients associated with Condition I and II events. Maximum flow conditions are limiting because hydraulic loads are a maximum. The most adverse flow conditions occur during a LOCA. These conditions are presented in Subsection 15.4.1.

Hydraulic loads at normal operating conditions are calculated considering the Mechanical Design Flow which is described in Section 5.1 and accounting for the minimum core bypass flow based on manufacturing tolerances. Core hydraulic loads at cold plant startup conditions are adjusted to account for the coolant density difference. Conservative core hydraulic loads for a pump overspeed transient, which create flow rates 20% greater than the Mechanical Design Flow, are evaluated to be greater than twice the fuel assembly weight.

Core hydraulic loads were measured during the prototype assembly tests described in Section 1.5. Reference 5 contains a detailed discussion of the results for STD fuel. Full scale hydraulic test results for VSH fuel are presented in reference 93.

The hydraulic loads during normal operation can be obtained from Reference 5 by adjusting the loads for the Sequoyah pressure drop and flow rate. The effect of startup and shutdown transients are shown to be inconsequential in Reference 5.

4.4.2.8 Correlation and Physical Data

4.4.2.8.1 Surface Heat Transfer Coefficients

Forced convection heat transfer coefficients are obtained from the familiar Dittus-Boelter correlation (Reference 53), with the properties evaluated at bulk fluid conditions:

$$\frac{hD_e}{K} = 0.023 \left(\frac{D_e G}{\mu}\right)^{0.8} \left(\frac{C_p \mu}{K}\right)^{0.4} \qquad (4.4\text{-}15)$$

where:

h	= heat transfer coefficient, BTU/hr-ft^2-°F
D_e	= equivalent diameter, ft
K	= thermal conductivity, BTU/hr-ft-°F
G	= mass velocity, lb/hr-ft^2
μ	= dynamic viscosity, lb/ft-hr
C_p	= heat capacity, BTU/lb-°F

This correlation has been shown to be conservative (Reference 54) for rod bundle geometries with pitch to diameter ratios in the range used by PWRs.

The onset of nucleate boiling occurs when the clad wall temperature reaches the amount of superheat predicted by Thom's (Reference 55) correlation. After this occurrence the outer clad wall temperature is determined by:

$$\Delta T_{sat} = [0.072 \exp(-P/1260)] (q'')^{0.5} \qquad (4.4\text{-}16)$$

where:

ΔT_{sat}	= wall superheat, T_w - T_{sat}, °F
q"	= wall heat flux, BTU/hr-ft^2
P	= pressure, psia
T_w	= outer clad wall temperature, °F
T_{sat}	= saturation temperature of coolant at P, °F

4.4.2.8.2 Total Core and Vessel Pressure Drop

Unrecoverable pressure losses occur as a result of viscous drag (friction) and/or geometry changes (form) in the fluid flow path. The flow field is assumed to be incompressible, turbulent, single-phase water. These assumptions apply to the core and vessel pressure drop calculations for the purpose of establishing the primary loop flow rate. Two-phase considerations are neglected in the vessel pressure drop evaluation because the core average void is negligible (see Paragraph 4.4.2.5 and Table 4.4.2-3). Two phase flow considerations in the core thermal subchannel analyses are considered and the models are discussed in Subparagraph 4.4.3.1.3. Core and vessel pressure losses are calculated by equations of the form:

$$\Delta P_L = (K + F\frac{L}{D_e}) \frac{pV^2}{2g_c} (144) \qquad (4.4\text{-}17)$$

where:

ΔP_L	=	unrecoverable pressure drop, lb_f/in^2
p	=	fluid density, lbm/ft^3
L	=	length, ft.
D_e	=	equivalent diameter, ft
V	=	fluid velocity, ft/sec
g_c	=	$32.174 \dfrac{lb_m\text{-}ft}{lb_f\text{-}sec^2}$
K	=	form loss coefficient, dimensionless
F	=	friction loss coefficient, dimensionless

Fluid density is assumed to be constant at the appropriate value for each component in the core and vessel. Because of the complex core and vessel flow geometry, precise analytical values for the form and friction loss coefficients are not available. Therefore, experimental values for these coefficients are obtained from geometrically similar models.

Values are quoted in Table 4.4.2-1 for unrecoverable pressure loss across the reactor vessel, including the inlet and outlet nozzles, and across the core. The results of full scale tests of core components and fuel assemblies were utilized in developing the core pressure loss characteristic. The pressure drop for the vessel was obtained by combining the core loss with correlation of 1/7th scale model hydraulic test data on a number of vessels (References 56 and 57) and form loss relationships (Reference 58). Moody (Reference 59) curves were used to obtain the single phase friction factors.

Tests of the primary coolant loop flow rates will be made (see Paragraph 4.4.4.1) prior to initial criticality to verify that the flow rates used in the design, which were determined in part from the pressure losses calculated by the method described here, are conservative.

4.4.2.8.3 Void Fraction Correlation

There are three separate void regions considered in flow boiling in a PWR as illustrated in Figure 4.4.2-10. They are the wall void region (no bubble detachment), the subcooled boiling region (bubble detachment) and the bulk boiling region.

In the wall void region, the point where local boiling begins is determined when the clad temperature reaches the amount of superheat predicted by Thom's (Reference 55) correlation (discussed in Subparagraph 4.4.2.8.1). The void fraction in this region is calculated using Maurer's (Reference 60) relationship. The bubble detachment point, where the superheated bubbles break away from the wall, is determined by using Griffith's (Reference 61) relationship.

The void fraction in the subcooled boiling region (that is, after the detachment point) is calculated from the Bowring (Reference 62) correlation. This correlation predicts the void fraction from the detachment point to the bulk boiling region.

The void fraction in the bulk boiling region is predicted by using homogeneous flow theory and assuming no slip. The void fraction in this region is therefore a function only of the thermodynamic quality.

4.4.2.9 Thermal Effects of Operational Transients

DNB core safety limits are generated as a function of coolant temperature, pressure, core power and axial power imbalance. Steady-state operation within these safety limits insures that the DNB design basis is met. Figure 15.1.3-1 show the DNBR limit lines and the resulting overtemperature Delta-T trip lines (see SQN Technical Specifications), plotted as Delta-T vs T-average for various pressures. This system provides adequate protection against anticipated operational transients that are slow with respect to fluid transport delays in the primary system. In addition, for fast transients, e.g., uncontrolled rod bank withdrawal at power incident (Subsection 15.2.2) specific protection functions are provided as described in Section 7.2 and the use of these protection functions are described in Chapter 15. (see Table 15.1.3-1). The thermal response of the fuel rod is discussed in Paragraph 4.4.3.7.

4.4.2.10 Uncertainties in Estimates

4.4.2.10.1 Uncertainties in Fuel and Clad Temperature

As discussed in Paragraph 4.4.2.2, the fuel temperature is a function of crud, oxide, clad, gap, and pellet conductances. Uncertainties in the fuel temperature calculation are essentially of two types: fabrication uncertainties such as variations in the pellet and clad dimensions and the pellet density; and model uncertainties such as variations in the pellet conductivity and the gap conductance. These uncertainties have been quantified by comparison of the thermal model to the in-pile thermocouple measurements (References 7 through 13), by out-of-pile measurements of the fuel and clad properties (References 16 through 27), and by measurements of the fuel and clad dimensions during fabrication. The resulting uncertainties are then used in all evaluations involving the fuel temperature. The effect of densification on fuel temperature uncertainties is also included in the calculation of the total uncertainty.

In addition to the temperature uncertainty described above, the measurement uncertainty in determining the local power, and the effect of density and enrichment variations on the local power are considered in establishing the heat flux hot channel factor. These uncertainties are described in Subparagraph 4.3.2.2.1.

Reactor trip setpoints as specified in the SQN Technical Specifications include allowance for instrument and measurement uncertainties such as calorimetric error, instrument drift and channel reproducibility, temperature measurement uncertainties, noise, and heat capacity variations.

Uncertainty in determining the cladding temperature results from uncertainties in the crud and oxide thicknesses. Because of the excellent heat transfer between the surface of the rod and the coolant, the film temperature drop does not appreciably contribute to the uncertainty.

4.4.2.10.2 Uncertainties in Pressure Drops

Core and vessel pressure drops based on the Best Estimate Flow, as described in Section 5.1, are quoted in Table 4.4.2-1. The uncertainties quoted are based on the uncertainties in both the test results and the analytical extension of these values to the reactor application.

A major use of the core and vessel pressure drops is to determine the primary system coolant flow rates as discussed in Section 5.1. In addition, as discussed in Paragraph 4.4.4.1, tests on the primary system prior to initial criticality will be made to verify that a conservative primary system coolant flow rate has been used in the design and analyses of the plant.

4.4.2.10.3 Uncertainties Due to Inlet Flow Maldistribution

The effects of uncertainties in the inlet flow maldistribution criteria used in the core thermal analyses is discussed in Subparagraph 4.4.3.1.2.

4.4.2.10.4 Uncertainty in DNB Correlation

The uncertainty in the DNB correlation (Paragraph 4.4.2.3) can be written as a statement on the probability of not being in DNB based on the statistics of the DNB data. This is discussed in Subparagraph 4.4.1.1.

4.4.2.10.5 Uncertainties in DNBR Calculations

The uncertainties in the DNBRs calculated by THINC analysis (see Subparagraph 4.4.3.4.1) due to uncertainties in the nuclear peaking factors are accounted for by applying conservatively high values of the nuclear peaking factors and including measurement error allowances. In addition, conservative values for the engineering hot channel factors are used as discussed in Subparagraph 4.4.2.3.4. The results of a sensitivity study (Reference 52) with THINC-IV show that the minimum DNBR in the hot channel is relatively insensitive to variations in the core wide radial power distribution (for the same value of $F^N_{\Delta H}$).

The ability of the THINC-IV computer code to accurately predict flow and enthalpy distributions in rod bundles is discussed in Subparagraph 4.4.3.4.1 and in Reference 63. Studies have been performed (Reference 52) to determine the sensitivity of the minimum DNBR in the hot channel to the void fraction correlation (see also Subparagraph 4.4.2.8.3); the inlet velocity and exit pressure distributions assumed as boundary conditions for the analysis; and the grid pressure loss coefficients. The results of these studies show that the minimum DNBR in the hot channel is relatively insensitive to variations in these parameters. The range of variations considered in these studies covered the range of possible variations in these parameters.

4.4.2.10.6 Uncertainties in Flow Rates

The uncertainties associated with loop flow rates are discussed in Section 5.1. For core thermal performance evaluations, a Thermal Design Loop Flow is used which is less than the Best Estimate Loop Flow (approximately 6% for the four-loop plant). In addition another 9.0%* of the Thermal Design Flow is assumed to be ineffective for core heat removal capability because it

* The maximum bypass flow has increased to 9.1%. This is applicable to Units 1 and 2, with or without the H-8 control rod assembly.

bypasses the core through the various available vessel flow paths described in Subparagraph 4.4.3.1.1.

4.4.2.10.7 Uncertainties in Hydraulic Loads

As discussed in Subparagraph 4.4.2.7.2, hydraulic loads on the fuel assembly are evaluated for a pump overspeed transient which create flow rates 20% greater than the Mechanical Design Flow. The Mechanical Design Flow as stated in Section 5.1 is greater than the Best Estimate or most likely flow rate value for the actual plant operating condition.

4.4.2.10.8 Uncertainty in Mixing Coefficient

The value of the mixing coefficient, TDC, used in THINC analyses for this application is 0.038.

The results of the mixing tests done on 17 x 17 geometry, as discussed in Subparagraph 4.4.2.3.3, had a mean value of TDC of 0.059 and standard deviation of σ = 0.007. Hence the current design value of TDC is almost 3 standard deviations below the mean for 26 inch grid spacing.

4.4.2.11 Plant Configuration Data

Plant configuration data for the thermal-hydraulic and fluid systems external to the core are provided in the appropriate Chapters 5, 6, and 9. Implementation of the Emergency Core Cooling System (ECCS) is discussed in Chapter 15. Some specific areas of interest are the following:

1. Total coolant flow rates for the Reactor Coolant System (RCS) and each loop are provided in Table 5.1-1. Flow rates employed in the evaluation of the core are presented in Section 4.4.

2. Total RCS volume including pressurizer and surge line, RCS liquid volume including pressurizer water at steady state power conditions are given in Table 5.1-1.

3. The flow path length through each volume may be calculated from physical data provided in Section 5.5.

4. The height of fluid in each component of the RCS may be determined from the physical data presented in Section 5.5. The components of the RCS are water filled during power operation with the pressurizer being approximately 60% water filled.

5. Components of the ECCS are to be located so as to meet the criteria for NPSH described in Section 6.3.

6. Line lengths and sizes for the safety injection system are determined so as to guarantee a total system resistance which will provide, as a minimum, the fluid delivery rates assumed in the safety analyses described in Chapter 15.

7. The flow areas for components of the RCS are presented in Section 5.5, Component and Subsystem Design.

8. The steady state pressure drops and temperature distributions through the RCS are presented in Table 5.1-1.

4.4.3 Evaluation

4.4.3.1 Core Hydraulics

4.4.3.1.1 Flow Paths Considered in Core Pressure Drop and Thermal Design

The following flow paths or core bypass flow are considered:

1. Flow through the spray nozzles into the upper head for head cooling purposes.

2. Flow entering into the RCC guide thimbles to cool the control rods.

3. Leakage flow from the vessel inlet nozzle directly to the vessel outlet nozzle through the gap between the vessel and the barrel.

4. Flow introduced between the baffle and the barrel for the purpose of cooling these components.

5. Flow in the gaps between the fuel assemblies on the core periphery and the adjacent baffle wall.

The above contributions are evaluated to confirm that the design value of core bypass flow is met. The design value of core bypass flow for Sequoyah is equal to 9.0%* of the total vessel flow. Of the total allowance, 5.5% is associated with the internals (Items 1, 3, 4, and 5 above) and 3.5%** for the core. Calculations have been performed using drawing tolerances on a worst case basis and accounting for uncertainties in pressure losses. Based on these calculations, the core bypass flow for Sequoyah is <9.0%.*** This design bypass value is also used in the evaluation of the core pressure drops quoted in Table 4.4.2-1, and the determination of reactor flow rates in Section 5.1.

Flow model test results for the flow path through the reactor are discussed in Section 4.4.2.8.2.

4.4.3.1.2 Inlet Flow Distributions

Data has been considered from several 1/7 scale hydraulic reactor model tests (References 56, 57, and 64) in arriving at the core inlet flow maldistribution criteria to be used in the THINC analyses (see Subparagraph 4.4.3.4.1). THINC I analyses made using this data have indicated that a conservative design basis is to consider a 5 percent reduction in the flow to the hot assembly (Reference 65). The same design basis of 5% reduction to the hot assembly inlet is used in THINC IV analyses.

---

* The maximum bypass flow is 9.1%. This is applicable to Units 1 and 2, with or without the H-8 control rod assembly.

** The bypass flow associated with the core has increased to 3.6%. This is applicable to Units 1 and 2, with or without the H-8 control rod assembly.

*** The maximum bypass flow is 9.1%. This is applicable to Units 1 and 2, with or without the H-8 control rod assembly.

The experimental error estimated in the inlet velocity distribution has been considered as outlined in Reference 52 where the sensitivity of changes in inlet velocity distributions to hot channel thermal performance is shown to be small. Studies (Reference 52) made with the improved THINC model (THINC-IV) show that it is adequate to use the 5% reduction in inlet flow to the hot assembly for a loop out of service based on the experimental data in References 56 and 57.

The effect of the total flow rate on the inlet velocity distribution was studied in the experiments of Reference 56. As was expected, on the basis of the theoretical analysis, no significant variation could be found in inlet velocity distribution with reduced flow rate.

4.4.3.1.3 Empirical Friction Factor Correlations

Two empirical friction factor correlations are used in the THINC-IV computer code (described in Subparagraph 4.4.3.4.1).

The friction factor in the axial direction, parallel to the fuel rod axis, is evaluated using the Novendstern-Sandberg correlation (Reference 66). This correlation consists of the following:

1. for isothermal conditions, this correlation uses the Moody (Reference 59) friction factor including surface roughness effects,

2. under single-phase heating conditions a factor is applied based on the values of the coolant density and viscosity at the temperature of the heated surface and at the bulk coolant temperature and

3. under two-phase flow conditions the homogeneous flow model proposed by Owens (Reference 67) is used with a modification to account for a mass velocity and heat flux effect.

The flow in the lateral directions, normal to the fuel rod axis, views the reactor core as a large tube bank. Thus, the lateral friction factor proposed by Idel' chik (Reference 58) is applicable. This correlation is of the form

$$F_L = ARe_L^{-0.2} \qquad (4.4\text{-}18)$$

where:

A is a function of the rod pitch and diameter as given in Reference 58.

Re_L is the lateral Reynolds number based on the rod diameter.

Extensive comparisons of THINC-IV predictions using these correlations to experimental data are given in Reference 63, and verify the applicability of these correlations in PWR design.

4.4.3.2 Influence of Power Distribution

The core power distribution which is largely established at beginning of life by fuel enrichment, loading pattern, and core power level is also a function of variables such as control rod worth and position, and fuel depletion throughout lifetime. Radial power distributions in various planes

of the core are often illustrated for general interest, however, the core radial enthalpy rise distribution as determined by the integral of power up each channel is of greater importance for DNB analyses. These radial power distributions, characterized by $F^N_{\Delta H}$ (defined in Subsection 4.3.2.2.1) as well as axial heat flux profiles are discussed in the following two sections.

4.4.3.2.1 Nuclear Enthalpy Rise Hot-Channel Factor, $F^N_{\Delta H}$

Given the local power density q' (kW/ft) at a point x, y, z in a core with N fuel rods and height H,

$$F^N_{\Delta H} = \frac{hot\ rod\ power}{average\ rod\ power} = \frac{\mathrm{Max}\int_o^H q'\ (xo,yo,z)dz}{\frac{1}{N}\sum allrods\int_o^H q'\ (x,y,z)dz} \qquad (4.4\text{-}19)$$

The way in which $F^N_{\Delta H}$ is used in the DNB calculation is important. The location of minimum DNBR depends on the axial profile and the value of DNBR depends on the enthalpy rise to that point. Basically, the maximum value of the rod integral is used to identify the most likely rod for minimum DNBR. An axial power profile is obtained which when normalized to the design value of $F^N_{\Delta H}$, recreates the axial heat flux along the limiting rod. The surrounding rods are assumed to have the same axial profile with rod average powers which are typical of distributions found in hot assemblies. In this manner worst case axial profiles can be combined with worst case radial distributions for reference DNB calculations. It should be noted again that $F^N_{\Delta H}$ is an integral and is used as such in the DNB calculations. Local heat fluxes are obtained by using hot channel and adjacent channel explicit power shapes which take into account variations in horizontal power shapes throughout the core. The sensitivity of the THINC-IV analysis to radial power shapes is discussed in Reference 52.

For operation at a fraction P of full power, the design $F^N_{\Delta H}$ used is given by:

$$F^N_{\Delta H} = F^{RTP}_{\Delta H}\ (1 + 0.3\ (1\text{-}P)) \qquad (4.4\text{-}20)$$

$F^{RTP}_{\Delta H}$ is set by the Core Operating Limits Report. The permitted relaxation of $F^N_{\Delta H}$ is included in the DNB protection setpoints and allows radial power shape changes with rod insertion to the insertion limits, thus allowing greater flexibility in the nuclear design.

4.4.3.2.2 Axial Heat Flux Distributions

As discussed in Paragraph 4.3.2.2, the axial heat flux distribution can vary as a result of rod motion, power change, or due to spatial xenon transients which may occur in the axial direction. Consequently, it is necessary to measure the axial power imbalance by means of the ex-core nuclear detectors (as discussed in Subparagraph 4.3.2.2.7) and protect the core from excessive axial power imbalance. The Reactor Trip System provides automatic reduction of the appropriate trip setpoints on excessive axial power imbalance; that is, when an extremely large axial offset corresponds to an axial shape which could lead to a DNBR which is less than that calculated for the reference DNB design axial shape or excessive fuel centerline temperature.

The reference DNB design axial shape used is a chopped cosine shape with a peak to average value of 1.55.

4.4.3.3 Core Thermal Response

A general summary of the steady-state thermal-hydraulic design parameters including thermal output, flow rates, etc., is provided in Table 4.4.2-1 for all loops in operation, and in Table 4.4.2-2 for operation with one coolant loop out of service.

As stated in Subsection 4.4.1, the design bases of the application are to prevent departure from nucleate boiling and to prevent fuel melting for Condition I and II events. The protective systems described in Chapter 7 (Instrumentation and Controls) are designed to meet these bases. The response of the core to Condition II transients is given in Chapter 15.

4.4.3.4 Analytical Techniques

4.4.3.4.1 Core Analysis

The objective of reactor core thermal design is to determine the maximum heat removal capability in all flow subchannels and show that the core safety limits (as presented in the SQN Technical Specifications) are not exceeded while compounding engineering and nuclear effects. The thermal design takes into account local variations in dimensions, power generation, flow redistribution, and mixing. THINC-IV is a realistic three-dimensional matrix model which has been developed to account for hydraulic and nuclear effects on the enthalpy rise in the core (References 52 and 63). The behavior of the hot assembly is determined by superimposing the power distribution among the assemblies upon the inlet flow distribution while allowing for flow mixing and flow distribution between assemblies. The average flow and enthalpy in the hottest assembly is obtained from the core-wide, assembly by assembly analysis. The local variations in power, fuel rod and pellet fabrication, and mixing within the hottest assembly are then superimposed on the average conditions of the hottest assembly in order to determine the conditions in the hot channel.

The following sections describe the use of the THINC Code in the thermal-hydraulic design evaluation to determine the conditions in the hot channel and to assure that the safety related design bases are not violated.

Steady State Analysis

The THINC-IV computer program as approved by the NRC (Reference 43) is used to determine coolant density, mass velocity, enthalpy, vapor void, static pressure, and DNBR distributions along parallel flow channels within a reactor core under all expected operating conditions. The THINC-IV code is described in detail in References 52 and 63, including models and correlations used. In addition, a discussion on experimental verification of THINC IV is given in Reference 63.

The effect of crud on the flow and enthalpy distribution in the core is accounted for directly in the THINC-IV evaluations by assuming a crud thickness several times that which would be expected to occur. This results in slightly conservative evaluations of the minimum DNBR.

Estimates of uncertainties are discussed in section 4.4.2.10.

Experimental Verification

Extensive experimental verification of THINC-IV is presented in Reference 63.

The THINC-IV analysis is based on a knowledge and understanding of the heat transfer and hydrodynamic behavior of the coolant flow and the mechanical characteristics of the fuel elements. The use of the THINC-IV analysis provides a realistic evaluation of the core performance and is used in the thermal analyses as described above.

Transient Analysis

The THINC-IV thermal-hydraulic computer code does not have a transient capability. Since the third section of the THINC-I program (Reference 41) does have this capability, this code (THINC-III) continues to be used for transient DNB analysis.

The conservation equations needed for the transient analysis are included in THINC-III by adding the necessary accumulation terms to the conservation equations used in the steady-state (THINC-I) analysis. The input description must now include one or more of the following time dependent arrays:

1. inlet flow variation,
2. heat flux distribution,
3. inlet pressure history.

At the beginning of the transient, the calculation procedure is carried out as in the steady state analysis. The THINC-III code is first run in the steady state mode to ensure conservatism with respect to THINC-IV and in order to provide the steady state initial conditions at the start of the transient. The time is incremented by an amount determined either by the user or by the program itself. At each new time step the calculations are carried out with the addition of the accumulation terms which are evaluated using the information from the previous time step. This procedure is continued until a preset maximum time is reached.

At preselected intervals, a complete description of the coolant parameter distributions within the array as well as DNB are printed out. In this manner the variation of any parameter with time can be readily determined.

At various times during the transient, steady state THINC-IV is applied to show that the application of the transient version of THINC-I is conservative.

The THINC-III code does not have the capability for evaluating fuel rod thermal response. This is treated by the methods described in Subsection 15.1.9.

4.4.3.4.2 Fuel Temperatures

As discussed in Paragraph 4.4.2.2, the fuel rod behavior is evaluated utilizing a semi-empirical thermal model which considers in addition to the thermal aspects such items as clad creep, fuel

swelling, fission gas release, release of absorbed gases, release of helium from IFBA, if present, cladding corrosion and elastic deflection, and helium solubility.

A detailed description of the thermal model can be found in References 85 and 91.

4.4.3.4.3 Hydrodynamic Instability

The analytical methods used to access hydraulic instability are discussed in Paragraph 4.4.3.5.

4.4.3.5 Hydrodynamic and Flow Power Coupled Instability

Boiling flow may be susceptible to thermohydrodynamic instabilities (Reference 73). These instabilities are undesirable in reactors since they may cause a change in thermohydraulic conditions that may lead to a reduction in the DNB heat flux relative to that observed during a steady flow condition or to undesired forced vibrations of core components. Therefore, a thermohydraulic design criterion was developed which states that modes of operation under Condition I and II events shall not lead to thermohydrodynamic instabilities.

Two specific types of flow instabilities are considered for Westinghouse PWR operation. These are the Ledinegg or flow excursion type of static instability and the density wave type of dynamic instability.

A Ledinegg instability involves a sudden change in flow rate from one steady state to another. This instability occurs (reference 73) when the slope of the reactor coolant system pressure drop-flow rate curve

$\frac{\partial \Delta P}{\partial G_{internal}}$ becomes algebraically smaller than the loop

supply (pump head) pressure drop-flow rate curve $\frac{\partial \Delta P}{\partial G_{external}}$

The criterion for stability is thus $\frac{\partial \Delta P}{\partial G_{internal}} > \frac{\partial \Delta P}{\partial G_{external}}$

The W pump head curve has a negative slope ($\partial\Delta P/\partial G$ external < 0) whereas the reactor coolant system pressure drop-flow curve has a positive slope ($\partial\Delta P/\partial G1$ internal > 0) over the Condition I and Condition II operational ranges. Thus, the Ledinegg instability will not occur.

The mechanism of density wave oscillations in a heated channel has been described by Lahey and Moody (reference 45). Briefly, an inlet flow fluctuation produces an enthalpy perturbation. This perturbs the length and the pressure drop of the single phase region and causes quality or void perturbations in the two-phase regions which travel up the channel with the flow. The quality and length perturbations in the two-phase region create two-phase pressure drop perturbations. However, since the total pressure drop across the core is maintained by the characteristics of the fluid system external to the core, then the two-phase pressure drop perturbation feeds back to the single phase region. These resulting perturbations can be either attenuated or self-sustained.

A simple method has been developed by Ishii (Reference 68) for parallel closed channel systems to evaluate whether a given condition is stable with respect to the density wave type of dynamic instability. This method had been used to assess the stability of typical Westinghouse reactor designs (References 69, 71, 74) under Condition I and II operation. The results indicate that a large margin to density wave instability exists, e.g., increases on the order of 200% of rated reactor power would be required for the predicted inception of this type of stability.

The application of the method of Ishii (Reference 68) to Westinghouse reactor designs is conservative due to the parallel open channel feature of Westinghouse PWR cores. For such cores, there is little resistance to lateral flow leaving the flow channels of high power density. There is also energy transfer from channels of high power density to lower power density channels. This coupling with cooler channels has led to the opinion that an open channel configuration is more stable than the above closed channel analysis under the same boundary conditions. Flow stability tests (Reference 75) have been conducted where the closed channel systems were shown to be less stable than when the same channels were cross connected at several locations. The cross connections were such that the resistance to channel cross flow and enthalpy perturbations would be greater than that which would exist in a PWR core which has a relatively low resistance to cross flow.

Flow instabilities which have been observed have occurred almost exclusively in closed channel systems operating at low pressures relative to the Westinghouse PWR operating pressures. Kao, Morgan and Parker (Reference 76) analyzed parallel closed channel stability experiments simulating a reactor core flow. These experiments were conducted at pressures up to 2200 psia. The results showed that for flow and power levels typical of power reactor conditions, no flow oscillations could be induced above 1200 psia.

Additional evidence that flow instabilities do not adversely affect thermal margin is provided by the data from the rod bundle DNB tests. Many Westinghouse rod bundles have been tested over wide ranges of operating conditions with no evidence of premature DNB or of inconsistent data which might be indicative of flow instabilities in the rod bundle.

In summary, it is concluded that thermohydrodynamic instabilities will not occur under Condition I and II modes of operation for Westinghouse PWR reactor designs. A large power margin (greater than doubling rated power) shows no predicted inception of such instabilities. Analysis has been performed which shows that minor plant to plant differences in Westinghouse reactor designs such as fuel assembly arrays, core power flow ratios, fuel assembly length, etc. will not result in gross deterioration of the above power margins.

4.4.3.6 Temperature Transient Effects Analysis

Waterlogging damage of a fuel rod could occur as a consequence of a power increase on a rod after water has entered the fuel rod through a clad defect. Water entry will continue until the fuel rod internal pressure is equal to the reactor coolant pressure. A subsequent power increase raises the temperature and, hence, could raise the pressure of the water contained within the fuel rod. The increase in hydrostatic pressure within the fuel rod then drives a portion of the water from the fuel rod through the water entry defect. Clad distortion and/or rupture can occur if the fuel rod internal pressure increase is excessive due to insufficient venting of water to the reactor coolant. This occurs when there is both a rapid increase in the temperature of the water within the fuel rod and a small defect. Zircaloy clad fuel rods which have failed due to

waterlogging (References 78 and 79) indicate that very rapid power transients are required for fuel failure. Normal operational transients are limited to about 40 cal/gm-min. (peak rod) while the Spert tests (Reference 78) indicate that 120 to 150 cal/gm is required to rupture the clad even with very short transients (5.5 msec. period). Release of the internal fuel rod pressure is expected to have a minimal effect on the reactor coolant system (Reference 78) and is not expected to result in failure of additional fuel rods (Reference 79). Ejection of fuel pellet fragments into the coolant stream is not expected (References 78 and 79). A clad breech due to waterlogging is thus expected to be similar to any fuel rod failure mechanism which exposes fuel pellets to the reactor coolant stream. Waterlogging has not been identified as the mechanism for clad distortion or perforation of any Westinghouse Zircaloy-4 clad fuel rods.

4.4.3.7 Potentially Damaging Temperature Effects During Transients

The fuel rod experiences many operational transients (intentional maneuvers) during its residence in the core. A number of thermal effects must be considered when analyzing the fuel rod performance.

The clad can be in contact with the fuel pellet at some time in the fuel lifetime. Clad-pellet interaction occurs if the fuel pellet temperature is increased after the clad is in contact with the pellet. Clad-pellet interaction is discussed in Subparagraph 4.2.1.3.1.

Increasing the fuel temperature results in an increased fuel rod internal pressure. One of the fuel rod design bases limits the fuel rod internal pressures such that clad rupture due to high internal gas pressure is precluded (Subparagraph 4.2.1.1.1).

The potential effects of operation with waterlogged fuel are discussed in Paragraph 4.4.3.6 which concluded that waterlogging is not a concern during operational transients.

Clad flattening, as noted in Subparagraph 4.2.1.3.1, has been observed in some operating power reactors. Thermal expansion (axial) of the fuel rod stack against a flattened section of clad could cause failure of the clad. This is no longer a concern because clad flattening is precluded during the fuel residence in the core. (See Subparagraph 4.2.1.3.1).

There can be a differential thermal expansion between the fuel rods and the guide thimbles during a transient. Excessive bowing of the fuel rods could occur if the grid assemblies did not allow axial movement of the fuel rods relative to the grids. Thermal expansion of the fuel rods is considered in the grid design so that axial loads imposed on the fuel rods during a thermal transient will not result in excessively bowed fuel rods (See Subparagraph 4.2.1.2.2).

4.4.3.8 Energy Release During Fuel Element Burnout

As discussed in Paragraph 4.4.3.3 the core is protected from going through DNB over the full range of possible operating conditions. In the extremely unlikely event that DNB should occur, the clad temperature will rise due to the steam blanketing at the rod surface and the consequent degradation in heat transfer. During this time there is a potential for chemical reaction between the cladding and the coolant. However, because of the relatively good film boiling heat transfer following DNB, the energy release resulting from this reaction is insignificant compared to the power produced by the fuel.

DNB With Physical Burnout - Westinghouse (Reference 72) has conducted DNB tests in a 25-rod bundle where physical burnout occurred with one rod. After this occurrence, the 25 rod test section was used for several days to obtain more DNB data from the other rods in the bundle. The burnout and deformation of the rod did not affect the performance of neighboring rods in the test section during the burnout or the validity of the subsequent DNB data points as predicted by the W-3 correlation. No occurrences of flow instability or other abnormal operation were observed.

DNB With Return to Nucleate Boiling - Additional DNB tests have been conducted by Westinghouse (Reference 80) in 19 and 21 rod bundles. In these tests, DNB without physical burnout was experienced more than once in single rod in the bundles for short periods of time. Each time, a reduction in power of approximately 10% was sufficient to reestablish nucleate boiling on the surface of the rod. During these and subsequent tests, no adverse effects were observed on this rod or any other rod in the bundle as a consequence of operating in DNB.

4.4.3.9 Energy Release or Rupture of Waterlogged Fuel Elements

A full discussion of waterlogging including energy release is contained in Paragraph 4.4.3.6. It is noted that the resulting energy release is not expected to affect neighboring fuel rods.

4.4.3.10 Fuel Rod Behavior Effects from Coolant Flow Blockage

Coolant flow blockages can occur within the coolant channels of a fuel assembly or external to the reactor core. The effects of fuel assembly blockage within the assembly on fuel rod behavior is more pronounced than external blockages of the same magnitude. In both cases the flow block- ages cause local reductions in coolant flow. The amount of local flow reduction, where it occurs in the reactor, and how far along the flow stream the reduction persists are considerations which will influence the fuel rod behavior. The effects of coolant flow blockages in terms of maintaining rated core performance are determined both by analytical and experimental methods. The experimental data are usually used to augment analytical tools such as computer programs similar to the THINC-IV program. Inspection of the DNB correlation (Paragraph 4.4.2.3 and Reference 44) shows that the predicted DNBR is dependent upon the local values of quality and mass velocity.

The THINC-IV code is capable of predicting the effects of local flow blockages on DNBR within the fuel assembly on a subchannel basis, regardless of where the flow blockage occurs. In Reference 63, it is shown that for a fuel assembly similar to the Westinghouse design, THINC-IV accurately predicts the flow distribution within the fuel assembly when the inlet nozzle is completely blocked. Full recovery of the flow was found to occur about 30 inches downstream of the blockage. With the reactor operating at the nominal full power conditions specified in Table 4.4.2-1, the effects of an increase in enthalpy and decrease in mass velocity in the lower portion of the fuel assembly would not result in the reactor violating the safety analysis DNBR limit.

From a review of the open literature it is concluded that flow blockage in "open lattice cores" similar to the Westinghouse cores cause flow perturbations which are local to the blockage. For

instance, A. Oktsubo, et. al., (Reference 81), show that the mean bundle velocity is approached asymptotically about 4 inches downstream from a flow blockage in a single flow cell. Similar results were also found for 2 and 3 cells completely blocked.

Basmer (Reference 82), et. al., tested an open lattice fuel assembly in which 41% of the subchannels were completely blocked in the center of the test bundle between spacer grids. Their results show the stagnant zone behind the flow blockage essentially disappears after 1.65 L/De or about 5 inches for their test bundle. They also found that leakage flow through the blockage tended to shorten the stagnant zone or in essence the complete recovery length. Thus, local flow blockages within a fuel assembly have little effect on subchannel enthalpy rise. The reduction in local mass velocity is then the main parameter which affects the DNBR. If the Sequoyah plants were operating at full power and nominal steady state conditions as specified in Table 4.4.2-1, a reduction in local mass velocity greater than 76% would be required to reduce the DNBR to the safety analysis DNBR limit. The above mass velocity effect on the DNB correlation was based on the assumption of fully developed flow along the full channel length. In reality a local flow blockage is expected to promote turbulence and thus would likely not effect DNBR at all.

Coolant flow blockages induce local crossflows as well as promote turbulence. Fuel rod behavior is changed under the influence of a sufficiently high crossflow component. Fuel rod vibration could occur, caused by this crossflow component, through vortex shedding or turbulent mechanisms. If the crossflow velocity exceeds the limit established for fluid elastic stability, large amplitude whirling results. The limits for a controlled vibration mechanism are established from studies of vortex shedding and turbulent pressure fluctuations. The crossflow velocity required to exceed fluid elastic stability limits is dependent on the axial location of the blockage and the characterization of the crossflow (jet flow or not). These limits are greater than those for vibratory fuel rod wear. Crossflow velocity above the established limits can lead to mechanical wear of the fuel rods at the grid support locations. Fuel rod wear due to flow induced vibration is considered in the fuel rod fretting evaluation (Section 4.2).

4.4.4 Testing And Verification

4.4.4.1 Tests Prior to Initial Criticality

A reactor coolant flow test (pre-operational test W-1.8), as noted in Table 14.1-2, was performed following fuel loading but prior to initial criticality. Coolant loop pressure drop data was obtained in this test. This data in conjunction with coolant pump performance information allows determination of the coolant flow rates at reactor operating conditions. This test verified that proper coolant flow rates have been used in the core thermal and hydraulic analysis.

4.4.4.2 Initial Power and Plant Operation

Core power distribution measurements are made at several core power levels (see Subparagraph 4.3.2.2.7). These tests are used to insure that conservative peaking factors are used in the core thermal and hydraulic analysis.

Additional demonstration of the overall conservatism of the THINC analysis was obtained by comparing THINC predictions to incore thermocouple measurements. These measurements were performed on the Zion reactor (Reference 84). No further in-pile testing is planned.

4.4.4.3 Component and Fuel Inspections

Inspections performed on the manufactured fuel are delineated in Paragraph 4.2.1.4. Fabrication measurements critical to thermal and hydraulic analysis are obtained to verify that the engineering hot channel factors employed in the design analyses (Subparagraph 4.4.2.3.4) are met.

4.4.5 Instrumentation Application

4.4.5.1 Incore Instrumentation

Instrumentation is located in the core so that by correlating movable neutron detector information with fixed thermocouple information radial, axial, and azimuthal core characteristics may be obtained for all core quadrants.

The incore instrumentation system is comprised of thermocouples, positioned to measure fuel assembly coolant outlet temperatures at preselected positions, and fission chamber detectors positioned in guide thimbles which run the length of selected fuel assemblies to measure the neutron flux distribution. Figure 4.4.5-1 shows the number and location of instrumented assemblies in the core.

The movable incore neutron detector system is used for detailed mapping of the core. The incore instrumentation system is described in more detail in Paragraph 7.7.1.9.

The core-exit thermocouples provide an information only backup to the flux monitoring instrumentation for monitoring power distribution.

The Incore Instrumentation is provided to obtain data from which fission power density distribution in the core, coolant enthalpy distribution in the core, and fuel burnup distribution may be determined.

4.4.5.2 Overtemperature and Overpower ΔT Instrumentation

The Overtemperature ΔT trip protects the core against low DNBR. The Overpower ΔT trip protects against excessive power (fuel rod rating protection).

As discussed in Subparagraph 7.2.1.1.2, factors included in establishing the Overtemperature ΔT and Overpower ΔT trip setpoints includes the reactor coolant temperature in each loop and the axial distribution of core power, as applicable, through the use of the two section ex-core neutron detectors.

4.4.5.3 Instrumentation to Limit Maximum Power Output

The outputs of the three ranges (source, intermediate, and power) of nuclear instruments, are used to limit the maximum power output of the reactor within their respective ranges.

There are six detectors installed around the reactor in the primary shield radial locations. Two fission chamber assemblies for the source/intermediate range are installed on opposite "flat" portions of the core containing the primary startup sources. Four dual section uncompensated ionization chamber assemblies for the power range installed vertically at the four corners of the core and located equidistant from the reactor vessel at all points and, to minimize neutron flux pattern distortions, within one foot of the reactor vessel. Each power range detector provides two signals corresponding to the neutron flux in the upper and in the lower sections of a core quadrant. The three ranges of instruments are used as inputs to monitor neutron flux from a completely shutdown condition to 120 percent of full power.

The difference in neutron flux between the upper and lower sections of the power range detectors is used to limit the trip setpoints, as applicable, and to provide the operator with an indication of the core power axial offset. In addition, the output of the power range channels are used for:

1. the rod speed control function,

2. to alert the operator to an excessive power unbalance between the quadrants,

3. protecting the core against the consequences of rod ejection accidents, and

4. protecting the core against the consequences of adverse power distributions resulting from dropped rods.

Details of the neutron detectors and nuclear instrumentation design and the control and trip logic are given in Chapter 7. The limits on neutron flux operation and trip setpoints are given in the SQN Technical Specifications.

4.5 REACTOR (HTP AND MARK-BW FUEL)

4.5.1 SUMMARY DESCRIPTION

Beginning in Cycle 9, both units were reloaded with Mark-BW fuel supplied by Framtome. Approximately two thirds of the Cycle 9 core was Westinghouse Vantage 5H fuel, with additional Mark-BW fuel being added with each successive fuel load. The current licensing basis in Chapters 4 and 15 of the FSAR is the analysis that was done by Westinghouse for Westinghouse fuel. Beginning with Cycle 19 for Unit 2 and Cycle 20 for Unit 1, each unit will be loaded with Advanced W17 HTP fuel supplied by AREVA NP, Inc. Approximately two thirds of each core was Mark-BW fuel with additional Advanced W17 HTP fuel being added with each successive fuel load.

This section provides the description of the Mark-BW and Advanced W17 HTP fuel designs and the methods, models, and analysis that AREVA NP Inc. uses to design the fuel and the fuel cycle. The portions of this section that are provided are numbered to correspond to portions of the current Section 4. The No. 5 has been inserted into the numbering sequence to distinguish the two. For example, 4.3.2.1 will appear as 4.5.3.2.1 in this new section. Where practical, the same system is followed in the numbering of tables and figures.

The Mark-BW fuel assembly is a 17x17, standard lattice fuel assembly design for use in Westinghouse-designed reactors. The Mark-BW fuel assembly consists of 264 fuel rods, 24 guide thimbles, and one instrument sheath in a 17x17 square array. The guide thimbles are annealed Zircaloy-4 or alloy M5 and provide guidance for control rod insertion. The fuel assembly contains 8 spacer grid assemblies, which consist of 6 Zircaloy-4 intermediate spacer grids, and 2 Inconel-718 end grids. The bottom nozzle is a proven debris resistant design. A detailed description of the Mark-BW fuel assembly may be found in the topical report BAW-10172P, “Mark-BW Mechanical Design Report,” (Reference 1).

The Advanced W17 HTP fuel assembly is a 17x17, standard lattice fuel assembly design for use in Westinghouse-designed reactors. The Advanced W17 HTP fuel assembly consists of 264 fuel rods, 24 guide tubes and one instrument tube in a 17x17 square array. The guide tubes are annealed Zircaloy-4 and provide guidance for control rod insertion. The fuel assembly contains 7 Zircaloy-4 spacer grid assemblies including the uppermost grid and 1 nickel alloy 718 lowermost spacer grid assembly. The Advanced W17 HTP fuel assembly also includes 3 Zircaloy-4 intermediate flow mixing spacer grid assemblies. The bottom nozzle is a proven debris resistant design. A detailed description of the Advanced W17 HTP assembly may be found in Reference 5.

The basic design parameters of the Mark-BW and Advanced W17 HTP fuel assemblies are comparable to those of the Westinghouse Standard and Vantage 5H 17x17 fuel assemblies. The Mark-BW and Advanced W17 HTP fuel assemblies incorporate proven AREVA NP Inc. design features while maintaining compatibility with the Westinghouse reactor internals and with resident fuel assemblies. Compatibility of the Mark-BW fuel with the Sequoyah plant and its resident fuel is discussed in detail in topical report BAW-10220P, A Mark-BW Fuel Assembly Application for Sequoyah Units 1 and 2 (Reference 2). Compatibility of the Advanced W17 HTP fuel assembly with Sequoyah plant and its resident fuel is discussed in Reference 6.

The analysis techniques employed in the core design are tabulated in Table 4.5.1-2. The reactor coolant system design transient group core power history and fatigue cycles are summarized in Tables 4.5.2-2 and 4.5.2-3. The thermal and hydraulic reactor design parameters with the Mark-BW and Advanced W17 HTP fuel assemblies are shown in Table 4.5.4.2-1. The specific or limiting loads

considered for design purposes for the fuel assembly structure are given in Subparagraph 4.5.2.1.1.2. The design evaluation for the fuel rods is given in Subparagraph 4.5.2.1.3.1 and the fuel assembly structure stresses and deflection evaluation is presented in Subparagraph 4.5.2.1.3.2.

Beginning with the Unit 2 Cycle 13 reload core, the design basis thermal-hydraulic analysis was revised to reflect removal of the fuel assembly thimble plugs (Reference 4). Use of thimble plugs in subsequent core designs shall be evaluated as part of the reload safety analysis.

4.5.2 MECHANICAL DESIGN

4.5.2.1 FUEL

4.5.2.1.1 Design Basis

4.5.2.1.1.1 Fuel Rods

Cladding Material Properties

Cold worked and stress relieved zirconium alloy grade R60804 (Zircaloy-4) or 1% niobium (Alloy M5) is used for fuel rod cladding (Reference 1) and fuel rod end plugs (Reference 2) due to its low neutron absorption characteristics.

Cladding Stress Limits

The fuel rod stress limits are based on criteria using as guidelines the ASME Boiler and Pressure Vessel Code (Reference 3). Stress level intensities are calculated in accordance with the ASME Code and Reference 21, which includes both normal and shear stress effects. These stress intensities are compared to S_m, the allowable stress level. Worst case or 2s tolerance dimensions are used in all cases except where noted and justified. For zirconium alloy fuel rod components, S_m equals two-thirds of the minimum specified unirradiated yield strength of the material at the operating temperature (650°F). Stress intensity calculations combine the stresses so that the stress intensity is maximized.

Pressure and temperature inputs to the stress intensity analyses are chosen so that the operating conditions for normal operation (Condition I) and all Condition II transients are enveloped.

The effects of cladding corrosion and fretting wear are considered when evaluating cladding stress.

Cladding Stress Intensities meet the following limits for Condition I & II events in general. Limits for M5 cladding are contained in Reference 21 and are considered proprietary to AREVA.

$P_m \leq S_m$
$P_l \leq 1.5\ S_m$
$P_m + P_b \leq 1.5\ S_m$
$P_m + P_b + Q \leq 3.0\ S_m$

Where:

P_m = General Primary Membrane Stress Intensity
P_l = Local Primary Membrane Stress Intensity
P_b = Primary Bending Stress Intensity
Q = Secondary Stress Intensity

Cladding Transient Strain

The uniform transient strain (elastic and inelastic) shall not exceed 1 percent. The transient strain is determined using the computer code COPERNIC (Reference 27) for fuel rods in transition or full cores containing Advanced W17 HTP assemblies (starting with Unit 2 Cycle 19 and Unit 1 Cycle 20). Fuel rods in cores containing all Mark-BW assemblies (up to and including Unit 2 Cycle 18 and Unit 1 Cycle 19) are analyzed with the TACO3 (Reference 4) and GDTACO (Reference 19) codes. Transient strain is defined as transient-induced cladding deformation with gage lengths corresponding to the cladding dimensions. The transient strain is calculated from the change in diameter of the pellet during the maximum power transient.

Cladding Strain Fatigue

The total fatigue usage factor for the clad is determined for all appropriate transients listed in the UFSAR in a manner consistent with References 21 and 24. The total fatigue usage factor does not exceed 0.9 as defined in References 21 and 24. The fatigue curve from Reference 5 shall be used.

Fuel Material

The fuel pellet density shall be 96% theoretical density (TD).

4.5.2.1.1.2 Fuel Assembly Structure

Design analyses are performed using standard Framatome codes licensed for use with the NRC. Stress analyses follow the general format and procedures outlined in Section III, Subsection NG, of the ASME Boiler and Pressure Vessel Code (Reference 3). Although Section III is not directly applicable to fuel rod analysis, it is used as a guide in classifying the stresses into various categories, assigning appropriate limits on criteria to these categories, and combining the stresses to determine the stress intensity.

Allowable stress levels for the hold-down springs are based on experience within the nuclear industry with the spring material.

Bolts are analyzed following the ASME Code guidelines for threaded structural fasteners.

Type A Components - Stress/Strain Limits

The Stress intensity limits for the Type A components (components fabricated from ASME Code recognized materials) are tabulated in the ASME Boiler and Pressure Vessel Code, Section III.

Type B Components - Stress/Strain Limits

Stress intensity limits for Type B components (components fabricated from non-ASME Code materials) are developed based on the guidelines of the ASME Code. The S_m used to determine the allowable stress, and other material properties from these materials are determined from sources other than the ASME Code. Irradiation induced changes in the material properties are considered in determining the allowable stress levels for design verification. For example, zirconium alloy material allowable, S_m, is 2/3 the unirradiated yield strength. Worst case or 2σ tolerance dimensions are used in all cases except where noted and justified.

Spacer Grids

The Mark-BW end and intermediate spacer grids position the fuel rods to be mutually parallel on the proper square pitch spacing, position the guide thimbles in the proper pattern, and provide lateral support to the fuel rods, guide thimbles, and instrument sheath.

Intermediate Spacer Grid Material Properties

Zircaloy-4 is used due to its low neutron capture characteristics. The material ductility is adequate to prevent localized failures due to forming. The effect on the mechanical properties by temperature, irradiation, and corrosion are accounted for in the design evaluation. The dynamic properties are determined by testing and used to benchmark analytical fuel assembly models.

End Grid Material Properties

Inconel 718 is used due to its corrosion resistance and high strength at elevated temperature. The material is solution annealed and mill processed to eliminate predominant secondary phases in the microstructure and grain boundaries. The lateral stiffness and dynamic properties are tested and used to benchmark analytical fuel assembly models.

Vibration and Fatigue

The spacer grids provide adequate support to maintain the fuel rods in a coolable geometry for all operating conditions. The grids also provide lateral and rotational restraint for the fuel rods. Contact surfaces for the fuel rods maintain acceptable cladding wear depths throughout the life of the fuel assembly. Fuel rod wear performance is established based on design verification testing and/or operating experience with similar designs.

Chemical Compatibility

For the Zircaloy-4 intermediate spacer grids, material corrosion resistance is established based on testing in steam at 750^{o}F and 1500 psi. All samples tested exhibit a continuous black, lustrous oxide film. The end spacer grids of Inconel 718 are very resistant to corrosion by the coolant under reactor conditions. Experience has shown that the hard protective oxide film that forms retards corrosion.

Guide Thimble Wear

Guide thimble wear is considered in the structural analyses of the fuel assembly. Wear characteristics are based on operation experience (post irradiation examinations), design verification testing, and/or similarities with existing designs (in order of preference).

The criteria for allowable guide thimble wear are determined based on structural analyses of the guide thimbles that account for tube wall thinning due to wear.

Corrosion Allowance

Material thinning due to corrosion is considered in the structural analyses as applicable. The corrosion allowance(s) are established based on operating experience.

Fatigue Analyses

The total fatigue usage factor for all Condition I and II Events plus one Condition III Event does not exceed 0.9 for the fuel rod assembly and 1.0 for all other fuel assembly components. Fatigue analyses are plant specific based on the transients given in Table 5.2.1-1. The fuel assembly permits the reactor to perform daily load follow.

Normal Operation

Structural integrity is verified for the fuel assembly and its components subjected to loading associated with normal operation and upset events (and emergency condition transients, if applicable).

LOCA/Seismic

Structural integrity is verified for the fuel assembly and its components subjected to loading associated with LOCA, Seismic (both OBE and SSE), and combined LOCA and Seismic events. Rod Cluster Control Assembly insertion requirements are presented below. A coolable geometry is maintained at all times:

(1) During all normal operation (Condition I).
(2) During all Condition II and III events.
(3) During a small LOCA ($\leq 0.5\ ft^2$) and following an OBE (Operating Base Earthquake)
(4) Following a SSE (Safe Shutdown Earthquake)

Handling and Shipping

The structural integrity shall be verified for the fuel assembly and its components subjected to loading associated with handling and shipping operations.

Fuel Handling Loads

Handling equipment setpoints limit the loads imposed on the fuel assembly. Handling procedures ensure that the actual accelerations are less than the design loads allowable.

Shipping Loads

The evaluation of the fuel assembly components for loads imposed on the fuel assembly during shipment addresses the following quasi static loadings:

Lateral:	6.0 G's load factor
Axial:	4.0 G's load factor

Fuel Assembly Bow

The fuel assembly is free standing as fabricated, and its bow and tilt are sufficiently small for ease of handling and to minimize fuel assembly bow during operation.

Fuel Assembly Growth Allowance

The fuel assembly to reactor internals gap allowance for differential growth and thermal expansion is designed to ensure that a positive clearance is maintained during the assembly life.

4.5.2.1.2 Design Description

Mark-BW Fuel Assembly

The Mark-BW fuel assembly shown in Figure 4.5.2-1, is a 17x17, standard lattice, Zircaloy-4 intermediate spacer grid fuel assembly designed for use in Westinghouse-designed reactors. The fuel assembly incorporates many standard Framatome design features while maintaining compatibility with the Westinghouse reactor internals and resident fuel assemblies. The nozzles and spacer grid designs are proven Framatome designs currently in operation in Westinghouse-designed reactor vessels. The guide thimble top section and dashpot diameters, the instrument sheath diameter, and the fuel rod outside diameter are compatible with the standard and Vantage 5H 17x17 Westinghouse designs. The fuel rod design has been developed based on standard Framatome methods applied to the Westinghouse outside cladding diameter. The features of the Mark-BW fuel assembly design include the Zircaloy-4 intermediate spacer grid, the intermediate spacer grid restraint system, reconstitutable top nozzle, and fuel rod plenum springs on both ends of the fuel stack.

The Mark-BW fuel assembly consists of 264 fuel rods, 24 guide thimbles, and one instrument sheath in a 17x17 square array. The annealed zirconium alloy guide thimbles provide guidance for control rod insertion and are attached to nozzles and Inconel end spacer grids at the top and bottom of the fuel assembly to form the structural skeleton. A reduced diameter section at the bottom of the guide thimbles acts as a dashpot and decelerates the control rod assembly during

trips. The annealed zirconium alloy instrument sheath occupies the center lattice position and provides guidance and protection for the incore instrumentation assemblies. The fuel rod and guide thimble spacing is maintained along the length of the assembly by five vaned and one vaneless Zircaloy-4 intermediate spacer grids.

The Low Pressure Drop (LPD) Mark-BW is a design variant of the Mark-BW that incorporates an improved top nozzle (see Figure 4.5.2-1 and Figure 4.5.2-7B) and an improved bottom nozzle (see Figure 4.5.2-5B). The LPD nozzles enhance the performance of the current Mark-BW fuel assemblies, while maintaining proper structural characteristics. These nozzles provide improved debris filtering capabilities and decrease the pressure drop across the fuel assembly.

Advanced W17 HTP Fuel Assembly

The Advanced W17 HTP fuel assembly shown in Figure 4.5.2-16, is a 17x17, standard lattice, Zircaloy-4 intermediate spacer grid fuel assembly designed for use in Westinghouse-designed reactors. The fuel assembly incorporates many standard AREVA design features while maintaining compatibility with the Westinghouse reactor internals and resident fuel assemblies. The nozzles and spacer grid designs are proven AREVA designs currently in operation in Westinghouse-designed reactor vessels. The guide tube top section and dashpot diameters, the instrument tube diameter, and the fuel rod outside diameter are compatible with the Mk-BW fuel assembly. The fuel rod design has been developed based on standard AREVA methods applied to the Westinghouse outside cladding diameter. The features of the Advanced W17 HTP fuel assembly design include the Zircaloy-4 intermediate HTP spacer grid, the nickel alloy 718 HMP lower most spacer grid, a welded cage structure system, reconstitutable top nozzle, debris resistant bottom nozzle and fuel rod plenum springs on both ends of the fuel stack.

The Advanced W17 HTP fuel assembly consists of 264 fuel rods, 24 guide tubes and one instrument tube in a 17x17 square array. The annealed zirconium alloy guide tubes provide guidance for control rod insertion and are attached to the nozzles and all end and intermediate spacer grids to form the structural cage assembly. The outside diameter of the guide tubes is constant along the entire length of the guide tube assembly with a reduced inside diameter section at the bottom of the guide tubes which acts as a dashpot and decelerates the control rod assembly during trips. The annealed zirconium alloy instrument tube occupies the center lattice position and provides guidance and protection for the incore instrumentation assemblies. The fuel rod and guide tube spacing is maintained along the length of the assembly by six HTP Zircaloy-4 intermediate spacer grids.

4.5.2.1.2.1 Fuel Rods

The two types of Mark-BW and Advanced W17 HTP fuel rods are UO_2 and the UO_2-Gd_2O_3 rod designs. The UO_2 design consists of sintered low enriched UO_2 pellets, and may be blanketed by lower enriched UO_2 pellets at both ends, contained in a zirconium alloy seamless tube with end caps welded at each end. The UO_2-Gd_2O_3 design is very similar, but its central pellet section consists of UO_2-Gd_2O_3 pellets. The small amount of gadolinia present acts as a poison, and its inclusion in some of the fuel rods in a fuel assembly allows a better power distribution within that fuel assembly. There is a small diametral clearance between the cladding inside the diameter and the outside diameter of the fuel pellets. The tube is sealed at both ends by welding zirconium alloy end caps to the cladding (Figures 4.5.2-3 and 4.5.2-18). A series of springs at both end (Figures 4.5.2-4 and 4.5.2-19) position the fuel stack within the cladding and provide protection against axial gap formation during shipping, handling, and irradiation. The fuel rod is evacuated and then backfilled with helium of high purity at high pressure prior to upper end cap welding. The high purity helium assures good heat transfer across the pellet-cladding gap. In addition, the high pressure fill gas prevents creep collapse of the fuel rod during the expected incore operation of the fuel rod. A schematic of the UO_2 fuel rod design is shown in Figures 4.5.2-2 and 4.5.2-17.

The fuel pellets are cylindrical in shape with a spherical dish at each end. The ends of the pellets are chamfered and include an outward land taper. The configuration on the pellet ends reduce hourglassing of the fuel pellet at power. The diameter of the fuel pellet is controlled within very tight limits. The density of the pellets is 96% TD.

The purpose of the fuel rod spring system is to prevent axial gaps from forming in the fuel column. Thermal and irradiation induced changes in the fuel stack length can cause gaps to form in the fuel stack. Axial acceleration of the fuel stack during shipping and handling can also produce gaps in the fuel stack. Axial gaps in the fuel stack cause power peaks in adjacent fuel rods, and allow for creep ovalization into the gap.

4.5.2.1.2.1.1 Blended Uranium Assemblies

Four lead test assemblies (LTAs) utilizing reprocessed uranium were fabricated to demonstrate the feasibility of using reprocessed uranium fuel in commercial nuclear power plants. These LTAs consist of standard Mark-BW fuel assemblies which contain UO_2 fuel pellets obtained by blending reprocessed highly enriched uranium with natural uranium. The LTAs do not contain axial blankets.

The LTA UO_2 fuel pellets contain concentrations of the minor uranium isotopes (^{232}U, ^{234}U, and ^{236}U), which are higher than typically found in UO_2 fuel. These isotopic differences only affect the nuclear properties and have no effect on the chemical, mechanical or thermal properties of the fuel pellets. The increased concentrations of ^{234}U and ^{236}U act as a fixed neutron poison and require that the concentration of ^{235}U be increased to have comparable reactivity with standard UO_2 fuel pellets.

Further design details and the impact of the mechanical, nuclear, thermal, thermal-hydraulic, and safety analyses of the LTAs are given in Reference 20.

Batch implementation of fuel assemblies containing reprocessed uranium commenced with Unit 2 Cycle 16. Design details related to the impact of batch implementation of reprocessed uranium on mechanical, nuclear, thermal, thermal-hydraulic, and safety analyses are described in Reference 26.

4.5.2.1.2.1.2 ALLIANCE Fuel Assemblies

Four Lead Test Assemblies (LTAs) were fabricated using standard Mark-BW fuel rods clad in M5 material to demonstrate the feasibility of using the new structural material and design features of ALLICANCE-type fuel assemblies in U.S. commercial nuclear power plants. M5 is a Framatome developed alloy composed of approximately 99 percent zirconium and 1 percent niobium. It was designed for high fuel rod burnup conditions and has shown to exhibit superior corrosion resistance and reduced irradiation-induced growth as compared to zircaloy-4. The M5 material was reviewed in Reference 21.

The ALLIANCE fuel assemblies are designed to be complete fit-and-function replacements for standard Mark-BW fuel assemblies that incorporate material and design changes to improve performance. The major differences are use of the new M5 alloy replacing zircaloy-4 structural parts and design modifications to the fuel rod end plugs to permit fuel rod pulling. These changes permit higher fuel burn-up with improved thermal-hydraulic and mechanical performance (i.e., reduced flow resistance pressure drops, greater geometric stability) of the fuel assemblies compared with standard Mark-BW assemblies.

Other differences include redesign of the spacer grids and guide tubes. ALLIANCE design details and the impact of the mechanical, nuclear, thermal, thermal-hydraulic, and safety analyses of the ALLIANCE LTAs were reviewed in Reference 22. These LTAs may be utilized on both units.

4.5.2.1.2.1.3 Advanced Mark-BW(A) Lead Use Assemblies

Four Lead Use Assemblies (LUAs) were fabricated to demonstrate the feasibility of the new structural material and design features of Advanced Mark-BW(A)-type fuel assemblies in U.S. commercial nuclear power plants. These changes are primarily intended to reduce fuel assembly bow and twist, and to improve mechanical integrity.

The Advanced Mark-BW(A) fuel assemblies are designed to be complete fit-and-function replacements for standard Mark-BW fuel assemblies that incorporate material and design changes to improve performance. The major differences are a welded cage with M5 MONOBLOC guide tubes and M5 Mark-BW structural mixing vane grids, HMP alloy 718 upper and lower end grids, a removable upper end fitting with a quarter-turn quick disconnect feature, and a FUELGUARD lower end fitting. The Sequoyah Advanced Mark-BW(A) will utilize a slightly longer fuel rod and a slightly higher uranium loading than the standard Mark-BW assemblies. Advanced Mark-BW(A) design details and the impact of the Advanced Mark-BW(A) LUAs on the mechanical, nuclear, thermal-hydraulic, and safety analyses were reviewed in Reference 25. All methodologies used to analyze the LUAs are NRC approved.

4.5.2.1.2.1.4 Reconstituted Fuel Assemblies

Fuel assemblies under irradiation in the reactor core may contain fuel rods that are not suitable for operation in planned subsequent fuel cycles. Fuel rods that develop those conditions may be replaced with non-heat producing zirconium alloy or stainless steel replacement rods in limited quantities, thus allowing the reconstituted fuel assemblies to continue to be utilized in subsequent fuel cycles. Fuel assemblies are allowed to be reconstituted with a maximum of ten replacement rods.

The replacement rods are designed and analyzed to ensure that no adverse impact on fuel assembly or core performance results from their use. The rod dimensions are set so that:

1. The replacement rod engages all spacer grid stops under all conditions.

2. Clearance is maintained between the replacement rod and the top grillage under reactor temperature and irradiation conditions.

The conditions that control the design are:

1. The difference is thermal expansion between the replacement rods and fuel rods in the radial direction shall not cause permanent deformation of the spacer grid spring stops and allow excessive strains of the grid cells.

2. The difference in mass between the replacement rods and the fuel rods shall not affect fuel assembly lift.

The presence of one or more non-heated replacement rods may cause a small flow redistribution within their respective fuel assembly array, and power peaking may be redistributed. Generic impacts of these effects on the fuel mechanical, nuclear, thermal-hydraulic, and safety analyses were analyzed in Reference 23. Each as-reconstituted fuel assembly is evaluated on a cycle-specific basis using the requirements specified in Reference 23 to ensure that its use is acceptable for its next cycle of residence in the core.

Replacement rods as described in this section may be utilized in fuel assemblies for both Sequoyah units.

4.5.2.1.2.2 Fuel Assembly Structure - Mark-BW Assembly

The fuel assembly structure consists of a bottom nozzle, top nozzle, guide and instrument thimbles, and grid assemblies. Each of these components is described in detail in the following paragraphs.

Bottom Nozzle

The bottom nozzle is either a flat stainless steel plate or grillage with legs welded to each corner as shown in Figure 4.5.2-5A or, in the Low Pressure Drop Mark-BW, a stainless steel structure supporting a high strength mesh plate filter as shown in Figure 4.5.2-5B. The bottom nozzle engages with the guide pins in diagonally opposing corners and rests directly on the lower core plate to support the weight of the fuel assembly plus the hold-down spring forces. The fuel rods are seated on the top surface of the bottom nozzle.

The flow holes in the nozzle are sized to filter out debris that could be captured between the nozzle and the lower end spacer grid. Debris captured in the spacer grid area has been known to cause damaging wear to the fuel rods. Hydraulic flow tests have been conducted on the bottom nozzle to verify that the effects on fuel assembly pressure drop are acceptable. The bottom nozzle is attached to the guide thimbles by a simple bolted connection illustrated in Figure 4.5.2-6. The bottom end plug of the guide thimble is internally threaded. The bottom end plug rests on the nozzle. The guide thimble bolt is inserted through a hole in the nozzle and engages the threads of the bottom end plug. The bolt head is tack welded to the underside of the nozzle. A stepped diameter hole through the shank and head of the bolt is provided to vent the bottom portion of the guide thimble.

Top Nozzle

The top nozzle assembly is a box-like structure of welded stainless steel plates as shown in Figure 4.5.2-7A and for the Low Pressure Drop Mark-BW in Figure 4.5.2-7B. The grillage of the nozzle consists of a plate with a machined hole pattern for attaching the guide thimbles and providing flow area for the reactor coolant exiting the fuel assembly. The top surface of the grillage provides the interface for fixed core components such as thimble plug assemblies and burnable poison rod assemblies.

The top plate of the top nozzle assembly provides the handling and reactor internals interface surfaces and supports four sets of three-leaf Inconel holddown springs. Two guide pins on the upper core plate engage with two holes in diagonally opposing corners of the nozzle to position the assembly during operation. The holddown springs are attached to the nozzle by clamp bolts. A tang extending from the main (top) leaf of the holddown springs is captured through a slot in the top plate to preload the spring and to capture the spring parts in the unlikely event of a spring fracture.

The top nozzle assembly is removable to allow for the replacement of fuel rods in the field. A ring nut and locking cup arrangement is used to attach the nozzle to the threaded collars at the top ends of the guide thimbles as shown in Figure 4.5.2-8A and Figure 4.5.2-8B.

The nuts may be removed and replaced in the field with a special tool.

Guide and Instrument Thimbles

The guide thimbles are structural members which also provide channels for the control rods, burnable poison rods, neutron source, or thimble plug assemblies. Each thimble is fabricated from zirconium alloy tubing having two different diameters. The tube diameter at the top section provides the annular area necessary for rapid control rod insertion during a reactor trip. The tube diameter at the bottom section provides a dashpot effect near the end of the control rod travel during normal reactor trip operation. Holes are located above the dashpot region to reduce control rod drop times. A stepped diameter hole through the guide thimble bolt is provided to vent the dashpot region of the guide thimble.

Grid Assemblies

End Spacer Grids

The end spacer grids of the Mark-BW fuel assembly are similar to the end spacer grids of the other Framatome fuel assembly designs. The grids are fabricated from Inconel-718 strips which are slotted at the top or bottom for assembly in an "egg crate" fashion. The strips are TIG welded at the top and bottom of the strip intersections to form an assembly. Punched projections on the strips form stops to support the fuel rods and saddles to support the guide thimbles and instrument tube. Each fuel rod cell contains two perpendicular sets of stops and each set consists of two hardstops near the edges of the strip opposed by one softstop at the center of the strip as shown in Figure 4.5.2-9. Keying windows are provided for the insertion of rectangular keys which open the cells (softstops) for scratch free and stress free insertion of the fuel rods during fuel bundle assembly.

The top and bottom end grid restraint designs are illustrated in Figures 4.5.2-10 and 4.5.2-11, respectively. Tabs are employed at the guide thimble locations on the top of the top end grid strips and on the bottom of the bottom end grid strips for the attachment of short 304L stainless steel sleeves. These sleeves are resistance welded to the tabs during the spacer grid assembly process. The top end grid sleeves are seated against the guide thimble collars to restrain the grid from upward motion and to transmit axial compression loads from the top nozzle to the fuel rods. The bottom end grid sleeves are crimped into circular grooves in the guide thimble bottom end plugs to restrain the grid in both axial directions.

Intermediate Spacer Grids

The grids are fabricated from Zircaloy-4 strips which are slotted at the top or bottom for assembly in an "egg crate" fashion. The strips are welded at the top and bottom at the strip intersections to form a grid assembly. Fuel rod, guide thimble and instrument tube supports are of the standard Framatome design previously described for the end

spacer grids. The standard Framatome keyable features are maintained for the Zircaloy-4 intermediate spacer grids allowing for scratch free and stress free fuel rod insertion during fuel bundle assembly. The generous lead in features and an improved corner have been created to facilitate ease of fuel assembly handling.

The five upper intermediate spacer grid assemblies employ flow mixing vanes on the downstream edges (top). The mixing vanes are small tabs bent approximately 30^{o} to the flow direction. The purpose of the mixing vanes is to improve the thermal performance of the fuel assembly by enhancing the coolant turbulence. The mixing vane design and pattern has been verified by CHF testing and is based on proven mixing vane designs of NFI in use in Japan. Mixing vanes are not used on the lowest intermediate spacer grid since the thermal enhancement is not needed in this cooler region of the fuel assembly.

As in all Framatome fuel assembly designs, the Mark-BW intermediate spacer grids are not attached to the guide thimbles, and the grids are free to follow the fuel rods early in life as they grow due to irradiation. This feature virtually eliminates axial friction forces suspected of contributing to fuel rod bow. Gross spacer grid movement is limited by stops incorporated on the instrument tube and selected guide thimbles shown in schematic form on Figure 4.5.2-12.

The Mark-BW intermediate spacer grid restraint system allows for floating grid assemblies. The intermediate spacer grids are allowed to follow the fuel rods as they grow due to irradiation until burnup effects have significantly relaxed the Zircaloy-4 spacer grids. At this burnup level, the intermediate spacer grids contact rigid stops to prevent further axial movement. The stops are short sleeves or ferrules dimpled to eight guide thimbles above each intermediate spacer grid and to the instrument sheath below each intermediate grid. The flow mixing vanes are removed from the walls of the eight guide thimbles and instrument tube cells which interface with the ferrules. This spacer grid restraint system employs these eight guide thimbles as restraining members. The locations of the eight restraining guide thimbles are shown in Figure 4.5.2-13. There is also one ferrule attached to the instrument sheath below the top end spacer grid and below each intermediate spacer grid to prevent downward motion during shipping and handling.

4.5.2.1.2.3 Fuel Assembly Structure - Advanced W17 HTP Fuel Assembly

The fuel assembly structure consists of a bottom nozzle, top nozzle, welded cage assembly that consists of guide and instrument tubes, and grid assemblies. Each of these components is described in detail in the following paragraphs.

Bottom Nozzle Assembly

The bottom nozzle is a stainless steel structure supporting a set of blades as shown in Figure 4.5.2-20. The bottom nozzle engages with the lower core plate guide pins in diagonally opposing corners and rests directly on the lower core plate to support the weight of the fuel assembly plus the hold-down spring forces. The fuel rods are slightly elevated from the top surface of the bottom nozzle.

The blades are positioned to filter out debris that could be captured between the nozzle and the lower end spacer grid. Debris captured in the spacer grid area has been known to cause damaging wear to the fuel rods. Hydraulic flow tests have been conducted on the bottom nozzle to verify that the effects on fuel assembly pressure drop are acceptable. The bottom nozzle is attached to the guide tubes by a simple bolted connection illustrated in Figure 4.5.2-21. The guide tube lower end fitting of the guide tube is internally threaded. The guide tube lower end fitting rests on the nozzle. The guide tube capture screw is inserted through a hole in the nozzle and engages the threads of the bottom end plug. The bolt head is crimped to the bottom nozzle. A stepped diameter hole through the shank and head of the bolt is provided to vent the bottom portion of the guide tube assembly.

Top Nozzle Assembly

The top nozzle assembly is a box-like structure of welded stainless steel plates as shown in Figure 4.5.2-22. The grillage of the top nozzle assembly consists of a plate with a machined hole pattern for attaching the guide tubes and providing flow area for the reactor coolant exiting the fuel assembly. The top surface of the grillage provides the interface for fixed core components such as thimble plug assemblies and burnable poison rod assemblies.

The top plate of the top nozzle assembly provides the handling and reactor internals interface surfaces and supports four sets of three-leaf nickel alloy 718 holddown springs. Two guide pins on the upper core plate engage with two holes in diagonally opposing corners of the nozzle to position the assembly during operation. The holddown springs are attached to the nozzle by clamp bolts. A tang extending from the main (top) leaf of the holddown springs is captured through a slot in the top plate to preload the spring and to capture the spring parts in the unlikely event of a spring fracture.

The top nozzle assembly is removable to allow for the replacement of fuel rods in the field. A ¼ turn quick disconnect is used to attach the nozzle to the top ends of the guide tubes as shwon in Figure 4.5.2-23. There are no loose parts with this design.

Cage Assembly

The welded cage assembly is shown in Figure 4.5.2-27. The individual HTP and IFM spacer grids are welded to the guide tubes at each elevation. The HMP spacer grid is held in place by small zirconium alloy rings called spacer capture rings above and below the HMP. The instrument tube is held in place with spacer capture rings and a counter bore in the top nozzle assembly.

Guide and Instrument Tubes

The guide tubes are structural members which also provide channels for the control rods, burnable poison rods, neutron source, or thimble plug assemblies. Each tube is fabricated from zirconium alloy tubing having two different inside diameters and a constant outside diameter (Monobloc). The tube diameter at the top section provides the annular area necessary for rapid control rod insertion during a reactor trip. The tube inside diameter at the bottom section provides a dashpot effect near the end of the control rod travel during normal reactor trip operation. Holes are located above the dashpot region to reduce control rod drop times. A stepped diameter hole through the guide tube cap screw is provided to vent the dashpot region of the guide tube.

Grid Assemblies

End Spacer Grids

The end spacer grids of the Advanced W17 HTP fuel assembly are similar to the end spacer grids of other AREVA NP Inc. HTP fuel assembly designs. The lower most HMP grid is fabricated from nickel alloy 718 strips and the upper most HTP grid is fabricated from Zircaloy-4 strips. The strips are formed as a singlet and welded together to form a doublet. The grid is assembled by loading the doublets which are slotted at the top or bottom for assembly in an “egg crate” fashion. The strips are laser welded at the top and bottom of the strip intersections to form an assembly. Formed projections on the strips form contact areas to support the fuel rods and to support the guide tubes and instrument tube. Each fuel rod cell contains four pairs of contact areas as shown in Figure 4.5.2-24. The HMP spacer is shown in Figure 4.5.2-25.

Intermediate Spacer Grids

The intermediate grids are fabricated from Zircaloy-4 strips which are slotted at the top or bottom for assembly in an “egg crate” fashion. The strips are welded at the top and bottom at the strip intersections to form a grid assembly. Fuel rod, guide tube and instrument tube supports are of the standard AREVA NP Inc. HTP design previously described for end spacer grids. The generous lead-in features and an improved corner have been created to facilitate ease of fuel assembly handling. The six intermediate spacer grid assemblies employ the curved flow channels on the downstream edges (top) (see Figure 4.5.2-24).

Intermediate Flow Mixing Spacers

The Advanced W17 HTP fuel assembly includes intermediate flow mixing (IFMs) (See Figure 4.5.2-26). These spacers are placed in the spans between HTP spacers to improve thermal-hydraulic performance.

4.5.2.1.3 Design Evaluation

4.5.2.1.3.1 Fuel Rods

Fuel Rod Vibration Analysis

Extensive out-of-core testing has demonstrated that flow-induced vibration of the fuel rod cladding causes neither fretting wear nor fatigue damage for PWR operating conditions. Further discussion of fretting wear can be found in ensuing discussions.

Fuel Rod Stress Evaluation

The fuel rod cladding is analyzed for the stresses induced during operation. The ASME pressure vessel stress intensity limits are used as guidelines. Conservative values are used for cladding thickness, oxide layer buildup, external pressure, internal fuel rod pressure, differential temperature, and unirradiated cladding yield strength. The maximum cladding stress intensities are within limits under all Condition I and II events.

Pellet-cladding interaction (PCI) and creep collapse-induced stresses are not of concern as small deformations of the cladding will relieve those stresses. Limits are based on ASME criteria and Reference 21. Stress level intensities are calculated in accordance with the ASME Code, which includes both normal and shear stress effects. These stress intensities are compared to S_m. S_m is equal to 2/3 of the minimum specified unirradiated yield strength of the material at the operating temperature. In general, the limits are as follows. Limits for M5 cladding are contained in Reference 21 and are considered proprietary to AREVA.

I. Primary general membrane stress intensities (P_m) must not exceed S_m.

II. Local primary membrane stress intensities (P_l) must not exceed 1.5 * S_m. These include the contact stresses from spacer grid-fuel rod contact.

   Primary membrane + Bending stress intensities (P_l +P_b) must not exceed 1.5 * S_m.

III. Primary membrane + Bending + Secondary stress intensities (P_l+P_b+Q) must not exceed 3.0 * S_m.

Stress intensity calculations combine the stresses so that the stress intensity is maximized. Pressure and temperature inputs to the stress intensity analyses are chosen so that the operating conditions for all Condition II transients are enveloped.

The type of stresses which are analyzed are as follows:

1. Pressure Stresses - These are membrane stresses due to the external and internal pressure on the fuel rod cladding.

2. Flow Induced Vibration - These are longitudinal bending stresses due to vibration of the fuel rod. The vibration is caused by coolant flow around the fuel rod.

3. Ovality - These are bending stresses due to external and internal pressure on the fuel rod cladding that is oval. This does not include the stresses resulting from creep ovalization into an axial gap.

4. Thermal Stresses - These are secondary stresses that arise from the temperature gradient across the fuel rod during reactor operation.

5. Fuel Rod Growth Stresses - These secondary stresses are due to the fuel rod slipping through the spacer grids. These may be due to the fuel assembly expanding more than the fuel rod due to heatup, or they may be due to fuel rod growth from irradiation.

6. Three Point Grid Stop Stresses - These are bending stresses due to the grid stop loads against the fuel rod cladding.

7. Fuel Rod / Spacer Grid Interaction - These are localized stresses due to contact between the fuel rod cladding and the spacer grid stops.

Classifications of Stresses:

Loading Condition	Stress Category
Pressure Stresses	P_m
Ovality Stresses	P_b
Spacer Grid Interaction	P_l
Flow Induced Vibration	P_b
Radial Thermal Expansion	Q
Differential Rod Growth	Q
Three Point Soft-Hardstop Loading	Q

where

P_m = primary membrane stresses
P_b = primary bending stresses
P_l = primary membrane local stresses
Q = secondary stresses

The results of the stress analysis for the Mark-BW fuel rod are as follows:

Loading Condition	Minimum Margin %
Primary Membrane	45
Primary Membrane + Bending	31
Primary Membrane + Bending + Local	0.2
Primary Membrane + Bending + Local + Secondary	73

The results of the stress analysis for the Advanced W17 HTP fuel rod are as follows:

Loading Condition	Minimum Margin %
Primary Membrane	50
Primary Membrane + Bending	22
Primary Membrane + Bending + Local	14
Primary Membrane + Bending + Local + Secondary	39

Margins are calculated by the following:

$$\text{Margin \%} = [(\text{Allowable} - \text{Predicted})/\text{Predicted}] \times 100\ \%$$

The minimum unirradiated yield strength of the cladding was used. Minimum rod prepressure and a bounding system pressure (2750 psia) were used to maximize the pressure differential across the cladding. Conservative cladding dimensions were used (maximum internal diameter combined with minimum external diameter). An oxidation layer equivalent to the cladding oxide limit was subtracted from the outer surface of the fuel rod.

The Mark-BW and Advanced W17 HTP designs will operate with sufficient margin for cladding stress for the requirements of References 17 and 21.

Material and Chemical Reaction

The excellent corrosion resistance of the Zircaloy-4 cladding has been developed by examination of production Mark-B fuel assemblies currently in-reactor. The cladding corrosion resistance is the result of a combination of high quality material standards and sound manufacturing techniques. To prevent the possibility of primary hydriding, the pellets are verified to be dry (UTL of 1 ppm of hydrogen).

Alloy M5 exhibits a superior corrosion performance to the previously used optimized (low tin) Zr-4. The alloying elements are Zr, Nb, S, and O. The chemical composition of M5 is the same for all components: cladding, guide tubes, and end plugs. Careful control of the chemistry and thermal-mechanical fabrication parameters imbue the alloy with excellent in-core performance characteristics. To prevent primary hydriding, the fuel pellets are verified to be dry (UTL of 1 ppm of hydrogen).

In the reactor operating environment, a thin, tightly adherent oxide film is initially formed on the surface of the cladding. Continued growth of the oxide layer has several effects. The effective thickness of the cladding wall is reduced as a portion of the base metal is converted to oxide. The cladding operates at a higher temperature because of the lower thermal conductivity of the oxide compared to the base metal. Hydrogen, released from the metal/water reaction, diffuses into the cladding and forms zirconium hydride which results in a decrease in cladding ductility. For Zircaloy-4, the maximum oxide thickness expected at 65,000 MWd/mtU is found to be 127 micron. The cladding hydrogen content at EOL was determined assuming an oxide layer of 127 micron thickness and a 12% hydrogen pickup fraction. The cladding hydrogen content was found to be less than 710 ppm which has been shown to be ductile at reactor operating temperatures. With Alloy M5, the maximum oxide thickness expected at 65,000 MWd/mtU burnup is less than 40 microns. The hydrogen content of M5 cladding is expected to be less than 100 ppm at 65,000 MWd/mtU. Therefore, the oxide growth that the Mark-BW and Advanced W17 HTP fuel rod designs are projected to experience will not result in embrittlement of the cladding.

Fuel Rod Stress-Accelerated Corrosion

Out-of-pile tests show that, in the presence of high cladding tensile stresses, large concentrations of fission products (such as iodine) can chemically attack the zirconium alloy cladding and cause eventual cracking. Extensive post-irradiation examinations (PIEs) have shown no evidence of stress corrosion cracking (SCC).

Fuel Rod Cycling and Fatigue

The fuel rods were analyzed for cladding fatigue using the ASME pressure vessel code (Reference 3) as a guideline. A maximum fatigue usage factor of 0.9 is allowed and determined

by the O'Donnell and Langer design curve[5] for all condition I and II events and one condition III event. The O'Donnell and Langer design curve for irradiated Zircaloy was modified by a factor of two on stress amplitude or twenty on the number of cycles, whichever is more conservative at each point. Further conservatism incorporated into the analysis includes dimensions, external pressure, and prepressure chosen to maximize clad stresses. Allowances for oxide layer buildup and differential temperature across the cladding are assumed. The results for fatigue utilization factor for the Zircaloy-4 clad fuel rods bound the utilization factor for the M5 clad fuel rods. The fuel rod cladding will experience at least 10/40 of the number of transients the reactor pressure vessel will experience in its forty year life (assuming a fuel rod life of at least ten years). The reactor coolant system design transients are summarized in Table 5.2.1-1. The combination of applicable transients and the power histories that are analyzed to determine the fuel rod fatigue usage factor are given in Table 4.5.2-2.

The results of the fatigue analysis for the Mark-BW and Advanced W17 HTP fuel rods show a maximum fatigue usage factor of 0.239 which is below the design limit of 0.9.

Fuel Rod Irradiation Stability

The Zircaloy-4 or alloy M5 cladding retains its high impact strength after irradiation, and overall strength is increased while the ductility is reduced when in service.

Axial gaps between the top nozzle and fuel rods provide sufficient margin to accommodate irradiation growth of the fuel rods in the axial direction.

Fuel Rod Creep Collapse and Creepdown

The fuel rods are analyzed for creep collapse using methods outlined in References 4, 6, 19 and 27. These are, respectively, the topical reports for the creep collapse code CROV and the fuel rod design codes TACO3 and GDTACO, and COPERNIC. TACO3 is used for the UO_2 rods, GDTACO is used for the UO_2-Gd_2O_3 (up to and including Unit 2 Cycle 18 and Unit 1 Cycle 19) rods while COPERNIC is used for both UO_2 and UO_2-Gd_2O_3 rods (starting with Unit 2 Cycle 19 and Unit 1 Cycle 20). The acceptance criterion is that the predicted creep collapse life of the fuel rod exceeds the maximum expected incore life. CROV predicts that the fuel rod will fail due to creep collapse when any of the following happens:

1. The bifurcation buckling pressure is exceeded.
2. The Timoshenko yield point pressure is exceeded.
3. The rate of creep ovalization exceeds 0.1 mils/hr.
4. The maximum generalized non-linear stress exceeds the unirradiated yield strength of the cladding.

The following conservatisms are used in determining creep collapse life of the fuel rod:

1. Minimum fuel rod pre-pressure is used.
2. No fission gas release is assumed.
3. Worst case densification is used.

4. A worst case or enveloping power history is used.
5. Worst case cladding dimensions are used.
   a. Lower tolerance limit for cladding thickness.
   b. Upper tolerance limit for cladding ovality.

Oxide layer growth is accounted for in the TACO3 or GDTACO and COPERNIC analyses, whose output serves as input to the CROV code. These conservatisms are used in determining the creep collapse life of the Mark-BW and Advanced W17 HTP fuel rods.

Using nuclear design inputs, power histories are determined for the Mark-BW and Advanced W17 HTP fuel rods. These histories, with appropriate uncertainty factors, are input into the fuel rod design code, to determine the temperature, pressure, and fast neutron flux level history of the Mark-BW and Advanced W17 HTP fuel rods. These parameters are input into CROV using conservative cladding dimensions. The CROV results determine the burnup where creep collapse is predicted for the Mark-BW and Advanced W17 HTP fuel rods. On a cycle-specific basis, the maximum fuel rod average burnup based upon the CROV creep collapse analysis for the Mark-BW and Advanced W17 HTP fuel rods is verified to be greater than 62,000 MWd/mtU.

Fuel Pellet Dimensional Stability

The mechanical design of the fuel accounts for the effects of densification, swelling, and fission product release. The pellet designs incorporate dished ends and chamfers to prevent hour- glassing and ridging. The dished ends also prevent axial expansion by allowing room for fuel center swelling.

Fuel Pellet Potential for Chemical Reaction

There is some potential for fuel/clad chemical interaction as a result of fission product release. Industry experience has shown this reaction to be minimal. In the event of a breach in the cladding, the reaction of water with the uranium dioxide would be slight. The ability of uranium dioxide to retain fission products coupled with the large volume of coolant results in the released fission products being significantly diluted.

Fuel Pellet Thermal Stability

Since the fuel pellets are basically sintered uranium dioxide, aside from melting, which is precluded by the design, no phase change will occur. The fuel thermal performance codes COPERNIC, TACO3 and GDTACO include models that account for gap conductance, fuel densification and swelling, fuel restructuring, gap conductance, fuel densification and swelling, fuel restructuring, gap closure and fission gas release.

Fuel Pellet Irradiation Stability

Densification has been observed to occur early in the life of the fuel and results in a shrinkage of the fuel pellet. Densification is a function of the temperature and irradiation conditions, initial fuel density, and material characteristics. Another irradiation phenomenon that affects fuel

density is swelling, caused by the generation of fission products. A burnup and power dependent densification and swelling model is presented in the NRC accepted topical report BAW-10162P-A, TACO3 (Reference 4) while a burnup dependent model is presented in the NRC accepted topical report BAW-10231P-A, COPERNIC (Reference 27). Fission gas production and release models are also included in TACO3 and COPERNIC. These models have been correlated to a substantial data base.

Fuel Rod Internal Pin Pressure

Maximum internal fuel rod pressure as a function of burnup is calculated using the best estimate fuel thermal performance codes TACO3, GDTACO and COPERNIC. The internal fuel rod pressure is determined using the computer code COPERNIC (Reference 27) for fuel rods in transition or full cores containing Advanced W17 HTP assemblies (starting with Unit 2 Cycle 19 and Unit 1 Cycle 20). Fuel rods in cores containing all Mark-BW assemblies are analyzed with the TACO3 (Reference 4) and GDTACO (Reference 19) codes (up to and including Unit 2 Cycle 18 and Unit 1 Cycle 19). These codes include models for gap conductance, fuel densification and swelling, fuel restructuring, cladding creep and deformation, gap closure, and fission gas release. An internal pin pressure analysis for the Mark-BW and Advanced W17 HTP fuel is performed for each cycle-specific reload safety evaluation. Based upon the requirements of the cycle-specific core design, the analysis verifies that the fuel can operate to a maximum rod average burnup of 62,000 MWd/mtU for UO_2 and Gd_2O_3 rods and 55,000 MWd/mtU for Gd_2O_3 rods analyzed using the COPERNIC code, resulting in pressures that meet the approved fuel rod gas pressure design criterion.

Pellet - Cladding Mechanical Interaction

The TACO3, GDTACO and COPERNIC codes will be used to predict the local linear heat rates as a function of burnup at which the cladding uniform hoop strain equals 1%. Cladding uniform hoop strain is limited to 1% during normal operation and anticipated operational occurrences. Cladding strain analyses will be performed with nominal fuel rod characteristics and enveloping power history across the range of operational burnups. The predictions will include the effects of cladding oxide formation.

The transient strain is determined using the computer code COPERNIC (Reference 27) for fuel rods in transition or full cores containing Advanced W17 HTP assemblies (starting with Unit 2 Cycle 19 and Unit 1 Cycle 20). Fuel rods in cores containing all Mark-BW assemblies are analyzed with the TACO3 (Reference 4) and GDTACO (Reference 19) codes (up to and including Unit 2 Cycle 18 and Unit 1 Cycle 19).

In the analysis for the Mark-BW and Advanced W17 HTP fuel rods, linear heat rate limits that preserve the transient cladding strain limit of 1%, up to a rod average burnup of 62,000 MWd/mtU for UO_2 and UO_2-Gd_2O_3 fuel rods and 55,000 MWd/mtU for UO_2-Gd_2O_3 fuel rods using COPERNIC, are determined on a cycle-specific basis for application in the reload safety evaluation.

Fuel Rod Temperatures

Fuel and cladding temperatures are evaluated using the best estimate fuel thermal performance codes TACO3 (Reference 4), GDTACO (Reference 19) and COPERNIC (Reference 27). These codes include models for gap conductance, fuel densification and swelling, fuel restructuring, cladding creep and deformation, gap closure, and fission gas release. The use of these codes for fuel and clad temperature analyses are discussed further in Section 4.5.4.2.2.

Peak clad temperatures for non-LOCA transients have been determined using the LYNXT (Reference 10) thermal-hydraulic code. The peak clad temperature was calculated to be less than 2200°F for the locked rotor accident, which is the most severe non-LOCA accident with respect to peak clad temperature. Therefore, the clad temperature requirement is met for the non-LOCA conditions.

Fuel Rod Bow

There are several features of the Mark-BW fuel assembly design that improve its fuel rod bow performance. These features include two spacer springs on each end of the fuel stack inside the fuel rod, not rigidly attaching the intermediate spacer grids to the guide thimbles, and using a keyable spacer grid design. These features reduce the contact stresses that the rod has during insertion and life. By providing a reduction in axial loading, the axial strains induced in the cladding are reduced which translates to lower rod bow. Similarities between the Mark-BW and other Framatome fuel designs (Mark-B, -BZ, -C) permit the use of the rod bow prediction as presented in the rod bow topical report (BAW-10147A-01) (Reference 8). This report has been approved by the NRC for licensing previous Framatome fuel designs.

In most cases, no DNBR penalty due to rod bowing is applied to the Advanced W17 HTP or Mark-BW fuel since predicted bow magnitudes are insufficient to cause a DNBR penalty greater than 1% in fuel with burnup values less than 24,000 MWd/mtU, and fuel with higher burnup does not produce sufficient power to attain design peaking factors. The 1% penalty is accounted for by the pin pitch reduction allowance that is incorporated into the engineering hot channel factor on hot pin average power, discussed in Section 4.5.4.2.3.4. In cases where the predicted rod bow magnitudes are sufficient to cause a DNBR penalty greater than 1%, an augmentation factor is applied to peaking values used to calculate margin to DNB. This penalty is calculated using the method outlined in Section 6.1.1 of BAW-10147PA-R1 (Reference 8).

The fuel rod bow performance of Zircaloy-4 grids has been verified by poolside post irradiation exams (PIE). Water channel measurements made on the Mk-BZ LTA following irradiation to 37.6 GWd/mtU showed the fuel rod bow was enveloped by the predictions from Reference 8.

Potential Effect for Fuel Rod Rupture (Waterlogging)

The Framatome fuel rod is designed to preclude the occurrence of waterlogging. A small defect in the fuel rod cladding, however, could allow water to enter the rod when the Reactor Coolant System is pressurized. The increase in temperature when the reactor is brought up to power causes the internal rod pressure to increase. The magnitude of this pressure increase depends on the amount of water contained in the fuel rod, the magnitude and rate of temperature

increase, and the size of the defect (the defect size defines the capability of the fuel rod to relieve the pressure buildup). SPERT experiments performed at INEL (Reference 11) on waterlogged rods suggest that an energy deposition of 120 cal./gm to 160 cal./gm at reactor periods of 5.5 ms are required to cause rupture of 100% waterlogged rods having no cladding penetration. Normal operational transients are limited to about 40 cal/gm-min (peak rod). Based on the SPERT test results and the conditions occurring in the plant during normal operation, the probability of failing a waterlogged fuel rod is quite small.

Temperature Effects During Transients

The reactor core is designed to preclude any temperature effect that may cause damage to fuel rods during Condition I and Condition II transients. To help assure this, a minimum DNBR of 1.50 BWCMV and a peak cladding temperature limit of 2200°F have been established. Further discussion on damaging temperature effects during transients can be found in Section 4.5.4.3.7.

Energy Release from Cladding Coolant Reaction

Although the reactor is designed to prevent DNB from occurring over the full range of operating conditions; there exists, due to the statistical basis of the BWCMV correlation used to define DNB, a small probability that a fuel rod may go through DNB. Also, there are accident situations categorized as infrequent events, considered and analyzed in Chapter 15, that would result in a predicted DNB. In the unlikely event that DNB occurs, the cladding temperature will begin to increase, causing an increase in the chemical reaction rate between cladding and coolant.

The Baker-Just equation (Reference 12) was used to estimate the energy produced and the thickness of cladding reacted as a function of time with temperature as a parameter. Cladding temperatures considered were 1000, 1200, and 1400°F with reaction times out to 50 minutes.

These temperatures and time ranges envelop the cladding temperatures and reaction times expected from the accident analyses in Chapter 15. The results show that only one percent of the cladding will have reacted after 50 minutes when the cladding temperature is 1400°F. At the same temperature, the energy release is about 0.004 kW/ft, which is less than 0.1% of the average heat rate of the core. From these results, it can be concluded that the potential for chemical reaction between fuel rod cladding and coolant is small and no adverse effects will result during normal operation through the infrequent event type accidents considered and analyzed in Chapter 15.

Energy Released from Waterlogged Rupture

Energy release from waterlogged rupture is not expected to affect neighboring rods. Reference 13 provides experimental results of measured pressure pulses resulting from the failure of two waterlogged fuel rods in an open lattice core. The most significant damage to the core was limited to the bowing of adjacent rods.

Fuel Rod Behavior Effects from Coolant Flow Blockage

The Mark-BW fuel assembly was analyzed for the reduction in flow area for a fully collapsed Mark-BW grid. A spacer grid full collapse is recommended as a worst-case of fuel assembly deformed geometry. A spacer grid collapse is defined as a state in which the grid deformations cause the soft stops to be fully compressed and both hard stops to be in contact. Due to the particular geometry of the Mark-BW grid cell, a collapsed grid as defined above is not geometrically possible. The fuel rod compresses the hardstops slightly. This adds conservatism to the analysis. Results show a 34.6 percent reduction in flow area. A discussion of the effects of a postulated flow blockage can be found in Section 4.5.4.3.10.

4.5.2.1.3.2 Fuel Assembly Structure Stresses and Deflections

Spacer Grids

The top and bottom vaneless spacer grids are constructed of Inconel 718. Inconel 718 has high strength, exceptional corrosion resistance and low thermal stress relaxation at operating temperature. Analytical models were based on tests results and the models determined that the end grids provide adequate stiffness throughout the life of the fuel assembly.

The Zircaloy-4 intermediate spacer grids are designed to follow initial fuel rod irradiation growth and are restrained from large movements which may result in grid mismatch. Through tests and analytical models the intermediate spacer grids were found to provide adequate structural stiffness throughout the life of the fuel assembly. The fuel assembly was analyzed and acceptable margins were found to exist to allow the spacer grids to maintain an adequate guide thimble pattern and diameter to permit control rod insertion during normal operation and upset conditions (Conditions I, II, III, and following a small LOCA, OBE or SSE).

Fuel Assembly Lift

The Mark-BW fuel assembly lift evaluation was performed by comparing the holddown force provided by the fuel assembly leaf springs with the hydraulic forces at various conditions, including the pump overspeed condition. The analysis indicated that the holddown springs provide enough holddown force to prevent fuel assembly liftoff under normal operating conditions. Under the 120% pump overspeed condition, the fuel assembly will experience liftoff but the liftoff will not compress the fuel assembly holddown spring to its solid height, nor will it cause plastic deformation in the spring.

LOCA and/or Seismic Loading

The following criteria have been established for the fuel assembly seismic and LOCA analysis:

(1) For Operational Basis Earthquake (OBE)
The fuel assembly is designed to ensure safe operation following an OBE.

(2) For Safe Shutdown Earthquake (SSE)
The fuel assembly is designed to allow control rod insertion and to maintain a coolable geometry.

(3) For Loss of Coolant Accident (LOCA) or Combined LOCA plus SSE.
The fuel assembly is designed to allow for the safe shutdown of the reactor systems.

In the accident analyses, the lateral effect (LOCA and seismic) and the vertical effect (LOCA) are investigated separately. This leads to a development of a lateral model representing a row of assemblies located on a symmetry axis of the core and a vertical model of the fuel assembly. Only the LOCA effect was analyzed in the vertical direction, as the seismic excitation in this direction will not cause fuel assembly liftoff.

Lateral Analysis

The seismic and LOCA time history motions of the upper grid plate, lower grid plate and core barrel upper core plate elevation were applied to the reactor core model and the fuel assembly deflection and grid impact force responses were determined using the general procedure outlined in the NRC approved topical report BAW-10172P, Rev-1 (Reference 17). In the reactor core model, the fuel assembly was represented by six masses as described in the topical.

The design basis LOCA time histories use “leak-before-break” methodology. The displacements provided are those associated with a worst case attached pipe break. For the cold legs, data for an accumulator line break are furnished. For the hot legs, data for a pressurizer surge line break are provided.

For the Safe Shutdown Earthquake (SSE), the loads experienced by the fuel assemblies were below the elastic load limit which begins to cause permanent deformation of the spacer grid. Since there is no permanent deformation, a coolable geometry is maintained and control rod insertion is allowed. Therefore the requirement for a safe shutdown earthquake is met. As the spacer grid impact loads were within the elastic load limit for the SSE, these results also satisfy the Operational Basis Earthquake (OBE) requirements that the assembly or component not exceed its yield limit. Usually the magnitude of the OBE is half the magnitude of the SSE. Hence, a seperate OBE analysis was not performed. The allowable loads for all categories of loss of coolant accident (LOCA) and a combined SSE and LOCA condition are limited by the requirement that a coolable geometry be maintained. Since none of the loads in any of these cases approach the elastic load limit for the spacer grid, the requirement of a core coolable geometry for LOCA and combined LOCA/SSE has been met.

A bounding analysis of a mixed core configuration (Mark-BW and Westinghouse Vantage 5H and Standard fuel assemblies) representative of a transition cycle was performed. The results of this analysis were compared with the faulted conditions analysis results of the full Mark-BW core configuration. The resulting change in the spacer grid impact loads are minor and within the elastic load limit. Hence, the requirement of a coolable core geometry is met.

Vertical LOCA Analysis

For the vertical LOCA analysis, a one-dimensional (axial) finite element model as described in BAW-10172P was used to represent the fuel assembly structure and was analyzed using a general purpose finite element code. The purpose of the analysis was to determine the loads on a Mark-BW fuel assembly resulting from a postulated LOCA. The vertical LOCA force time histories for the fuel assembly response analysis were calculated. The design basis LOCA provided for the fuel assembly analysis was the "leak-before-break" LOCA event. The force time histories for the cold legs are for an accumulator line break and those for the hot legs are for a pressurizer line break.

Analyses were performed at both beginning and end of life to determine the worst case loading condition. The results of the analysis show that because of the holddown spring applied preload and stiffness, the fuel assembly during the LOCA does not contact the upper core plate. These forces are well below conservatively calculated allowable loads for the guide thimbles and the fuel rods.

Fuel Assembly Structural Analysis

The fuel assembly was evaluated for structural integrity under faulted conditions. It was shown that the fuel assembly mechanical integrity is maintained for the SSE and a combined SSE plus LOCA event with adequate structural margin. The results of the SSE analysis meet the design criteria for OBE described in Section 3 of FCF Topical Report BAW 10133P Rev 1 (Reference 14). So separate OBE stress results were not required. Also the SSE requirement of control and insertion was fulfilled for a combined SSE plus LOCA and therefore provides added conservatism for the analysis. ASME Code subsection NG-3000 (Reference 3) stress criteria is used for the OBE (Code Level B) and Appendix F (Ref. 3) for the SSE plus LOCA (Code Level D). In some cases, failure loads as established by testing were incorporated per the ASME code.

The Mark-BW fuel assembly is structurally adequate for the faulted conditions presented for the Sequoyah Nuclear Plant Units 1 and 2.

Shipping Loads

An analysis was performed to ensure the structural adequacy of the Mark-BW design under the shipping loads specified in Section 4.5.2.1.1.2. The results of the analysis showed that the fuel assembly and its components will maintain their structural integrity under the specified shipping loads. Crush tests have been performed to ensure that the spacer grid dimensional stability is maintained during normal shipping and handling conditions. Summaries of the results are provided below.

1. The upper and lower plenum springs maintained the fuel column position and prevented the formation of axial gaps. This was done by maintaining a preload on the fuel stack to counter acceleration loads up to '4G' which is significantly above those expected to occur during shipping and handling.

2. The fuel rod did not slip through the spacer grids under the maximum axial shipping loads.

3. The spacer grids maintained their structural integrity under the maximum lateral shipping loads, and the maximum clamping loads.

4. Spacer grid soft stops maintained acceptable fuel rod grip forces under the '6G' lateral shipping loads.

Handling Loads

The Zircaloy-4 intermediate spacer grids of the Mark-BW fuel assembly include several design features which promote resistance to hanging-up with other fuel assemblies or equipment during fuel handling. The Mark-BW design utilizes lead-in tabs between the fuel rods on the upper and lower edges of the outer strips of the spacer grid assemblies. The leading edges of the exterior strips of the spacer grid assemblies are inboard of the plane of the outer surface of the peripheral fuel rods, to provide better resistance to hangup during fuel handling. In addition, the minimum margin of safety for handling during assembly shutdown is shown to be adequate.

Cycling and Fatigue

The fuel assembly is subjected to cyclic fatigue loading due to transients, seismic events and flow induced vibration. The effects of this loading has been assessed and, where appropriate, a fatigue analysis has been performed. The results of these analyses show that the cumulative fatigue usage factor is less than 1.0. The allowable fatigue life is determined by using ASME fatigue curves or taking the mean fatigue life curve and applying a factor of 2 on stress or 20 on cycles, whichever is most conservative. The fatigue curve used for Zircaloy material is the O'Donnell and Langer design curve (Ref. 5).

The cyclic loads on the fuel assembly and its components have been divided into three categories: Conditions I, II and III transients; seismic and LOCA events; and flow induced vibration. Seismic and LOCA events are discussed earlier in this section. Transients and flow induced vibration including tests performed are discussed below.

Transients

The reactor transients are mainly variations of temperature and pressure. Flow velocities do not increase significantly over the steady state value. The fuel assembly structural components are not pressure retaining boundaries and remain at bulk coolant temperature. Therefore, many transients do not cause significant loads on the fuel assembly or its components. In particular, pressure changes are insignificant loads. With respect to the design transients from Table 5.2.1-1, for a fuel assembly with an assured life of seven years, the allowable stress taken from the appropriate fatigue curve for the corresponding number of cycles is far in excess of the allowable values used in the static analysis. Since the static analysis accounts for the maximum loads caused by these transients then the cumulative usage factor is assured to be less than one.

Flow-Induced Vibration

The fuel assembly is subjected to vibration induced by flow of the reactor coolant. A Mark-BW prototype fuel assembly was fabricated for use in the test program. The end of life condition was simulated by intentionally oversizing the rod cells of the spacer grids. The Inconel end spacer grids were relaxed approximately 60% and the Zircaloy-4 intermediate spacer grids were relaxed approximately 90%. The fuel rod internals were typical of production parts with pressed tungsten-nickel-copper powder pellets used to simulate the fuel pellets. End of life conditions are the worst case for testing fuel assembly vibration and wear characteristics and mechanical properties. Hydraulic flow testing of the prototype fuel assembly was conducted in the Control Rod Drive Line (CRDL) facility at the Alliance Research Center (ARC). Life and wear tests were conducted to verify the wear resistance due to vibrations. Two 500 hour tests were conducted with the prototype fuel assembly and a thorough examination revealed no abnormal wear.

Testing was conducted to determine the dynamic response to the relaxed Mark-BW fuel assembly to a quick release in air. The effects of temperature and flow on these responses are based on past testing of the Mark-C 17X17 fuel assembly. The frequency and damping characteristics of the fuel assembly were used to benchmark analytical models for the seismic and LOCA analyses. The frequencies used were adjusted for water, temperature, and flow.

Assembly Bow

Fuel assembly bow was measured on the four Mark-BW lead assemblies during Duke Power's McGuire, EOC-5 PIE campaign. The data shows a maximum bow of approximately 0.8 inch on these once burned assemblies. Fuel assembly bow is therefore not a significant concern in Mark-BW fuel assemblies.

Fretting Wear

The fuel assembly design shall be shown to provide sufficient support to limit fuel rod vibration and clad fretting wear to within acceptable depths. A life and wear test was conducted at maximum reactor flow conditions for more than 1000 hours to evaluate the fretting characteristics of fuel rods and spacer grids. The results indicated that there exists an initial "wearing-in period" during which the fuel rods and grid stop interfaces experience high contact forces. After wearing-in, the grids tend to relax slightly and there is irradiation hardening of the material of interest, reducing the contact force. The long-term progressive wear rate then decreases significantly. There was no indication of adverse fretting wear or progressive wear of the cladding. After 1000 hours of testing, the deepest wear measured was 1.2 mils.

4.5.2.1.3.3 Operational Experience

Framatome had considerable experience with its Mark-BW fuel assembly design starting with the lead test assemblies in Duke Power’s McGuire Unit 1, Cycle 5. The design has since been

proven in both Duke Power's McGuire and Catawba Units and Portland General Electric's Trojan Unit, reaching an EOC fuel assembly burnup to-date in excess of 52,000 MWd/mtU in Catawba 1, Cycle 8.

AREVA NP Inc. has considerable experience with its Advanced W17 HTP fuel assembly design. As of December 2011, 1,838 Advanced W17 HTP fuel assemblies are either in core or have been discharged reaching an EOC fuel assembly maximum burnup of 68,000 MWd/mtU. The Advanced W17 HTP fuel design has been used in reload batch quantities at Harris Unit 1 and numerous reactors worldwide.

4.5.2.1.3.4 Test Rod And Test Assembly Experience

Four lead assemblies at Duke Power's McGuire 1 Nuclear Station began their irradiation in cycle 5 in 1987. These assemblies were irradiated for three cycles and reached a maximum fuel assembly burnup of 42,200 MWd/mtU. The assemblies and selected fuel rods were examined after each cycle of irradiation. The PIE scope for each examination is shown in Table 4.5.2-1. Results from these examinations have been combined with results from a similar program for the Framatome Mark-B fuel assembly design, which reached an assembly burnup of 58,300 MWd/mtU, as well as industry programs, and the results have been reflected in currently approved Framatome methods.

4.5.2.1.4 Testing and Inspection Plan

4.5.2.1.4.1 Quality Assurance Program

AREVA NP Inc. engineering specifications require that core components be fabricated under an approved quality control program. This includes shop quality control procedures which are audited by AREVA NP Inc. quality assurance personell. In addition, special process procedures are approved by AREVA NP Inc. design personnel as required by the procurement documents.

AREVA NP Inc. manufactures core components under a controlled manufacturing system, which includes complementary written process procedures and inspection provisions. Extensive attention is given to processing details to ensure a reliable, reproducible, quality product. The fabrication activities are supported and monitored by quality control as described in the Fuel Management Manual. The inspections described herein are those specified for the various components and assemblies. Additional inspections are performed routinely along with the required inspection program to further assure the quality of the final product

4.5.2.1.4.2 Quality Control

The spacer grids are fabricated by an AREVA NP Inc. affiliate. After assembly of the grids, the welds are visually inspected for conformance, and sample quantities of the welds from each grid are optically enlarged and dimensionally inspected. Dimension inspection is accomplished using a vision inspection measuring machine interconnected to a computer.

The cage assembly is fabricated by AREVA NP Inc. The spacers are positioned by use of precise fixtures and after insertion of guide tube assemblies are welded at each elevation of a spacer (HTP & IFM). The HMP spacer due to its material make-up (nickel alloy 718) is held in place by the welding of Zircaloy-4 spacer capture rings above and below the HMP spacer.

The fuel assembly envelope dimensions are checked with a gauge. The assembly is checked for straightness, twist, bow, and envelope. Water channels are measured at axial locations. The guide tubes are checked for alignment and restriction of control rod insertion. Final visual inspection is performed using high-intensity lights.

The fuel pellets are fabricated by AREVA NP subject to the following inspections:

- Analytical examinations include total uranium content, ^{235}U weight percent and grams/inch, open porosity, hydrogen content, O:U ratio, chemical impurities, equivalent boron content and loadability.
- Dimensional and density inspection including surface finish, surface condition, and cleanliness.
- Resinter test.

During assembly, the fuel rod goes through various testing and quality control programs including:

- After the welding of the first end cap, the weld is inspected for presence of upset on the exterior of the fuel rod.
- The rods are loaded after the fuel stack is weighed and the column length is measured.
- The plenum at the open end of the fuel rod is then measured to verify proper seating and length of the column.
- The weld on the second end cap is inspected in the same manner as the first.
- The sealed rods are scanned to verify fuel column integrity, the fuel column length, and the proper enrichment of the pellets.
- The final fuel rod inspection includes alpha-scan of the end of the rod in which the fuel pellets were loaded to ensure that there is no fissile material contamination; dimensional and visual inspection; and helium leak test.

For the UO_2-Gd_2O_3 fuel rods, the fuel rod cladding, springs, and end cap bar stock are inspected at AREVA NP Inc. then sent to the vendor.

4.5.2.1.4.3 Onsite Inspection

AREVA NP Inc. provides documentation for handling fuel assemblies and shipping containers and site support for the inspection of reload assemblies manufactured and delivered by AREVA NP Inc.

4.5.2.2 REACTOR VESSEL INTERNALS

Applicable information is contained in Section 4.2.2.

4.5.2.3 REACTIVITY CONTROL SYSTEM

Applicable information is contained in Section 4.2.3.

4.5.2.3.1 Reactivity Control Components

In addition to the information contained in Section 4.2.3, the following is applicable:

Burnable Poison Assembly

The Framatome 17x17 burnable poison rod assembly (BPRA) consists of a cluster of up to 24 burnable poison rods attached to a common upper structure assembly. The BPRA is a temporary reactivity control component that is inserted into the guide thimbles of the fuel assembly. Each assembly may consist of a combination of burnable poison rods and thimble plugs. The position of these devices remain constant throughout a given cycle. The BPRA is shown in Figure 4.5.2-14.

The burnable poison rods each contain a 126 inch column of poison pellets encapsulated within cold-worked, seamless, Zircaloy-4 clad. The rods are plugged and seal welded to provide isolation from the primary coolant, fuel assembly, and guide thimble surfaces. The individual pellets are solid, circular cylinders of sintered ceramic comprised of a uniform dispersion of boron carbide (B_4C) in an alumina (Al_2O_3) matrix. The pellets are made with varying concentrations of B_4C. The Al_2O_3-B_4C pellet stack is positioned axially within the rod by a zirconium solid spacer. An upper end plug seals the top end of the rod and provides for a threaded attachment between the finished rod assembly and the control component holddown mechanism. A lower end plug seals the rod bottom end and provides lead-in guidance with the fuel assembly guide thimbles. A stainless steel spring spacer, located in the plenum region above the pellet stack, prevents gross movement of the stack during shipping and handling conditions. Prior to final seal welding of the lower end plug, each rod is pressurized with high purity helium for improved heat transfer and reduced cladding creep ovality in core. A burnable poison rod is shown in Figure 4.5.2-15.

The thimble plugs are short, sealed rods as shown in Figure 4.5.2-14. These rods may be placed in those guide thimble locations which do not contain burnable poison rods. When present, the thimble plugs reduce the amount of coolant that flows through an otherwise empty guide thimble.

The poison rods and thimble plugs in each BPRA are grouped and attached together at the top end of the rods to a holddown assembly by a flat perforated retaining plate that fits within the fuel assembly top nozzle and rests on the adapter plate. The retaining plate and the poison rods are held down and restrained against vertical motion through a spring pack which is attached to

the plate and is compressed by the upper core plate when the reactor upper internals assembly is lowered into the reactor vessel. Their lateral position is maintained by the guide thimbles of the fuel assembly. This arrangement ensures that the poison rods cannot be ejected from the core by flow forces.

The individual poison rods are shouldered against the underside of the retainer plate and securely fastened at the top by a threaded nut which is then locked in place by a single weld between the two components. The square dimension of the retainer plate is larger than the diameter of the flow holes through the core plate. Thus a failure of the holddown bar or spring pack does not result in ejection of the burnable poison rods from the core.

4.5.3 NUCLEAR DESIGN

4.5.3.1 DESIGN BASES

This section describes the design bases and functional requirements used in the nuclear design of the fuel and reactivity control system and relates these design bases to the General Design Criteria (GDC) in 10 CFR 50, Appendix A. The following sections indicate how these design bases have been implemented in the licensing basis for Advanced W17 HTP fuel and Mark-BW fuel that is operated in Sequoyah Units 1and 2.

4.5.3.1.1 Fuel Burnup

4.5.3.1.2 Negative Reactivity Feedbacks (Reactivity Coefficient)

No change to this entire section. See Section 4.2.1.1.

4.5.3.1.3 Control of Power Distribution

Basis:

The nuclear design basis is that:

(1) Under normal operating conditions, at full power, the fuel will not be operated at a linear power greater than the HFP average linear power multiplied by the factor $F_Q^{RTP} * K(z)$, including as a minimum allowances for calorimetric errors, nuclear uncertainty, and densification effects. F_Q^{RTP} is the maximum heat flux hot channel factor, $F_Q(X, Y, Z)$, at 100 percent power and is specified in the Core Operating Limits Report as required by Technical Specification 3.2.1. K(z) is the normalized $F_Q(X, Y, Z)$ as a function of core height and is set in the Core Operating Limits Report.

(2) Under abnormal conditions including the maximum overpower condition, the fuel peak power will not cause fuel melting as defined in Section 4.4.1.2.

(3) The fuel will not operate with a power distribution that violates the departure from nucleate boiling (DNB) design basis (as discussed in Section 4.4.1.1) under Condition I and II events including the maximum overpower condition.

(4) Fuel management will be such as to produce rod powers and burnups consistent with the assumptions in the fuel rod mechanical integrity analysis of Section 4.2 (Westinghouse fuel) and 4.5.2 (AREVA fuel).

The above basis meets GDC 10.

Discussion:

Approved methodology is employed to analyze core power distributions and to set core safety and operating limits. Calculation of limiting power distributions is accomplished by simulating xenon transients that are assumed to initiate within normal operating limits. Limiting xenon conditions are calculated from the transients to simulate the limiting power distributions.

Peaking allowances are applied to account for effects that are not explicitly modeled or that must be included to account for uncertainties. A calculational nuclear uncertainty factor is applied, which contains allowances for the nuclear reliability uncertainty, manufacturing tolerances, irradiation-induced rod bow, and irradiation-induced assembly bow. The peaking allowances described above are utilized for the analysis of both normal operation and anticipated transients. During power operation, periodic flux maps are generated using the movable incore detector system to verify that the reactor core is operating as designed.

4.5.3.1.4 Maximum Controlled Reactivity Insertion Rate

Applicable information is contained in Section 4.3.1.4.

4.5.3.1.5 Shutdown Margins

Basis:

The discussion contained in Section 4.3.1.5 remains valid for Advanced W17 HTP fuel and Mark-BW fuel. Additionally, Technical Specification 3.1.1 requires Shutdown Margin be within the limits specified in the COLR for Mode 2 with keff < 1.0, and Modes 3, 4 and 5. Maintaining the Shutdown and Control Bank Insertion limits in accordance with Technical Specifications 3.1.5 and 3.1.6 will ensure adequate shutdown margin for Mode 2 with keff ≥ 1.0 and in Mode 1. The most limiting accident for the SDM requirements is based on a main steam line break accident as described in Section 15.4.2.

In all analyses involving reactor trip, the single, highest-worth RCCA is postulated to remain in the fully withdrawn position (stuck rod criterion). This satisfies GDC-26.

4.5.3.1.6 Stability

Basis:

The core will be inherently stable to power oscillations of the fundamental mode or such oscillations will be reliably and readily detected and suppressed. This satisfies GDC 12.

Discussion:

The presence of Advanced W17 HTP fuel and Mark-BW fuel in Sequoyah does not alter the conclusions reached by Section 4.3.1.6. The cycle-specific power distribution analysis verifies that the reactor core design is self-damped with regard to axial xenon oscillations. Plant procedures ensure that any axial power oscillations will be readily dampened. Additionally, the presence of the OPDT and OTDT trips provides final assurance that fuel design limits are never exceeded.

4.5.3.1.7 Anticipated Transients Without Trip

Applicable information is contained in Section 4.3.1.7.

4.5.3.2 DESCRIPTION

4.5.3.2.1 Nuclear Design Description

The implementation of the Advanced W17 HTP and Mark-BW assembly designs does not change the basic conclusions drawn in Section 4.3.2.1; however, differences as a result of assembly design changes are as noted in Table 4.5.3-1. The Advanced W17 HTP, Mark-BW, Advanced Mark-BW(A), and ALLIANCE™ fuel assemblies have similar neutronic characteristics. Core average and assembly-specific data assuming full cores of Advanced W17 HTP and Mark-BW assemblies are shown in Table 4.5.3-1.

4.5.3.2.2 Power Distribution

4.5.3.2.2.1 Definitions

Analytical F_{Qc}

For the purposes of discussion it is convenient to define subfactors of F_Q; however, design limits are set in terms of the total peaking factor. The analytical or calculated value of F_Q denoted as F_{Qc} is defined as:

F_{Qc} = total local peaking factor (calculated heat flux hot channel factor)

$$= \frac{\text{Maximum Local kW/ft}}{\text{Average kW/ft}}$$

$$F_{Qc} = F^N_Q(x,y,z) \times (F^E_Q \times F^U_Q \times F_R \times F_A \times F_{BP})^{95/95} \times F_i$$

where

F^N_Q (x,y,z) = the three-dimensional local power in the peak pin,

F^E_Q = local engineering heat flux hot channel factor (i.e., fuel rod manufacturing tolerance defined in Section 4.5.4.2.2.4),

F^U_Q = the calculational nuclear reliability factor,

F_R = fuel rod bow factor,

F_A = Assembly bow factor

F_{BP} = Burnable Poison (BP) manufacturing tolerance,

F_i = other factors to account for grid effects, quadrant power tilt, and cycle flexibility (further discussed in Section 4.5.3.2.2.6).

F^E_Q, F^U_Q, F_R, F_A, and F_{BP} are statistically combined at the 95% probability level with 95% confidence, and this is referred to as the Combined Nuclear Uncertainty Factor. The spike factor associated with fuel pellet gap formation has been shown to cause negligible peaking increases with the higher density fuel now currently in use. Therefore, no specific penalty is applied.

Measured F_{Qm}

The measured value of F_Q, denoted as F_{Qm}, is computed at a minimum of five segment levels in the core using flux traces from the movable incore fission detectors. F_{Qm} is determined for each segment as:

$$F_{Qm} = F^M_Q\,(x,y,z) \times MRF$$

where

MRF = the measurement reliability factor and

F^M_Q (x,y,z) = the three-dimensional measured peak.

When the core power distribution is monitored, the moveable incore detector system is used to compare the measured power distribution with the design steady-state power distribution. The design steady-state power distribution includes an expected variation, called the Deviation Allowance, which represents the amount that the measured power can exceed the predicted value and still be considered within the design. The Deviation Allowance was developed by comparisons of measured power distributions with predicted power distributions (Reference 1).

If a measured value at a given location fails the comparison described above, a margin calculation is performed to verify that adequate margin exists for the location of interest. When surveillance margin calculations are performed, F_{Qm} is processed further for comparison to F_{Qc} to assure that the core is operating as designed. Should negative margin be calculated, the Technical Specifications provide required actions and completion times to ensure that core peaking is reduced to less than the allowed limits.

4.5.3.2.2.2 Radial Power Distribution

4.5.3.2.2.3 Assembly Power Distributions

Applicable information is contained in Section 4.2.2.3.

4.5.3.2.2.4 Axial Power Distributions

Applicable information is contained in Section 4.2.2.4.

4.5.3.2.2.5 Local Power Peaking

The spike densification peaking factor is used to account for the increased peaking due to inter-pellet gap formation. This factor currently is not applied to LOCA linear heat rate limits for either Advanced W17 HTP fuel or Mark-BW fuel. The power peaking effect due to inter-pellet gap formation to be applied to centerline fuel melt (CFM) limits is subsequently discussed.

The concern over the increased power peaking due to inter-pellet gap formation began in the early 1970s when unpressurized PWR fuel rods exhibited cladding collapse. Axial gaps were caused by fuel pellet hang-up and densification. In an area where a gap formed, the pressure differential between the rod and the primary water caused the failure of the cladding. The gaps formed between pellets also caused an increase in power in the region near the gap and thus was a concern in terms of power peaking.

Both Advanced W17 HTP and Mark-BW fuels are designed to alleviate the formation of large gaps and to prevent cladding creep collapse. The fuel fabrication produces fuel which undergoes a smaller amount of densification and the fuel rods are pre-pressurized. These features have led to gap sizes that are an order of magnitude smaller than those observed in the non-pressurized, highly densified fuel rods. In order to determine the effect of inter-pellet gaps on power peaking, AREVA addressed the size and distribution of gaps, and effect of gaps on power peaking.

The result of the analyses demonstrated that a conservative estimate of the peaking factor due to spike densification for AREVA fuel is less than 1%. This factor is overly conservative in light of the thermal expansion characteristics of the Advanced W17 HTP and Mark-BW fuel designs. Two other factors support not including an explicit peaking factor due to inter-pellet gap formation. First, the crucial time for power peaking is early in the life of the fuel rod. The fuel rods measured after a single cycle of irradiation showed no gaps in any of eight rods examined. Since no gaps were present, no additional peaking increase occurred in these rods due to axial gaps at the time in life which is a major concern for power peaking. Second, an EPRI report (Reference 2) utilizing axial gap data from three PWR fuel suppliers (including AREVA) obtained similar results and reached a similar conclusion concerning axial gap induced power peaking. Therefore, a penalty for densification to augment calculated power peaking is not applied to the calculation of CFM limits for the Advanced W17 HTP and Mark-BW fuel assembly designs.

4.5.3.2.2.6 Limiting Power Distributions

Core power distributions are influenced by fuel cycle design parameters and operational conditions. Major factors in the fuel cycle design include fuel enrichment, burnable poison loading, control bank pattern, and type of fuel management scheme employed. During power operation, the core power distribution is dependent primarily upon fuel depletion, power level, control bank position, and xenon distribution. Core power distributions resulting from operation over the entire expected range of these parameters is analyzed and compared with the thermal

design limits and accident initial condition limits to define the necessary restrictions on f(ΔI), axial flux difference (AFD), and control bank position. Power distributions are calculated in three-dimensional geometry using an approved nuclear design code with thermal feedback effects modeled.

A complete discussion of the analysis of core power distributions is provided in an NRC-accepted topical report (Reference 1). This section summarizes the considerations and calculational methods used to determine the core safety and operating limits.

Fuel Cycle Depletion

The core power distribution under steady-state core conditions is obtained from a steady-state depletion of the as-designed fuel cycle. The depletion is simulated with a small amount of control bank insertion to allow for potential rod shadowing effects near the top of the active fuel in the power distributions.

Reduced Power Operation

Perturbations to both the local and global power distributions due to reduced power operation are addressed by providing control bank operation guidelines and recommendations. The guidelines preclude operation with power distributions that would cause the peaking limits to be exceeded as a result of extended operation at reduced power.

Xenon Transient Simulations

The three-dimensional power distribution analysis requires determination of peaking increases due to potential transient xenon. Since the core xenon distribution is dependent upon power level, fuel depletion, time at a particular power level, and control rod movements, transient xenon simulation for reload cores must consider the combined impact of these factors.

Xenon transients are simulated at various times in core life to obtain the effects of transient xenon re-distribution on power peaking. Both maximum and minimum xenon conditions are generated from the transients. The extremes of core operation, such as excessive insertion of the control banks, are simulated at maximum and minimum xenon conditions to generate the limiting power distributions.

Peaking Factors

Once the equilibrium and transient xenon power distributions have been established, peaking margins are defined in order to determine the limits on f(ΔI) and AFD. Peaking margin is defined as follows:

Margin (%) = 100 x (1 - Augmented Calculated Peak/Allowable Peak)

Correlations between peaking margin and axial flux difference can be formulated to determine the fΔI) and AFD limits. For comparison to the allowable limits, the calculated peaking factors are augmented to account for manufacturing tolerances, calculational uncertainties, and modeling simplifications. For calculation of LOCA and CFM peaking margins, the augmentation factors are applied in the following manner:

$$F_{Qc}(x,y,z) = P_t(x,y,z) \times F_1 \times F_2 \times F_3 \times F_4$$

where

$F_{Qc}(x,y,z)$ = augmented calculated peak,

$P_t(x,y,z)$ = total 3D local peaking factor for an assembly node

F_1 = axial peaking increase due to grids,

F_2 = allowance for excore quadrant power tilt,

F_3 = combined calculational uncertainty,

F_4 = operational flexibility.

The large and small break LOCA analyses that support the Advanced W17 HTP and Mark-BW fuel designs were performed to support a rated thermal power level of 3455 MW(th), based upon a maximum allowable normalized local power density of 2.65 for $F_{Q.}$ The ECCS analyses demonstrated that the small break LOCA is not limiting with respect to large break LOCA analysis results.

The augmented calculated radial peak is defined as follows:

$$F_{\Delta H}(x,y) = [P_t(x,y,z)/Ax(x,y)] \times F_2 \times F_4$$

where

$F_{\Delta H}(x,y)$ = augmented calculated radial peak,

$Ax(x,y)$ = axial peak for the assembly,

and $P_t(x,y,z)$, $P_{rl}(x,y)$, F_2, and F_4 are defined as before. For calculation of DNB peaking margins, the allowable peak used in the margin equation is determined by dividing the Maximum Allowable Peak (MAP) limit by Ax(x,y). The MAP limits contain allowances for calculational uncertainty and effects of spacer grids; therefore, augmentation factors for these items are not included in the calculated peak. See Reference 1 for a description of MAP limits.

Spacer Grids

Fuel assembly spacer grids are located at discrete axial locations along the fuel assembly, causing local flux depressions due to neutron absorption in the grid material. This effect is not

modeled in most three-dimensional design calculations, and therefore a peaking factor is applied to the calculated nodal peaks to account for the axial peaking increase due to the presence of grids. This factor may vary based on the type of grid material in the assembly and the type of material in neighboring assemblies.

Excore Quadrant Power Tilt

Quadrant power tilt is monitored by the excore detectors to measure global changes in the radial power distribution between incore flux maps. The incore flux maps are used to monitor core peaking and to verify that all peaking limits are satisfied. After taking an incore flux map associated with an incore-excore calibration, the excore quadrant power tilt is calibrated to zero. Thus, the quadrant power tilt represents the change in quadrant tilt from the previous calibration of the excore detectors. The relationship between peaking increase and excore quadrant power tilt is determined from simulation of various tilt-causing mechanisms. Including the allowance for quadrant tilt in the calculation of F_{QC} allows the reactor core to operate at the f(ΔI) and AFD limits with a quadrant tilt up to the steady-state limit specified in the COLR.

Combined Calculational Uncertainty

The following calculational uncertainties are combined to provide a single peaking factor: calculational nuclear reliability factor, fuel and burnable poison manufacturing tolerances, irradiation-induced rod bow, and irradiation-induced assembly bow.

The fuel manufacturing tolerance accounts for the variations in fuel density, pellet dimensions, enrichment, and cladding dimensions within their tolerance limits. Including the full factor is conservative because the effects of these variations are implicitly contained in the Combined Nuclear Uncertainty Factor.

Fuel rod bowing has the potential to affect both local power peaking and the margin to DNB. The Advanced W17 HTP and Mark-BW fuel assembly designs incorporate several features that make their fuel rod bow performance similar to that of other AREVA fuel designs. As a result, the predicted rod bow for both the Advanced W17 HTP and Mark-BW fuel designs can be taken from BAW-10147P-A, Rev. 1 (Reference 3). Using this prediction, no DNBR penalty due to rod bowing is applied to these AREVA fuel designs, since predicted bow magnitudes are insufficient to cause a DNBR penalty greater than 1% in fuel with burnups less than 24,000 MWd/mtU. The 1% penalty is accounted for by the pin pitch reduction allowance that is incorporated into the engineering hot channel factor on pin average power. This factor is combined statistically with other uncertainties to establish the statistical design DNBR limit from which the DNB maximum allowable peaking limits are computed. Therefore, it is not applied as a peaking augmentation factor in DNB peaking margin calculations. Fuel with higher burnup incorporates an additional burnup dependent augmentation for peaking due to the assumed increase in DNB penalty caused by fuel rod bow.

BAW-10147P-A, Rev. 1 also addressed peaking effects due to fuel assembly bow. The peaking increase due to assembly bow was determined based upon the maximum assembly bow with a boron concentration of 17 ppm. The peaking increase will be smaller for reduced bow and at higher boron concentrations. The assembly bow peaking factor is not applied toward LOCA limits since the increased gap provided by the assembly bow will result in improved cooling for the increased RPD.

The peaking increase due to the power spike that results from a gap between UO_2 pellets has been analyzed and documented in topical report BAW-10054, Rev. 2 (Reference 4). These gaps may occur when pellet-cladding interaction causes a pellet to stick to the cladding. The underlying pellets densify and a gap beneath the stuck pellet is formed. Gap measurements have been performed on modern irradiated AREVA fuel rods, and only very small gaps have been observed ($\leq$ 0.1 inch, Reference 5). The reported gap measurements were performed on fuel at cold temperature conditions. Since the fuel rod stack increases in length during heatup at a rate greater than the cladding (0.5 to 1 inch), the gaps are eliminated or reduced to less than 0.1 inch at power operation. Any remaining gaps during power operation will produce negligible power peaking effects. Therefore, no explicit penalty is included to account for densification spike effects.

The uncertainty factors described in this section are applicable to both the Advanced W17 HTP and Mark-BW fuel assembly designs. Appropriate uncertainty factors will be applied to other fuel assembly designs.

Operational Flexibility

This factor accommodates minor variations in fuel cycle operation relative to the design, and allows operational flexibility without requiring changes to the basic design (such as cycle length flexibility). It is determined by the fuel cycle designer on a cycle-by-cycle basis.

4.5.3.2.2.7 Experimental Verification of Power Distribution Analysis

4.5.3.2.2.8 Testing

Applicable information is contained in Section 4.3.2.2.8.

4.5.3.2.2.9 Monitoring Instrumentation

The AFD limits resulting from analysis of core power distributions relative to the initial condition peaking limits comprise a power-dependent envelope of acceptable AFD values. During steady-state operation, the core normally is controlled to a target AFD within a narrow (approximately ±5% AFD) band. However, the limiting AFD values may be somewhat greater than the extremes of the normal operating band.

Monitoring of control bank and axial flux difference is accomplished using the instrumentation described in section 4.3.2.2.9. Monitoring of core power peaking factors is performed at regular intervals defined by the Technical Specifications using the movable incore detector system.

4.5.3.2.3 Reactivity Coefficients

The reactivity coefficients discussed below are calculated on a cycle-specific basis and compared to reference bounding values specified in this FSAR. This comparison ensures that the cycle-specific values do not exceed the values used in the accident analysis for the plant.

4.5.3.2.3.1 Fuel Temperature (Doppler) Coefficient

The fuel temperature (Doppler) coefficient is defined as the change in reactivity per degree change in fuel temperature and is primarily a measure of the Doppler broadening of U-238 and Pu-240 resonance absorption peaks. Doppler broadening of other isotopes such as U-236, Np-237, etc is also considered but their contributions to the Doppler effect is small. An increase in fuel temperature increases the effective resonance absorption cross sections of the fuel and produces a corresponding reduction in reactivity.

The fuel temperature coefficient is calculated by performing two-group, three dimensional calculations. The moderator temperature distribution is held constant and the rated power level is varied: this produces a change in the fuel temperature distribution without changing the moderator temperature distribution. Spatial variation of fuel temperature is taken into account by calculating the fuel temperature as a function of power density.

4.5.3.2.3.2 Moderator Density and Temperature Coefficients

The moderator coefficient is calculated for various plant conditions by performing two group, three dimensional calculations, varying the moderator temperature (and density) by approximately $\pm 5^{o}F$ about each of the mean temperatures. The moderator temperature coefficient is calculated as a function of core temperature and boron concentration. The temperature range covered is from cold ($50^{o}F$) to HFP conditions.

4.5.3.2.3.3 Power Coefficient

The combined effect of moderator temperature and fuel temperature change as the core power level changes is called the total power coefficient and is expressed in terms of reactivity change per percent power. The power coefficient becomes more negative with burnup reflecting the combined effect of moderator and fuel temperature coefficients with burnup.

4.5.3.2.3.4 Comparison of Calculated and Experimental Reactivity Coefficients

Applicable information is contained in Section 4.2.3.4.

4.5.3.2.3.5 Reactivity Coefficients Used in Transients Analysis

Applicable information is contained in Section 4.2.3.5.

4.5.3.2.4 Control Requirements

Applicable information is contained in Section 4.3.2.4.

4.5.3.2.5 Control

Applicable information is contained in Section 4.3.2.5.

4.5.3.2.6 Control Rod Patterns and Reactivity Worth

Applicable information is contained in Section 4.3.2.6.

4.5.3.2.7 Criticality of Fuel Assemblies

Verification that appropriate shutdown criteria, including uncertainties, are met during refueling is achieved using standard AREVA reactor design methods. The subcriticality of the core during refueling is continuously monitored as described in Technical Specification 3.9.1.

A criticality safety analysis has been performed for fresh and spent fuel storage of Advanced W17 HTP and Mark-BW fuel assemblies, and the results showed the Advanced W17 HTP and Mark-BW fuel assemblies are neutronically equivalent to the Westinghouse Standard and Vantage 5H fuel assemblies. The comparison was based on the current U-235 enrichment limit of 5.0 wt% for the fresh and spent fuel storage racks. Therefore, the current limits are applicable to Advanced W17 HTP fuel and Mark-BW fuel. The reprocessed uranium LTAs are neutronically less reactive than the standard Advanced W17 HTP and Mark-BW fuel assemblies at the same U-235 enrichment, therefore, the current limits are also applicable to the LTAs.

4.5.3.2.8 Stability

4.5.3.2.8.1 Introduction

Applicable information is contained in Section 4.3.2.8.1.

4.5.3.2.8.2 Stability Index

Applicable information is contained in Section 4.3.2.8.2.

4.5.3.2.8.3 Prediction of the Core Stability

Prediction of the axial stability for a typical Sequoyah fuel cycle operating with AREVA fuel is verified on a cycle-specific basis by examination of the simulated xenon transients. The transient results indicate that induced xenon oscillations are self-damped near BOC, but may become unstable near MOC. The regulating rods are used to control any power oscillations such that fuel design limits are not violated. The addition of axial blanket fuel effectively shortens the core and increases core stability.

4.5.3.2.8.4 Stability Measurements

Applicable information is contained in Section 4.3.2.8.4

4.5.3.2.8.5 Comparisons of Calculations with Measurements

Applicable information is contained in Section 4.3.2.8.5.

4.5.3.2.8.6 Stability Control and Protection

Applicable information is contained in Section 4.3.2.8.6.

4.5.3.2.9 Vessel Irradiation

Applicable information is contained in Section 4.3.2.8.9

4.5.3.3 ANALYTICAL METHODS

The functions of the nuclear codes are to generate neutronics data and to calculate space-dependent nuclear parameters in order to license the fuel cycles. The approved design codes used by AREVA are CASMO3 (Reference 6) and NEMO (Reference 7). Sections 4.3.3.1 through 4.3.3.3 remain applicable for Westinghouse fuel and are not shown here. The following discussions cover the AREVA nuclear codes.

CASMO3

Neutron spectrum and few-group parameters are obtained from the CASMO3 code. CASMO3 computes burnup-dependent, spectrum-weighted few-group transport data for fuel lattices. A production library contains multigroup neutron cross section data for all materials of interest. The user inputs a physical and geometric description of the fuel assembly to CASMO3 and a case structure which will determine the depletion and restart cases.

CASMO3 also computes the multigroup two-dimensional neutron transport theory solution for a fuel assembly or a single fuel rod. A fundamental mode calculation is performed to account for leakage effects. Burnup-dependent calculations are performed over a wide range of reactor operating conditions. The output from CASMO3 is post-processed into a fuel cross section library and a fuel pin power library, both of which are used as input to the NEMO code.

NEMO

The cycle design and calculation of other physics parameters are performed with the NEMO code. The NEMO code was developed in a joint effort between AREVA and its predecessors. In NEMO, the nodal balance equation is solved in three dimensions to yield neutron flux, power, and reactivity. The nodal expansion method calculates nodal fluxes and currents. Discontinuity factors provide continuity of the heterogeneous fluxes at the node surfaces, and fuel discontinuities are treated by varying the axial node lengths. Fuel assembly rod powers are individually calculated via the pin power reconstruction method.

NEMO uses a two-group microscopic depletion model which accounts for over 20 different isotopes, including a special treatment for those isotopes which are not individually modeled.

Microscopic cross sections are interpolated against variables which include: burnup, boron concentration, moderator specific volume, and others. The major characteristics of the NEMO model include:

1. Three-dimensional, quarter-core or full-core geometry as needed.

2. Pin-by-pin power representation for each assembly.

3. Thermal-hydraulic feedback.

Pin power reconstruction is used to calculate fuel pin relative power densities in NEMO.

The CASMO3-NEMO code package was subjected to an extensive verification program that quantified uncertainties associated with the use of these codes (Reference 7).

4.5.4 THERMAL AND HYDRAULIC DESIGN

4.5.4.1 DESIGN BASES

Section 4.4.1 defines the performance and safety criteria that are the basis of thermal and hydraulic core design. Sections 4.4.1.1 through 4.4.1.5 establish a number of design bases that ensure that those criteria are met. The following section describes how AREVA has addressed these design bases in licensing Mark-BW and Advanced W17 HTP fuel for Tennessee Valley Authority's Sequoyah Plant.

4.5.4.1.1 Departure from Nucleate Boiling (DNB) Design Bases

Basis:

There will be at least a 95-percent probability that DNB will not occur on the limiting fuel rods during normal operation and operational transients and any transient conditions arising from faults of moderate frequency (Condition I and II events) at a 95-percent confidence level. Historically, this criterion has been conservatively met by adhering to the following thermal design basis: there must be at least a 95-percent probability that the minimum departure from nucleate boiling ratio (DNBR) of the limiting power rod during Condition I and II events is greater than or equal to the DNBR limit of the DNB correlation being used. The DNBR limit for the correlation is established based on the variance of the correlation such that there is a 95-percent probability with 95-percent confidence that DNB will not occur when the calculated DNBR is at the DNBR limit.

Discussion:

For the SQN licensing analyses, AREVA has implemented a thermal-hydraulic analysis method referred to as the Statistical Core Design (SCD) method. SCD is an approved methodology that has been documented in BAW-10170P-A (Reference 1). The CHF correlation that has been implemented is the BWCMV correlation documented in BAW-10159P-A (Reference 2) and the BHTP correlation documented in BAW-10241P-A (Reference 22). BWCMV was specifically developed for mixing vane fuel designs and is applicable to the Mark-BW fuel in a full-core of Mark-BW fuel and in a transition cycle where both Mark-BW and Advanced W17 HTP fuel is present. In addition, in BAW-10189P-A (Reference 3), AREVA presented additional test data that showed that the Mark-BW Zircaloy-4 mixing grid performed at a level that was superior to the original data base. This enhanced CHF performance of the Mark-BW mixing grid is incorporated into the thermal-hydraulic analysis through the use of design-specific equivalent grid spacing. When using the BWCMV correlation in this manner, referenced specifically to BAW-10189P, it is referred to as BWCMV-A. BHTP was specifically developed for non-mixing vane fuel designs and is applicable to the Advanced W17 HTP fuel in a full core of advanced W17 HTP fuel and in a transition cycle where other fuel is present.

In their standard application, BWCMV/BWCMV-A and BHTP DNBR design limits of 1.21 and 1.132, respectively, ensure that the 95/95 DNBR design basis is met for each fuel type. Under that application, all uncertainties in the thermal-hydraulic analysis input parameters are assumed to be at their worst case level. With the SCD method, uncertainties in the operating conditions, the peaking distribution and the fuel fabrication process are combined statistically and a statistical design limit (SDL) is determined. For the Sequoyah application, an SDL value of 1.345 has been established for the Mark-BW fuel and an SDL value of 1.363 has been established for the Advanced W17 HTP fuel. To provide an extra measure of flexibility in the core design process a third design limit is also established. That design limit, the thermal design limit (TDL), includes a provision for retained thermal margin. This retained thermal margin is included to offset conditions that are not included in the SDL development. Examples of offsets that might be assessed against the retained margin include transition core effects and penalties for input uncertainties greater than those considered in the SDL development.

For Mark-BW fuel, the SCD method and the BWCMV-A CHF correlation have been used to calculate reactor core safety limits and to evaluate transients. For Advanced W17 HTP fuel, the SCD method and the BHTP CHF correlation have been used to calculate reactor core safety limits and to evaluate transients. Transient analyses are discussed in Chapter 15.

4.5.4.1.2 Fuel Temperature Design Basis

Basis:

During modes of operation associated with Condition I and Condition II events, the maximum fuel temperature for the UO_2 fuel rods shall be less than the melting temperature of UO_2 and the maximum fuel temperature for the UO_2-Gd_2O_3 fuel rods shall be less than the melting temperature of UO_2-Gd_2O_3.

Discussion:

To determine the linear heat rates at which fuel melting occurs, AREVA employs the fuel thermal analysis codes; TACO3 for the UO_2 only rods and GDTACO for the UO_2-Gd_2O_3 rods. TACO3 is documented in BAW-10162P-A (Reference 4); GDTACO is documented in BAW-10184P-A (Reference 5). Starting with Unit 1 Cycle 20 and Unit 2 Cycle 19, the COPERNIC fuel performance code (Reference 20) will be utilized to predict the centerline fuel melt limits. The COPERNIC computer code (Reference 20) is the fuel performance code approved for fuel rod design and analysis of slightly enriched uranium dioxide fuels and urania-gadolinia fuels with the advanced cladding material M5®. For all codes, conservatism is incorporated in the analysis by reducing the best-estimate fuel melt temperature to account for the uncertainties. By precluding fuel melting, the fuel geometry is preserved and possible adverse effects of molten fuel on the cladding are eliminated. To preclude center melting and as a basis for overpower protection system setpoints, the respective UO_2 and UO_2-Gd_2O_3 fuel melt temperatures have been selected as the basis for setting the overpower limit.

4.5.4.1.3 Core Flow Design Basis

See Section 4.4.1.3

4.5.4.1.4 Hydrodynamic Stability Design Basis

No change to this entire section. See Sections 4.4.1.4, 4.4.3.5 and 4.5.4.3.5.

4.5.4.1.5 Other Considerations

Discussion:

As discussed in Section 4.4.1.5, the design bases defined above, along with those defined in Sections 4.2.1 and 4.5.2.1, are sufficiently comprehensive so that additional limits are not required.

However, there are additional conservatisms that are incorporated into the design methodologies that ensure plant safety. These include, but are not limited to, the treatment of the inlet flow distribution in the inputs to the core thermal-hydraulic (LYNXT) evaluation and the application of a clad temperature limit on those transients that experience a departure from nucleate boiling (i.e. the Loss-of-Coolant Accident [LOCA], the control rod ejection, and the locked rotor accident).

4.5.4.2 DESCRIPTION OF THERMAL AND HYDRAULIC DESIGN OF THE REACTOR CORE

4.5.4.2.1 Summary Comparison

Table 4.5.4.2-1 provides a listing of reactor design parameters applicable with Framatome ANP's Mark-BW 17x17 fuel design and the Statistical Core Design (SCD) methodology. Table 4.5.4.2-1 also provides a listing of reactor design parameters applicable with AREVA's Advanced W17 HTP 17 x 17 fuel design and the SCD methodology. On that table, the SCD parameters are compared to those that have been previously applied for the Westinghouse fuel and design methodologies.

4.5.4.2.2 Fuel and Cladding Temperatures (Including Densification)

As specified in Section 4.5.4.1.2, during Condition I and Condition II events, the maximum fuel temperature is required to be less than the fuel melting temperature. To verify that this criterion is met, AREVA uses the fuel thermal analysis codes TACO3 (for UO_2 rods) and GDTACO (for UO_2-Gd_2O_3 rods). TACO3 is documented in BAW-10162P-A (Reference 4); GDTACO is documented in BAW-10184P-A (Reference 5). Starting with Unit 1 Cycle 20 and Unit 2 Cycle 19, the COPERNIC fuel performance code (Reference 20) will be utilized to predict the fuel temperature for M5® rods. As discussed in these reports, and summarized in Section 4.5.4.1.2, the codes reduce the best-estimate fuel melt temperatures to account for uncertainties in fuel fabrication data and in the code predictions. Time dependent densification effects are considered by all fuel performance codes.

The principal factors that are employed in the fuel performance codes to calculate fuel temperatures are discussed below.

4.5.4.2.2.1 Thermal Conductivity

In both TACO3 and GDTACO, quasi-cubic Hermite splines are used to model the temperature dependence of the thermal conductivity. The modified Loeb correlation has been selected to compensate for the unrestructured porosity effects. For the UO_2 rods, expressions for both the thermal conductivity and the porosity factor are contained in Appendix C of BAW-10162P-A (Reference 4). Sections 2.1.1 and 2.1.2 of BAW-10184P-A (Reference 5) provide a complete discussion of the method used to derive the thermal conductivity for the UO_2-Gd_2O_3 rods.

The COPERNIC fuel thermal conductivity model considers the effect from burnup degradation and radiation damage. Hence, the COPERNIC code explicitly models degradation of fuel thermal conductivity resulting from burnup, and does not require any correction to the analysis results in order to account for fuel thermal conductivity degradation. The fuel thermal conductivity is also corrected by a temperature-dependent porosity factor. Section 4.3 of BAW-10231P-A (Reference 20) provides a detailed discussion of thermal conductivity model used in COPERNIC.

4.5.4.2.2.2 Radial Power Distribution in Fuel Rods

Fuel pin radial power profiles for UO_2 fuel pellets were calculated using the PEEL/NULIF neutronics codes (References 15 and 16). Data was generated for the following range of conditions:

Density, %TD:	90 to 98
Enrichment, $\%U^{235}$:	0.71 to 9
Pellet OD, in:	0.30 to 0.50
Burnup, MWd/mtU:	0 to 75,000

To determine the pellet radial power at a specific point, TACO3 uses a table-look-up using the data generated over these ranges. A complete discussion of the methods used to determine the radial power profiles used in TACO3 is contained in Appendix E of BAW-10162P-A (Reference 4).

For the UO_2-Gd_2O_3 rods, fuel pin radial power profiles are generated using a stand alone code called MICBURN, with output from MICBURN feeding directly into GDTACO. By modeling the radial effects of the gadolinia burnout, MICBURN is able to accurately predict the radial power distribution in the UO_2-Gd_2O_3 rods. A complete discussion of the use of MICBURN for radial power profile generation is provided in Section 2.1.3 of BAW-10184P-A (Reference 5).

Fully discussed in Section 4.5 of BAW-10231P-A (Reference 20), the fuel pellet radial power profiles were determined separately with a neutronic transport code and the produced tabulated data were incorporated in COPERNIC. The generic tables for UO_2 were established to cover the range of conditions commonly used in the reactors. For the UO_2-Gd_2O_3 fuel, the fuel radial power profile tables are generated by MICBURN and entered by the user.

4.5.4.2.2.3 Gap Conductance

The gap conductance model used in TACO3, GDTACO and COPERNIC is made up of three components, open-gap conductance (gas conduction and transport), solid-solid (contact conductance), and radiation heat transfer. A complete discussion of the gap conductance models used in TACO3 is contained in Appendix D of BAW-10162P-A (Reference 4). The gap conductance models used in GDTACO are identical to those used in TACO3. The gap conductance models used in COPERNIC are provided in Section 4.2 of BAW-10231P-A (Reference 20).

4.5.4.2.2.4 Surface Heat Transfer Coefficients

The fuel rod surface heat transfer coefficients used during subcooled forced convection and nucleate boiling are presented in Sections 4.4.2.8.1 and 4.5.4.2.8.1.

4.5.4.2.2.5 Fuel Clad Temperatures

Applicable information is contained in Section 4.4.2.2.5.

4.5.4.2.2.6 Treatment of Peaking Factors

For AREVA thermal-hydraulic analyses for the Mark-BW and Advanced W17 HTP fuel, the value of the total heat flux hot channel factor, F_Q, and the enthalpy rise hot channel factor, $F_{\Delta H}(x,y)$, have been set at 2.50 and 1.64, respectively. (Subparagraph 15.4.1.1.7 discusses the F_Q value used in LOCA.

The radial peak of 1.64 corresponds to a maximum allowable radial peak of 1.70 when a 4% total rod power uncertainty factor is included.) Applying these factors to a design power level of 3455 MWt results in a peak local power of 13.8 kW/ft. In addition, the AREVA fuel melt limit methodology (outlined in Section 4.5.4.1.2) has shown that the peak linear power for prevention of centerline for melt for Mark-BW fuel is greater than 21.9 kW/ft for UO_2 rods and greater than 19.4 kW/ft for UO_2-Gd_2O_3 rods (see Table 4.5.4.2-1). For Advanced W17 HTP fuel, the AREVA fuel melt limit methodology (outlined in Section 4.5.4.1.2) has shown that the peak linear power for prevention of centerline fuel melt is greater than 20.05 kW/ft for UO_2 rods and greater than 18.95 kW/ft for UO_2-Gd_2O_3 rods (see Table 4.5.4.2-1).

4.5.4.2.3 Critical Heat Flux Ratio or DNBR and Mixing Technology

The minimum DNBR values for the nominal operating condition and for the design transient condition are given on Table 4.5.4.2-1. For this application, the DNBR for Mark-BW fuel values are calculated using the BWCMV-A CHF correlation and DNBR values for Advanced W17 HTP fuel are calculated using the BHTP CHF correlation. A complete discussion of the development of BWCMV-A is included in BAW-10159P-A (Reference 2) and BAW-10189P-A (Reference 3). A complete discussion of the development of BHTP is included in BAW-10241P-A (Reference 22).

4.5.4.2.3.1 Departure from Nucleate Boiling Technology

Over the years experimental studies of DNB have progressed from crude single channel configurations to more realistic rod bundle arrays. As the technology developed, it was discovered that correlations based on local subchannel conditions were more accurate predictors of critical heat flux (CHF) than were correlations based on bundle average values. To meet this need for the prediction of local subchannel conditions, AREVA has developed the LYNXT thermal-hydraulic analysis code. LYNXT determines core conditions by solving a set of conservation equations for mass, momentum, and energy. LYNXT provides a one-pass analysis by dividing the core into discrete subchannels and axial control volumes. The subchannel conditions generated by this code provide the basis for the determination of CHF.

AREVA's BWCMV CHF correlation, is for mixing vane fuel designs and is applicable to Mark-BW fuel. BWCMV was developed from a data base that consists of 1418 points from 26 separate test sections. Included in the test sections were six non-uniform axial flux shapes, six hydraulic diameters, three heated lengths, six spacer grid spacings, two fuel pin sizes, both the guide tube and unit cell geometries and three different mixing vane grid designs. By correlating to this large data base, BWCMV has been demonstrated to apply to a number of different fuel designs, including the Westinghouse 15x15 fuel assemblies (both L-grid and R-grid), Westinghouse 17x17 fuel assemblies (standard, Vantage 5H, and OFA) and all Framatome designed replacement assemblies.

The applicable range of variables for BWCMV is as follows:

Pressure (psia)	1485 to 2455
Mass Velocity (10^6 lbm/hr-ft^2)	0.95 to 3.75
Thermodynamic Quality (%)	-22 to 22
Hydraulic Diameter (inches)	0.3747 to 0.5335
Heated Length (inches)	96 to 168
Spacer Grid Spacing (inches)	13 to 32

In August 1993, Framatome submitted additional test data (BAW-10189P-A) that showed that the Mark-BW Zircaloy-4 mixing grid performed at a level that was superior to the original data base. This enhanced CHF performance of the Mark-BW mixing grid is incorporated into the thermal-hydraulic analysis through the use of design-specific equivalent grid spacing. When using the BWCMV correlation in this manner, referenced specifically to BAW-10189P-A, it is referred to as BWCMV-A.

The applicable range of variables for the application of BWCMV-A to the Mark-BW spacer grid is as follows:

Pressure (psia)	1475 to 2465
Mass Velocity (10^6 lbm/hr-ft^2)	0.87 to 3.55
Thermodynamic Quality (%)	Less than 27
Hydraulic Diameter (inches)	0.3747 to 0.4637

Using the one-sided tolerance theory from Owen, it was determined that for both BWCMV and BWCMV-A a correlation limit of 1.21 would provide assurance that there is at least a 95% probability at the 95% confidence level that a departure from nucleate boiling will not occur.

When conditions for a particular analysis (for example, steam line break) fall outside the applicable range of BWCMV and BWCMV-A, Framatome employs additional NRC-approved CHF correlations that bound the required range of conditions. The additional correlations may include, but are not limited to, W-3 (Reference 17), BWU (Reference 18), and Biasi (Reference 23).

AREVA's BHTP correlation is for non-mixing vane designs and is applicable to the Advanced W17 HTP fuel. BHTP was developed from a data base that is described in BAW-10241P-A (Reference 22).

The applicable range of variables for BHTP is as follows:

Pressure (psia) 1385 to 2425

Mass Velocity (10^6 lbm/hr-ft^2) 0.492 to 3.549

Thermodynamic Quality (%) (no lower limit) to .512

Hydraulic Diameter (inches) 0.4517 to 0.5334

Heated Length (inches) 117.6 to 168

Axial Spacer Span (inches) 10.5 to 26.2

Using the distribution-free method from Sommerville, it was determined that for BHTP a correlation limit of 1.132 would provide assurance that there is at least a 95% probability at the 95% confidence level that a departure from nucleate boiling will not occur.

When conditions for a particular analysis (for example, steam line break) fall outside the applicable range of BHTP, AREVA employs additional NRC-approved CHF correlations that bound the required range of conditions. The additional correlations may include, but are not limited to, W-3 (Reference 17) and BWU (Reference 18).

4.5.4.2.3.2 Definition of Departure from Nucleate Boiling Ratio

BWCMV is based on a form that uses local subchannel conditions with modifiers to account for nonuniform axial heat generation and bundle global conditions, and with a bundle-specific multiplier to account for the effects of grid spacing and heated length. Based on that form, DNBR is calculated with BWCMV as follows:

$$DNBR = q_u / q_{oc}$$

where

q_u = FLS q / ^oF

q_{oc} = local surface heat flux (BTU/hr-ft^2)

and

q_u = Nonuniform CHF (BTU/hr-ft^2)

FLS = Bundle multiplier for length and grid spacing

q_u = Uniform CHF (BTU/hr-ft^2)

F = Nonuniform modifier on q_u

This same form also applies to BWCMV-A, however, in that application an equivalent grid spacing is used in the calculation of the FLS term which results in a higher critical heat flux value.

BHTP is based on a form that uses local subchannel conditions to calculate the heat flux that would cause DNB. The method used to calculate that value is described in BAW-10241P-A (Reference 22). Based on tht, DNBR is calculated with BHTP as follows:

$$DNBR = q_{dnb} / q_{loc}$$

Where

q_{dnb} = the heat flux that would cause DNB, calculated by the BHTP correlation (BTU/hr-ft^2)

q_{loc} = local surface heat flux (BTU/hr-ft^2)

4.5.4.2.3.3 Mixing Technology

Based on analysis of Laser Doppler Velocimeter testing of the Mark-BW Zircaloy-4 spacer grid, a turbulent mixing coefficient of 0.062 was determined to be applicable to the Mark-BW fuel design. The test, performed by Nuclear Fuel Industries (NFI) of Japan, provided an indication of the turbulent intensity at various distances downstream of the spacer grids. Research has shown that the turbulent mixing coefficient is proportional to the turbulent intensity. Although a value of 0.062 was calculated for the Mark-BW geometry, a conservative value of 0.038 is applied in thermal-hydraulic analyses.

The mixing coefficient applicable to the Advanced W17 HTP fuel assembly is calculated based on test data in Appendix A of ANF-1224P-A (Reference 21).

4.5.4.2.3.4 Hot Channel Factors

Engineering hot channel factors (HCF's) are used to account for the effects of manufacturing variations on the maximum linear heat generation rate and enthalpy rise.

Local Heat Flux Engineering Hot Channel Factor:

The local heat flux engineering hot channel factor, F^E_Q, is used in the evaluation of the maximum linear heat generation rate. This factor is determined by statistically combining manufacturing variances for pellet enrichment and weight and typically has a value of 1.03 or less at the 95% probability level with 95% confidence. It has been shown that relatively small heat flux spikes, such as those represented by F^E_Q, have no effect on DNB, therefore this factor is not used in DNBR calculations.

Average Pin Power Engineering Hot Channel Factor:

The average pin power factor, $F^E_{\Delta H}$, accounts for the effects of variations in fuel stack weight, enrichment, fuel rod diameter, and pin pitch on hot pin average power. This factor, which typically has a value of 1.03 or less, is combined statistically with other uncertainties to establish the statistical design limit (SDL) DNBR used with the statistical core design method.

Since $F^E_{\Delta H}$ is incorporated into the statistical design limit (SDL), this factor is not included in the LYNXT model used for SCD analyses. For non-SCD analyses, $F^E_{\Delta H}$ is incorporated into the LYNXT model as a multiplier on the hot pin average power.

4.5.4.2.3.5 Effects of Rod Bow on DNBR

The bowing of fuel rods during reactor operation has the potential to affect both local power peaking and the margin to DNB. As discussed in Section 4.1.1.7 of BAW-10172P (Reference 7), the Mark-BW fuel design has several features that make its fuel rod bow performance similar to that of other AREVA fuel designs. In BAW-10186P-A, Rev. 1 (Reference 14), Framatome (AREVA) presented new data that extended the rod bow data base for Framatome (AREVA) fuel to 58,300 MWd/mtU. That topical concluded that the rod bow correlations from BAW-10147PA-R1 (Reference 13) are applicable at extended burnups and apply to the Mark-BW.

Since the fuel rods used in the Advanced W17 HTP fuel assemblies are hydraulically identical to those used in Mark-BW fuel (within the heated length), and because the fuel rod and assembly pitches are identical between the two fuel types, conclusions regarding the rod bow penalties for Mark-BW fuel are applicable to the Advanced W17 HTP fuel as well.

In most cases, no DNBR penalty due to rod bowing is applied to the Advanced W17 HTP or Mark-BW fuel, since predicted bow magnitudes are insufficient to cause a DNBR penalty greater than 1% in fuel with burnup values less than 24,000 MWd/mtU, and fuel with higher burnup does not produce sufficient power to attain design peaking factors. The 1% penalty is accounted for by the pin pitch reduction allowance that is incorporated into the engineering hot channel factor on hot pin average power, discussed in Section 4.5.4.2.3.4.

In cases where the predicted rod bow magnitudes are sufficient to cause a DNBR penalty greater than 1%, an augmentation factor is applied to the peaking values used to calculate margin to DNB. This penalty is calculated using the method outlined in Section 6.1.1 of BAW-10147PA-R1 (Reference 13).

4.5.4.2.4 Flux Tilt Considerations

The description of flux tilt considerations provided in Section 4.4.2.4 remains applicable for the Mark-BW Fuel and for the transition to the Advanced W17 HTP fuel design.

4.5.4.2.5 Void Fraction Distribution

The void models that are employed in the AREVA thermal-hydraulic analysis are described in the LYNXT topical report (BAW-10156-A, Rev. 1 -- Reference 6).

4.5.4.2.6 Core Coolant Flow Distribution

Assembly average coolant mass velocity and enthalpy at various radial and axial core locations were calculated for both a-full Mark-BW core and a full Advanced W17 HTP core. Coolant enthalpy rise and flow distributions for the 4-ft elevation (1/3 of core height), 8-ft elevation (2/3 core height), and core exit are shown in Figures 4.5.4.2-7, 4.5.4.2-8, and 4.5.4.2-9, respectively. These distributions are for the full power conditions used in AREVA's SCD analysis, as given in Table 4.5.4.2-1, and for a typical radial power density distribution near the beginning of life. The LYNXT code analysis for this case utilized a uniform core inlet enthalpy and inlet flow distribution.

4.5.4.2.7 Core Pressure Drops and Hydraulic Loads

4.5.4.2.7.1 Core Pressure Drop

The pressure drops presented in Table 4.5.4.2-1 for the Mark-BW and Advanced W17 HTP fuel assemblies are based on the best estimate flow for actual plant operating conditions as described in Section 5.1. The pressure drop characteristics of the Mark-BW and Advanced W17 HTP designs were determined through a series of prototype flow tests. Results from those tests were used as the basis for the calculation of component formloss coefficients.

The pressure drops presented in Table 4.5.4.2-1 are for full-cores of Mark-BW and Advanced W17 HTP fuel.

4.5.4.2.7.2 Hydraulic Loads

The holddown spring system is designed to maintain fuel assembly contact with the lower support plate during Condition I and II events except for the pump overspeed transient. The fuel assembly top and bottom nozzles will maintain engagement with the reactor internals for all Condition I through IV events. Hydraulic loss characteristics of the Mark-BW and Advanced W17 HTP designs were determined as part of the prototype testing described in Section 4.5.4.2.7.1. An analysis of the predicted Mark-BW and Advanced W17 HTP lift forces, which are based on the mechanical design flow and the minimum bypass, indicates that the assemblies will not lift off under any normal operating condition. At the 120% pump overspeed condition, the Mark-BW fuel assembly will experience some lift-off, but the lift-off will not compress the fuel assembly holddown spring to its solid height, nor will it cause plastic deformation in the spring.

4.5.4.2.8 Correlation and Physical Data

4.5.4.2.8.1 Surface Heat Transfer Coefficients

The correlations that are used in the AREVA analyses to determine the forced convection heat transfer coefficient and to determine the onset of nucleate boiling are the same as those described in Section 4.4.2.8.1. A more complete discussion of the models that are available in the AREVA thermal-hydraulic analysis code can be found in the LYNXT topical report, BAW-10156-A, Rev. 1 (Reference 6).

4.5.4.2.8.2 Total Core and Vessel Pressure Drop

Section 4.4.2.8.2 provides a description of the models that are used to determine vessel and core pressure drop. To determine the mixed core pressure drop, these models are applied to each unique fuel design in the core and to mixed cores with various loading patterns. Assessments of core pressure drop are performed using the LYNXT thermal-hydraulics code. These assessments have shown that small differences in total assembly pressure drop have a negligible impact on the total vessel pressure drop. The pressure drop changes associated with hardware upgrades for the Mark-BW and Advanced W17 HTP product are factored into the core pressure drop predictions and are addressed during transition core analyses.

4.5.4.2.8.3 Void Fraction Correlation

Figure 4.4.2-10 illustrates the three separate void regions that are considered in flow boiling in a PWR. The AREVA thermal-hydraulic analysis code, LYNXT, uses a number of different models and correlations to represent these three regions. A discussion of the various models and correlations is contained in Appendix B of the LYNXT topical report, BAW-10156-A, Rev. 1 (Reference 6).

4.5.4.2.9 Thermal Effects of Operational Transients

Section 4.4.2.8 briefly describes the core protection system that is employed to ensure that the minimum DNBR in the core is not less than the design limit DNBR. The implementation of AREVA Mark-BW and Advanced W17 HTP fuel does not alter the function of this system nor the basis for setpoint calculation. In general, previously defined core protection setpoints have been maintained with the licensing analyses merely verifying their applicability.

4.5.4.2.10 Uncertainties in Estimates

4.5.4.2.10.1 Uncertainties in Fuel and Clad Temperatures

As stated in Section 4.4.2.10.1, uncertainties in fuel temperature calculations can be defined in two categories: fabrication uncertainties and model uncertainties. In the methodology that has been established for use with the TACO3, GDTACO and COPERNIC thermal analysis codes, both of these areas have been addressed. For fuel temperature calculations, all inputs are treated at their nominal level and the resulting temperatures are treated as best estimate values. However, for specific applications (e.g. fuel centerline melt analyses and internal pin pressure calculations), uncertainties in these parameters are factored into the calculation. For the centerline melt analysis, this method results in a statistically reduced fuel melt temperature. For the internal pin pressure analysis, this method generates a bounding pin pressure that accounts for the discussed uncertainties.

4.5.4.2.10.2 Uncertainties in Pressure Drop

The core pressure drop reported on Table 4.5.4.2-1 for the Mark-BW and Advanced W17 HTP fuel designs are based on the best estimate flow and are regarded as a best estimate number. Uncertainties in the pressure drop analysis are treated implicitly and are not included as an uncertainty on the final pressure drop value.

4.5.4.2.10.3 Uncertainties Due to Inlet Flow Maldistribution

The implementation of the Mark-BW and/or Advanced W17 HTP fuel does not affect the uncertainties that are treated in the inlet flow maldistribution factor. Therefore, the discussion contained in Section 4.4.2.10.3 remains applicable.

4.5.4.2.10.4 Uncertainty in DNB Correlation

The uncertainty in the BWCMV/BWCMV-A CHF correlation has been treated in the determination of the correlation design limit and as part of the statistical core design methodology for Mark-BW fuel. The uncertainty in the BHTP CHF correlation has been treated in the determination of the correlation design limit and as part of the statistical core design methodology for Advanced W17 HTP fuel.

4.5.4.2.10.5 Uncertainties in DNBR Calculations

A code uncertainty of 5 percent is included in the statistical core design methodology to account for uncertainties in the DNBR calculations.

4.5.4.2.10.6 Uncertainties in Flow Rates

For thermal performance evaluations, a thermal design flow rate which conservatively bounds the best estimate flow rate, as stated in Section 5.1, is used. In addition, 9.0* percent of thermal design flow is assumed to bypass the core and is therefore ineffective for heat transfer. A flow measurement uncertainty is included in the SDL.

4.5.4.2.10.7 Uncertainties in Hydraulic Loads

For hydraulic lift evaluations, a mechanical design flow rate which conservatively bounds the best estimate flow rate is used. In addition, the core bypass flow is assumed to be a minimum, thereby increasing the lift forces in the core.

Starting with the Unit 1 Cycle 15 reload core, NRC approved probabilistic methods are used to treat some of the uncertainties in the fuel assembly hold down analysis. This methodology, known as statistical fuel assembly hold down methodology, is described in BAW-10243P-A (Reference 19). The methodology provides 95 percent protection at the 95% confidence level that each fuel assembly has adequate hold down protection when the net hold down force is predicted to be zero. The analysis technique is applicable to full cores containing the same fuel design as well as for transition cores where multiple fuel designs are co-resident. For the mixed or transition core, when multiple fuel designs co-reside in the core, the net hold down force determination is addressed for each specific fuel design.

4.5.4.2.10.8 Uncertainty in Mixing Coefficient

Based on an analysis of Laser Doppler Velocimeter testing of the Mark-BW Zircaloy-4 spacer grid, a turbulent mixing coefficient of 0.062 was determined to be applicable to the Mark-BW fuel design. However, a conservative value of 0.038 is used in the thermal-hydraulic analyses.

The mixing coefficient applicable to the Advanced W17 HTP fuel assembly is calculated based on test data in Appendix A of ANF-1224P-A (Reference 21).

4.5.4.2.11 Plant Configuration Data

The discussion of the Sequoyah Plant Configuration provided in Section 4.4.2.11 remains applicable for the transition to the Mark-BW fuel design. It also remains applicable for the transition to the Advanced W17 HTP fuel design.

4.5.4.3 EVALUATION

The thermal-hydraulic methods that AREVA has used to license Mark-BW and Advanced W17 HTP fuel for operation in the Sequoyah Plant are outlined in BAW-10220P (Reference 12). The following sections briefly describe some of those methods.

4.5.4.3.1 Core Hydraulics

4.5.4.3.1.1 Flow Paths Considered in Core Pressure Drop and Thermal Design

Section 4.4.3.1.1 provides a description of the flow paths considered when determining the nominal core bypass flow. That discussion remains applicable for the Mark-BW fuel design and the transition to the Advanced W17 HTP fuel design.

---

* The maximum bypass flow has increased to 9.1%. This is applicable to Units 1 and 2, with or without the H-8 control rod assembly.

4.5.4.3.1.2 Inlet Flow Distributions

Thermal-hydraulic analyses impose a 5-percent reduction in inlet flow to the hot assembly.

4.5.4.3.1.3 Empirical Friction Factor Correlations

The AREVA thermal-hydraulic analysis code, LYNXT, uses the Framatome (AREVA) single-phase friction factor model with multipliers for the subcooled and two-phase flow regimes. A description of this model is contained in Appendix B of the LYNXT topical report, BAW-10156-A, Rev. 1 (Reference 6). LYNXT also has a variable lateral resistance model in which the crossflow resistance coefficient varies with the pitch to diameter ratio and Reynolds number.

4.5.4.3.2 Influence of Power Distribution

Section 4.4.3.2 provides a discussion of the Westinghouse method for defining the core power distribution through the use of the nuclear enthalpy rise hot channel factor, $F_{H}(x,y)$, and the axial power distribution. The following two sections discuss how AREVA has implemented these two parameters in its analyses for the Sequoyah plant.

4.5.4.3.2.1 Nuclear Enthalpy Rise Hot Channel Factor

Section 4.4.3.2.1 defines the nuclear enthalpy rise hot channel factor as the ratio of the hot rod total power to the average rod total power. This definition is applicable for both the Westinghouse methodology and the AREVA methodology. AREVA has utilized a design $F_{\Delta H}(x,y)$ value of 1.64 in its thermal-hydraulic analysis. To determine a design core power distribution, a real power distribution is generated with a core depletion code, like NEMO, and the power in the hot bundle is adjusted so that the hot pin is at the design $F_{\Delta H}(x,y)$ value. A conservative flux shape is imposed across the core uniformly. For operation at power levels less than 100 percent full power, the design peak is adjusted according to the following relationship:

$$F_{\Delta H}(x,y) = 1.64\ [1 + 0.3(1 - P)]$$

where

P = the fraction of rated power

This permitted relaxation allows greater flexibility in the nuclear design. An $F_{H}(x,y)$ measurement uncertainty is included in the Statistical Design Limit. The radial peak of 1.64 corresponds to a maximum allowable radial peak of 1.70 when a 4% total rod power uncertainty factor is included.

For transients which trip on the plant's OTΔT trip, a design peak which is a function of core power must be used. This is a result of the implementation of the core safety limit lines as described in Section 15.1.3. The variable design peak to be used for these transients is given in Figure 15.1.3-2.

4.5.4.3.2.2 Axial Heat Flux Distributions

As discussed in Section 4.4.3.2.2, the axial heat flux distribution can vary as a result of rod motion, power change, or due to a spatial xenon transient which may occur in the axial direction. For its thermal-hydraulic design calculations, AREVA has assumed a chopped cosine axial distribution with a peak to average value of 1.55. As stated in Section 4.4.3.2.2, the core protection system provides an automatic reduction in the trip setpoints for conditions in which

the measured axial offset differs from the design value. AREVA determines the magnitude of this axial offset correction by investigating a wide range of both inlet and outlet skewed flux shapes and verifying that the actual DNB margin is greater than or equal to that which is available with the design shape. This process is done for both steady-state operating conditions and for transient initialization conditions.

4.5.4.3.3 Core Thermal Response

A general summary of steady-state thermal-hydraulic design parameters applicable with AREVA's Mark-BW 17x17 and Advanced W17 HTP fuel designs and the Statistical Core Design (SCD) methodology is provided in Table 4.5.4.2-1 for all loops in operation. On that table, the SCD parameters are compared to those that have been previously applied for the Westinghouse fuel and design methodologies.

4.5.4.3.4 Analytical Techniques

4.5.4.3.4.1 Core Analysis

To perform the various thermal-hydraulic analyses needed to license the Mark-BW and Advanced W17 HTP designs, AREVA typically employs its LYNXT thermal-hydraulic analysis code. LYNXT, a single-pass code, evaluates subchannel thermal-hydraulic conditions for both steady-state and transient modes of operation using crossflow methodologies to determine core conditions. A more complete description of the code is provided in the following paragraph and in topical report BAW-10156A Rev. 01 (Reference 6). Comparisons of code predictions to experimental data are contained in the topical report.

LYNXT

LYNXT is approved by the NRC and provides the capability for single-pass core thermal-hydraulic analysis for both steady state and transient conditions. It also has the capability to analyze conditions with high lateral flow and/or recirculating flow, such as encountered in the analysis of a steamline break with reactor coolant pumps off. The single pass LYNXT model has been extensively benchmarked to multi-pass analyses and appropriate experimental data. LYNXT is used almost exclusively for determining core flow redistribution and for predicting the DNB performance of various fuel designs.

LYNXT has been qualified for the BHTP, BWC, BWCMV, BWCMV-A, BWU B&W2, Biasi and W3 correlations by data base analysis. In each case, where this evaluation has been performed, LYNXT supported the licensed DNBR limit for the respective CHF correlation. Some of the features of LYNXT include:

1. Reverse/recirculating flow option
2. RELAP5-type "strip" option
3. Exit pressure profile boundary condition and transient pressure drop boundary condition
4. Generalized DNBR subroutine
5. Internal code generation of the axial power shape
6. Transient radial and axial power shapes input capability
7. Dynamic gap conductance fuel model patterned after TACO2
8. Transient DNBR summary table and steady-state/time step most limiting and second most limiting axial DNBR distributions
9. Restart option
10. ANSI Fortran 77
11. Enhancements to the conducting wall model to allow rectangular and cylindrical walls
12. User enhancements that minimize the user efforts to set up, run, and understand the code predictions.

4.5.4.3.4.2 Fuel Temperatures

As discussed in Section 4.5.4.2.2, AREVA employs the fuel thermal performance codes TACO3, GDTACO, and COPERNIC to predict fuel rod temperature and internal pressure conditions during core operation. These analyses are used to determine the centerline melt limit and the maximum fuel rod burnup limit, which is based on the fuel rod internal pressure. In addition, the TACO3 and GDTACO analyses provide initial fuel temperature and pressure conditions for LOCA and non-LOCA safety analyses. A more complete discussion of the codes and their associated analysis methods is contained in the paragraphs below and the respective topical report; BAW-10162P-A (Reference 4) for TACO3, BAW-10184P-A (Reference 5) for GDTACO, BAW-10231P-A (Reference 20) for COPERNIC. These reports also contain comparisons of the code predictions to measured data.

TACO3

The TACO3 code, with its Fuel Rod Gas Pressure Criteria, is a state-of-the-art methodology for fuel rod thermal performance analysis. This package applies to fuel rod burnups to 62,000 MWd/mtU. As the need for burnups approaching these limits increases, AREVA continually acquires data supporting the extension of burnup limits and evaluates the existing code models for suitability. The integration of French technology will aid this process by providing access to additional extended burnup data, models, codes, and methods.

The TACO3 fuel performance code is a major evolution in the prediction of fuel rod performance. TACO3 uses best-estimate models benchmarked to an extensive data base of fuel performance data from numerous industry sponsored experimental programs. TACO3 uses a complete set of new thermal and mechanical models, as well as new fuel and cladding material relations. Several models represent advances in the state-of-the-art. The TACO3 fuel temperature predictions have less uncertainty than other comparable codes. The NRC has reviewed and approved TACO3. TACO3 predicts the following as a function of burnup:

- Centerline Fuel Melt
- Fuel Rod Internal Gas Pressure
- LOCA Analysis Initialization Parameters
- Cladding Strain
- Creep Collapse Analysis Initialization Parameters

TACO3 uses best-estimate inputs to provide best-estimate predictions. Statistical evaluations are performed to estimate uncertainties and provide conservative results for use in licensing evaluations. Code and power prediction uncertainties and manufacturing variations are considered for internal gas pressure uncertainties. Statistical parameters obtained from the analysis of an extensive code benchmark database evaluate fuel temperature uncertainties. Transient fission gas release and cladding oxide effects are also represented to provide appropriate conservatism.

GDTACO

GDTACO is a quasi-best-estimate steady-state fuel pin thermal analysis code that was written to provide a conservative assessment of the thermal performance of UO_2-Gd_2O_3 fuel. The code includes models that predict gap conductance, fuel densification and swelling, cladding creep and deformation, gap closure and fission gas release. GDTACO, which was derived from the TACO3 best-estimate uranium dioxide code, has incorporated code models that are based on fuel performance data gathered from the UO_2-Gd_2O_3 fuel lead test assembly program run at Duke Power Company's Oconee-1 Plant. That test program, sponsored by Framatome, Duke Power Company and the U.S. Department of Energy, provided fuel performance data that was used to benchmark the UO_2-Gd_2O_3 models in GDTACO. Where no benchmark data was available, an appropriate degree of conservatism was added to the GDTACO models to compensate for the uncertainty.

COPERNIC

The COPERNIC computer code is the fuel performance code for fuel rod design and analysis of slightly enriched uranium dioxide fuels and urania-gadolinia fuels with the advanced cladding material, M5®. The COPERNIC code can be used for a broad range of fuel rod design, analysis and optimization tasks. Its primary focus is fuel rod licensing-type analyses, which include fuel rod internal gas pressure, LOCA initialization, fuel melt, cladding strain, creep collapse initialization, and cladding peak oxide thickness analysis.

The COPERNIC is an amalgam of individual phenomenological models tied together by a master program that integrates the geometric and temporal solution. These individual phenomenological models simulate the various mechanisms at work in a fuel rod – heat generation, heat transfer and thermal expansion in the fuel and cladding; fuel densification and swelling; fuel fracture and relocation; fission gas generation and release; pellet and cladding stresses and strains; and cladding corrosion and hydriding.

The thermal models include the coolant-rod heat transfer, the fuel-cladding gap conductance, the fuel thermal conductivity, the heat transfer gap closure, and the fuel radial power distribution. The COPERNIC fuel thermal conductivity model considers the effect from burnup degradation and radiation degradation. The fuel thermal conductivity is corrected by a temperature-dependent porosity factor.

The effects of pellet and cladding dimension change are considered in the COPERNIC code. The COPERNIC code calculates the total pellet strains from solid swelling, gaseous swelling, densification, thermal expansion, and relocation models. The total cladding strains are calculated from the thermal, creep, elastic, and high stress creep models.

Two fission gas release models operate within the COPERNIC code: a steady-state model and a transient model that tracks the fuel response to rapid power changes. The COPERNIC steady-state model has two parts: an athermal knockout-recoil component and thermally activated diffusion component, leading to a grain boundary accumulation, saturation, and release. The transient gas release model consists of an enhanced diffusion model for short times, and a burst model that involves controlled release of the grain boundary gas inventory on a time basis related to the current diffusion coefficient.

The waterside cladding corrosion model in COPERNIC determines the growth of the oxide layer that forms on the outer surface of the fuel rod cladding as a function of environmental condition. The corrosion model is formulated with pre-transition and post-transition corrosion relationships.

4.5.4.3.4.3 Hydrodynamic Instability

The analytical methods used to assess hydraulic instability are discussed in Paragraph 4.4.3.5. Those methods are not affected by the insertion of the Mark-BW and/or Advanced W17 HTP fuel design.

4.5.4.3.5 Hydrodynamic and Flow Power Coupled Instability

Section 4.4.3.5 states that minor plant-to-plant differences in Westinghouse reactor designs such as fuel assembly arrays, core power to flow ratios, fuel assembly length, etc., will not result in gross deterioration of the power margin that is available to offset thermohydrodynamic instabilities. Since

the Mark-BW fuel design is both thermally and hydraulically similar to the Westinghouse design it is replacing, there will be no adverse impact on the power margins that are available. For the transition to the Advanced W17 HTP fuel design, the fuel design is both thermally and hydraulically similar to the Mark-BW design (which is similar to the Westinghouse design it replaced), there will be no adverse impact on the power margins that are available.

4.5.4.3.6 Temperature Transient Effects Analysis

Water-logging damage of a previously defected fuel rod has occasionally been postulated as a mechanism for subsequent rupture of the cladding. However, fuel rod failures of this type have never been observed in AREVA fuel. In addition, testing performed at INEL (Reference 8) has shown that energy depositions much greater than those experienced during normal operating transients are required for fuel failure. This is discussed further in Sections 4.4.3.6 and 4.5.2.1.3.1. Additional testing (Reference 9) showed that if a failure did occur, the ruptured rod would not be expected to cause significant damage to the rest of the core. That test, which was performed under conditions that are much more severe than those seen under normal operation, showed that when a rupture did occur, there was no failure propagation and the most significant damage caused to the remainder of the core was the bowing of adjacent fuel rods.

4.5.4.3.7 Potentially Damaging Temperature Effects During Transients

The fuel rod experiences many operational transients during its residence in the core. A number of thermal effects must be considered when analyzing the fuel rod performance. The clad can be in contact with the fuel pellet at some time in the fuel lifetime. Clad-pellet interaction occurs if the fuel pellet temperature is increased after the clad is in contact with the pellet. Clad-pellet interaction is discussed in Section 4.5.2.1.3.1.

Increasing the fuel temperature results in an increased fuel rod internal pressure. One of the fuel rod design bases requires that the fuel rod internal pressure of the peak fuel rod in the reactor be limited to a value below that which would cause (1) the fuel-clad gap to increase due to cladding outward creep during steady-state operation and (2) extensive departure from nucleate boiling (DNB) propagation to occur. (see Sections 4.5.2.1.1.1 and 4.5.2.1.3.1).

The potential effects of operation with water-logged fuel are discussed in Section 4.5.4.3.6. As discussed in that section, water-logging is not a concern during operational transients.

If axial gaps in the fuel pellet column occur due to densification, the cladding has the potential of collapsing into a gap (i.e. flattening). As discussed in Sections 4.5.2.1.1.1 and 4.5.2.1.3.1, creep collapse is precluded by ensuring that the predicted creep collapse life of the fuel rod exceeds the maximum expected incore life.

There can be a differential thermal expansion between the fuel rods and the guide thimbles during a transient. Excessive bowing of the fuel rods could occur if the grid assemblies did not allow axial movement of the fuel rods relative to the grids. Thermal expansion of the fuel rods is considered in the grid design so that axial loads imposed on the fuel rods during a thermal transient will not result in excessively bowed fuel rods (see Sections 4.5.2.1.1.1, 4.5.2.1.2.1, and 4.5.2.1.2.2).

4.5.4.3.8 Energy Release During Fuel Element Burnout

As discussed in Section 4.4.1, the reactor core is designed to preclude any temperature effect that may cause damage to fuel rods during normal operation and Condition I and II transients. However, in the unlikely event that DNB occurs, the cladding temperature will begin to increase, causing a potential increase in the chemical reaction rate between cladding and coolant. As discussed in Section 4.5.2.3.1, the Baker-Just equation (Reference 10) has been used to estimate the energy produced and the thickness of cladding reacted as a function of time with temperature as a parameter. Based on those results, it was concluded that the potential for chemical reaction between fuel rod cladding and coolant is small and no adverse effects will result during normal operation or the infrequent event type accidents considered in Chapter 15 of this document.

4.5.4.3.9 Energy Release or Rupture of Water-logged Fuel Elements

A full discussion of water-logging including energy release is contained in Section 4.5.4.3.6. It is noted that the resulting energy release is not expected to adversely affect neighboring fuel rods.

4.5.4.3.10 Fuel Rod Behavior Effects from Coolant Flow Blockage

Coolant flow blockages can occur within the coolant channels of a fuel assembly or external to the reactor core. In either case, the flow blockage will cause a local reduction in coolant flow. The effects of these flow reductions on core performance must be investigated.

A subchannel DNBR analysis that determines the effect of a flow blockage in the hot subchannel has been performed. That analysis has shown that flow blockages of up to 70% have only a minimal effect on the hot channel DNBR. This is due to the fact that flow recovery occurs rapidly above the blockage.

AREVA has also developed an evaluation model for the LOCA that complies with the flow blockage requirements of Appendix K of 10 CFR 50. Discussion of that evaluation model and its specific application to Sequoyah are contained in BAW-10168-A Rev. 3 and BAW-10220P (References 11 and 12), respectively. A further discussion of that evaluation can be found in Section 15.4.1.

4.5.4.4 TESTING AND VERIFICATION

4.5.4.4.1 Tests Prior to Initial Criticality

A reactor coolant flow test is performed following fuel loading but prior to power operation. This test verifies that proper coolant flow rates have been used in the core thermal and hydraulic analysis. The required flow rate is specified in Technical Specification 3.4.1.

4.5.4.4.2 Initial Power and Plant Operation

Core power distribution measurements are made at regular intervals during core operation. These measurements ensure that conservative peaking factors are used in the core thermal and hydraulic analysis. Allowable peaking factors are specified in the Core Operating Limits Report (COLR).

4.5.4.4.3 Component and Fuel Inspections

Inspections performed on the manufactured fuel are delineated in Section 4.5.2.4. Fabrication measurements are obtained to verify that the assumptions made in the fuel thermal analysis regarding fuel densification and manufacturing variations bound the actual fabrication data.

4.5.4.5 INSTRUMENTATION APPLICATION

Section 4.4.5 describes the instrumentation systems that are in place at the Sequoyah Plant to verify the core power and temperature distribution during plant operation. AREVA has developed plant verification methodologies that are consistent with these systems. Therefore, the descriptions contained in Section 4.4.5 remain applicable for the Mark-BW fuel design and for the transition to the Advanced W17 HTP fuel design.

Table 4.5.1-3 Design Loading Conditions for Reactor Core Components

No change to this table. See Table 4.1-3

Table 4.5.2-1

Post-Irradiation Examination Scope

The following inspections of the four Mark-BW lead assemblies were performed after McGuire 1, Cycles 5, 6, 7, and 8*

1. Visual Inspection (Video)
2. Fuel Assembly Length
3. Shoulder Gap (on selected peripheral rods)
4. Holddown Spring Set
5. Fuel Rod Length (on selected peripheral rods)
6. Spacer Grid Axial Position
7. Fuel Rod Cladding Oxide Thickness
8. Fuel Rod Diameter
9. Fuel Assembly Bow

* One assembly was removed for cycle 7 and reinserted for Cycle 8.

Table 4.5.2-2

Reactor Coolant System Design Transient Group Core Power History for Fuel Rod Fatigue Analysis (Full Core Mark-BW)

Transient	**Number of Fatigue Cycles**	**Core Power History (% FP)**
Heatup and cooldown at 100 F/hr. (pressurizer cooldown 200 F/hr.)	200 + 200	100-HZP-0-HZP-100
Unit loading and unloading at 5% of full power/minute Step load increase and decrease of 10% of full power (FP) Steady-state fluctuations.	(18300x2)/2000x2/infinite	100-95-100-90-100
Large step load decrease (95% of FP with steam dump) Loss of power (blackout with natural circulation in the reactor coolant system) Loss of flow (partial loss of flow, one pump only) Reactor trip from FP Inadvertent auxiliary spray	200/200/80/400/10	100-HZP
Loss of load, without immediate turbine or reactor trip Loss of power (blackout with natural circulation in the reactor coolant system)	80/40	100-0
Minor loss of coolant accident or secondary steam line break	1	100-0

Terms: HZP - Hot Zero Power
FP - Full Power

Note: The cyclic/transient limits used for the fuel rod fatigue analysis, as summarized in this table, are bounding for the replacement steam generator cyclic/transient limits given in Table 5.2.1-1.

Table 4.5.2-3

Reactor Coolant System Design Transient Group Core Power History for Fuel Rod Fatigue Analysis (Full and Transition Core Advanced W17 HTP)

Transient	Number of Fatigue Cycles	Core Power History (% FP)
Heatup and cooldown at 100 °F/hr	200 + 200	0-HZP-100 100-HZP-0
Unit loading and unloading at 5% of full power/minute	18300×2	15-100 100-15
Step load increase and decrease of 10% of full power Steady-state fluctuations	2000×2 Infinite	90-100 100-90
Large step load decrease (95% of FP) Reactor trip from FP Pressurizer auxiliary spray actuation	200 400 12	100-HZP
Loss of flow in one reactor coolant loop	80	100-HZP
Loss of load, without immediate turbine or reactor trip Loss of offsite A.C. electrical power (blackout with natural circulation in the reactor coolant system)	80 40	100-HZP
Main reactor coolant pipe break or steam pipe break	1	100-0

Terms: HZP - Hot Zero Power
FP - Full Power

Note: The cyclic/transient limits used for the fuel rod fatigue analysis, as summarized in this table, are bounding for the replacement steam generator cyclic/transient limits given in Table 5.2.1-1.

Table 4.5.3-1

REACTOR CORE DESCRIPTION

This Table remains unchanged from Table 4.3.2-1 except as noted below, which address the Advanced W17 HTP and Mark-BW fuel assembly designs.

Fuel assemblies	Mark-BW	Advanced W17 HTP
Number	193	193
Rod Array	17 X 17	17X17
Rods per assembly	264	264
Rod pitch, in.	0.496	0.496
Overall transverse dimensions, in.	8.425 X 8.425	8.424 x 8.424
Fuel weight (as UO_2), lb per assembly	1141	1140.23
Zirconium alloy weight, lb per assembly	295	304.68
Number of grids per assembly	8 1 top 1 bottom 6 Intermediate	11 3 IFM 's 1 end 7 Intermediate
Composition of grids	Inconel-718 (top and bottom) Zircaloy-4 (interm.)	Inconel-718 (end) Zircaloy-4 (interm. and IFM's)
Weight of grids per assembly, lbs.	4 (Inconel-718) 15 (Zircaloy-4)	2.87 (Inconel-718) 25.57 (Zircaloy-4)
Number of Guide Thimbles per assembly	24	24
Composition of guide thimbles	Zircaloy-4 or M5	Zircaloy-4
Diameter of guide thimbles (upper part), in.	0.450 ID x 0.482 OD	0.450 ID X 0.482 OD
Diameter of guide thimbles (lower part), in.	0.397 ID x 0.429 OD	0.397 ID X 0.482 OD

5.0 REACTOR COOLANT SYSTEM AND CONNECTED SYSTEMS

5.1 SUMMARY DESCRIPTION

The Reactor Coolant System (RCS) shown in Figure 5.1-1 consists of four similar heat transfer loops connected in parallel to the reactor pressure vessel. Each loop contains a reactor coolant pump, steam generator and associated piping and valves. In addition, the system includes a pressurizer, a pressurizer relief tank, and interconnecting piping and instrumentation. All the principal components are located in the containment building.

During operation, the RCS transfers the heat generated in the core to the steam generators where steam is produced to drive the turbine generator. Borated demineralized water is circulated in the RCS at a flow rate and temperature consistent with achieving the reactor core thermal-hydraulic performance (See Section 4.4). The water also acts as a neutron moderator and reflector, and as a solvent for the neutron absorber used in chemical shim control.

The RCS pressure boundary provides a barrier against the release of radioactivity generated within the reactor, and is designed to ensure a high degree of integrity throughout the life of the plant. (See Section 5.2)

RCS pressure is controlled by the pressurizer where water and steam are maintained in equilibrium by electrical heaters and/or water sprays. Steam can be formed (by the heaters) or condensed (by the pressurizer spray) to minimize pressure variations due to contraction and expansion of the reactor coolant. Spring-loaded safety valves and power operated relief valves are connected to the pressurizer and discharge to the pressurizer relief tank, where the steam is condensed and cooled by mixing with water.

The extent of the RCS is defined as:

1. The reactor vessel including control rod drive mechanism housings

2. The reactor coolant side of the steam generators

3. Reactor coolant pumps

4. A pressurizer

5. Safety and relief valves

6. The interconnecting piping, valves and fittings between the principal components listed above

7. The Reactor Coolant System auxiliary and connecting piping as identified in Section 5.5.3.2.

Reactor Coolant System Components

Reactor Vessel

The reactor vessel is cylindrical, with a welded hemispherical bottom head and a removable, flanged and gasketed, hemispherical upper head. The vessel contains the core, core supporting structures, control rods and other parts directly associated with the core. The upper head is provided with penetrations for the Upper Head Injection system, CRDMs instrumentation, and vents. The lower head is provided with penetration for the incore neutron monitors.

The vessel has inlet and outlet nozzles located in a horizontal plane just below the reactor vessel flange but above the top of the core. Coolant enters the vessel through the inlet nozzles and flows down the core barrel-vessel wall annulus, turns at the bottom and flows up through the core to the outlet nozzles.

Original Steam Generators (Historical) and Replacement Steam Generators

Both the original steam generators (OSGs) and replacement steam generators (RSGs) are vertical shell and U-tube evaporators with integral moisture separating equipment. The reactor coolant flows through the inverted U-tubes, entering and leaving through the nozzles located in the hemispherical bottom head of the steam generator. Steam is generated on the shell side and flows upward through the moisture separators to the outlet nozzle at the top of the steam generator.

Reactor Coolant Pumps

The reactor coolant pumps are single-speed centrifugal units driven by water-to-air-cooled, three-phase induction motors. The shaft is vertical with the motor mounted above the pumps. A flywheel on the shaft above the motor provides additional inertia to extend pump coast down. The inlet is at the bottom of the pump; discharge is on the side. The reactor coolant pump logic is shown in Figure 5.1-2.

Piping

The Reactor Coolant loop piping is specified in sizes consistent with system requirements.

The inside diameter of the hot leg is 29 inches and the cold leg return line to the reactor vessel is 27-1/2 inches. The piping between the steam generator and the pump suction is increased to 31 inches in diameter to reduce pressure drop and improve flow conditions to the pump suction.

Pressurizer

The pressurizer is a vertical, cylindrical vessel with hemispherical top and bottom heads. Electrical heaters are installed through the bottom head of the vessel while the spray nozzle, relief and safety valve connections are located in the top head of the vessel.

Pressurizer Relief Tank (PRT)

The pressurizer relief tank is a horizontal, cylindrical vessel with elliptical ends. Steam from the pressurizer safety and relief valves is discharged into the pressurizer relief tank through a sparger pipe under the water level. This condenses and cools the steam by mixing it with water. The PRT is equipped with two rupture discs which release to the containment.

Safety and Relief Valves

Three safety valves and two PORVs, connected to the top of the pressurizer, are provided to protect against overpressurization. The pressurizer safety valves are of the totally enclosed pop-type. The safety valves are spring-loaded, self activating with back pressure compensation. The power operated relief valves (PORV) are solenoid type valves which are operated automatically or manually from the MCR.

Block Valve Power Operated Relief Valve

One block valve per PORV is provided upstream of the PORV (i.e., between the PORV and the pressurizer). The block valves are used to isolate the solenoid operated relief valve for repair if excessive leakage occurs and to meet RCPB requirements. The respective block valves and PORVs are powered by opposite trains to assure reliable isolation during a stuck open PORV event.

Reactor Coolant System Performance Characteristics

Tabulations of important design and performance characteristics of the RCS are provided in Table 5.1-1.

Reactor Coolant Flow

The reactor coolant flow, a major parameter in the design of the system and its components, was established with a detailed design procedure supported by operating plant performance data, by pump model test and analysis, and by pressure drop tests and analyses of the reactor vessel and fuel assemblies. Data from all operating plants have indicated that the actual flow was well above the flow specified for the thermal design of the plant. By applying the design procedure described below, it was possible to specify the expected operating flow with reasonable accuracy.

Initially, three flow rates were used as the design basis for the reactor coolant system flow rate. These flow rates were based on various plant design considerations. The definitions of these flows are presented in the following paragraphs, and the application of the definitions is illustrated by the system and pump hydraulic characteristics on Figure 5.1-3.

The basis for the current reactor coolant system thermal design flow is also discussed under Thermal Design Flow.

Best Estimate Flow

The best estimate flow was the most likely value for the actual plant operating condition. This flow was based on the best estimate of the reactor vessel, steam generator and piping flow resistance, and on the best estimate of the reactor coolant pump head, with no uncertainties assigned to either the system flow resistance or the pump head. System pressure losses based on best estimate flow are presented in Table 5.1-1. Although the best estimate flow is the most likely value to be expected in operation, more conservative flow rates are applied in the thermal and mechanical designs.

Thermal Design Flow

The thermal design flow represents the minimum protected flow and is the basis for the reactor core thermal performance, the steam generator thermal performance, and the nominal plant parameters used throughout the design. To provide the required margin, the thermal design flow accounts for the uncertainties in reactor vessel, steam generator and piping flow resistance. The combination of these uncertainties, which includes a conservative estimate of the pump discharge flow resistance, was equivalent to increasing the best estimate reactor coolant system flow resistance by approximately 18 percent. The intersection of this conservative flow resistance with the best estimate pump curve, as shown in Figure 5.1-3, established the original design basis thermal design flow. This procedure provided a design flow margin for thermal design. The thermal design flow was confirmed by pre-operational test W.16.

The thermal design flow also represents the Technical Specification minimum operability flow which has been reduced by the maximum flow measurement uncertainty (3.5 percent). For Fuel Cycles 1 through 8, the thermal design flow served as the basis for core specific reload fuel cycle design and analysis. Beginning with the Cycle 9 operation of each unit, a statistical thermal-hydraulic analysis method was employed. With this statistical methodology, flow uncertainty is accounted for through the use of a statistically adjusted DNBR limit such that the Technical Specification minimum operability flow serves as the basis for the reload design. Both the thermal design flow and the Technical Specification minimum operability flow contain sufficient margin to allow for future increases in loop flow resistance due to steam generator tube plugging.

The thermal design flow and minimum operability flow are contained in Table 5.1-1 along with important design parameters based on the thermal design flow. Flow margin to the operability limit is verified a minimum of once every eighteen months through plant Surveillance Instructions and Test Instructions.

Mechanical Design Flow

The original design basis mechanical design flow was the conservatively high flow used in the mechanical design of the reactor vessel internals and fuel assemblies. To assure that a conservatively high flow was specified, the mechanical design flow was based on a reduced system resistance (90 percent of best estimate) and on the maximum uncertainty on pump head capability (105.5 percent of best estimate for machined pump impellers). The intersection of this flow resistance with the higher pump curve, as shown on Figure 5.1-3, established the original design basis mechanical design flow. The resulting flow is greater than the best estimate flow (101,700 gpm).

Beginning with the Cycle 9 operation of each unit, a more empirical approach was followed in establishing the mechanical design flow used in the determination of hydraulic loads in the fuel. Actual measured flow rates from the previous three cycles for each unit were used to establish a mechanical design flow rate of 410,000 gpm for fuel analyses. This flow represented a design value that exceeded the highest measured flow by over 6 percent. Subsequent to Cycle 9 operation, the reload fuel design was changed to contain low pressure drop fuel nozzles. Based on the nozzle changes, the mechanical design flow limit for those assemblies increased from 410,000 gpm to 420,000 gpm (see References 1 and 2).

Beginning with Cycle 15 operation for both units, the deterministic methodology used to establish the fuel mechanical design flow limit of 420,000 gpm was replaced with the statistical analysis methodology summarized in Reference 3. The statistical methodology was used to support a reduction in fuel assembly spring holddown force to eliminate excessive compression loads which were contributing to assembly distortion during operation. Revised holddown forces were established using a nominal primary system flow rate which bounds all measured flow rates for the previous six operating cycles for each unit. Based on the results of the statistical analysis, the modified fuel assembly springs will provide adequate holddown forces for primary system flows up to 404,000 gpm. Based on the assembly spring modifications, the 404,000 gpm value is the current fuel assembly mechanical design flow of record (see Reference 4). It should be noted that the mechanical design flow rate of 404,000 gpm is a nominal value and the uncertainty of 3.5% is addressed separately in the analyses. Therefore, the measured plant flow can be compared directly to the 404,000 gpm value without adjustment provided the actual measured flow uncertainty is less than or equal to the 3.5% value. The mechanical design flow used for all other RCS components remains 423,000 gpm.

Pump overspeed, due to a turbine-generator overspeed of 20 percent, resulted in a peak reactor coolant flow of 120 percent of the mechanical design flow. The overspeed condition is applicable only to operating conditions when the reactor and turbine-generator are at power.

Interrelated Performance and Safety Functions

The interrelated performance and safety functions of the RCS and its major components are listed below:

1. The RCS provides sufficient heat transfer capability to transfer the heat produced during power operation and when the reactor is subcritical, including the initial phase of plant cooldown, to the Steam and Power Conversion System.

2. The system provides sufficient heat transfer capability to transfer the heat produced during the subsequent phase of plant cooldown and cold shutdown to the Residual Heat Removal System.

3. The system heat removal capability under power operation and normal operational transients, including the transition from forced to natural circulation, shall assure no fuel damage within the operating bounds permitted by the Reactor Control and Protection Systems.

4. The RCS provides the water used as the neutron moderator and reflector and as a solvent for chemical shim control.

5. The system maintains the homogeneity of soluble neutron poison concentration and rate of change of coolant temperature such that uncontrolled reactivity changes do not occur.

6. The reactor vessel is an integral part of the RCS pressure boundary and is capable of accommodating the temperatures and pressures associated with the operational transients. The reactor vessel functions to support the reactor core and control rod drive mechanisms.

7. The pressurizer maintains the system pressure during operation and limits pressure transients. During the reduction or increase of plant load, reactor coolant volume changes are accommodated via the surge line to the pressurizer.

8. The reactor coolant pumps supply the forced coolant flow necessary to remove heat from the reactor core and transfer it to the steam generators.

9. The steam generators provide high quality steam to the turbine. The tube and tube sheet boundary are designed to prevent the transfer of activity generated within the core to the secondary system.

10. The RCS piping serves as a boundary for containing the coolant under operating temperature and pressure conditions and for limiting leakage (and activity release) to the containment atmosphere. The RCS piping contains demineralized light water which is circulated at the flow rate and temperature consistent with achieving the reactor core thermal and hydraulic performance.

System Operation

Brief descriptions of normal anticipated system operations are provided below. These descriptions cover plant startup, power generation, hot shutdown, cold shutdown and refueling.

Plant Startup

Plant startup encompasses the operations which bring the reactor plant from cold shutdown to no-load power operating temperature and pressure. Before plant startup, the reactor coolant loops are filled completely, by the use of the charging pumps or RHR pumps, with water containing the cold shutdown concentration of boron. The secondary side of the steam generator is filled to normal startup level with water which meets the steam plant water chemistry requirements.

Upon completion of venting, the RCS is pressurized by the use of the low pressure letdown control valve and the centrifugal charging pumps. After the RCS reaches a certain specified pressure, the pressurizer heaters are energized to draw a bubble in the pressurizer. Then the reactor coolant pumps are started provided that the minimum NPSH requirements are met, a steam bubble is formed in the pressurizer, and a minimum RCP seal injection flow rate is confirmed. The RCPs and the pressurizer heaters are used to heat the reactor coolant. Meanwhile, the pressurizer liquid level is reduced until the no load power level volume is established. Fracture prevention temperature limitations of the reactor vessel impose an upper limit of approximately 450 psig. The charging pump supplies seal injection water for the reactor coolant pump shaft seals. A nitrogen atmosphere and normal operating temperature, pressure and water level are established in the pressurizer relief tank.

During the initial heatup phase, hydrazine is added to the reactor coolant to scavenge the oxygen in the system; the heatup is not taken beyond 250°F until the oxygen level has been reduced to the specified level.

The reactor coolant pumps and pressurizer heaters are used to raise the reactor coolant temperature to a level beyond which the overall moderator temperature coefficient is negative.

As the reactor coolant temperature increases, the pressurizer heaters are manually controlled to maintain adequate suction pressure for the reactor coolant pumps. The pressurizer heat and spray controls can be transferred from manual to automatic control later in the heatup sequence.

Power Generation and Hot Shutdown

Power generation includes steady state operation, ramp changes not exceeding the rate of five percent of full power per minute, step changes of ten percent of full power (not exceeding full power), and step load changes with steam dump not exceeding the design step load decrease.

During power generation, RCS pressure is maintained by the pressurizer pressure control at or near 2235 psig, while the pressurizer liquid level is controlled by the charging-letdown flow control of the Chemical and Volume Control System. The pressurizer pressure, level, and charging flow controls are contained within the plant Distributed Control System (DCS).

When the reactor power level is less than 15 percent, the reactor power is controlled manually. At power above 15 percent, the automatic Rod Control System, contained within the plant DCS, maintains the average coolant temperature, consistent with the power relationships, by control rod movement.

During the hot shutdown operations, when the reactor is subcritical, the RCS temperature is maintained by steam dump to the main condenser. This is accomplished by the Steam Dump Control System (SDCS), contained within the plant DCS, operating in the pressure control mode, which is set to maintain the steam generator steam pressure. Residual heat from the core or operation of a reactor coolant pump provides heat to overcome RCS heat losses.

Plant Shutdown

Plant shutdown is the operation which brings the reactor plant from no load power operating temperature and pressure to cold shutdown. During the plant cooldown, charging is provided to makeup for coolant contraction. During the initial phase of the cooldown, the makeup is provided from the boric acid tanks. The boric acid tanks should be used until at least the technical requirement manual minimum volume has been charged. At that point, operators can continue using the boric acid tanks if additional volume is available, or shift suction of the charging pumps to the refueling water storage tank. If the boric acid tanks are used, pure boric acid should be charged until the reactor coolant system reaches the desired cold shutdown concentration. The cooldown is completed by using blended makeup at the cold shutdown concentration. If the RCS is to be opened during the shutdown, the hydrogen and fission gas in the reactor coolant is reduced by degassing the coolant in the Volume Control Tank.

Plant shutdown is accomplished in two phases, the first is by the combined use of the RCS and steam systems, and the second by the Residual Heat Removal System. During the first phase of shutdown, residual core and reactor coolant heat is transferred to the steam system via the steam generator. Steam from the steam generator is dumped to the main condenser. At least one reactor coolant pump is kept running to assure uniform RCS cooldown.

When the reactor coolant temperature and pressure are below approximately 350°F and 380 psig, respectively, the second phase of shutdown commences with the operation of the Residual Heat Removal System. With RHR in service, RCS pressure is maintained less than or equal to 380 psig. This provides sufficient margin to prevent the RHR suction relief valve from lifting at its setpoint of 450 psig. The pressurizer heaters are maintained energized while filling the pressurizer water solid to prevent stratification of the pressurizer water volume and to maintain an outflow of hot water from the surge line. With the heaters energized, the pressurizer is deliberately filled by creating a charging and letdown mismatch. After the pressurizer is filled, the heaters are deenergized to allow the pressurizer to cool.

At approximately 140°F the last operating reactor coolant pump(s) may be turned off or cooldown may continue using a reactor coolant pump(s) and its associated steam generator to expedite cooldown to a reactor coolant system temperature of approximately 100°F. After the last reactor coolant pump is turned off, pressurizer cooldown is continued by initiating auxiliary spray flow from the Chemical and Volume Control System.

Refueling

Before removing the reactor vessel head for refueling, the system temperature has been reduced to 140°F or less and hydrogen and fission product levels are reduced. Installed plant instrumentation is provided to monitor RCS level during drain down activities. Draining continues until the water level is below the reactor vessel flange. The vessel head is then raised and the refueling cavity is flooded. Upon completion of refueling, the system is refilled for plant startup.

5.1.1 Schematic Flow Diagram

The Reactor Coolant System is shown in Figure 5.1-1. Principal pressures, temperatures, flow rates, and coolant volume data under normal steady-state, full power operating conditions are provided in Table 5.1-1.

5.1.2 Piping and Instrumentation Diagram

A piping and instrumentation diagram of the Reactor Coolant System is shown on Figure 5.1-1. The diagram shows the extent of the systems located within the containment, the points of separation between the Reactor Coolant System and the secondary (heat utilization) system.

5.1.3 Elevation Drawing

Figure 1.2.3-13 is an elevation drawing providing principal features of the Reactor Coolant System in relation to surrounding concrete structures.

5.2 INTEGRITY OF THE REACTOR COOLANT SYSTEM BOUNDARY

In adjusting the Sequoyah FSAR format to fit the NRC Format Guide it has been necessary in certain areas to use terminology which is basically inappropriate to plants of the Sequoyah era. However in using certain of the terminology which follows, we make the distinction that we are stating what the system is capable of being measured against; not the actual rules used in the original design.

The ASME Section III Nuclear Power Plant Components Code 1971 edition is inapplicable to the Sequoyah Plants. However, since the reactor coolant loop vessels (reactor vessel, pressurizer and steam generators) are basically standard components, analysis on these vessels with the more recent ASME Code conditions (normal, upset, emergency and faulted) have been performed with the load combinations and associated stress limits given in Tables 5.2-1 through 5.2-5. This analysis includes the dynamic effects of equipment operation as transmitted to various components by system piping.

Reactor Coolant System components have been designed, fabricated, inspected, tested, and procured in accordance with Tables 3.2.2-1 and 3.2.2-2.

The Reactor Coolant System boundary is designed to accommodate the system pressures and temperatures attained under all expected modes of plant operation including all anticipated transients, and to maintain the stresses within applicable stress limits. Design conditions are given in Paragraph 5.2.1.1. The system is protected from overpressure by means of pressure relieving devices as required by applicable codes. Materials of construction are specified to minimize corrosion and erosion and to provide a structural system boundary throughout the life of the plant. Fracture prevention measures are taken to prevent brittle fracture. Inspection in accordance with applicable codes and provisions (see Subsection 5.2.8) are made for surveillance of critical areas to enable periodic assessment of the boundary integrity.

5.2.1 Design of Reactor Coolant System Boundary Components

The original design basis conditions as discussed in this section included the effects of postulated main reactor coolant loop pipe breaks. These breaks have been eliminated from the design basis through application of leak before break technology (see Section 3.6.1.1). The original design basis evaluation is described below. These results envelope the effects of the remaining postulated LOCAs.

5.2.1.1 Performance Objectives and Design Conditions

The performance objectives of the Reactor Coolant System (RCS) are described in Section 5.1. Equipment Code and classification list for the components within the RCS boundary are given in Section 3.2.

The RCS in conjunction with the Reactor Control and Protection Systems is designed to maintain the reactor coolant at conditions of temperature, pressure and flow adequate to protect the core from damage. The design requirement for safety is to prevent conditions of high power, high reactor coolant temperature or low reactor coolant pressure or combinations of these which could result in a DNBR less than 1.3.

The RCS is designed to avoid uncontrolled reductions in boric acid concentration or reactor coolant temperature. The reactor coolant is the core moderator, reflector, and solvent for the chemical shim.

As a result, changes in coolant temperature or boric acid concentration affect the reactivity level in the core.

The following design bases have been selected to ensure that the uniform RCS boron concentration and temperature will be maintained:

1. Coolant flow is provided by either a reactor coolant pump or a residual heat removal pump to ensure uniform mixing of the boron.

2. The design arrangement of the Reactor Coolant System eliminates dead ended sections and other areas of low coolant flow in which nonhomogeneities in coolant temperature or boron concentration could develop.

3. The RCS is designed to operate within the operating parameters, particularly the coolant temperature change limitations.

The design pressure for the RCS is 2485 psig except for the pressurizer relief line from the safety valve to the pressurizer relief tank, which is 600 psig, and the pressurizer relief tank, which is 100 psig. For components with design pressures of 2485 psig, the normal operating pressure is 2235 psig. The design temperature for the RCS is 650°F except for the pressurizer and its surge line which are designed for 680°F, and the pressurizer relief line from the safety valve to the pressurizer relief tank, which is designed for 600°F.

The following five ASME operating conditions are considered in the design of the RCS.

1. Normal Conditions

   Any condition in the course of startup, operation in the design power range, hot standby and system shutdown, other than upset, emergency, faulted or testing conditions.

2. Upset conditions

   Any deviations from normal conditions anticipated to occur often enough that design should include a capability to withstand the conditions without operational impairment. The upset conditions include those transients which result from any single operator error or control malfunction, transients caused by a fault in a system component requiring its isolation from the system and transients due to loss of load or power. Upset conditions include any abnormal incidents not resulting in a forced outage and also forced outages for which the corrective action does not include any repair of mechanical damage. The estimated duration of an upset condition is included in the design specifications.

3. Emergency conditions

   Those deviations from normal conditions which require shutdown for correction of the conditions or repair of damage in the system. The conditions have a low probability of occurrence but are included to provide assurance that no gross loss of structural integrity will result as a concomitant effect of any damage developed in the system. The total number of postulated occurrences for such events shall not cause more than twenty-five stress cycles having a S_a value greater than that for 10^6 cycles from the applicable fatigue design curves of the ASME code Section III.

4. Faulted conditions

   Those combinations of conditions associated with extremely low probability, postulated events whose consequences are such that the integrity and operability of the nuclear energy system may be impaired to the extent that considerations of public health and safety are involved. Such conditions require compliance with safety criteria as may be specified by jurisdictional authorities.

5. Testing conditions

   Testing conditions are those tests in addition to the hydrostatic or pneumatic tests required by ASME code Section III including leak tests or subsequent hydrostatic tests.

To provide the necessary high degree of integrity for the equipment in the RCS, the transient conditions selected for equipment fatigue evaluation are based upon a conservative estimate of the magnitude and frequency of the temperature and pressure transients resulting from various operating conditions in the plant. To a large extent, the specific transient operating conditions to be considered for equipment fatigue analyses are based upon engineering judgment and experience. The transients selected are representative of operating conditions which prudently should be considered to occur during plant operation and are sufficiently severe or frequent to be of possible significance to component cyclic behavior. The transients selected may be regarded as a conservative representation of transients which, used as a basis for component fatigue evaluation, provide confidence that the component is appropriate for its application over the design life of the plant.

The following five transients are considered normal conditions:

1. Heatup and Cooldown

   For design evaluation, the heatup and cooldown cases are represented by continuous heatup or cooldown at a rate of 100°F per hour which corresponds to a heatup or cooldown rate under abnormal or emergency conditions. The heatup occurs from ambient to the no load temperature and pressure condition and the cooldown represents the reverse situation. In actual practice, the rate of temperature change of 100°F per hour will not be usually attained because of other limitations such as:

   a. Criteria for prevention of non-ductile failure which establish maximum permissible temperature rates of change, as a function of plant pressure and temperature.

   b. Slower initial heatup rates when using pumping energy only.

   c. Interruptions in the heatup and cooldown cycles due to such factors as drawing a pressurizer steam bubble, rod withdrawal, sampling, water chemistry and gas adjustments.

   The heatup and cooldown rates, imposed by plant operating procedures, are in accordance with the Sequoyah Technical Specifications. Ideally, heatup and cooldown would occur only before and after refueling. In practice, additional unscheduled plant cooldowns may be necessary for plant maintenance. The frequency of maintenance shutdowns is expected to decrease as the plant matures.

2. Unit Loading and Unloading

The unit loading and unloading cases are conservatively represented by a continuous and uniform ramp power change of 5 percent per minute between 15 percent load and full load. This load swing is the maximum possible consistent with operation under automatic reactor control. The reactor temperature varies with load as prescribed by the Reactor Control System.

3. Step Increase and Decrease of Ten Percent

The ± 10 percent step change in load demand is a control transient which is assumed to be a change in turbine control valve opening which might be occasioned by disturbances in the electrical network into which the plant output is tied. The Reactor Control System is designed to restore plant equilibrium without reactor trip following a ± 10 percent step change in turbine load demand initiated from nuclear plant equilibrium conditions in the range between 15 percent and 100 percent full load, transients producing an overpower condition are controlled/terminated by other control/protective functions within the power range for automatic reactor control. In effect, during load change conditions, the Reactor Control System attempts to match turbine and reactor outputs in such a manner that peak reactor coolant temperature is minimized and reactor coolant temperature is restored to its programmed set point at a sufficiently slow rate to prevent excessive pressurizer pressure decrease.

Following a step load decrease in turbine load, the secondary side steam pressure and temperature initially increase since the decrease in nuclear power lags behind the step decrease in turbine load. During the same increment of time, the Reactor Coolant System average temperature and pressurizer pressure also initially increase. Because of the power mismatch between the turbine and reactor and the increase in reactor coolant temperature, the control system automatically inserts the control rods to reduce core power.

With the load decrease, the reactor coolant temperature is ultimately reduced from its peak value to a value below its initial equilibrium value at the inception of the transient. The reactor coolant average temperature setpoint change is made as a function of turbine-generator load as determined by first stage turbine pressure measurement. The pressurizer pressure also decreases from its peak pressure value and follows the reactor coolant decreasing temperature trend. At some point during the decreasing pressure transient, the saturated water in the pressurizer begins to flash which reduces the rate of pressure decrease. Subsequently the pressurizer heaters come on to restore the plant pressure to its normal value.

Following a step increase in turbine load, the reverse situation occurs, i.e., the secondary side steam pressure and temperature initially decrease and the reactor coolant average temperature and pressure initially decrease. The control system automatically withdraws the control rods to increase core power. The decreasing pressure transient is reversed by actuation of the pressurizer heaters and eventually the system pressure is restored to its normal value. The reactor coolant average temperature is raised to a value above its initial equilibrium value at the beginning of the transient..

4. Large Step Decrease in Load

This transient applies to a step decrease in turbine load from full power of such magnitude that the resultant rapid increase in reactor coolant average temperature and secondary side steam pressure and temperature automatically initiates a secondary side steam dump that prevents a reactor shutdown or lifting of steam generator safety valves. Thus, when a plant is designed to

accept a step decrease of 95 percent from full power, it signifies that a steam dump system provides a heat sink to accept 85 percent of the turbine load. The remaining 10 percent of the total step change is assumed by the rod control system. If a steam dump system were not provided to cope with this transient, there would be such a large mismatch between what the turbine is demanding and what the reactor is furnishing that a reactor trip and lifting of steam generator safety valves would occur. Although the Sequoyah plant has been designed for a 50 percent step change, the transient for the 95 percent step-load decrease is considered since it represents a more severe condition.

5. Steady State Fluctuations

The reactor coolant average temperature, for purposes of design, is assumed to increase or decrease a maximum of 6°F in one minute. The temperature changes are assumed to be around the programmed value of T_{avg}, (T_{avg} + 3°F). The corresponding reactor coolant average pressure is assumed to vary accordingly.

The following six transients are considered upset conditions:

1. Loss of Load Without Immediate Turbine or Reactor Trip

This transient applies to a step decrease in turbine load from full power occasioned by the loss of turbine load without immediately initiating a reactor trip and represents the most severe transient on the RCS under upset conditions. The reactor and turbine eventually trip as a consequence of a high pressurizer level trip initiated by the Reactor Trip System. Since redundant means of tripping the reactor are provided as a part of the reactor protection system, transients of this nature are not expected, but are included to insure a conservative design.

2. Loss of Power

This transient applies to a blackout situation involving the loss of outside electrical power to the station with a reactor and turbine trip. Under these circumstances, the reactor coolant pumps are de-energized and following the coastdown of the reactor coolant pumps, natural circulation builds up in the system to some equilibrium value. This condition permits removal of core residual heat through the steam generators which at this time are receiving feedwater from the auxiliary feed system operating from diesel generator power. Steam is removed for reactor cooldown through atmospheric relief valves provided for this purpose.

3. Loss of Flow

This transient applies to a loss of flow accident from full power in which a reactor coolant pump is tripped out of service as a result of an electrical or mechanical failure. The consequences of such an accident are reactor and turbine trip, on low reactor coolant flow, followed by automatic opening of the steam dump system and flow reversal in the affected loop. The flow reversal results in reactor coolant at cold leg temperature being passed through the steam generator and cooled still further. This cooler water then passes through the hot leg piping and enters the reactor vessel outlet nozzles. The net result of the flow reversal is a sizable reduction in the hot leg coolant temperature of the affected loop.

4. Reactor Trip From Full Power

A reactor trip from full power may occur for a variety of causes resulting in temperature and pressure transients in the RCS and in the secondary side of the steam generator. This is the result of continued heat transfer from the reactor coolant in the steam generator. The transient continues until the reactor coolant and steam generator secondary side temperatures are in equilibrium at zero power conditions. A continued supply of feedwater and controlled dumping of secondary steam remove the core residual heat and prevent the steam generator safety valves from lifting. The reactor coolant temperature and pressure undergo a rapid decrease from full power values as the Reactor Trip System causes the control rods to move into the core.

5. Inadvertent Auxiliary Spray

The inadvertent pressurizer auxiliary spray transient will occur if the auxiliary spray valve is opened inadvertently during normal operation of the plant. This will introduce cold water into the pressurizer with a very sharp pressure decrease as a result.

The temperature of the auxiliary spray water is dependent upon the performance of the regenerative heat exchanger. The most conservative case is when the letdown stream is shut off and the charging fluid enters the pressurizer unheated. Therefore, for design purposes, the temperature of the spray water is assumed to be 100°F. The spray flow rate is assumed to be 200 gpm. It is furthermore assumed that the auxiliary spray will, if actuated, continue for five minutes until it is shut off.

The pressure decreases rapidly to the low pressure reactor trip point. At this pressure the pressurizer low pressure reactor trip is assumed to be actuated; this accentuates the pressure decrease until the pressure is finally limited to the hot leg saturation pressure. At five minutes, the spray is stopped and all the pressurizer heaters return the pressure to 2250 psia. This transient is more severe on a two loop plant than on a three or four loop plant, e.g., a bigger and more rapid pressure decrease. Therefore, the transient for a two loop plant is used as design basis for all plants.

For design purposes it is assumed that no temperature changes in the Reactor Coolant System will occur as a result of initiation of auxiliary spray except in the pressurizer.

6. 1/2 Safe Shutdown Earthquake (1/2 SSE)

The earthquake loads are a part of the mechanical loading conditions specified in the equipment specifications. The origin of their determination is separate and distinct from those transient loads resulting from fluid pressure and temperature. Their magnitude, however, considered in the design analysis is for comparison with appropriate stress limits.

No transient is classified as an emergency condition.

The following four transients are considered faulted conditions:

1. RCS Boundary Pipe Break

This accident involves the postulated rupture of a pipe belonging to the RCS boundary. It is conservatively assumed that the system pressure is reduced rapidly and the Emergency Core Cooling System is initiated to introduce water into the RCS. The safety injection signal also will initiate a turbine and reactor trip.

Westinghouse has used the criteria given in Section 3.6 in the design of the supports and restraints of the RCS in order to assure continued integrity of vital components and engineered safety systems.

Analyses reported in Reference (3) and service experiences show that the criteria given in Section 3.6 offer a practical equivalent to assure the same degree of protection to public health and safety as postulating both longitudinal and circumferential breaks at any location. Westinghouse Nuclear Steam Supply System piping and support components have been designed to these criteria. Westinghouse has performed this analysis for the Sequoyah plant including the Westinghouse Nuclear Steam Supply System equipment and the support structures designed by Westinghouse.

Protection criteria against dynamic effects associated with pipe breaks is covered in Section 3.6.

2. Steam Line Break

For component evaluation, the following conservative conditions are considered.

a. The reactor is initially in hot, zero power subcritical condition assuming all rods in except the most reactive rod which is assumed to be stuck in its fully withdrawn position.

b. A steam line break occurs inside the containment resulting in a reactor and turbine trip.

c. Subsequent to the break the reactor coolant temperature cools down to 212°F.

d. The Emergency Core Cooling System pumps restore the reactor coolant pressure.

The above conditions result in the most severe temperature and pressure variations which the component will encounter during a steam break accident.

The dynamic reaction forces associated with circumferential steam line breaks have been considered in the design of supports and restraints in order to assure continued integrity of vital components and engineered safety features. Both Unit 2 and Unit 1 (subsequent to steam generator replacement) are qualified for the postulated conditions that result in maximum severity. Protection criteria against dynamic effects associated with RCS pipe breaks is covered in Section 3.6.

3. Steam Generator Tube Rupture

This accident postulates the double ended rupture of a steam generator tube resulting in a decrease in pressurizer level and RCS pressure. Reactor trip occurs due to a safety injection signal on low pressurizer pressure. The planned procedure for recovery from this accident calls for isolation of the steam line leading from the affected steam generator. (Reference Section15.4) Therefore, this accident results in a transient which is no more severe than that associated with a reactor trip. Note that both Unit 2 and Unit 1 (subsequent to steam generator replacement) are qualified for the postulated conditions that result in maximum severity.

4. Safe Shutdown Earthquake (SSE)

The mechanical stress resulting from the safe shutdown earthquake is considered on a component basis.

The above design conditions are given in the Equipment-Specifications which are written in accordance with the appropriate ASME Codes.

The design transients and the number of cycles of each that is normally used for fatigue evaluations are shown in Table 5.2.1-1. In accordance with the ASME Boiler and Pressure Vessel Code, faulted conditions are not included in fatigue evaluations.

The following tests were performed prior to plant startup:

1. Turbine Roll Test

   This transient is imposed upon the plant during the hot functional test period for turbine cycle checkout. Reactor coolant pump power is used to heat the reactor coolant to operating temperature and the steam generated is used to perform a turbine roll test. However, the plant cooldown during this test exceeds the 100°F per hour maximum rate.

2. Hydrostatic Test Conditions

   The pressure tests are outlined below:

   a. Primary Side Hydrostatic Test Before Initial Startup

      The pressure tests covered by this section include both shop and field hydrostatic tests which occurred as a result of component or system testing. This hydro test was performed prior to initial fuel loading at a water temperature compatible with reactor vessel fracture prevention criteria requirements and a maximum test pressure of 3107 psig or 1.25 times the design pressure. In this test the Reactor Coolant System was pressurized to 3107 psig coincident with increasing the pressure on the steam generator secondary side, as required, to maintain less than 1600 psi differential pressure across the steam generator tubes. The Chemical and Volume Control System provides the means to hydrostatically test the RCS.

   b. Secondary Side Hydrostatic Test Before Initial Startup

      The secondary side of the original steam generator (OSG) is pressurized to 1.25 times the design pressure of the secondary side coincident with the primary side at 0 psig.

   c. Primary Side Leak Test

      Subsequent to system closure after the primary system is opened, a leak test is performed. During this test the primary system pressure is, for design purposes, assumed to be raised to 2500 psia, with the system temperature above design transition temperature, while the system is checked for leaks.

      In actual practice, the primary system is brought to normal operating temperature and pressure to prevent the pressurizer safety valves from lifting during the leak test and to prevent exceeding the 1600 psid tube sheet differential pressure limit.

5.2.1.2 Normal Condition Pipe Stress Analysis

The Unit 1 Reactor Coolant Loop Structural Analysis is summarized in WCAP-7957 Part 1 while the Unit 2 analysis is still based on Westinghouse Reports SD-105 and SD-119.

The stresses due to primary loadings of pressure and weight are summed. The thermal expansion stress is secondary in nature and hence is not combined with the primary stresses. The calculations for RCL is piping minimum wall thickness, pressure stress, and thermal expansion stress are performed in accordance with USAS B31.1 power piping code.

The RCL piping is made from a material called A351 GR CF 8 M. This material is not shown in USAS B31.1, however the material is shown in USAS B31.7. Therefore, the material allowable used for the qualification of the RCL piping was based upon USAS B31.7.

A code allowable stress value (S_h) of 14,800 psi was used to evaluate the maximum Unit 1 and Unit 2 calculated stress due to primary loadings of pressure and weight in the reactor coolant loop piping.

A code allowable stress value (S_A per USAS B31.1) of 25,575 psi was used to evaluate the maximum Unit 1 and Unit 2 calculated stress due to thermal expansion in the reactor coolant loop piping.

Upset Condition

The 1/2 SSE stresses are added to the stresses due to primary loadings of pressure and weight. It is conservatively assumed that the maximum stress values occur at the same point around the pipe circumference.

The maximum combined stresses due to 1/2 SSE, weight, and pressure in the reactor coolant loop piping were compared to a code allowable of (1.2 S_h) 17,760 psi.

Faulted Conditions

The SSE and LOCA stresses are added to the stresses due to primary loadings of pressure and weight. It is conservatively assumed that the maximum stress values occur at the same point around the pipe circumference.

The maximum combined stresses due to SSE, LOCA, weight, and pressure in the reactor coolant loop piping were compared to a code allowable of (2.4 S_h) 35,520 psi.

The procedure for evaluation of the piping stresses due to combined loadings of weight, pressure, SSE and LOCA is as described below.

The LOCA RCL piping analysis yields a time-history of results at various locations in the reactor coolant loop piping. The results are maximized from all of the LOCA conditions considered.

5.2.1.3 Support Stress Analysis

5.2.1.3.1 Design Conditions

Normal Conditions

Thermal, weight, and pressure forces (obtained from the RCL analysis) acting on the support structures are combined algebraically. The combined load component vector is multiplied by member influence coefficient matrices to obtain all force components at each end of each member in the support system.

The adequacy of each member is verified by solving the AISC-69 stress, interaction, and dimensional ratio equations.

Upset Condition

1/2 SSE support forces were assigned positive then negative signs and, in each case, were added algebraically to normal condition forces. The interaction and stress equations are the allowable specified limits permitted by AISC-69.

Faulted Condition

SSE LOCA support forces are combined with Normal loads and used in the above stress and interaction equations. For this loading condition, limiting values of 1.5 times allowables were used. This limit represents a stress of about 0.9 yield and provides a 10 percent margin against buckling for short stocky members whose buckling mode is highly inelastic and up to 30 percent for members whose buckling mode is elastic.

Design of the reactor coolant pump anchorages and the lower steam generator supports, used the leak before break (LBB) technology for the reactor coolant loop pipe break loads.

5.2.1.3.2 Initial Conditions

The load combinations that are considered in the design of structural steel members of component supports are summarized in Table 5.2-5. The design is described in Paragraph 5.5.14.2.

Deadweight

The deadweight loading imposed by the piping on the supports is defined to consist of the dry weight of the coolant piping and the weight of the water contained in piping during normal operation. In addition, the total weight of the primary equipment components including water forms a deadweight loading on the individual component supports.

Thermal Expansion

The free vertical thermal growth of the reactor vessel nozzle centerlines is considered in the thermal analysis of the reactor coolant loop (RCL) piping.

The cold and hot moduli of elasticity, the coefficient of thermal expansion at the metal temperature, and the temperature rise above the ambient temperature define the required input data to perform the flexibility analysis for thermal expansion.

Earthquake Loads

The intensity and character of the earthquake motion which produces forced vibration of the equipment mounted within the containment building are specified in terms of the floor response spectrum curves at various elevations within the containment building. The 1/2 SSE and SSE floor response spectrum curves for earthquake motions were developed by the Tennessee Valley Authority.

Pressure

The steady state hydraulic forces based on the system initial pressure are applied as external loads to the RCL model for determination of the RCL/support system deflections and support forces. The design pressure is also included in the evaluation of the piping stress.

Pipe Rupture Loads

Blowdown loads are developed in the broken and unbroken reactor coolant loops as a result of the transient flow, pressure fluctuations following a postulated loss-of-coolant accident (LOCA) in one of the reactor coolant loops. Note that “broken loop” refers to the loop which contains the auxiliary line nozzle break (surge, accumulator, or RHR) and “unbroken loop” refers to any of the remaining three loops. The postulated LOCA is assumed to have one millisecond opening time to simulate the instantaneous occurrence.

Analytical Methods

The static and dynamic structural analyses assume linear elastic behavior and employ the displacement (stiffness) matrix method and the normal mode theory for lumped-parameter, multi-mass structural representation to formulate the solution. The complexity of the physical system to be analyzed requires the use of a computer for solution. Herein lies the need for accurate and adequate representation of the physical system by means of an idealized (mathematical) model.

The loadings on the component supports are obtained from the analysis of an integrated reactor coolant loop supports system dynamic structural model as shown in Figure 5.2.1-4.

5.2.1.3.3 Design Evaluation

The support loads are computed by multiplying the support stiffness matrix, and the displacement vector, at the support point. The support loads are saved on magnetic tape for use in support member evaluation.

The STAAD and STRUDL computer programs are used to obtain support stiffness matrices and member influence coefficients for the equipment supports. Unit force along and unit moment about each coordinate axis are applied to the models at the equipment vertical centerline joint. Stiffness analysis is performed for each unit load for each model. Printed output includes all six components of displacement at the joint at which loads are applied and six force components at each end of each member in the support system.

Joint displacements for applied unit loads are formulated into flexibility matrices. These are inverted to obtain support stiffness matrices which are included in the RCL model. Figures 5.2.1-5 through 5.2.1-7 illustrate the support models and show the member locations.

The pressurizer base support ring and upper lateral support structures were analyzed conservatively for SSE and accident loads. Accident loads were obtained for breaks in both the surge line and the relief lines attached to the pressurizer. The forces and stresses in the pressurizer supports are well within permissible values for all loading conditions.

The reactor vessel support structures were analyzed using a finite element model with the STASYS computer program for an applied force resulting from all loading conditions. Dynamic forces applied to these structures are the combination of forces obtained from the reactor coolant loop analysis and the reactor vessel internals analysis.

5.2.1.4 Component Stress Evaluation

The RCS provides for heat transfer from the reactor to the steam generators under conditions of forced circulation flow and natural circulation flow. The heat transfer capabilities of the RCS are analyzed in Chapter 15 for various transients.

The heat transfer capability of the steam generators is sufficient to transfer, to the Steam and Power Conversion System, the heat generated during normal operation, and during the initial phase of plant cooldown under natural circulation conditions.

During the second phase of plant cooldown and during cold shutdown and refueling, the heat exchangers of the Residual Heat Removal System are employed. Their capability is discussed in Section 5.7.

Tests are performed to determine the total delivery capability of the Reactor Coolant Pumps. Thus, it is confirmed prior to plant operation that adequate circulation is provided by the RCS.

To assure a heat sink for the reactor under conditions of natural circulation flow, the steam generators are at a higher elevation than the reactor. In the design of the steam generators (both OSG and RSG) consideration is given to provide adequate tube area to ensure that the residual heat removal rate is achieved with natural circulation flow.

Whenever the boron concentration of the RCS is reduced, plant operation will be such that good mixing is provided in order to ensure that the boron concentration is maintained uniformly throughout the RCS.

Although mixing in the pressurizer will not be achieved to the same degree, the fraction of the total RCS volume which is in the pressurizer is small. Thus the pressurizer liquid volume is of a minor concern with respect to its effect on boron concentration.

Also, the design of the RCS is such that the distribution of flow around the system is not subject to the degree of variation which would be required to produce nonhomogeneities in coolant temperature or boron concentration as a result of areas of low coolant flow rate. An exception to this is the pressurizer; the surge line has been evaluated for thermal issues as necessary.

The range of coolant temperature variation during normal operation is limited and the associated reactivity change is well within the capability of the rod control group movement.

For design evaluation, the heatup and cooldown transients are analyzed by using a rate of temperature change equal to 100°F per hour which corresponds to abnormal or emergency heatup and cooldown conditions. Over certain temperature ranges, fracture prevention criteria will impose a lower limit to heatup and cooldown rates.

Before plant cooldown is initiated and during the plant cooldown process, the boron concentration in the RCS is adjusted to meet or exceed the shutdown margin requirements as specified in the plant's Technical Specifications.

It is therefore concluded that the temperature changes imposed on the RCS during its normal modes of operation do not cause any abnormal or unacceptable reactivity changes.

The design cycles as discussed in the preceding section are conservatively estimated for equipment design purposes and not intended to be an accurate representation of actual transients or for all cases reflect operating experience.

Certain design transients, with an associated pressure and temperature curve, have been chosen and assigned an estimated number of design cycles for the purpose of equipment design. These curves represent an envelope of pressure and temperature transients on the RCS boundary with margin in the number of design cycles chosen based on operating experience.

To illustrate this approach the reactor trip transient can be mentioned. Four hundred design cycles are considered in this transient. One cycle of this transient would represent any operational occurrence which would result in a reactor trip. Thus, the reactor trip transient represents an envelope design approach to various operational occurrences.

This approach provides a basis for fatigue evaluation to ensure the necessary high degree of integrity for the RCS components.

System hydraulic and thermal design parameters are used as the basis for the analysis of equipment, coolant piping, and equipment support structures for normal and upset loading conditions. The analysis is performed using a static model to predict deformation and stresses in the system. Results of the analysis give six generalized force components, three bending moments and three forces. These moments and forces are resolved into stresses in the pipe in accordance with the applicable codes. Stresses in the structural supports are determined by the material and section properties assuming linear elastic small deformation theory.

In addition to the loads imposed on the system under normal and upset conditions, the design of mechanical equipment and equipment supports requires that consideration also be given to abnormal loading conditions such as seismic and pipe rupture.

Analysis of the reactor coolant loops and support systems for seismic loads is based on a three dimensional, multi-mass elastic dynamic mode. The appropriate level floor spectral accelerations are used as input forcing functions to the detailed dynamic model which includes the effects of the supports and the supported equipment. The loads developed from the dynamic model are incorporated into a detailed loop and support model to determine the support member stresses.

The dynamic analysis employs the displacement method, lumped parameter, stiffness matrix formulations and assumes that all components behave in a linearly elastic manner. Seismic analyses are covered in detail in Section 3.7.

Analysis of the reactor coolant loops and support systems for blowdown loads resulting from a loss of coolant accident is based on the time history response of simultaneously applied blowdown forcing functions on a broken and unbroken loop dynamic model. The broken loop is the loop where the auxiliary line nozzle (surge, accumulator, or RHR) has broken. The unbroken loops are the other three loops where no breaks have occurred. The forcing functions are defined at points in the system loop where changes in cross section or direction of flow occur such that differential loads are generated during the blowdown transient. Stresses and loads are checked and compared to the corresponding allowable values.

The stresses in components resulting from normal sustained loads and the worst case blowdown analysis are combined with the worst case seismic analysis to determine the maximum stress for the combined loading case. This is considered a very conservative method since it is highly improbable that both maxima will occur at the same instant. These stresses are combined to determine that the reactor coolant loops and support system will not lose its intended functions under this highly improbable situation.

Protection criteria against dynamic effects associated with RCS pipe breaks is covered in Section 3.6.

For component fatigue evaluations, in accordance with the ASME Boiler and Pressure Vessel Code, maximum stress intensity ranges are derived from combining the normal and upset condition transients given in Paragraph 5.2.1.1 in a conservative manner. The stress ranges and number of occurrences are then used in conjunction with the fatigue curves in the ASME Boiler and Pressure Vessel Code to get the associated cumulative usage factors.

The criterion presented in the ASME Boiler and Pressure Vessel Code is used for the fatigue failure analysis. The cumulative usage factor is less than 1.0 and hence the fatigue design in adequate.

The reactor vessel vendor's stress report includes a summary of the stress analysis for regions of discontinuity analyzed in the vessel, a discussion of the results including a comparison with the corresponding code limits, a statement of the assumptions used in the analysis, descriptions of the methods of analysis and computer programs used, a presentation of the actual hand calculations used, a listing of the input and output of the computer programs used, and a tabulation of the references cited in the report. The content of the stress report is in accordance with the requirements of the ASME Boiler and Pressure Vessel Code and all information in the stress report is reviewed and approved by Westinghouse.

The Westinghouse analysis of the original steam generator tube-tubesheet complex is included as part of the stress report requirement for ASME Code Class 1 nuclear pressure vessels. The evaluation is based on the stress and fatigue limitations outlined in ASME Section III. Similar analysis has been performed for the replacement steam generators for Unit 1 and Unit 2.

The stress analysis techniques utilized include all factors considered appropriate to conservative determination of the stress levels utilized in evaluation of the tube sheet complex. The analysis of the tube sheet complex includes the effect of all appurtenances attached to the perforated region of the tube sheet which are considered appropriate for conservative analysis of the stresses for evaluation on the basis of the ASME Code Section III stress limitations. The evaluation involves the heat conduction and stress analysis of the tube sheet, channel head, secondary shell structure for particular steady design conditions for which code stress limitations are to be satisfied and for discrete points during transient operation for which the temperature/pressure conditions must be known to evaluate stress maximum and minimum for fatigue life usage.

The steam generator tube-tubesheet complex integrity is verified for both the OSG and RSG by analysis for most adverse conditions resulting from a rupture of either primary or secondary piping.

For a secondary piping rupture event, the primary to secondary differential pressure is less than the primary hydrotest differential pressure. The faulted condition allowable for the tube-tubesheet complex exceeds the hydrotest allowable. For this condition the membrane and bending stresses in the ligaments of the tubesheet satisfy the ASME Section III limits for this faulted event. In the case of a primary pressure loss accident, the secondary-primary pressure differential is significantly lower than the primary-secondary maximum pressure differential. Analysis shows that no stress in excess of those covered by the ASME Boiler and Pressure Vessel Code for faulted conditions are experienced by the tube sheet for this accident.

The tubes have been designed to the requirements of the ASME Boiler and Pressure Vessel Code assuming 2485 psi as the design pressure differential. Hence, neither a primary nor a secondary pressure loss accident imposes stresses beyond that normally expected and considered as normal operation by the Code. ASME Section III and Code Case N-20 establish the allowable external pressure of 1479 psi for the Inconel 690 tubes. The maximum external pressure on the tubes at secondary hydrotest is 1356 psi which is less than the allowable. The ASME Code requirements for external pressure provide adequate margin against collapse.

Consideration has been given to the superimposed effects of secondary side pressure loss and the design basis earthquake loading. For the case of the tube sheet, the design basis earthquake loading will contribute negligible static pressure loading over the tube sheet for the vertical shock. The increase is small when compared to the pressure differentials (up to 3125 psid) for which the tube sheet is designed.

The replacement steam generators supplied by CENP-Westinghouse have triangular tubesheet arrays. Therefore, the tubesheet analysis of the RSGs complies with the rules in the Boiler and Pressure Vessel Code.

A complete tube-tubesheet complex analysis is also performed to verify structural integrity for a primary pressure loss accident plus the design basis earthquake.

Although the Boiler and Pressure Vessel Code provides for rules and techniques in analysis of perforated plates, it should be noted that the stress intensity levels for perforated plate are given for triangular perforation arrays. Westinghouse tube sheets contain square hole arrays. Hence, Westinghouse utilizes its own data and that obtained from Pressure Vessel Research Committee research in square array perforation patterns for development of similar charts for stress intensity factors and elastic constants. The resulting stress intensity levels and fatigue stress ranges are evaluated according to the stress limitation of the code.

The vessels, piping, valves, pumps and supports thereof of the reactor coolant pressure boundary are designated ASME Code Class A.

Loading combination and allowable stresses for ASME Section III Class A components, piping and supports are given in Tables 5.2-1 through 5.2-5.

When the components and systems for the Sequoyah units were being designed, only general design requirements existed for faulted conditions. There were no specific stress limits or associated methods of analysis established for faulted conditions. To provide a conservative basis for the analysis of Class 1 components, the collapse curves given in the PSAR were developed. The criterion represented by the collapse curves have evolved into the criteria of Table 5.2-3 of the FSAR. The methods and criteria in Table 5.2-3 should thus be reviewed with respect to the criterion agreed to in the PSAR, rather than with the more recently derived methods and limits established in the nonmandatory Appendix F of the ASME Code, Section III. These methods of analysis in conjunction with the faulted condition stress limits ensure that the general design requirements of the NRC for faulted conditions are met and the plant can thus be safely shut down under accident conditions.

For the reactor coolant loop and components, the elastic system analysis option of Table 5.2.1-1 was used. Inelastic component analysis was used for the reactor coolant pump support feet.

The pump casing with the pump support feet is shown in Figure 5.2.1-12. The pump foot was analyzed for a set of umbrella loads which are greater than the loads expected in any plant. The umbrella loads are calculated for the faulted condition and each of the maximum of the six load components, F_X, F_Y, . . . , M_Z, are assumed to occur simultaneously.

For example, the maximum F_X is chosen by surveying many past plants, and this is applied simultaneously with the maximum F_X, F_Z,. . ., M_Z, all determined similarly. The actual plant loads are calculated and compared to the umbrella loads. Conformance indicates adequacy of the component for the specific plant application. If conformance is not demonstrated, an individual plant analysis would be performed. Table 5.2.1-22 indicates the relationship between the Sequoyah specific plant loads for four different faulted conditions (from four different break locations) and the umbrella loads for which the pump foot was designed. It is noted that the four specific sets of loads cited here are from large breaks in the main reactor coolant loop piping that had originally been considered in the design of the plants, but have since been eliminated. The actual plant loads are, in themselves, also conservative since the maximum for each of the six load components is determined and assumed to act concurrently with the others. For the LOCA condition, the dynamic time history analyses show that the maximum values of the six load components do not act concurrently. The seismic event, although evaluated by response spectra analysis, is also dynamic and the load component maximums at the foot clearly will not coincide. Note from Table 5.2.1-23 that the umbrella loads are

greater than these actual plant loads by a factor ranging from 1.15 to 24.1. From the preceding discussion, the conservatisms in the actual plant loads and the adequacy of the umbrella loads are therefore demonstrated.

The entire casing foot was analyzed by means of a 3-dimensional stress analysis. The foot model utilized symmetry about the bolt hole radial centerline (Figure 5.2.1-13). The completed model contains 1584 node points and 1518 3-dimensional solid elements with 4088 active degrees of freedom in the model. The 3-dimensional finite elements are a mixture of rectangular prisms, triangular prisms, and tetrahedrons. The vertical side and horizontal plate sections have a minimum of four elements through the thickness. The model therefore yields bending stresses as well as direct stresses through the thickness. The higher stress regions have a finer model mesh consisting of smaller tetrahedrons and triangular prism elements.

The ANSYS computer code (Reference 9) plastic analysis options were employed. The plasticity program is based upon incremental strain equations with the Prandlt-Reuss flow rule (Reference 10). The virgin stress-strain option was used to input the true stress-true strain material curve. To yield the required accuracy, loading increments were computed to keep the size of the plastic strain increments near the size of the material yield strain. The smaller load steps keep the solution process from diverging from the input stress-strain curve.

The resulting faulted condition plastic analysis stress intensity was compared with the Faulted Condition Criteria of $.7S_{UT}$ = 59,650 psi for 304 SS at 600°F. This is the limit for the primary membrane plus bending stress intensities as given in Table 5.2.1-1. Since the foot is similar to a beam type structure, the average stress across the section is very low. The primary bending stresses therefore control. The true ultimate stress, S_{ut}, is determined from the engineering ultimate stress (the engineering stress at the point of maximum load) by assuming constancy of volume. Using this assumption, the true ultimate stress (S_{ut}) is given by:

$$S_{ut} = S_u(1 + \varepsilon)$$

where ε is the engineering strain corresponding to the point of maximum load.

The stresses in the pump foot to casing attachment zone and weld fillet region were not controlling. The maximum stress in the foot occurred in the horizontal plate member near the vertical to horizontal plate intersection and in line with the bolt. Since the faulted allowables are based upon primary

stresses and not peak stresses the stress components in the high stress region were linearized through the plate thickness. The resulting maximum stress intensity of the section was found from these linearized maximum principal stresses. The stress intensity was

$$(\sigma)max = 59,614 \text{ psi}$$

which was less than the inelastic allowable.

The maximum localized outer fiber strain corresponding to this stress was approximately 12-14%. The incremental strains, however, for each load step were kept to approximately 0.2%. The

maximum deflection calculated by the statically applied loads was approximately one inch at the radial symmetry line passing through the hole. If geometry modifications had been made for this deflection, the load induced in the high stress regions would have been lowered since the moment arm for the beam-like structure would decrease. The present analysis is therefore considered conservative from the analysis as well as the loads standpoint.

The stress and deflection analysis is based on a static application of loads which are physically short duration, dynamically applied loads. For this reason, the actual deflections due to the short duration peak loads could be expected to be much lower than those calculated by the static analysis. The actual plant loads are also considerably lower than the design loads so that this will further reduce the true magnitude of the deflections.

Pumps and valves are classified as either operative or inactive components for faulted conditions. Operative components are those whose operability is relied upon to perform a safety function as well as reactor shutdown function during the transient or events considered on the respective operating condition categories. Inactive components are those whose operability (e.g., valve opening, or closure pump operation or trip) are not relied upon to perform the system function during the transients or events considered in the respective operating condition category. The reactor coolant pumps are the only pumps in the reactor coolant system boundary that are classified as inactive for pipe rupture. Table 5.2.1-24 list the operative and inactive valves in each line connected to the Reactor Coolant System up to and including the system boundary. The design requirements for active class A valves are as specified in Table 3.2.2-1.

Reactor Coolant Pump overspeed evaluations are covered in Paragraph 5.5.1.3.

Every valve and pump is hydrostatically tested to ASME Boiler and Pressure Vessel Code requirements to insure the integrity of the pressure boundary parts.

5.2.1.5 Computer Codes Used in Analysis

Reactor Coolant Loop Model

The reactor coolant loop (RCL) model is constructed for the WESTDYN computer program. This is a special purpose program designed for the static and dynamic analysis of piping systems with arbitrary loads and boundary conditions. The RCL lumped-mass model represents an ordered set of data that numerically describes the physical system to WESTDYN program.

The spatial geometry of the RCL model is based on the RCL and equipment drawings. The node point coordinates and the incremental lengths of the elements are calculated from these drawings. Node point coordinates are input on network cards and incremental lengths are input on element cards. The lumping of distributed mass of a segment or elbow is accomplished by locating the total mass at the mass center of gravity.

A valid representation of the effect of the equipment motion on the RCL piping and its support system is assured by modeling the mass and stiffness characteristics of the equipment in the overall RCL model. Since the reactor pressure vessel is very massive and relatively rigid, it is represented by a fixed boundary condition for the RCL model except in LOCA analysis, where the RPV motion is applied. The requirement in the time history dynamic analysis, that the external hydraulic forcing functions be applied at only mass points, influences the construction of the steam generator and reactor coolant pump models described below.

The steam generator is represented by a multi-mass, lumped model. The mass points are located so as to ensure they represent the general behavior and frequency response of the equipment.

The reactor coolant pump is represented by a two-mass, lumped model. The lower mass position is located at the intersection of the pump suction and discharge nozzles. The upper mass position is located at a location satisfying the zero, first, and second mass moment for the two-mass RCP model.

Support Structure Models

The equipment support structure models are dual-purpose since they are required: 1) to quantitatively represent in terms of 6 x 6 stiffness matrix the elastic restraints which the supports impose upon the loop and, 2) to evaluate the individual support member stresses due to the forces imposed upon the supports by the loop.

The STAAD and STRUDL computer programs (Reference 1) are used to obtain support stiffness matrices and member influence coefficients for the equipment supports. Unit force along and unit moment about each coordinate axes are applied to the models at the equipment vertical centerline joint. Stiffness analysis are performed for each unit load for each model. Printed output includes all six components of displacement at the joint at which loads are applied and six force components at each end of each member in the support system.

Models for the STAAD and STRUDL computer programs are constructed for the steam generator lower and upper lateral support structures. The structure geometry and member properties are obtained from the certified for construction structural drawings.

Hydraulic Models

Hydraulic models are used to generate time-dependent hydraulic forcing functions used in the analysis of the reactor coolant loop for each break case described in Section 3.6.2 and the break locations are shown in Figure 3.6.2-1.

The hydraulic model is used to define the space-time dependent hydraulic forcing functions generated by the fluid in the primary coolant loops and reactor pressure vessel during a design basis loss-of-coolant accident.

Thrust forces resulting from a postulated LOCA are calculated in two steps, using two digital computer programs. The first program, MULTIFLEX, Reference 13, calculates transient pressure, flow rates, and other coolant properties as a function of time. The second program, THRUST, uses results obtained from MULTIFLEX and calculates the time-history forces at locations where there is a change in either direction or area of flow within the reactor coolant loop. These force-loading locations are shown in Figure 5.2.1-14.

In evaluating the hydraulic forcing functions during a LOCA, the pressure and moment flux terms at the two end surfaces of a control volume are dominant. MULTIFLEX evaluates the local fluid condition, taking into account internal and gravitational terms.

The MULTIFLEX computer code calculates the hydraulic transients within the entire primary coolant system, separately representing both broken and unbroken loops. This hydraulic program considers a

coupled fluid-system interaction by accounting for core support barrel deflection. System depressurization is calculated using the method of characteristics applicable to transient flow of a homogeneous fluid in thermal equilibrium. The ability to treat multiple flow branches and large number of mesh points gives the MULTIFLEX code the required flexibility to represent the various flow passages within the primary RCS. The system geometry is represented by network of one-dimensional flow passages. Further information on this analysis is provided in Topical Report WCAP-8709, Reference 13.

In the THRUST calculation of blowdown forces on the RCL, the entire reactor coolant system is represented by the model employed in the MULTIFLEX program. Twenty-six node points are selected along the model. The vector forces and their components are calculated at these points. There may be one or two blowdown control volumes associated with each force node, depending upon its location. For force nodes, 2, 3, 6, 7, 11, 12, 15, 16, 19, 20, 24, and 25, only a single aperture (flow area) is assigned. For all other nodes, two apertures are assigned. For each aperture, the force is calculated by the equation:

$$F = \left[144(p - p_a) + \frac{G(G)}{g\rho} \right] A$$

where:

p = system pressure, psi

p_a = external pressure, psi

G = mass flow rate, lbm/sec ft2

ρ = density, lbm/ft3

g = gravitational constant, lbm-ft/lb sec2

A = aperture area, ft2

The force components at each aperture are vectorially summed to obtain total force components in the global coordinate system at the nodes. The total force components are stored for use in the static pressure analysis at zero time and dynamic LOCA.

Additionally, the forces representing the thrust and jet forces, which are applied at the nozzle break location, are calculated as:

Thrust force: $F_{thrust} = C\tau \times P_o \times A_e$

where: $C\tau$ = Steady-state thrust coefficient

P_o = Initial pressure

A_e = Break plane area

Jet Force: $F_{jet} = C\tau \times P_o \times A_B \times f \times SF \times FA$

where: $C\tau$ = Steady-state thrust coefficient

P_o = Initial presssure

A_B = Break opening area

f = Fraction of jet interception by target

SF = Target shape factor

FA = Impingement angle factor

Static Load Solutions

The static solutions for deadweight, thermal expansion and pressure load conditions are obtained by using the WESTDYN computer program. The computer input consists of the RCL model, stiffness matrices representing various supports for static behavior, and the appropriate load condition. Coordinate transformations for rotation from the local or support coordinate system to the global system are applied to the stiffness matrices prior to their input.

Normal Mode Response Spectral Seismic Load Solution

The stiffness matrices representing various supports for dynamic behavior are incorporated into the RCL model after transformations for rotation from local to the RCL global system. The response spectra for the 1/2 SSE or SSE load case are applied along the X or Z, and Y axes simultaneously. From the input data, the overall stiffness matrix, of the three-dimensional RCL is generated. The stiffness matrix is manipulated to obtain a reduced stiffness matrix, associated with the mass points only. Using the mass and stiffness matrices, the frequencies and mode shapes are determined. The model participation factor matrix is computed and combined with the appropriate seismic response spectra values to give the amplitude of the model coordinate for each mode. Then the forces, moments, deflections, rotations, support structure reactions and stresses are calculated for each significant mode. The total seismic response is computed by combining the contributions of the significant modes by the square root of the sum of the squares method. Closely spaced modes are combined per methodology in 3.7.3.4.

Time History Dynamic Solution for LOCA Loading

The initial displacement configuration of the mass points is defined by applying the initial steady state hydraulic forces to the unbroken RCL model. For this calculation, the support stiffness matrices for the static behavior are incorporated into the RCL model. For dynamic solution, the unbroken RCL model is modified to simulate the physical severance of the pipe due to the postulated LOCA under consideration. This model includes definition of the support stiffness matrices for dynamic behavior

selected on the basis of anticipated displacement response at the support points. The natural frequencies and normal modes for the modified RCL dynamic model are determined. After proper coordinate transformation to the RCL global coordinate system, the hydraulic forcing functions to be applied at each lumped mass point are stored on magnetic tape for later as input to the FIXFM program.

The initial displacement conditions, natural frequencies, normal modes and the time-history hydraulic forcing functions form the input to the FIXFM program which calculates the dynamic time-history displacement response for the dynamic degrees of freedom in the RCL model. The displacement response is plotted at all mass points. The displacement response at support points is reviewed to validate the use of the chosen support stiffness matrices for dynamic behavior. If the calculated support point response does not match with the anticipated response, the dynamic solution is revised using a new set of support stiffness matrices for dynamic behavior. This procedure is repeated until a valid dynamic solution is obtained.

The time-history displacement response from the valid solution is saved on magnetic tape for later use to compute the support loads and to analyze the RCL piping stresses.

Evaluation of Support Structures

The support loads are computed by multiplying the support stiffness matrix, and the displacement vector, at the support point.

5.2.1.6 Notes on Stress Analysis

5.2.1.6.1 Methods

In addition to the terms related to stress analysis defined by ASME Section III NB-2313, the following are defined.

Elastic analysis is defined as that method which assumes that stress is directly proportional to strain with the constant of proportionality being the modulus of elasticity. For cases of elastic system analysis and elastic component analysis, the stress limits of Table 5.2-3 are conservative and prove the safety of the components or system. Strain limits are not required to assure the safety of the components or system.

Plastic analysis is that method which computes the structural response under given loads by considering nonlinear, irreversible stress-strain relations of the material's behavior. This method considers the strain hardening characteristics of the materials, strain-rate effects, permanent deformations and stress redistribution occurring in the structure.

1. For plastic analysis, the true stress-strain curve determined from a mean value curve for the material used based on at least 3 samples shall be adjusted to correspond to the tabulated value at the appropriate temperature in Table I-2.1 or I-2.2 of the Code and shall be included and justified in the Stress Report.

2. The yield criteria and associated flow rule used in performing a plastic analysis may be either those associated with the maximum shear stress (Tresca) or the distortion energy (Mises) method.

Limit analysis computes the structure collapse load defined by the lower bound theorem of limit analysis. The lower bound limit is defined as that produced from the analysis of an ideally plastic material where deformation increases with no further increase of load.

The stress ratio method is a psuedo-elastic analysis method which may be used as an approximate plastic analysis when the required interaction formulas or curves are available.

1. The formulas and curves of the stress ratio method are developed for specific configuration, for specific loading combinations and for specific materials, considering the strain hardening characteristics of the material. The method may be used for statically or dynamically applied loads.

2. The stress ratio method may be used to determine the maximum loads which may be carried by the structure without exceeding an assigned apparent stress. The symbol used to designate this load is P_R.

The methods of analysis are as follows:

The system or subsystem analysis used to determine the loads which act on components, and which loads are specified in the Design Specification for the specific component, is generally a dynamic analysis because of the nature of the loading postulated. If stress limits are used in the evaluation of the effects of these loads on a component such that significant inelastic response occurs within the component, the original elastic system analysis may require modification. Therefore, the type of system analysis, elastic, or inelastic, as well as the associated component loads, will be specified in the Design Specification.

Components are analyzed using any of the following methods used in evaluating Faulted Conditions, subject to the limits given below:

1. Elastic Analysis
2. Limit Analysis
3. Plastic Analysis
4. Stress Ratio
5. Test

The allowable limits for primary stresses given in Table 5.2-2 are used for the methods specified above with the following considerations:

1. The symbols P_m and P_b do not represent single quantities but rather sets of six quantities representing the six stress components σ_τ, σ, σ_r, τ_{tl}, τ_{lr}, and τ_{rt} combined.

2. Bolts and structural fasteners fabricated with the materials included in Table I-1.1 and I-1.2 of the code must satisfy the same stress limits as the rest of the structures. High strength materials (σ_u > 100,000 psi) are considered separately.

3. The statically applied or equivalent static external pressure is less than 150 percent of that given by the rules of NB-3133, except that the pressure is permitted to be 250 percent of the given value when the ovality is limited to 1 percent or less. When dynamic pressure (load) is involved, a dynamic instability analysis may be performed, in which case the permissible external pressure (load) will be limited to 75 percent of the dynamic instability pressure (load).

4. Deformation limits are outside the scope of this Criteria and should be established in the Design Specifications and/or the Safety Analysis Report, if necessary.

Elastic or plastic system analysis and component stress ratio analysis is an acceptable method of evaluation if the rules used in evaluating the Faulted Conditions are as follows:

1. The component stresses are derived on an elastic basis.

2. The method of evaluation of P_m is acceptable if the apparent stress S_{ap} associated with the loads P_R do not exceed the lesser of 2.4 S_m or 0.70 S_u derived at the approximate temperature for materials included in Table I-1.2 of the Code. For materials included in Table I-1.1 use 0.70 S_u only.

3. The method of evaluation for P_m and P_b is acceptable if the apparent stress S_{ap} associated with the loads P_R in (2) above has been increased by an appropriate factor to account for the type of stress field.

The limits established for the analysis need not be satisfied if it can be shown from the test of a prototype or model that the specified loads (dynamic or static equivalent) do not exceed 80 percent of L_T, where L_T is the ultimate load or load combination used in the test. In using this method, account will be taken of the size effect and dimensional tolerances (similitude relationships) which may exist between the actual component and the tested models to assure that the loads obtained from the test are a conservative representation of the load carrying capability of the actual component under postulated loading for faulted conditions.

5.2.1.6.2 <u>Criteria for Specific Components</u>

For vessels the procedures of Subparagraph 5.2.1.6.1 must be used.

The criteria for supports depends on their type. In these Criteria all component supports are categorized into two separate types:

1. <u>Plate and Shell Type Supports</u>

   Plate and shell type component supports such as vessel skirts and saddles which are fabricated from plate and shell elements and which are normally subjected to a biaxial stress field.

2. <u>Non-Integral (Mechanical) Attachments</u>

   Non-integral attachments are those attachments which are bolted, pinned, or bear on the pressure boundary components, including sliding joints, clamps, cradles, saddles, or straps which mechanically connect to the integral attachment or boundary component and transmits the loadings induced in the component.

For linear structures (frames, beams, columns, trusses, cables, etc.) the following limits may also be used:

1. When the load coefficient method is used, the factor C' to be used in the analysis, for other conditions, should be C' = 0.60. (for design procedures see Part 1 of AISC-69).

2. When the load factor method is used, the load factor should be 1.1 (for design procedures as specified in Part 2 of AISC-69).

For core support structures the procedures of Subparagraph 5.2.1.6.1 are used.

5.2.1.7 Reactor Pressure Vessel Support Loads

5.2.1.7.1 Introduction

This section presents the method of computing the reactor pressure vessel loss of coolant accident (LOCA) support loads and displacements. The structural analysis considers simultaneous application of the time-history loads on the reactor vessel resulting from the reactor coolant loop vessel nozzle mechanical loads, internal hydraulic pressure transients, and reactor cavity pressurization (for postulated breaks in the reactor coolant pipe at the vessel nozzles). The vessel is restrained by reactor vessel support pads and shoes beneath each nozzle (two inlet, two outlet) and the reactor coolant loops with the primary supports of the steam generators and the reactor coolant pumps. The objective of this analysis is to obtain reactor vessel displacements and the reactor vessel supports loads.

Pipe displacement restraints installed in the primary shield wall limit the break opening area of the vessel nozzle pipe breaks to less than 100 square inches. This 100 square inch area was determined to be an upper bound by using worst case vessel and pipe relative motions based on a preliminary analysis of this plant. Detailed studies have shown that pipe breaks at the hot or cold leg reactor vessel support loads and the highest vessel displacements, primarily due to the influence of reactor cavity pressurization. By considering these breaks, the most severe reactor vessel support loads are determined. For completeness, a break outside the shield wall, for which there is no cavity pressurization, is also analyzed; specifically, the pump outlet nozzle pipe break is considered. In summary, three loss of coolant accident conditions are analyzed:

1. Reactor vessel inlet nozzle pipe break
2. Reactor vessel outlet nozzle pipe break
3. Reactor coolant pump outlet nozzle pipe break

5.2.1.7.2 Interface Information

The Tennessee Valley Authority is responsible for reactor containment design and analysis. Stiffness of the primary shield wall beneath the reactor vessel supports was provided by TVA to Westinghouse.

All other input information was developed within Westinghouse. These items are as follows: reactor internals properties, loop mechanical loads and loop stiffness, internal hydraulic pressure transients, asymmetric cavity pressure time history loads, and reactor support stiffness. These inputs allowed formulation of the mathematical models and performance of the analyses, as will be described.

5.2.1.7.3 Loading Conditions

Following the postulated pipe rupture at the reactor vessel nozzle, the reactor vessel is excited by time-history forces. As described, these forces are the combined effect of three phenomena:

(1) reactor coolant loop mechanical loads, (2) reactor cavity pressurization forces and (3) reactor internal hydraulic forces.

The reactor coolant loop mechanical forces are derived from the elastic dynamic analyses of the loop piping for the postulated break. This analysis is described in Section 5.2.1.5. The dynamic reactions on the nozzles of all the unbroken piping legs are applied to the vessel in the RPV blowdown analysis.

Reactor cavity pressurization forces arise for the pipe breaks at the vessel nozzles for the steam and water which is released in the reactor cavity through the annulus around the broken pipe. The reactor cavity is pressurized asymmetrically with higher pressure on the side adjacent to the break. These differences in pressure horizontally across the reactor cavity result in horizontal forces applied to the reactor vessel. Smaller vertical forces arising from pressure on the bottom on the vessel and the vessel flanges are also applied to the reactor vessel. The cavity pressure analysis is described in Section 6.2.

The internals reaction forces develop from asymmetric pressure distributions inside the reactor vessel. For a vessel inlet nozzle break and pump outlet nozzle break, the depressurization wave path is through the broken loop inlet nozzle and into the region between the core barrel and reactor vessel (see Figure 3.9.1-5). This region is called the downcomer annulus. The initial waves propagate up, down and around the downcomer annulus and up through the fuel. In the case of an RPV outlet nozzle break, the wave passes through the outlet nozzle and directly into the upper internals region, depressurizes the core, and enters the downcomer annulus from the bottom of the vessel. Thus, for an outlet nozzle break, the downcomer annulus is depressurized with much smaller differences in pressure horizontally across the core barrel than for the inlet break. For both the inlet and outlet nozzle breaks, the depressurization waves continue their propagation by reflection and transmission through the reactor vessel fluid but the initial depressurization wave has the greatest effect on the loads.

The reactor internals hydraulic pressure transients were calculated including the assumption that the structural motion is coupled with the pressure transients. This phenomena has been referred to as hydroelastic coupling or fluid-structure interaction. The hydraulic analysis considers the fluid-structure interaction of the core barrel by accounting for the deflections of constraining boundaries which are represented by masses and springs. The dynamic response of the core barrel in its beam bending mode responding to blowdown forces compensates for internal pressure variation by increasing the volume of the more highly pressurized regions. The analytical methods used to develop the reactor internals hydraulics are described in Reference 13.

5.2.1.7.4 Reactor Vessel and Internals Modeling

The reactor vessel and internals general assembly is shown in Figure 3.9.1-5. The reactor vessel is restrained by two mechanisms: (1) the four attached reactor coolant loops with the steam generator and reactor coolant pump primary supports and (2) four reactor vessel supports at alternate nozzles. The reactor vessel supports are described in Section 5.5.14 and are shown in Figure 5.5.14-1. The support shoe provides restraint in the horizontal directions and for downward reactor vessel motion.

The reactor vessel model consists of two separate non-linear elastic models connected at a common node. One model represents the dynamic vertical characteristics of the vessel and its internals, and the other model represents the translational and rotational characteristics of the structure. These two

models are combined in the DARI-WOSTAS (Reference 11) to represent motion of the reactor vessel and its internals in the plane of the vessel centerline and the broken pipe centerline.

A model for horizontal motion is shown in Figure 5.2.1-15. Each node has one translational and rotational degree of freedom in the vertical plane containing the centerline of the nozzle attached to the broken pipe and the centerline of the vessel. A combination of beam elements and concentrated masses are used to represent the components including the vessel, core barrel, neutron panels, fuel assemblies, and upper support columns. Connections between the various components are either pin-pin rigid links, translational impact springs with damping, or rotational springs.

The model for vertical motion is shown in Figure 5.2.1-16. Each mass node has one translational degree of freedom. The structure is represented by concentrated masses, springs, dampers, gaps, and frictional elements. The model includes the core barrel, lower support columns, bottom nozzles, fuel rods, top nozzles, upper support columns, upper support structure, and reactor vessel.

The horizontal and vertical models are coupled at the elevation of the primary nozzle centerlines. Node 1 of the horizontal model is coupled with Node 2 of the vertical model at the reactor vessel nozzle elevation. This coupled node has external restraints characterized by a 3x3 matrix which represents the reactor coolant loop stiffness characteristics, by linear horizontal springs which describe the tangential resistance of the supports, and by individual non-linear vertical vessel support by dynamic elements (spring-dashpot system) which provide restraint only in the vertically downward direction.

The supports as represented in the horizontal and vertical models (Figures 5.2.1-15 and 5.2.1-16) are not indicative of the complexity of the support system used in the analysis. The individual supports are located at the actual support pad locations and accurately represent the independent non-linear behavior of each support.

5.2.1.7.5 Analytical Methods

The time history effects of the cavity pressurization loads, internals loads and loop mechanical loads are combined and applied simultaneously to the applicable nodes of the mathematical model of the reactor vessel and internals. The analysis is performed by numerically integrating the differential equations of motion to obtain the transient response. The output of the analysis includes, among other things, the displacements of the reactor vessel and the loads in the reactor vessel supports. The loads from the postulated pipe break on the vessel supports are combined with other applicable faulted condition loads and subsequently used to calculate the stresses in the supports. Also, the reactor coolant loop is analyzed by applying the reactor vessel displacements to the reactor coolant loop model. The resulting loads and stresses in the piping, components and supports are then combined with those from the loop dynamic blowdown analysis and the adequacy of the system is verified. Thus, the effect of vessel displacements upon loop response and the effect of loop blowdown upon vessel displacements are both evaluated.

5.2.1.7.6 Results of the Analysis

As described, the reactor vessel and internals were analyzed for three postulated break locations. The LOCA loads are combined with other applicable faulted condition loads and the total applied loads are obtained. This total combined load is applied to the reactor vessel supporting structure, which is analyzed into two independent components: (1) the U shaped vessel shoe and (2) the cooling box which is the structure between the shoe and the concrete. Final analyses have been performed on the support shoe and the cooling box structure and the results are presented in Section 5.2.1.3.3.

The reactor coolant loop piping was evaluated for the faulted condition as detailed in Section 5.2.1.2. The loads included in the evaluation result from the SSE inertia loading, deadweight, pressure, LOCA loop hydraulic forces, and reactor vessel motion. The stress intensities at all locations were under the faulted condition stress limit. It is therefore, concluded that the reactor coolant loop piping of the unbroken loop or the unbroken legs of the broken loop meets the faulted condition requirements and is capable of withstanding the consequences resulting from a break at the reactor vessel inlet or outlet nozzle.

For the evaluation of the design adequacy of equipment, the maximum loads at the primary equipment nozzles resulting from the analysis of each loading condition were determined. The external loads imposed upon primary equipment by the reactor coolant loop produce stress intensities which are below the faulted condition allowable values.

The effects of the postulated breaks at the reactor vessel inlet and outlet nozzle locations on the CRDMs, reactor vessel internals, RCS component supports, and the reactor core are presented in Sections 5.2.1.7.3, 3.9.3.8, 5.2.1.3.3 and 4.2.1.3.2, respectively.

5.2.2 Over Pressurization Protection

5.2.2.1 Location of Pressure-Relief Devices

Pressure relief devices on the Reactor Coolant System (RCS) comprise the three pressurizer safety valves and two power operated relief valves shown on Figure 5.1-1. These discharge to the pressurizer relief tank by common header. Other relief valves connected to the primary side through auxiliary systems that discharge to the pressurizer relief tank are itemized in Table 5.2.2-1. The secondary side SG overpressure protection is discussed in Section 10.3.

5.2.2.2 Mounting of Pressure-Relief Devices

The pressurizer relief devices and associated piping are designed and installed in accordance with ANSI B31.1-1967, Power Piping Code.

The pressurizer relief devices and associated piping are designed to accommodate the RCS temperatures and pressure attained under all expected modes of plant operations (normal, upset, emergency, and faulted), and to maintain the pipe stresses within allowable limits. See paragraph 3.9.2.5. Specifically, the system is designed to withstand the maximum valve discharge thrust in an upset condition combined with internal pressure, dead weight, and earthquake loads acting simultaneously.

Transient hydraulic forces are imposed at various points in the pressurizer relief system from the time a safety or relief valve begins to open until steady flow is completely developed. A dynamic or time history analysis of the thermal-hydraulic forces for the most critical combination of valves discharging was performed with the aid of computer programs RELAP 5 and REPIPE. In this analysis, the relief system is defined as a network of fluid control volumes connected by flow paths with appropriate considerations of flow condition, energy state, and friction effect. The mass and energy stored in each control volume and flow path are calculated from the basic fluid flow conservation equations.

The dynamic time history is used in a structural analysis performed with the aid of the computer program TPIPE. Utilizing a normal mode theory and a step-by-step direct integration procedure, the complete response time histories of the piping system displacement and member forces are generated. The results of this analysis are subsequently used in the stress combinations for the upset and faulted condition for the piping system.

The RCS design and operating pressure together with the safety, power relief and the pressurizer spray valve setpoints and the protection system setpoint pressures are listed in Table 5.2.2-2.

System components whose design pressure and temperature are less than the RCS limits are provided with overpressure protection devices and redundant isolation means. System discharge from overpressure protection devices is collected in the pressurizer relief tank in the RCS.

5.2.2.3 Report on Overpressure Protection

The pressurizer is designed to accommodate pressure increases (as well as decreases) caused by load transients. The spray system condenses steam to prevent the pressurizer pressure from reaching the setpoint of the power-operated relief valves during a step reduction in power level of ten percent of load.

The spray nozzles are located near the top of the pressurizer. Spray is initiated when the pressure controlled spray demand signal is above a given setpoint. The spray rate increases proportionally with increasing pressure rate and pressure error until it reaches a maximum value.

The pressurizer is equipped with power-operated relief valves which limit system pressure for a large power mismatch and thus prevent actuation of the high pressure reactor trip. The relief valves are operated automatically or manually from the MCR. The operation of these valves also limits the undesirable opening of the spring loaded safety valves. Remotely operated stop valves are provided to isolate the power operated relief valves if excessive leakage occurs. The relief valves are designed to limit the pressurizer pressure to a value below the high pressure reactor trip set point for all design transients up to and including the design percentage step load decrease with steam dump but without reactor trip.

Isolated output signals from the pressurizer pressure protection channels are used for pressure control. These are used to control pressurizer spray and heaters and power operated relief valves.

In the event of a complete loss of heat sink, i.e., no steam flow to the turbine, protection of the RCS against overpressure is afforded by pressurizer and steam generator safety valves along with any of the following reactor trip functions:

1. Reactor trip on turbine trip (if the turbine is tripped)
2. High pressurizer pressure reactor trip
3. Overtemperature ΔT reactor trip
4. Low-low steam generator water level reactor trip.

The ASME code pressure limit is 110 percent of the 2485 design pressure. This limit is not exceeded as discussed in Reference 3. The report describes in detail the pressure relief devices, location, reliability, and sizing. Transient analysis data is provided for the worst cases that require safety valve actuation as well as those cases which do not.

The upper limit of overpressure protection is based upon the positive surge of the reactor coolant produced as a result of turbine trip under full load, assuming the core continues to produce full power. The self-actuated safety valves are sized on the basis of steam flow from the pressurizer to accommodate this surge at a setpoint of 2500 psia and a total accumulation of 3 percent. Note that no credit is taken for the relief capability provided by the power operated relief valves during this surge.

The RCS design and operating pressure safety valve and pressurizer spray valve setpoints and the protection system setpoint pressures are listed in Table 5.2.2-2.

System components whose design pressure and temperature are less than the RCS design limits are provided with overpressure protection devices and/or redundant isolation means. System discharge from overpressure protection devices is collected in the pressurizer relief tank (PRT) in the RCS. The PRT is equipped with rupture disks.

5.2.2.4 <u>RCS Pressure Control During Low Temperature Operation</u>

Administrative procedures have been developed to aid the operator in controlling RCS pressure during low temperature operation. However, to provide a back-up to the operator and to minimize the

frequency of RCS overpressurization, an automatic low temperature over pressure protection (LTOP) system, when manually armed from the main control room, will mitigate the pressure excursion within the allowable pressure limits.

Analysis has shown that one PORV is sufficient to mitigate the pressure excursions produced by anticipated mass and heat input transients. However, redundant protection against such overpressurization event is provided through use of two PORVs. The LTOP mitigation system is required only during low temperature operation and is manually enabled for automatic actuation.

5.2.2.4.1 LTOP System Operation

Two pressurizer power operated relief valves are both supplied with actuation logic, and a normal and emergency power supply to ensure that redundant and independent RCS pressure control back-up feature is provided for the operator during low temperature operations. The feature is normally armed when at low temperature. The LTOP system setpoints for the PORVs are provided in Figure 2-1 of the Pressure Temperature Limit Report (PTLR) for each unit. The LTOP system is contained within the Plant DCS. Refer to Sections 5.5.7, 5.5.10, 5.5.13, 7.6.7, and 9.3.4 for additional information on RCS pressure and inventory control during other modes of operation.

The basic function of the system logic is to continuously monitor RCS temperature and pressure conditions whenever plant operation is at low temperatures. An auctioneered system temperature will be continuously converted to an allowable pressure and then compared to the actual RCS pressure. This system logic will first annunciate a main board alarm whenever the measured pressure approaches within a predetermined amount of the allowable pressure, thereby indicating a pressure transient is occurring. On a further increase in measured pressure, an actuation signal is transmitted to the power operated relief valves when required to mitigate the pressure transient.

5.2.2.4.2 Evaluation of Low Temperature Overpressure Transients

Pressure Transient Analysis

10 CFR 50, Appendix G, establishes guidelines and upper limits for RCS Pressure primarily for low temperature conditions (<350°F). Because the limiting low temperature overpressurization events occur under static shutdown conditions, the steady state cooldown curve (Figure 2-2 in the PTLR for each unit) is used as the Appendix G limit for analysis of LTOPS operation. The LTOP mitigation system discussed above maintains the RCS within these limits as discussed in the following paragraphs.

Transient analyses were performed to determine the maximum pressure for the postulated mass input and heat input events. For the purposes of analysis the RHR system is assumed to be isolated from the RCS per References 26 and 27.

The mass input pressure transient which would occur most frequently during the course of normal plant operation with LTOPs armed, would involve letdown isolation with the charging pumps delivering an input less than or equal to 180 gpm (maximum cleanup flow). However, the mass input analysis was performed assuming letdown isolation with one charging pump operating in the configuration producing the maximum possible delivery rates for the RCS system pressure (40 gpm to 500 gpm). This more unlikely event and more severe configuration was chosen to provide additional system flexibility for pressure control. Mass injection events, which could potentially produce higher injection rates than the overpressure mitigation system is capable of mitigating, are prevented from occurring by locking out the required valves and pumps. The administrative controls are included in the plant procedures.

The heat input transient analysis is performed over the entire RCS shutdown temperature range. This analysis assumes an inadvertent start of a reactor coolant pump with a 50°F mismatch between the RCS and the temperature of the hotter secondary side of the steam generators with the RCS in a water solid condition.

Both heat input and mass input analyses took into account the single failure of one PORV therefore, only one Power Operated Relief Valve (PORV) was assumed to be available for pressure relief. The evaluation of the transient results concludes that the allowable limits will not be exceeded and therefore will not constitute an impairment to vessel integrity and plant safety. Framatome ANP has conducted LTOP safety analyses with replacement steam generators (RSGs) and have concluded that the acceptance criteria are met and system integrity is assured following steam generator replacement.

5.2.2.4.3 Operating Basis Earthquake (OBE) Evaluation

A fluid systems evaluation has been performed considering the potential for overpressure transients following an Operating Basis Earthquake (OBE).

The power-operated relief valves have been designed in accordance with the ASME code to provide integrity required for the reactor coolant pressure boundary. They have been analyzed for accident loads and for loads imposed by seismic events and have been shown to maintain their integrity. Therefore, the PORVs will be available to provide pressure relief following an OBE.

5.2.2.4.4 Administrative Procedures

Administrative procedures are provided to manually arm the LTOP system described to mitigate the pressure excursions approaching allowable pressure limits. Operability and surveillance requirements for the LTOP system are provided in the Technical Specifications. Additional administrative procedures are provided as listed below to minimize the potential for any transient that could actuate the LTOP system. Additional requirements for system operation exist while the RHR system is in service and are described in Section 5.5.7.3.3.

Normal plant operating procedures maximize the use of a pressurizer cushion (steam bubble) during periods of low pressure and low temperature operation. This cushion will dampen the plants response to potential transients, providing easier pressure control with the slower response rates.

A pressurizer steam cushion substantially reduces the severity of some potential pressure transients such as reactor coolant pump induced heat input and slows the rate of pressure rise for others. In conjunction with the previously discussed alarms, this provides reasonable assurance that most potential transients can be terminated by operator action before the overpressure relief system actuates.

However, for those modes of operation when water solid operation may still be possible, procedures provide precautions that minimize the potential for developing an overpressurization transient. The following specific recommendations are made:

1. Do not isolate the residual heat removal inlet lines from the reactor coolant loop unless isolation is required to respond to RHRS overpressure events, see Section 5.5.7.3.3. This precaution is to assure there is a relief path from the reactor coolant loop to the residual heat removal suction line relief valves when the RCS is at low pressure and is water solid.

2. Whenever the plant is water solid and the reactor coolant pressure is being maintained by the low pressure letdown control valve, letdown flow must bypass the normal letdown orifices, the valve in the bypass line should be in the full open position. During this mode of operation, all three letdown orifices must also remain open unless LTOPs is operable.

3. If all reactor coolant pumps have stopped for more than 5 minutes during plant heatup, and the reactor coolant temperature is greater than the charging and seal injection water temperature, do not attempt to restart a pump unless a steam bubble is formed in the pressurizer. This precaution will minimize the pressure transient when the pump is started and the cold water previously injected by the charging pumps is circulated through the warmer reactor coolant components. The steam bubble will accommodate the resultant expansion as the cold water is rapidly warmed. This precaution is not applicable to reactor coolant pump operation in Mode 5 when steam generator temperatures on the secondary side are no more than 25 degrees F warmer than the reactor coolant system temperature.

4. If all reactor coolant pumps are stopped and the RCS is being cooled down by the residual heat exchangers, nonuniform temperature distribution may occur in the reactor coolant loops. Do not attempt to restart a reactor coolant pump unless a steam bubble is formed in the pressurizer.

5. During plant cooldown, all steam generators should be connected to the steam header to assure a uniform cooldown of the reactor coolant loops until less than 200 degrees F.

6. At least one reactor coolant pump must remain in service until the reactor coolant temperature is reduced to 160 degrees F.

In addition to Technical Specification requirements for the LTOP system, specific plant operating instructions for plant cooldown and surveillance instructions for ECCS testing include administrative controls and procedures to preclude overpressure transients. These include:

1. To prevent inadvertent ECCS actuation during plant heatup and cooldown, procedures require blocking portions of the safety injection signal actuation logic. The pressurizer and steamline low pressure actuation signals are blocked when RCS pressure is below the P-11 permissive setpoint.

2. The Safety Injection System (SIS) low pressure accumulator isolation valves are closed and tagged with power removed when RCS pressure is reduced below approximately 1000 psig.

3. The Safety Injection pumps are locked out when the RCS temperature is reduced as required by Technical Specifications.

4. One centrifugal charging pump will be locked out when the RCS temperature is reduced as required by Technical Specifications.

5. ECCS pump performance testing in hot shutdown and cold shutdown require charging pump discharge valve closure and RHRS alignment to isolate potential ECCS pump input and to provide backup benefit of the RHRS relief valves.

6. "S" signal circuitry testing (safety injection actuation testing), if done during cold shutdown, requires RHRS alignment and non-operating charging pump power lockout or discharge valve closure to preclude developing cold overpressurization transients.

The above procedural recommendations covering normal operations with a steam bubble, transitional operations where potentially water solid, and by specific cool down and test operations, provide defense in depth augmenting the installed LTOP.

5.2.3 General Material Considerations

5.2.3.1 Material Specifications

The material specifications used for the principal pressure retaining applications in each component comprising the reactor coolant pressure boundary are listed in Table 5.2.3-1 for Class A Primary Components and Table 5.2.3-2 for Auxiliary Components. These materials are procured in accordance with the specification requirements and include supplemental requirements of the applicable ASME Code Rules.

There are four Upper Head Injection (UHI) penetrations in each reactor vessel which terminate inside the shroud. These pipe stub ends are capped; however, one head contains a 3/8" orifice and is used as the RCS vent. The vent vertically exits the shroud and continues as 1 (one) piece above the head platform to preclude pipe rupture concerns (see 5.5.15).

The welding materials used for joining the ferritic base materials of the reactor coolant boundary, conform to or are equivalent to ASME Material Specifications SFA 5.1, 5.5, 5.17, 5.18, 5.20, and 5.23. They are tested and qualified to the requirements of ASME Section III rules.

The welding materials used for joining the austenitic stainless steel base materials of the reactor coolant boundary conform to ASME Material Specifications SFA 5.4, 5.9, 5.14, and 5.22. They are tested and qualified according to the requirements stipulated in Subsection 5.2.5 of this safety analysis report.

The welding materials used for joining nickel-chromium-iron alloy in similar base material combination and in dissimilar ferritic or austenitic base material combination of the reactor coolant boundary conform to ASME Material Specifications SFA 5.11 and 5.14 and Code Case 2142 (SFA 5.14) and 2143 (SFA 5.11). They are tested and qualified to the requirements of ASME Section III rules and are used only in procedures which have been qualified to these same rules.

5.2.3.2 Compatibility With Reactor Coolant

All of the ferritic low alloy and carbon steels which are used in principal pressure retaining applications are provided with a .125 inch minimum thickness of corrosion resistant cladding on all surfaces that are exposed to reactor coolant (individual areas have cladding which is 0.08 inch thick as a result of local grinding). This cladding material has a chemical analysis which is at least equivalent to the corrosion resistance of Types 304 and 316 austenitic stainless steel alloys or nickel-chromium-iron alloy. The other base materials which are used in principal pressure retaining applications which are exposed to the reactor coolant are austenitic stainless steel, nickel-chromium-iron alloy, and martensitic stainless steel. Ferritic low alloy and carbon steel nozzles are safe ended with stainless steel weld metal analysis A-7 or nickel-chromium-iron alloy weld metal F-Number 43 using buttering techniques followed by a post weld heat treatment. The latter buttering material requires further safe ending with austenitic stainless steel base material after completion of the post weld heat treatment when the nozzle is larger than 4-inch nominal I.D. and/or the wall thickness is greater than 0.531 inch.

The cladding on ferritic type base materials receives a post weld heat treatment.

All of the austenitic stainless steel and nickel-chromium-iron alloy base materials are used in the solution anneal heat treat condition. The heat treatments are as required by the material specifications. During subsequent fabrication, these pressure retaining materials are not heated above 800°F other than instantaneously and locally by welding operations. The solution annealed surge line material is subsequently formed by hot bending followed by a resolution annealing heat treatment. Corrosion tests are performed in accordance with ASTM A 393.

5.2.3.3 Compatibility With External Insulation and Environmental Atmosphere

In general, all of the materials listed in Tables 5.2.3-1 and 5.2.3-2, which are used in principal pressure retaining applications and which are subject to elevated temperature during system operation, are in contact with thermal insulation that covers their outer surfaces.

The principle thermal insulation used on the reactor coolant boundary is reflective stainless steel type. When non-metallic insulation is procured for use on austenitic stainless steel reactor coolant pressure boundary piping, Reg. Guide 1.36 will be followed.

In the event of coolant leakage, the ferritic materials will show increased general corrosion rates. Where minor leakage is anticipated from service experience, such as; valve packing, pump seals, etc., materials which are compatible with the coolant are used. These are shown in Tables 5.2.3-1 and 5.2.3-2.

5.2.3.4 Chemistry of Reactor Coolant

The Reactor Coolant System chemistry specifications are given in Table 5.2.3-3.

The Reactor Coolant system water chemistry is selected to minimize corrosion. A periodic analysis of the coolant chemical composition is performed to verify that the reactor coolant quality meets the specifications.

The Chemical and Volume Control System provides a means for adding chemicals to the Reactor Coolant System which control the pH of the coolant during initial startup and subsequent operation, scavenge oxygen from the coolant during startup, control the oxygen level of the coolant due to radiolysis during all power operations subsequent to startup, and modifies the primary system corrosion film layer. The Reactor Coolant water chemistry specifications for power operations are shown in Table 5.2.3-3.

The pH control chemical employed is lithium hydroxide. This chemical is chosen for its compatibility with the materials and water chemistry of borated water/stainless steel/zirconium/Inconel systems. In addition, lithium is produced in solution from the neutron irradiation of the dissolved boron in the coolant. The lithium hydroxide is normally introduced into the Reactor Coolant system via the chemical mixing tank and charging flow. The cation bed demineralizer can be utilized for lithium removal. As the temperature of the reactor coolant increases, the pH of the solution increases due to the hydrolysis of boric acid. The concentration range for Lithium is variable depending on the Boron concentration.

The pH control program used is within the constraints of fuel vendor recommendations and the EPRI PWR primary water chemistry guidelines (Reference 19) and will be specified in site procedures.

During reactor startup from the cold condition, hydrazine is employed as an oxygen scavenging agent. The hydrazine solution is normally introduced into the Reactor Coolant System via the chemical mixing tank and charging flow. Dissolved hydrogen is employed to control and scavenge oxygen produced due to radiolysis of water in the core region. Sufficient partial pressure of hydrogen is maintained in the volume control tank such that the specified equilibrium concentration of hydrogen is maintained in the reactor coolant. A self-contained pressure control valve maintains a minimum pressure in the vapor space of the volume control tank. This can be adjusted to provide the correct equilibrium hydrogen concentration.

Components with stainless steel sensitized in the manner expected during component fabrication and installation will operate satisfactorily under normal plant chemistry conditions in pressurized water reactor systems, because chlorides, fluorides, and particularly oxygen, are controlled to very low levels. The Reactor Coolant System specification limits the chloride and fluoride concentrations to less than 0.15 ppm at all times (regardless of system temperature) to prevent stress corrosion cracking.

During power operation when zinc addition is desired, an aqueous solution of zinc acetate is injected into the RCS via the sample system return line to the VCT for reducing radionuclide content in the primary system corrosion films. Residual zinc level is maintained at 2 - 8 ppb nominal. Cobalt, nickel, and zinc are removed from the RCS by the mixed bed demineralizers via normal letdown.

5.2.4 Fracture Toughness

5.2.4.1 Compliance With Code Requirements

Assurance of adequate fracture toughness of ferritic materials in the reactor coolant system boundary is provided by compliance with Section III of the 1968 ASME Boiler and Pressure Vessel Code. These requirements although different from the requirements of 10 CFR 50 Appendix G (effective date - August 16, 1973) meet all the Sequoyah licensing commitments. The fracture toughness data available for these materials are included in the QA data packages which are available for NRC review. Typical data is included in Westinghouse Topical Report WCAP-7924 along with the Westinghouse method of correlating data of Sequoyah vintage with 10 CFR 50 Appendix G. This report has been accepted by the NRC.

A comparison of the applicable Code versus the 10 CFR 50 Appendix G requirements is discussed below. For pressure retaining ferritic materials (excluding bolting) in the pressurizer and steam generators, Appendix G requires at least 50 ft-lb absorbed energy and 35 mils lateral expansion (by reference to current ASME Code Section III paragraph NB-2330 requirements). The applicable Code requirements include a minimum 20 ft-lb average absorbed energy with no mils lateral expansion requirement for SA 216 Grade WCC and a minimum 30 ft-lb average absorbed energy with no mils lateral expansion requirement for SA 508 Class 2 and SA 533 Grade A Class 1.

A limited review of the steam generator and pressurizer materials has been conducted. In all cases, the ASME Code requirements were satisfied; the following information regarding the Appendix G requirements was gathered:

- For the steam generator channel head castings (A 216 Grade WCC), four out of eight data points exceed the Appendix G requirement of 50 ft-lb, with the values ranging from 21.3 to 76 ft-lb at 10°F. No lateral expansion data is available.

- For the steam generator manway cover material (SA 533 Grade A Class 1), all eight data points exceed the Appendix G 50 ft-lb requirement, with the values ranging from 88 to 110 ft-lb at 10°F. The Appendix G 35 mils requirement is exceeded with the values ranging from 63 to 70 mils. (It should be noted that lateral expansion measurements were not required by the Code.)

- For the pressurizer materials (A 508 Class 2, A 533 Grade A Classes 1 and 2), twenty six out of twenty eight data points exceed the Appendix G 50 ft-lb requirements, with the values ranging from 40 to 102 ft-lb at 10°F. No lateral expansion data is available.

As previously stated, the Sequoyah equipment was fabricated in accordance with ASME Code requirements in effect prior to the effective date of the 10 CFR 50 Appendix G requirements. However, as indicated by this summary of the reviewed data, in most cases the Appendix G minimum ft-lb requirement has been satisfied. Although in most cases lateral expansion data is not available, where it is available, the Appendix G minimum mils requirement has also been satisfied.

Bolting materials meet the fracture toughness requirements of the applicable Code, which although different from the requirements of 10 CFR 50 Appendix G (effective date, August 16, 1973) meet all Sequoyah licensing commitments. The fracture toughness data available for these materials are included in the QA data packages which are available for NRC review. For ferritic materials for bolting with nominal diameters exceeding 1 inch, Appendix G requires at least 45 ft-lb absorbed energy and 25 mils lateral expansion. The applicable Code requirement for SA 193 Grade B7 bolting material is 30 ft-lb absorbed energy with no mils lateral expansion requirement.

A limited review of bolting materials has been conducted. In all cases, the ASME Code requirements were satisfied; the following information regarding the Appendix G requirements was gathered:

- For the steam generator and pressurizer manway bolting material (SA 193 Grade B7), all eleven data points exceed the Appendix G 45 ft-lb requirement, with the values ranging from 65-71 ft-lb at 10°F. No lateral expansion data is available. As previously stated, the Sequoyah equipment was fabricated in accordance with ASME Code requirements in effect prior to the effective date of the 10 CFR 50 Appendix G requirements. However, as indicated by this summary of the reviewed data, the Appendix G minimum ft-lb requirement has been satisfied, but lateral expansion data is not available.

Quality Assurance for materials was in accordance with applicable Code requirements. Dropweight and impact testing was in accordance with ASTM E 208 and ASTM A 370. Appendix IX to the 1968 Code required the manufacturer to qualify subcontractors QA and QC programs. Calibration of test equipment and recording of results were not in accordance with 10 CFR 50 Appendix G because Appendix G was not issued at that time. Calibration and reporting was in accordance with the subcontractors quality control procedures which were received and approved by Westinghouse.

Fracture toughness of the reactor pressure vessel material was established by obtaining NDTT by the drop weight test (ASTM E-208) and Charpy V-notch impact specimens oriented in the strong direction. Formulated methods were used to convert "strong" direction impact data to "weak" direction impact data and to establish RT_{NDT}, (Reference 6). The method of conversion meets 10 CFR Part 50 Appendix G Section III Paragraph 2.A. Weak direction impact data were obtained for materials in the beltline region as part of the surveillance program. Test results for the materials contained in the reactor vessel are given in Table 5.2.4-8. Test results for the materials used in the vessel closure head bolting are given in Table 5.2.4-1.

5.2.4.2 Acceptable Fracture Energy Levels

Initial upper shelf fracture energy levels for the materials of the reactor vessel beltline (including welds) as determined by Charpy V-notch tests on specimens oriented in the "weak" direction of the material were established for the vessel irradiation surveillance test program. No initial upper shelf energy criteria has been established for the beltline materials. However, inservice requirements for these materials will be adhered to in accordance with 10 CFR Part 50, Appendix G, Section V.

5.2.4.3 Operating Limitations During Startup and Shutdown

The reactor coolant system heatup and cooldown curves, PTLR Figures 2-1 and 2-2, were generated in accordance with the methods given in Appendix G. The Unit 2 curves were generated in accordance with Appendix G of Section XI of the 1995 ASME Code (through 1996 Addendum) as updated by Code Case N-640, “Alternate Reference Fracture Toughness for Development of P-T Limit Curves for Section XI, Division 1” dated February 26, 1999. The 10CFR50 Appendix G reactor vessel flange temperature limit was not applied to the curves based on Reference 37. These curves define the allowable pressure limits for the indicted temperature as a function of rate of temperature change. Allowances for instrument error in temperature and pressure measurements have been incorporated into the curves.

The heatup and cooldown curves were calculated using the unirradiated nil ductility transition temperature (RT_{NDT}) of the limiting reactor vessel material adjusted to account for the effects of irradiation in accordance with Regulatory Position 1.1 of Regulatory Guide 1.99, Revision 02. The curves were calculated for reactor vessel radiation exposure associated with 32 EFPYs of operation. Irradiation changes to the material properties were evaluated for the 1/4T and 3/4T (one quarter and three quarters of the vessel wall thickness) locations in the limiting materials to account for a potential flaw at both OD and ID locations.

The methodologies, equations, limiting materials, and other details associated with the calculation of the heatup and cooldown curves are documented in Reference 26 for Unit 1 and Reference 27 for Unit 2.

Appendix G of 10 CFR Part 50 imposes toughness requirements on the reactor vessel throughout life. The toughness requirements are such as to require at least 50 ft-lb Charpy energy absorption normal to the major working direction of the forging throughout life. This requirement is equivalent to requiring a shelf energy of at least 50 ft-lbs or requiring that RT_{NDT} be determined throughout life since RT_{NDT} is defined in terms of the 50 ft-lb level. Based on the results of the final scheduled reactor vessel surveillance program capsule testing (see Section 5.4.3.7) in References 33 and 34, all reactor vessel beltline materials exhibit a more than adequate upper shelf energy level for safe plant operation and will maintain an upper shelf energy greater than 50 ft-lb throughout the life of the vessels (32 EFPY) as required by 10CFR50, Appendix G.

5.2.4.4 Compliance with Reactor Vessel Materials Surveillance Program Requirements

Changes in fracture toughness of the core region forgings, weldments, and associated heat affected zones due to radiation damage will be monitored by a surveillance program which conforms with ASTM E185, “Recommended Practice for Surveillance Tests for Nuclear Reactor Vessels.” ASTM E185-73 is the basis for the original surveillance program; however, removal and evaluation of surveillance capsules are in accordance with ASTM E185-82. The evaluation of the radiation damage in this surveillance program is based on pre-irradiation and post-irradiation testing by Charpy V-notch, and tensile specimens and post-irradiation testing of wedge opening loading specimens carried out during the lifetime of the reactor vessel. Specimens are irradiated in capsules located near the core midheight and are removed from the vessel at specified intervals. For additional details of the irradiation surveillance program refer to Paragraph 5.4.3.7.

5.2.4.5 Reactor Vessel Annealing

See Paragraph 5.4.3.8 for a discussion of reactor vessel annealing.

5.2.4.6 Pressurized Thermal Shock (PTS)

The NRC Unresolved Safety Issue (USI) Task A-49 addresses the situation in which a severe system overcooling event is followed by repressurization of the reactor vessel. The mechanical response of the reactor vessel to the propagation of crack-like defects in the wall depends on the reduction of

fracture toughness due to neutron flux during the operation of the plant. As long as the fracture resistance of the reactor vessel material remains relatively high, an overcooling event will not cause failure. After the fracture toughness of the vessel is reduced by neutron irradiation, thermal transients could cause fairly small flaws to propagate near the inner surface of the vessel.

The vessels of concern are those which have accumulated high neutron radiation exposure and which are made of material that has a high sensitivity to neutron irradiation such as those with welds in the reactor vessel beltline region with high copper content. The base material chemistry, properties, and flaw content should not be ignored.

The reactor system overcooling events that can lead to PTS result from a variety of causes including instrumentation and control system malfunctions and postulated accidents such as small break loss-of-coolant accidents (SBLOCAs), main steam line breaks (MSLBs), feedwater pipe breaks, or stuck open valves in either the primary or secondary system. Rapid cooling of the reactor vessel internal surface causes a temperature gradient across the reactor vessel wall. The temperature gradient results in thermal stresses, with a maximum tensile stress at the inside surface of the vessel and a compressive stress at the outside surface. These stresses combine with the stress caused by the internal pressure in the vessel. The magnitude of the thermal stress depends on the temperature differences across the reactor vessel wall.

In order to threaten the adequacy of core cooling by PTS events, a number of contributing factors must be present. These factors are: (1) a reactor vessel flaw of correct size to propagate, (2) high copper content, (3) a relatively high level of irradiation, (4) a severe overcooling transient with repressurization; and (5) a resulting crack of such size and location that the ability of the reactor vessel to maintain core cooling is affected.

The final PTS rule issued in 10 CFR Part 50.61 dated July 23, 1985, paragraph (b) (2) establishes the screening criteria rule for PTS for all domestic operation PWR plants for the RT_{PTS} reference temperature as follows:

RT_{PTS} 270°F for plates, forgings, axial welds
RT_{PTS} 300°F for circumferential weld materials

The final rule requires that a RT_{PTS} projection be calculated and evaluated to these screening criterion. The RT_{PTS} for beltline materials is sensitive to copper content, nickel content, and initial RT_{NDT}. The RT_{PTS} values are projected for the inner reactor vessel surfaces of the beltline materials from the time of submittal to expiration date of the operating license as required by 10 CFR 50.61.

The beltline materials in Sequoyah units 1 and 2 consist of intermediate forgings, lower forgings, and intermediate-to-lower forging circumferential welds. The copper contents, nickel contents, and initial RT_{NDT}s for units 1 and 2 beltline materials are presented below.

Unit 1	Cu (Percent)	Ni (Percent)	Initial $RT_{NDT(1)}$ (°F)
Intermediate Forging	0.15[2]	0.86[3]	40
Lower Forging	0.13[4]	0.76[4]	73
Circumferential Weld	0.35[4,6]	0.11[4,6]	-40

Unit 2	Cu (Percent)	Ni (Percent)	Initial $RT_{NDT(1)}$ (°F)
Intermediate Forging	0.13(5)	0.76(5)	10
Lower Forging	0.14(2)	0.76(3)	-22
Circumferential Weld	0.12(5)	0.11(5)	-4

(1)These initial RT_{NDT}s are measured values based on Charpy V-notch test and dropweight test. These values are taken from Table 5.2.4-8.

(2)These values are taken from Table 5.2.4-8.

(3)This value is taken from WCAP-12970 (Unit 1) and WCAP-12971 (Unit 2) Heatup and Cooldown Limit Curves for Normal Operations, June 1991.

(4)These values are taken from WCAP-15293, R1 (Sequoyah Unit 1 Heatup and Cooldown Limit Curves for Normal Operation and PTLR Support Documentation, April 2001).

(5)These values were taken from WCAP-15321, R1 (Sequoyah Unit 2 Heatup and Cooldown Curves for Normal Operation and PTLR Support Documentation, April 2001).

(6)The best estimate was determined using data from WCAP-15293 (surveillance weld and three Rotterdam tests averaged together).

The projected RT_{PTS}s are also a function of accumulated neutron fluence at the inner surfaces of the beltline materials. The calculated peak neutron fluence at the inner surfaces of the beltline materials at end-of-life (expiration of operation license) is taken from the results of the 1.3% power uprating program and all past capsule analyses. The neutron fluence analysis and results are documented in the Sequoyah 1 & 2 Power Uprate Licensing Report (Reference 28).

The projected RT_{PTS}s for units 1 and 2 beltline material were determined by using equation 1 in 10 CFR 50.61, paragraph (b) (2), and the resulting values are presented below.

Unit 1	RT_{PTS} (F) 32 EFPY
Intermediate Forging	209
Lower Forging	231
Circumferential Weld	204
Unit 2	
Intermediate Forging	155
Lower Forging	133
Circumferential Weld	143

The projected end-of-life RT_{PTS}s for the forgings meet the screening criteria of 270°F, and the projected end-of-life RT_{PTS}s for the circumferential welds meet the screening criteria of 300°F. Therefore, no further action is required until changes in core loadings, surveillance measurements, or other information indicate a need for updated projections.

5.2.5 Austenitic Stainless Steel

The unstabilized austenitic stainless steel material specifications used for the (1) Reactor Coolant System Boundary, (2) systems required for reactor shutdown, and (3) systems required for emergency core cooling are listed in Tables 5.2.3-1 and 5.2.3-2.

The unstabilized austenitic stainless steel material specifications used for the reactor vessel internals which are required for emergency core cooling for any mode of normal operation or under postulated accident conditions, and for core structural load bearing members are listed in Table 5.2.5-1.

All of the above tabulated materials are procured in accordance with the specification requirements and include supplemental requirements of the applicable ASME Code Rules.

5.2.5.1 Cleaning and Contamination Protection Procedures

It is required that all austenitic stainless steel materials used in the fabrication, installation and testing of nuclear steam supply components and systems be handled, protected stored and cleaned according to recognized and accepted methods and techniques. The rules covering these controls are stipulated in the following Westinghouse Electric corporation process specifications. These process specifications supplement the equipment specification and purchase order requirements of every individual austenitic stainless steel component or system which Westinghouse procures for a nuclear steam supply system, regardless of the ASME Code Classification. They are also given to TVA for use within their scope of supply and activity.

To assure that manufacturers and installers adhere to the rules in these specifications surveillance of operations by Westinghouse personnel is conducted either in residence at the manufacturer's plant and the installer's construction site or during periodic engineering and quality assurance visitations and audits at these locations.

The process specifications which establish these rules and which are in compliance with the more current American National Standards Institute N-45 Committee specifications are as follows:

Process Specification

82560HM Requirements for Pressure Sensitive Tapes for Use on Austenitic Steels.

83336KA Requirements for Thermal Insulation Used on Austenitic Stainless Steel Piping and Equipment.

83860LA Requirements for Marking of Reactor Plant Components and Piping.

84350HA Site Receiving Inspection and Storage Requirements for Systems, Material and Equipment.

84351NL Determination of Surface Chloride and Fluoride on Austenitic Stainless Steel Materials. TVA will apply this specification to piping with an operating temperature over 140°F and will use the acceptance standards of Paragraph 4.3.2, RDT F5-1T, January, 1978, for halogen contamination.

85310QA Packaging and Preparing Nuclear Components for Shipment and Storage.

292722 Cleaning and Packaging Requirements of Equipment for Use in the NSSS.

597756 Pressurized Water Reactor Auxiliary Tanks Cleaning Procedures.

597760 Cleanliness Requirements During Storage Construction, Erection and Start-up Activities of Nuclear Power Systems. TVA will apply this specification to piping with an operating temperature over 140°F.

5.2.5.2 Solution Heat Treatment Requirements

All of the austenitic stainless steels listed in Tables 5.2.3-1, 5.2.3-2 and 5.2.5-1 are procured from raw material producers in the final heat treated condition required by the respective ASME Code Section II material specification for the particular type or grade of alloy.

5.2.5.3 Material Inspection Program

All of the wrought austenitic stainless steel alloy raw materials which require corrosion testing after the final mill heat treatment are tested in accordance with ASTM A 393 using material test specimens obtained from specimens selected for mechanical testing. The materials are obtained in the solution annealed condition.

5.2.5.4 Unstabilized Austenitic Stainless Steels

The unstabilized austenitic stainless steels used in the reactor coolant pressure boundary and components are listed in Tables 5.2.3-1 and 5.2.3-2.

These materials are used in the as-welded condition as discussed in Paragraph 5.2.5.2 of this safety analysis report. The control of the water chemistry is stipulated in Paragraph 5.2.3.4 of this safety analysis report. These chemistry controls coupled with the satisfactory experience with components and internals using unstabilized austenitic stainless steel materials which have been post weld heat treated above 800°F show acceptability of these heat treatments for stainless steel in a PWR chemistry environment (Reference 17). Actual observations of post weld heat treated austenitic stainless steels after actual operation indicate no effects of such treatments. Internals heat treated above 800°F from H. B. Robinson, Unit 2, Zorita, Connecticut Yankee, San Onofre, Beznau 1, Yankee Rowe, Selni, R. Ginna, and SENA have been examined after service and show acceptable material condition.

5.2.5.5 Avoidance of Sensitization

The unstabilized austenitic stainless steels used for core structural load bearing members and component parts of the reactor coolant pressure boundary are processed and fabricated using the most practicable and conservative methods and techniques to avoid partial or local severe sensitization.

After the material has been heat treated as described in Paragraph 5.2.5.2, the material is not heated above 800°F during subsequent fabrication except as described in Paragraph 5.2.3.2 and paragraphs below.

Methods and material techniques that are used to avoid partial or local severe sensitization are as follows:

1. Nozzle Safe Ends

    a. Weld deposit with Inconel (Ni-Cr-Fe weld metal F number 43) then attach safe end after final post weld heat treatment. (This was used for the pressurizer).

    b. Use of a stainless steel weld metal analysis A-7 containing more than 5 percent ferrite. (This was used for the steam generator and reactor vessel.

2. The Unit 1 lower internals core barrel and thermal shield, which are austenitic stainless steel, have been given a stress relieving treatment above 800°F, i.e., a high temperature stabilizing procedure is used. This is performed in the temperature range of 1600-1900°F, with holding times sufficient to allow chromium carbides to go into solution and to limit the effects of sensitization or chromium carbide precipitation in the grain boundary.

The upper half of the Unit 2 lower internals thermal shield has also been stress relieved in the 1600 - 1900°F range. The lower internals core barrel and lower half of the thermal shield for Unit 2 were stress relieved below 800°F.

The upper internals assemblies for Units 1 and 2 do not have any components which have been heat treated above 800°F. The UHI support columns are electron beam welded under a vacuum shield; this welding process does not require a postweld heat treatment. Corrosion studies have shown that this welding process does not sensitize the stainless steel used to manufacture the UHI support columns. Also, this process will not cause dimensional instability of the internals at operating temperatures.

3. All welding is conducted using those procedures that have been qualified to the ASME Code Rules of section III and IX, by nondestructive testing.

    When welding procedure tests are being performed on test welds that are made from base metal and weld metal materials which are from the same lot(s) of materials used in the fabrication of components, additional testing is frequently required to determine the metallurgical, chemical, physical, corrosion, etc. characteristics of the weldment. The additional tests that are conducted on a technical case basis are as follows: light and electron microscopy, elevated temperature mechanical properties, chemical check analysis, fatigue tests, intergranular corrosion tests and static and dynamic corrosion tests within reactor water chemistry limitations.

4. The following welding methods have been tested individually and in multi-process combinations as outlined in (3) above using these prudent energy input ranges for the respective method, as calculated by the following formula:

$$H = \frac{Exlx60}{S}$$

where E = volts
I = amperes
S = Travel Speed in inches/minute
H = Joules/inch

WELDING PROCESS METHOD	ENERGY INPUT RANGE (Kilojoules/inch)
Manual Gas Tungsten Arc	20 to 50
Manual Shielded Metal Arc	15 to 120
Semi-Automatic Gas Metal Arc	40 to 60
Automatic Gas Shielded Tungsten Arc-Hot Wire	10 to 50
Automatic Submerged Arc	60 to 140
Automatic Electron Beam-Soft Vacuum	10 to 50

5. The interpass temperature of all welding methods is limited to 350°F maximum.

6. All full penetration welds require inspections in accordance with Article 6 of the ASME Section III Code rules.

5.2.5.6 Retesting Unstabilized Austenitic Stainless Steels Exposed to Sensitizing Temperatures

In general, it is not feasible to remove samples from fabricated production components to prepare specimens for retest to determine the susceptibility to intergranular attack. These tests are only performed on test welds when meaningful results would predict production material performance and are as described in Paragraph 5.2.5.5 of this safety analysis report. No intergranular tests are planned because of satisfactory service experience (see 5.2.5.4).

5.2.5.7 Control of Delta Ferrite

All austenitic stainless steel welding materials used in joining Class 1, 2, or 3 components procured prior to February, 1976, contain a minimum of 3 percent delta ferrite and those procured since contain a minimum of 5 percent delta ferrite.

The delta ferrite content of welds made with filler metal containing less than 5 percent delta ferrite is determined to ensure that the welds contain a minimum of 3 percent delta ferrite. Delta ferrite content is determined using a magnetic measurement device. Its calibration is traceable through secondary standards to a Magne-Gage and National Bureau of Standards. The delta ferrite content is determined on all welds over 1 inch thick. A statistical sampling plan is used to verify the delta ferrite content of all other welds except single pass welds, welds less than 1/4 inch thick, or fillet welds with a throat thickness of 3/8 inch or less.

If a weld made with filler metal containing less than 5 percent delta ferrite, is shown to contain less than 3 percent delat ferrite, it is either removed or sampled by metallographic examination. If the metallographic examination of the sample reveals no microfissure longer than 1/16 inch, nor more than three fissures between 1/64 and 1/16 inches long in any 0.2 square inch, the weld is considered acceptable.

Until November 1977, the delta ferrite content of welding filler materials was determined from a Schaeffler or Modified Schaeffler diagram using the chemical analysis of a weld deposit made with the flux-filler metal combination used in fabrication. Chemical analysis of base filler materials including consumable inserts, used in inert gas shielded welding processes may have been obtained from the base filler material rather than from a weld deposit.

Since November 1977, delta ferrite content of filler metals has been determined by magnetic measurement of a weld deposit. The deposit is made with the flux-filler metal combination and shielding gas used in production. The magnetic measurement devices are calibrated in accordance with American Welding Society Specification A 4.2.

5.2.6 Pump Flywheel

The integrity of the reactor coolant pump flywheel is assumed by the following analysis.

The flywheel consists of two plates, approximately five inches and eight inches thick, bolted together. Each plate is fabricated from vacuum degassed A-533 Grade B Class I steel. Supplier certification reports are available for all plate materials providing three C_V impact energy values at 10°F parallel and normal to the rolling direction.

Determining acceptability of the flywheel material involves two steps as follows:

1. Establish a reference curve describing the lower bound fracture toughness behavior for the material in question.

2. Use Charpy impact energy values obtained in certification tests at 10°F to fix position of the heat in question on the reference curve.

A lower bound K_{Id} reference curve (see Figure 5.2.6-1) has been constructed from dynamic fracture toughness data generated by Westinghouse (Reference 5) on A-533 Grade B Class I steel. All data points are plotted on the temperature scale relative to the NDT temperature. The construction of the lower bound below which no single test point falls, combined with the use of dynamic data when flywheel loading is essentially static, together represent a large degree of conservatism.

The applicability of a 30 ft-lb Charpy energy reference value has been derived from sections on Special Mechanical Property Requirements and Tests in Article 3, Section III of the ASME Boiler and Pressure Vessel Code. The implication is that the test temperature lies a safe margin above NDT. Flywheel plates exhibit an average value of 30 ft-lbs or greater in the weak direction and, therefore, meet the specific requirement "C.1.a" stated in Regulatory Guide 1.14 that NDT must be no higher than 10°F, one is able to reassign the "zero" reference temperature position in Figure 5.2.6-1 value of 10°F.

Flywheel operating temperature at the surface is 120°F. The lower bound toughness curve indicates a value of 116 ksi-in$^{1/2}$ at the (NDT + 110) position corresponding to operating temperature. Regulatory Guide 1.14 requirement "C.1.e" is fulfilled with considerable margin for safety.

By assuming a minimum toughness at operating temperature in excess of 100 ksi-in$^{1/2}$, it can be seen by examination of the correlation in Figure 5.2.6-1 that the C_V upper shelf energy must be in excess of 50 ft-lb, therefore, the requirement "C.1.b" that the upper shelf energy must be at least 50 ft-lb, is satisfied.

It is concluded that flywheel plate materials are suitable for use and can meet these Regulatory Guide 1.14 acceptance criteria on the bases of supplier's material certification data. To assure pump flywheel integrity, each finished flywheel is qualified ultrasonically examined in accordance with procedures and to acceptance criteria equivalent to those specified for Class 1 vessels in the ASME B&PV Code Section III - Nuclear Power Plant Components. The flywheel design is such that it is accessible for periodic augmented examination. These augmented examination requirements are stated in Regulatory Position C.4.b of Regulatory Guide 1.14.

The calculated stresses at operating speed are based on stresses due to centrifugal forces. The stress resulting from the interference fit of the flywheel on the shaft is less than 2000 psi at zero speed, but this stress becomes zero at approximately 600 rpm because of radial expansion of the hub.

The primary coolant pumps run at approximately 1190 rpm and may operate briefly at overspeeds up to 109% (1295 rpm) during loss of outside load. For conservatism, however, 125% of operating speed was selected as the design speed for the primary coolant pumps.

Precautionary measures taken to preclude missile formation from primary coolant pump components, assure that the pumps will not produce missiles under any anticipated accident condition. Each component of the primary pump motors has been analyzed for missile generation. Any fragments of the motor rotor would be contained by the heavy stator. The same conclusion applies to the pump impeller because the small fragments that might be ejected would be contained by the heavy casing.

5.2.7 RCPB Leakage Detection Systems

The leakage detection systems comply with applicable parts of NRC General Design Criterion 30 and Regulatory Guide 1.45 with the exception of the capability of the air particulate and gas radiation monitors to function after a seismic event. However, the degree of compliance of the total leakage detection systems with Regulatory Guide 1.45 has been evaluated by the NRC and documented in their SER (NUREG 0011) to be an acceptable basis for satisfying the requirements of GDC 30. These systems provide a means of detection, to the extent practical, leakage from the reactor coolant pressure boundary.

5.2.7.1 Methods of Detection

The following methods are used to measure reactor coolant pressure boundary leakage. The methods are not considered Engineered Safety Feature Systems and are not designed to IEEE 279 Criteria. However, certain of the radiation monitors are designed to IEEE 279 Criteria.

5.2.7.1.1 Containment Building Upper Compartment Air Radiation Monitor and Containment Building Lower Compartment Air Radiation Monitor

The containment air from the lower and upper compartments is normally sampled and monitored by separate monitor assemblies. One assembly normally monitors the lower compartment and one assembly normally monitors the upper compartment (for a detailed description of these monitors, see Subsection 11.4.2). Each assembly consists of a particulate and noble gas monitors.

These separate Monitor Systems are interconnected by stainless steel tubing to allow monitoring lower containment by either monitor in case one monitor assembly malfunctions. The particulate and noble gas monitors are each indicated, recorded, and annunciated in the MCR. Visual and audible alarms are initiated on high radiation and instrument malfunction.

The ICS computer utilizes the count rate input signal from these radiation monitors to calculate an ICS computer alarm setpoint to further comply with GDC-30 and Regulatory Guide 1.45. The ICS computer alarm setpoint is calculated with a predetermined percent increase of count rate above a continuous updated hourly background count rate which reflects current plant conditions. When the lower containment one minute current average background count rate exceeds the predetermined percent increase of the hourly averaged background count rate, an ICS computer alarm in the MCR will initiate.

5.2.7.1.2 Humidity Monitoring

The Humidity Detector System offers another means of detecting leakage into the containment. Two humidity sensors (one in lower compartment and one in upper compartment) are installed within each containment. The humidity detectors (one in lower compartment and one in upper compartment) output is recorded in the MCR. Visual and audible alarms are initiated in the MCR on a high rate of increase of moisture content.

The ice condenser has negligible effect on the humidity detector sensitivity for all coolant leaks which do not open the inlet doors.

5.2.7.1.3 Reactor Vessel Flange Leakoff

Leakage between the double O-ring of the reactor vessel main flange is sensed in the leakoff line by a temperature detector. Leakage into the reactor vessel flange is indicated in the MCR. An increase in temperature actuates an audible and visual alarm in the MCR.

5.2.7.1.4 Condenser Vacuum Pump Radiation Monitors

These monitors continuously monitor the mechanical vacuum pump air exhaust for an indication of a primary-to-secondary leak. A description of the operational characteristics is given in Subsection 11.4.2.

These monitors are off-line gas type and the gas is continuously monitored by beta scintillation detectors. The normal and intermediate range monitors are indicated, recorded, and annunciated in the MCR. Visual and audible alarms are initiated in the MCR on high radiation and instrument malfunction.

5.2.7.1.5 Component Cooling System Radiation Monitors

Three monitors continuously monitor downstream of each of the three component cooling heat exchangers for activity levels indicative of a reactor coolant leak from either the RCS or RHR Systems. A description of the operational characteristics is given in Subsection 11.4.2. The monitors are indicated, recorded, and annunciated in the MCR. Visual and audible alarms are initiated in the MCR on high radiation and instrument malfunction. In the event of high activity, the monitors automatically close the component cooling surge tank vent.

5.2.7.1.6 Steam Generator Blowdown Radiation

Radiation monitors are provided on the liquid discharge and provide an indication of a primary-to-secondary leak by sampling the liquid phase of the steam generators secondary side. A description of the operational characteristics is given in Subsection 11.4.2. These monitors are indicated, recorded, and annunciated in the MCR. Visual and audible alarms are initiated on panel in the MCR on high radiation and instrument malfunction. In the event of high activity, the liquid discharge monitors automatically isolate the blowdown discharge.

5.2.7.1.7 Charging Pump Operation and Excessive Makeup Volume

Gross loss of reactor coolant is measured by the charging pump flow rate and unscheduled decreases in the chemical and volume control tank level. The charging pump flow rate is indicated in the MCR. The chemical and volume control tank level is indicated and the low level is annunciated (visual and audible) in the MCR. The pocket sump level change rate is annunciated (visual and audible) for a level change rate exceeding 1 gal/min.

5.2.7.1.8 RB Containment Floor and Equipment Drain Sump

The RB containment floor and equipment drain sump and pocket sump (located outside crane wall) will collect liquid from the containment floor and equipment drains and the containment pit sump (located on the bottom of the reactor cavity). The pit sump pump discharges to the pocket sump. The pocket sump (also called the auxiliary containment floor and equipment drain sump) discharges to the containment floor and equipment drain sump. The RB containment floor and equipment drain sump level is annunciated (visual and audible) on high and low level in the MCR. The pocket sump is also annunciated in the MCR.

A pocket sump is installed inside the RB containment floor and equipment sump in order to separate the drains (Figure 5.2.7-1). The drains are separated and the crane wall is sealed to ensure sufficient post-LOCA water inventory inside the crane wall. The pocket sump pumps can be manually started from the control room upon receipt of a high level alarm. The pumps are stopped either manually from the control room or automatically upon reaching the low water level setpoint. There are two independent level switches to assure positive cutoff of the pump. The containment floor and equipment drain sump pumps stop automatically upon receipt of low sump level or an SI signal.

A break in the Reactor Coolant (RC) System results in an increase in water level in one of the sumps which are monitored by level transmitters. The pocket sump level change rate instrumentation annunciates in the MCR when the level change rate (inches per hour) exceeds a sump inflow rate of 1 gal/min). The sensitivity is such that a 1 gal/min inflow rate can be detected in approximately 1 hour.

The pocket sump complies with Regulatory Guide 1.45, Rev. 0. However, the environmental conditions during power operations and the physical configuration of lower containment will obstruct the total RCS leakage from entering the pocket sump directly and subsequently, will lengthen the sump's level response time. The reactor coolant unidentified leakage during normal power operations will (1) initially flash into steam and become trapped between the system piping and the RCS piping insulation, (2) as the leakage progresses, it will exit the insulation and enter a turbulent lower containment atmosphere imposed by the Reactor Building Lower Compartment HVAC that will impede RCS leakage condensation and accumulation, (3) subsequently, a portion of the leakage inventory must be blown through unsealed crane wall penetrations above 693' into the Raceway due to the turbulent containment atmosphere, (4) and the portion of the leakage inventory forced into the Raceway may condense and remain isolated from the pocket sump for detection. As the leakage

conditions approach a state of equilibrium with respect to the environmental conditions and the physical configuration inside lower containment, and the RCS leakage begins to enter the sump, the instrumentation has the sensitivity to detect a one gallon per minute leakrate within one hour. Subsequently, RCS pressure boundary leakage detection by the pocket sump will typically occur following other means of leakage detection discussed in FSAR 5.2.7. Given these conditions, it may be difficult for the pocket sump to detect an actual one gallon per minute RCS leak within one hour.

5.2.7.1.9 Main Steam Line Rad Monitors

See Section 11.4.2. These monitors are post accident, but may be used to identify a ruptured SG with a high leak rate.

5.2.7.1.10 Leak Detection/Valve Position Indication

The PORVs and safety valves are provided with various positive valve position indications. The valve position indication systems meet seismic and environmental qualification requirements as specified by the NRC for Sequoyah. An alarm in the main control room indicates when any valve is not in the fully closed position.

1. The positive indication of the PORV position is obtained by an electromagnetic "Reed"-switch (single channel for each PORV). Additional indications that a PORV is not fully closed is provided by accelerometers (acoustic monitors) attached to the PORV tail piping.

2. The position indication of the PORV block valve is obtained from gear limit switches on the respective block valve.

3. Position indication for the safety valves is provided by accelerometers (acoustic monitors) (single channel for each valve) attached to the safety valve tail piping.

The Sequoyah design incorporates only a single channel of positive position indication for each safety valve. In accordance with the NRC position and clarification, TVA has backup methods of determining valve positions installed; these include temperature sensors downstream of each valve, pressurizer relief tank temperature/pressure/level indicators and pressurizer high pressure sensors. All the above instrumentation is indicated and alarmed in the main control room. These methods have also been incorporated into the plant operating procedures.

5.2.7.2 Deleted (combined into 5.2.7.1)

5.2.7.3 Limits for Reactor Coolant Leakage

Limits for reactor coolant leakage rates are described in the technical specifications.

5.2.7.4 Characteristics of the Leakage Detection Methods

Containment Air Particulate Monitors

Particulate activity resulting from abnormal leakage is normally detected by the Containment Building lower compartment air monitor. The response time of the air particulate monitors is dependent upon many factors although for most leakage locations it is limited to a minimum of approximately 120 seconds. This is the time required for mixing inside the lower compartment plus transit time to the detector. (If leakage occurs very near one of the sample inlets, the minimum response time could approach 50 seconds.) Particulate activity is detected by means of a plastic beta scintillator which views a constantly moving filter paper. This filter paper is exposed to the air stream pumped from the containment atmosphere. The response time of the particulate monitor is also dependent on the abnormal leakage rate, normal baseline leakage, fraction of particulates which escape the leakage water, the amount of plate out on containment surfaces, the collection rate of the filter mechanism, and the amount of corrosion product and fission product activity in the coolant. The amount of fission product inventory in the reactor coolant depends on the fraction of failed fuel, fission product inventory in the failed fuel, escape rates from fuel to coolant of the fission products in the failed fuel, and reactor coolant processing history.

The particulate channel of the normal range lower compartment atmosphere monitor will detect a 1 gpm increase in primary coolant leakage in less than 1 hour when the baseline leakage is 1% RCM/day for 3 months. A 1 gpm leak can be detected in less than 7 minutes if there is no baseline leakage. Thus the particulate channel satisfies the requirements of Regulatory Guide 1.45. Increasing the containment purge frequency would decrease the background seen by the particulate channel and would decrease the response time. However, since the initial count rate in the particulate channel is mainly from Rb-88, and the Rb-88 activity reaches equilibrium in about a day, the containment purge frequency has only a small effect on the response time. See FSAR Reference 5.2.9.18.

Containment Radioactive Gas Monitor

Radioactive gas resulting from abnormal leakage is normally monitored by the Containment Building Lower Compartment Air Monitor System; the detector is a plastic beta scintillator. As in the case of the particulate monitor, the response time of the gas detector has an absolute minimum value which lies somewhere between 50 and 120 seconds. The response time is the sum of this minimum and a time which is dependent on the abnormal leakage rate, normal baseline leakage, and the amount of gaseous fission product activity in the coolant. While less important than in the case of the particulate detector, the frequency of containment purging is also a consideration.

The noble gas detection response capability will vary significantly depending on the containment background count rate, the higher the lower containment atmosphere background count rate the slower the detector response. The detection of RCS leakage with the noble gas monitors ultimately is a function of the quantity of isotopes that are contained in the RCS. For situations where there is little or no activity (such as when there are no fuel leaks and/or at startup), these monitors cannot satisfy the 1 gpm leakage detection (since there is no activity to detect). Contrarily, for situations where fuel leaks and RCS leakage has occurred simultaneously for example at 1%RCM/day for 3 months, it may be difficult for these monitors to satisfy the 1 gpm leakage detection. This is due to the masking affect high containment atmosphere background activity will have on a new RCS leakrate. Other methods of RCS leakage detection specified in Regulatory Guide 1.45 would be necessary as discussed in FSAR 5.2.7. However, given anticipated RCS radioisotope levels, these monitors meet the intent of Regulatory Guide 1.45. See FSAR Reference 5.2.9.18.

Humidity Monitoring

Humidity Detector System is sensitive to leakage of the order of 2 to 10 gal/min depending on the cooling water temperature, containment air temperature variation, and containment air recirculation rate. It is also sensitive to both radioactive and nonradioactive discharge. The humidity detector itself has a sensitivity of ± 2 percent absolute humidity. Response time for the system ranges from approximately 10 minutes for a 10 gal/min leak to about 50 minutes for a 2 gal/min leak. The system is an indirect indication of leakage to the containment, in accordance with NRC Regulatory Guide 1.45.

Condenser Vacuum Pump Monitors

Gaseous activity in the secondary system resulting from a primary-to- secondary leak is detected by these monitors. The detectors are plastic beta scintillators which monitor pump exhaust flow enroute to a vent pipe located atop the Turbine Building (see Subsection 11.3.7 for a detailed description of the vent). The response time of these monitors to detect an increase in leakage is dependent upon transit time from the point of leakage to the monitor, baseline leakage, the increase in leakage rate, and the amount of fission product gaseous activity in the primary coolant.

With no preexisting (baseline) leakage present, the condenser vacuum pump normal range monitor can detect in one hour a less than 0.1 gpm leak of reactor coolant containing radioactivity corresponding to ANSI/ANS-18.1-1984 activities modified for Sequoyah parameters into the secondary side. This leak rate is much less than the Regulatory Guide 1.45 minimum detection criterion of 1 gpm within one hour. The minimum detectable leak rate at equilibrium (about 7 days after the start of the leak) is less than 0.1 gpm. (See Reference 20.)

A baseline leak, plus any additional leakage up to a total leakage of 1 gpm, is detectable in less than one hour after the increase in leakage begins.

Component Cooling System Monitors

These monitors detect leakage into the Component Cooling (CC) System from the RC System during power operation or from the Residual Heat Removal (RHR) System during plant cooldown. The monitors are of the off line type; the detectors are gamma scintillators. A complete description of the operational characteristics is given in Subsection 11.4.2. The monitor response time is dependent upon the time needed for transport from point of leakage to point of detection, the leakage rate, and the amount of fission product and corrosion product activity in the primary coolant.

Sequential isolation of various components after detection of leakage can be used to identify the point of leakage within a relatively short time. The monitors provide an effective means of detection and identification of the source of a 1 gal/min leak. This is consistent with the guidance provided in Regulatory Guide 1.45, Rev. 0.

Detection of activity in the CC System water does not always indicate leakage from the RC System pressure boundary since leakages from radioactive systems, other than the RC System or the RHR System, that are served by the CC System may also produce detector response after a period of time. However, since the activities in these other systems will generally be much less than reactor coolant activity, the leakages will, of necessity, need to be much larger to produce the same monitor

response that leakage from the RC System or the RHR System would produce. Leakage from these other systems that result in activity detection would result in large changes in the CC System surge tank level. (See Reference 23.)

Steam Generator Blowdown Liquid Discharge Monitor

Combined samples from each of the four steam generators are continuously monitored for radioactivity by means of an off-line Radiation Monitoring System; the detectors are gamma scintillators. A complete description of the operational characteristics of this monitoring system is given in Subsection 11.4.2. The monitor response time is dependent upon mixing time in the steam generator secondary side water volume, transit time to the monitor, steam generator blowdown rate, abnormal leakage rate, and the amount of fission product and corrosion product activity in the primary coolant.

With no preexisting (baseline) leakage present, the steam generator blowdown liquid discharge monitor can detect a primary-to-secondary leak, containing radioactivity corresponding to ANSI/ANS-18.1-1984 values modified for Sequoyah parameters, of less than 0.1 gpm at minimum blowdown conditions one hour after the leak begins. This leakage detection capability is within Regulatory Guide 1.45 RO guidelines. The minimum detectable leak rate at equilibrium (1 day) for maximum blowdown conditions is less than 0.1 gpm. (See Reference 21.)

With baseline leakage at minimum or maximum blowdown conditions, the monitors can detect a new leak of up to 1 gpm in less than one hour after the increase in leakage begins.

Gross Leakage Monitoring

Gross leakage is indicated by the abnormal charging pump operation, abnormal containment sump pump operation, containment sump level rise, and reactor coolant liquid inventory. These are generally useful only for detection of leaks much larger than 10 gal/min.

Through-wall Flow

The length of a through-wall crack that would result in a detectable increase in the normal leakage rate is a function of pipe wall thickness, crack opening width, and pipe roughness. Detectable crack length has been calculated and is reported in Reference 8. Figures F-5 and F-6 of the referenced report show detectable leakage crack length as a function of detectable leakage rate. Figure F-5 presents curves for longitudinal cracks in various sizes of pipe, i.e., various wall thicknesses; and Figure F-6 presents similar curves for circumferential cracks. Knowing the detectable leakage rate, the detectable crack length can be determined from these figures.

Margins of Safety

Margins of safety for a detectable crack to assure critical size are also tabulated in Reference 8. Safety margins for circumferential and longitudinal cracks are listed for several sizes of pipe in Table 6-5 of that report.

Margins of safety are based on the percent increase in length required for a detectable crack to become a critical crack. The minimum value listed, 25 percent, occurs for a circumferential crack in a 2-inch RC System pipe. The increase in leakage rate for this case is 86 percent above the detectable rate. Longitudinal flows in the 2-inch pipe and flows in larger diameter pipes result in larger margins of safety.

Criteria

Components of the Leakage Detection System have been described in preceding paragraphs. Built-in redundancy and diversity is a key factor in the system. Various types of detectors serve to supplement one another, since the range of each detector either overlaps or duplicates the range of other detectors. Detector sensitivities are such that they provide the capability to sense a leak well before the leakage becomes unacceptable.

Using several types of detectors with various sensitivities results in a system more than adequate to detect abnormal leakage. Multiple types of sensors assure early leak detection in case of failure of one or more types, thereby assuring that the margin of safety as discussed above will not be exceeded.

5.2.7.5 Maximum Allowable Identified Total Leakage

The maximum allowable identified leakage rate of reactor coolant is 10 gal/min as specified by the SQN Technical Specifications.

Leakage is made up by the Charging System. The ratio of makeup capacity to identified leak rate is 15 for each of the two centrifugal charging pumps.

Leakage from the RC System is collected in the Reactor Building floor and drain sump, and is pumped to the Waste Disposal System in the Auxiliary Building by one or both sump pumps. The minimum ratio of pumpout rate to identified leak rate is 5.

5.2.7.6 Differentiation Between Identified and Unidentified Leaks

Typically leakage into the RB pocket sump is considered unidentified leakage until the source is identified. The leakage from the reactor vessel main flange leaks between the double O-ring seal until the leakoff initiates a high temperature alarm in the MCR. The reactor coolant pump seals are equipped with temperature sensors to detect leakage through the seals.

The CC System liquid radiation monitors give indication of a leak from either the RC System or the RHR System into the CC System. Leakage from the RC System during normal power operation may occur via the nonregenerative letdown heat exchanger. Identification of a leaking RHR heat exchanger can be made by alternately isolating the heat exchanger and noting any change in the rate of increase of the component cooling liquid activity.

The steam generator blowdown and condenser vacuum pump radiation monitors give an indication of primary-to-secondary leakage. Specific determination of the leaking steam generator may then be accomplished by individual sampling of each of the steam generators for activity through the use of the remotely operated valves in each of the steam generator blowdown lines. This procedure will take only a few minutes and will provide rapid determination of the leaking steam generator since the activity in the secondary of the leaking steam generator will initially be higher than in the secondaries of the other steam generators.

If the humidity detector detects an increase in containment moisture without a corresponding increase in activity level, the indicated source of leakage may be judged to be a nonradioactive system except when the reactor coolant activity level may be low.

5.2.7.7 Sensitivity and Operability Tests

Periodic testing of leakage detection systems will be conducted to verify the operability and sensitivity of the detection equipment.

The containment radiation, steam generator blowdown, condenser vacuum pump air exhaust, and component cooling monitors will have operational, response, and calibration tests performed per the test description presented in Subsection 11.4.4.

Calibration and response checks for the other leakage detection systems during reactor operation will be performed according to a predetermined schedule.

5.2.7.8 ECCS Intersystem Leakage

Leakage from the RC System into low pressure portions of several ECCS lines is prevented by the use of two check valves in series. The check valves are tested for leakage in accordance with the applicable surveillance instructions. The probability of a major leak through any pair of check valves will therefore be limited to approximately 5.5×10^{-9} per reactor year (as indicated in Reference 14). This probability is low enough to eliminate any concern for a major intersystem leak into low pressure ECCS Systems. However, means are available to continuously monitor and alarm intersystem leakage across the interfaces between the RC System and the following: Cold Leg Accumulators (CLA), Chemical and Volume Control System (CVCS), Safety Injection System (SIS), and RHR System. Leakage into these systems can be detected both by monitoring for signs of incoming leakage and by monitoring the RC System for signs of outgoing leakage.

Incoming and outgoing leakage is described in greater detail in the two following subsections:

ECCS In-Leakage

1. Intersystem leakage across the two check valves in each of the four CLA lines would increase the liquid inventory in the respective four accumulator tanks. Two level sensors are provided on each accumulator each having continuous indication and alarm available in the MCR. The time span required to identify this leakage and also the leakages discussed across the check valves in the other system is a function of the leakage rate across the check valves. However, since level indication is continuously available in the MCR, indication of the increasing level would be available in the MCR at all times.

2. There are no intersystem leakage problems of practical concern in the CVCS because of the high system design pressure for the interfacing CVCS piping and because the CVCS will generally be at a higher pressure than the RC System to provide the normal charging and seal injection functions.

3. Intersystem leakage across the two check valves in each of the four SIS cold leg injection lines or across the two check valves and one normally closed gate valve in each of the four SIS hot leg injection paths would increase the pressure in those segments of the lines. A separate pressure sensor is provided in each of the two SIS pump discharge lines with indication continuously available in the MCR. The two pump discharge lines are connected with a normally open crossover line so a pressure increase in this segment would be detectable by either sensor.

Three pressure relief valves are provided that discharge to the PRT. Discharge into this tank would increase the tank level, pressure, and temperature. A level sensor is provided on the tank having both continuous indication and alarm available in the MCR. A pressure sensor is provided on the PRT having both continuous indication and alarm available in the MCR. In addition, a temperature sensor is provided on the PRT having both continuous indication and alarm in the MCR.

4. Intersystem leakage across the two check valves in each of the four RHR System cold leg injection lines or across the two check valves and one normally closed gate valve in each of the two RHR System hot leg injection paths would increase the pressure in those segments of the lines. The two pump discharge lines are connected with a normally open crossover line so pressure increase in this segment would be sensed by three pressure relief valves also provided for these RHR System lines. The relief valves discharge to the pressurizer relief tank. Leakage into this tank is monitored continuously as described for the SIS leakage. The source of the intersystem leakage can be confirmed by local inspection of the 3 headers/relief valves and/or utilizing the SIS test system.

RC System Out-Leakage

At steady state power operation, intersystem leakage from the RCS would reduce the system inventory and affect inventory control operations. Monitoring of the RCS inventory and inventory control operations would enable significant leakage to be detected. If signs of this significant leakage were not observed in the primary containment, it could be assumed that it was intersystem leakage and possibly into the ECCS. Monitoring the RCS would not aid in identifying the leakage path. At steady state, intersystem leakage would cause the pressurizer level to drop which would automatically increase the CVCS charging pump flow rate. A flow element is provided in the common discharge of the two charging pumps with indication in the MCR. The CVCS Volume Control Tank (VCT) level would drop due to increased charging flow rate. When a VCT low level setpoint was reached, automatic makeup would be initiated. A level sensor is provided on the VCT having both continuous indication and alarm in the MCR. In addition to monitoring the inventory control operations, an RCS inventory balance is performed periodically during steady state operation in accordance with the technical specifications.

If the leakage detection methods described above indicate that the ECCS check valves have excessive leakage, the permanent test lines provided in the system design could be used to determine the amount and identify the location of the leakage. The technical specifications provide actions for reactor shutdown and repair of the check valves should allowable leakage limits be exceeded.

5.2.8 Inservice Inspection Program

The TVA ASME Section XI Inservice Inspection Programs for Sequoyah Nuclear Plant outline requirements for performing the inservice examinations of the ASME Code Class 1, 2, and 3 (Equivalent) components (and their supports) containing water, steam, or radioactive material (other than radioactive waste management systems) and ASME Code Class MC and CC (Equivalent) components. The programs have been organized to fulfill inservice examination requirements of applicable QA program documents and to comply as practical with the requirements of Section XI of the ASME Boiler and Pressure Vessel Code except where specific relief has been granted by the NRC. In addition, this program implements applicable portions of the Sequoyah Nuclear Plant technical specifications.

5.2.8.1 Provisions for Access to Reactor Coolant Pressure Boundary

The reactor coolant pressure boundary is designed to the extent practical for provisions for access for examinations as required by ASME Section XI. Any limitations of examinations will be handled in accordance with the Inservice Inspection Program, ASME Section XI, and 10CFR50-55a.

Consideration has been given to the inspectability of the Reactor Coolant System in the design of components, in the equipment layout, and in the support structure to permit access for the purpose of inspection. Access for inspection is defined as access for examination by direct or remote means and/or by contacting vessel surfaces during nuclear unit shutdown.

Reactor Vessel

Access for inspection of the reactor vessel is as follows:

1. The vessel flange area, closure head, and outlet nozzles can be examined during normal refueling operations. All reactor internal components can be removed to allow examination of the reactor internal surfaces and welds to the extent practical.

2. The closure head is stored dry during refueling to facilitate direct visual, surface, and volumetric examinations. Typically, reactor vessel studs, nuts, and washers are removed to dry storage during refueling; and are available for direct visual, surface, and volumetric examinations as applicable.

3. Inner surfaces of the vessel flange-to-upper-shell-weld (1); shell welds (3); lower-shell-to-bottom-head-weld (1); bottom-head-spherical-ring-meridional-welds (6); bottom-head-dollar-plate-weld (1); nozzle-to-shell-welds (8); and the nozzle inner radius area (8), are examined by remote means from the vessel inside surface. Only the outlet nozzles are accessible during normal refueling. The lower internals (core barrel) must be removed to access the other reactor vessel welds and vessel interior surfaces for remote examination.

4. External surfaces of the vessel nozzle-to-piping welds can be examined following removal of access covers and insulation.

Pressurizer

The external surface will be accessible for surface and volumetric examination to the extent practical. Manways are provided to allow access for internal examination.

Steam Generator

The external surfaces of the steam generator are accessible for surface and/or volumetric examination to the extent practical. The primary and secondary sides of the steam generator can be examined internally by direct or remote visual means by removing manway covers. The manway covers on the lower head also allow access for the volumetric examination of the tubing.

Reactor Coolant Pumps

The external surfaces of the pump casings are accessible for examination. The internal surface of the pump is available for examination by removing the pump internals.

Piping

The reactor coolant piping, fittings, and attachments to the piping external to the primary shield will be accessible for external surface and volumetric examination to the extent practical.

Design and Construction Phase

During the design and construction phase, consideration was given to provide access as practical to equipment to be examined as listed below:

1. 100 percent of reactor vessel welds and surface (either from the inside or outside, or a combination of both).

2. Reactor vessel internals.

3. Welds on other Class A vessels.

4. Reactor coolant piping welds.

5. Interior surfaces of other Class A vessels.

6. Reactor coolant pump casings.

7. External coolant pump casings.

8. Integrally welded supports.

9. Mechanical connection supports.

10. Control rod drive penetrations.

5.2.8.2 Equipment for Inservice Inspection

TVA will use remote ultrasonic scanning equipment for the examination of reactor vessel nozzles and welds for both the preservice and inservice inspections.

The ultrasonic scanners shall be indexed to ensure position reproducibility for future examinations.

5.2.8.3 Recording and Comparing Data

5.2.8.3.1 Remote Automated Reactor Vessel Inspection Equipment

Sequoyah will use an electronic recording system to record the ultrasonic data.

5.2.8.3.2 Manual or Automated Inspections

The manual or automated scanning technique may be used to examine the welds in the reactor vessel closure head, steam generator primary heads, pressurizer, and piping. All reportable indications are mapped giving necessary parameters for locating and comparing future examination results.

5.2.8.4 Reactor Vessel Acceptance Standards

Acceptance of the reactor vessel for service shall follow the guidelines set forth in IWA-3000 of Section XI of the ASME Code.

5.2.8.5 NRC Order for Augmented Reactor Pressure Vessel (RPV) Head Inspections

NRC's Order (References 29 and 35) has been withdrawn as of December 17, 2008, when TVA ASME Section XI Inservice Inspection Program for Sequoyah Nuclear Plant was revised to incorporate the examination requirements from ASME Code Case N-729-1.

These inspections are implemented and controlled at SQN by various site procedures. In those cases when it is determined either before or during an inspection of a specific nozzle in which the required coverage cannot be obtained (e.g., visual inspection criteria, or NDE coverage, etc.), TVA will submit a relief request in accordance with 10CFR50.55(a)(3), as prescribed in the Order.

5.2.9 Borated Water Corrosion (BWC) Program Description

NRC Generic Letter (GL) 88-05, "Boric Acid Corrosion of Carbon Steel Reactor Pressure Boundary Components in PWR Plants," indicates that boric acid leakage potentially affecting the integrity of reactor coolant pressure (RCP) boundary should be procedurally controlled to ensure continued compliance with the licensing basis. TVA letters to NRC dated June 1, 1988 and July 29, 1988 provided TVA's commitment to this program. This program is implemented at SQN by various site procedures.

LOAD COMBINATIONS AND OPERATING CONDITIONS

	Load Combination	Operating Conditions
1.	Normal (deadweight, thermal and pressure)	Normal Condition
2.	Normal and 1/2 safe shutdown earthquake	Upset Condition
3.	Normal and safe shutdown earthquake	Faulted Condition
4.	Normal and design basis accident	Faulted Condition
5.	Normal and safe shutdown earthquake and design basis accident	Faulted Condition

TABLE 5.2.1-1 (Sheet 1)

SUMMARY OF REACTOR COOLANT SYSTEM CYCLIC OR TRANSIENT LIMITS

CONDITION	CYCLIC OR TRANSIENT LIMIT	DESIGN CYCLE OR TRANSIENT
Normal	200 heatup cycles at $\leq$ 100°F/hr and 200 cooldown cycles at < 100°F/hr per unit	Heatup cycle - T_{avg} from $\leq$ 200°F to $\geq$ 550°F. Cooldown cycle -T_{avg} from ≥ 550°F to ≤ 200°F
	200 pressurizer cooldown cycles at < 200°F/hr per unit	Pressurizer cooldown cycle temperatures from > 650°F to < 200°F.
	13,900 loading and unloading power changes per unit at 5% per minute, for RSGs (See Note 1)	> 15% of Rated Thermal Power to 100% of Rated Thermal Power
	2000 step load increases and decreases of 10% per unit (See Note 2)	> 15% of Rated Thermal Power to 100% of Rated Thermal Power
	200 large step load decreases of 95%	From 100% of Rated Thermal Power
	3.0E6 of steady state fluctuations for RSGs (See Note 3)	RCS temperature changes of ±6°F per minute at T_{avg}, (T_{avg} + 3°F)
Upset	80 loss of load cycles, without immediate turbine or reactor trip	> 15% of RATED THERMAL POWER to 0% of RATED THERMAL POWER
	40 cycles of loss of offsite A.C. electrical power (blackout with natural circulation in the RCS)	Loss of offsite A.C. electrical power source supplying the onsite ESF Electrical System
	80 cycles of loss of flow in one reactor coolant loop	Loss of only one reactor coolant pump at 100% of Rated Thermal Power
	400 reactor trip cycles	100% to 0% of Rated Thermal Power.
	10 pressurizer auxiliary spray actuation cycles	Spray water temperature differential > 320°F and < 560°F
	200 cycles of 1/2 Safe Shutdown Earthquake	Reactor Vessel
	50 cycles of 1/2 Safe Shutdown Earthquake	Steam Generator and Pressurizer
	10 low temperature water-solid overpressure events**	Water-solid system actuation

Faulted Conditions*	Occurrences
Main reactor coolant pipe break	1
Steam pipe break	1
Steam generator tube rupture	Included in 400 reactor trip cycles from full power
Safe Shutdown Earthquake	1

Test Conditions	Occurrences
Turbine roll test	10
Hydrostatic test conditions	
a. Primary side pressurized to 3110 psig	10
b. Secondary side pressurized to 1360 psig	10
c. Primary side leak test pressurized to 2485 psig	200

TABLE 5.2.1-1 (Sheet 2)

SUMMARY OF REACTOR COOLANT SYSTEM CYCLIC OR TRANSIENT LIMITS

NOTES

* In accordance with ASME Boiler and Pressure Vessel Code, Section III, faulted conditions are not included in fatigue evaluations.

** Low Temperature Over Pressure events are not specified in the Upset Conditions for the Unit 1 RSGs. Refer to design specification S1RSG-CD-C201, Revision 2 (Reference 38) for details.

1. Since a limit of 13,900 cycles for loading and for unloading is permitted by fatigue calculations, the allowed normal loading and unloading transient cycles are NOT expected to be challenged during the extended life of the plant. Therefore, this transient is NOT recorded by monitoring instructions.
2. Over a 60-year plant life, 2,000 step load increases/decreases equates to more than one (1) allowed per week. Due to the stability of the TVA grid, step load changes of +/-10 percent seldom occur. Therefore, this transient will NOT be recorded by monitoring instructions.
3. This cyclic limit equates to approximately 6 cycles per hour for 60 years. Since 6 cycles per hour bounds SQN normal operation for 60 years of plant life, this transient will NOT be recorded by monitoring instructions.

TABLE 5.2.1-22

*There is a possibility for these valves to be open when the accident occurs.

TABLE 5.2-2

LOADING CONDITIONS AND STRESS LIMITS: CLASS A COMPONENTS

LOADING CONDITIONS	STRESS INTENSITY LIMITS	NOTE
1. Normal Condition	(a) $P_m \leq S_m$	
	(b) $P_L \leq 1.5\ S_m$	
	(c) P_m (or P_L) + $P_B \leq 1.5S_m$	1
	(d) P_m (or P_L) + P_B + Q $\leq 3.0S_m$	2
2. Upset Condition	(a) $P_m \leq S_m$	
	(b) $P_L \leq 1.5S_m$	
	(c) P_m (or P_L) + $P_B \leq 1.5S_m$	1
	(d) P_m (or P_L) + P_B + Q $\leq 3.0S_m$	2
3. Faulted Condition	(i) $P_m \leq 1.2S_m$ or S_y, whichever is larger $P_L \leq 1.5\ (1.2)\ S_m$ or $1.5S_y$, whichever is larger, and (ii) Faulted condition limits in Table 5.2-3.	3

where:

P_m	=	primary general membrane stress intensity
P_L	=	primary local membrane stress intensity
P_B	=	primary bending stress intensity
Q	=	secondary stress intensity
S_m	=	stress intensity value for ASME B&PV Code, Section III, Nuclear Vessels, 1968
S_y	=	minimum specified material yield (ASME B&PV Code, Section III, 1968, Table N-421 or equivalent)

Note 1: The limits on local membrane stress intensity ($P_L \leq 1.5S_m$) and primary membrane plus primary bending stress intensity (P_M (or P_L) + $P_B \leq 1.5S_m$) need not be satisfied at the specific location if it can be shown by means of limit analysis or by tests that the specified loadings do not exceed 2/3 or the lower bound collapse load per paragraph N-417.6(b) of the ASME B&PV Code, Section III, Nuclear Vessels, 1968.

Note 2: In lieu of satisfying the specific requirements for the local membrane ($P_L \leq 1.5S_m$) or the primary plus secondary stress intensity (P_M (or P_L) + P_B + Q $\leq 3S_m$) at a specific location, the structural action may be calculated on a plastic basis and the design will be considered to be acceptable if shakedown occurs, as opposed to continuing deformation, and if the deformations prior to shakedown do not exceed specified limits, as per paragraph N-417.6(a)(2) of the ASME B&PV Code, Section III, Nuclear Vessels, 1968.

Note 3: The limits on local membrane stress intensity ($P_L \leq 1.8S_m$ or $1.5S_y$) and primary membrane plus primary bending stress intensity (P_M (or P_L) + $P_B \leq 1.8\ S_m$ or $1.5\ S_y$) need not be satisfied at a specific location if it can be shown by means of limit analysis or by tests that the specified loadings do not exceed 120 percent of 2/3 of the lower bound collapse load as per paragraph N-417.10(c) of the ASME B&PV Code, Section III, Nuclear Vessels, 1968, Summer 1968 Addenda.

<tr><td>Elastic</td></tr>
</table>

TABLE 5.2-3 (Sheet 2)

Notes for Table 5.2-3

(1) L_1 = Lower bound limit loads with an assumed yield point equal to $2.3S_m$.

(2) These limits are based on a bending shape factor of 1.5 for simple bending cases with different shape factors, the limits will be changed proportionally.

(3) When elastic system analysis is performed the effect of component deformation on the dynamic system response should be checked.

(4) L_T = The limits established for the analysis need not be satisfied if it can be shown from the test of a prototype or model that the specified loads (dynamic or static equivalent) do not exceed 80 percent of L_T, where L_T is the ultimate load or load combination used in the test. In using this method, account shall be taken of the size effect and dimensional tolerances (similitude relationships) which may exist between the actual component and the tested models to assure that the loads obtained from the test are a conservative representation of the load carrying capability of the actual component under postulated loading for faulted conditions.

S_y = Yield stress at temperature
S_u = ultimate stress from engineering stress-strain curve at temperature
S_{ut} = ultimate stress from true stress-strain curve at temperature
S_m = Stress intensity from ASME Section III at temperature.

Stems	SA479 Type 410 or Type 304
Closure Bolting & Nuts	SA453 Gr 660 and SA193 Gr B6

Auxiliary Heat Exchangers

Heads	SA182 Gr F304 or SA240 Type 304 or 316
Flanges	SA182 Gr F304 or F316
Flange Necks	SA182 Gr F304 or SA240 Type 316 or SA312 Type 304 Seamless
Tubes	SA213 TP304
Tube Sheets	SA240 Type 304 or 316 or SA182 Gr F304 or SA515 Gr 70 with stainless steel weld Metal Analysis A-7 cladding
Shells	SA351 Gr CF8
Pipe	SA312 Type 304 Seamless

* 1,2-FCV-68-332 and 1,2-FCV-68-333 stem material is A638 GR 660 Type 2

TABLE 5.2.3-2 (Sheet 2)

REACTOR COOLANT PRESSURE BOUNDARY MATERIALS
AUXILIARY COMPONENTS

Auxiliary Pressure Vessels Tanks, filters, etc.	
Shells & Heads	SA240 Type 304 or SA264 Type 304 Clad to SA516 Gr 70 or SA516 G70 with Stainless Steel Weld Metal Analysis A-7 Cladding
Flanges & Nozzles	SA182 Gr F304 and SA105 or SA350 Gr LF2 with Stainless Steel Weld Metal Analysis A-7 Cladding
Piping	SA312 TP304 or TP316 Seamless
Pipe Fittings	SA403 WP304 Seamless
Closure Bolting & Nuts	SA193 Gr B7 or B8 and SA194 Gr 2H (filter bolting materials coated with maganese phosphate)
Auxiliary Pumps	
Pump Casings Heads	SA351 Gr CF8 or CF8M, SA182 Gr F304 or F316
Flanges & Nozzles	SA182 Gr F304 or F316, SA403 Gr WP316L Seamless
Piping	SA312 TP304 or TP316 Seamless
Stuffing or Packing Box Cover	SA351 Gr CF8 or CF8M, SA240 TP304 or TP316
Pipe Fittings	SA403 Gr WP316L Seamless
Closure Bolting & Nuts	SA193 Gr B6, B7 or B8M and SA194 Gr 2H or Gr 8M

TABLE 5.2.3-3

REACTOR COOLANT WATER CHEMISTRY SPECIFICATION

Solution pH	Determined by the concentration of boric acid and alkali present. Expected values range between 4.2 (high boric acid concentration) to 10.5 (low boric acid concentration) at 25°C; values will be 5.0 or greater at normal operating temperatures.
Oxygen, ppm, maximum	Oxygen concentration of the reactor coolant is maintained below 0.1 ppm steady state or 1.0 ppm transient for plant operation above 250°F. Hydrazine may be used to chemically scavenge oxygen during heatup.
Chloride, ppm, maximum	0.15 steady state, 1.5 transient
Fluoride, ppm, maximum	0.15 steady state, 1.5 transient
Hydrogen, cc(STP)/kg H_2O	
Prior to exceeding one percent reactor power	≥ 15
Normal operation	25 - 50
Total Suspended Solids, ppm, maximum	0.1
pH Control Agent (Li^7OH), ppm Li^7	Variable depending on Boron concentration and reactor mode.
Boric Acid, ppm as B	Variable from 0 to approximately 2500
Zinc, ppb (Normal power operation)	2 - 8 ppb

TABLE 5.2-4

LOADING CONDITIONS AND STRESS LIMITS: PRESSURE PIPING

	LOADING CONDITIONS		STRESS LIMITS
1.	Normal Condition	(a)	$P \leq S$
2.	Upset Condition	(a)	$P \leq 1.2S$
3.	Faulted Condition		$P \leq 1.2\ (2.0)\ S$

where:

P = piping stress calculated per USAS B31.1 1967 Code for Power Piping.

S = allowable stress from USAS B31.1 Code 1967 and USAS B31.7 Code 1969 for Power Piping.

Notes
(1) A-B and T-P designations refer to opposite ends of a bar or tube.
(2) Studs machined from heat Y6866 will only be used on Unit No. 2.
(3) Lateral expansion results were obtained for information only, value reported represents measurement made on only one charpy specimen from each set of 3 charpy tests.
(4) Hardness measurement was not performed, value reported was converted per ASME specification SA-370, Paragraph 18 and Table 111 of Paragraph 19.

5.3 THERMAL HYDRAULIC SYSTEM DESIGN

5.3.1 Analytical Methods and Data

The nuclear, thermal, and hydraulic design bases of the Reactor Coolant System (RCS) are described in Sections 4.3 and 4.4 in terms of core heat generation rates, DNBR, analytical models, peaking factors, and other relevant aspects of the reactor.

5.3.2 Operating Restrictions on Pumps

The operating procedures state that the pressure differential across the RCP number 1 seal must be at least 220 psid before operating the reactor coolant pump. A minimum flow of 0.2 gpm (except for short periods of time after seal maintenance, provided some flow can be verified) must be present through the number 1 seal and a minimum backpressure of 15 psi on the number 1 seal.

The Advanced W17 HTP fuel design includes a hold down spring system to maintain the fuel assembly in a seated condition during all Condition I and II events, except for the 120% pump overspeed event. In calculating assembly lift forces it is assumed that no more than three reactor coolant pumps will be in operation at RCS cold leg temperatures less than 300º F plus instrument error. This assumption will be applied to full cores of Advanced W17 HTP assemblies after the fuel transition and also to mixed cores of Advanced W17 HTP and Mark-BW assemblies during the transition.

5.3.3 (BWR)

5.3.4 Temperature-Power Operating Map

A typical RCS Temperature-Percent Power map with nominal values is shown in Figure 5.3.4-1. Note that the exact values are cycle dependent. Refer to the current cycle reload analysis.

The effects of reduced core flow due to inoperative pumps or natural circulation are discussed in Sections 4.4.3.3, 5.5, and 15.3.6.

5.3.5 Load Following Characteristics

The reactor coolant pumps utilize constant speed drives, and the reactor power is controlled to maintain average coolant temperature at a value which is a linear function of load.

5.3.6 Transient Effects

Transient effects are evaluated in the following sections: Complete Loss of Forced Reactor Coolant Flow (15.3.4), Partial Loss of Forced Reactor Coolant Flow (15.2.5), Startup of an Inactive Loop (15.2.6), Loss of Load (15.2.7), Loss of Normal Feedwater (15.2.8), Loss of Offsite Power (15.2.9), Accidental Depressurization of the Reactor Coolant System (15.2.12).

5.3.7 Thermal and Hydraulic Characteristics Summary Table

The thermal and hydraulic characteristics are given in Tables 4.4.2-1and 4.4.2-2.

5.4 REACTOR VESSEL AND APPURTENANCES

Section 5.4 has been divided into four principal subsections via., design bases, description, evaluation and test and inspections for the reactor vessel and its appurtenances consistent with the requirements of the introductory paragraph of 5.4 of the Standard Format and Content Guide Revision 1. The following specific information required by the guide is cross referenced below.

	Guide Reference	FSAR Section
5.4.1	Protection of Closure Studs	5.4.2.2
5.4.2	Special Processes for Fabrication and Inspection	5.4.2.1, 5.4.4
5.4.3	Features for Improved Reliability	5.4.1, 5.4.2
5.4.4	Quality Assurance Surveillance	5.4.2, 5.4.4
5.4.5	Materials and Inspections	5.2.3, 5.4.4
5.4.6	Reactor Vessel Design Data	Table 5.4.2-1
5.4.7	Reactor Vessel Schematic (BWR)	Not Applicable

5.4.1 Design Bases

5.4.1.1 Codes and Specifications

The reactor vessel and closure head are Safety Class A. Design and fabrication of the vessel were carried out in strict accordance with ASME Section III, Class A. Material specifications are in accordance with the ASME code requirements and are given in Section 5.2.

The completed closure head was modified at the plant site to include the addition of four UHI head adapters. These modifications were treated as alterations to the head and were done in accordance with National Board requirements. The National Board requirements are that the alterations be performed in accordance with the applicable ASME Code rules and data forms must be filed with the National Board by the fabricator making the alterations.

The Upper Head Injection (UHI) head adapters were designed and manufactured in accordance with the rules of Section III of the ASME Code. Refer to subsection 5.4.2 for UHI modification description.

5.4.1.2 Design Transients

Cyclic loads are introduced by normal power changes, reactor trip, startup and shutdown operations. These design base cycles are selected for fatigue evaluation and constitute a conservative design envelope for the projected plant life. Vessel analyses result in a usage factor that is less than 1.0.

With regard to the thermal and pressure transients involved in the Loss Of Coolant Accident (LOCA), the reactor vessel and closure head are analyzed to confirm that the delivery of cold emergency core cooling water to the vessel following a LOCA does not cause a loss of integrity of the vessel and head.

The design specifications require analysis to prove that the vessel is in compliance with the fatigue limits of Section III of the ASME Boiler and Pressure Vessel code. The loadings and transients specified for the analysis are based on the most severe conditions expected during service.

A control rod housing failure does not cause propagation of failure to adjacent housings or to any other part of the Reactor Coolant System (RCS) boundary.

The UHI head adaptors, which are still in place on the reactor vessel head, are analyzed and compared to the corresponding ASME code stress and fatigue limits to assure that the adaptor design is acceptable. Refer to subsection 5.4.2 for UHI modification description.

Design transients are discussed in detail in Section 5.2.

5.4.1.3 Protection Against Non-Ductile Failure

Protection against non-ductile failure is discussed in Section 5.2.

5.4.2 Description

The reactor vessel manufactured by DeRotterdame Drodgdak Mattschappu N.V. (The Rotterdam Dockyard Company) is cylindrical with a welded hemispherical bottom head and a removable, bolted flanged and gasketed, hemispherical upper head. The reactor vessel closure region is sealed by two hollow metallic O-rings. Seal leakage is detected by means of two leakoff connections, one between the inner and outer ring and one outside the outer O-ring. The vessel contains the core, core support structure, control rods, and other parts directly associated with the core. The reactor vessel closure head will contain the control rod drive mechanism (CRDM) and UHI head adaptors (UHI was removed Unit 1 Cycle 4 and Unit 2 Cycle 4).

The bottom head of the vessel contains penetrations for connection and entry of the nuclear incore instrumentation. Each penetration consists of a tubular member made of either an Inconel or an Inconel-stainless steel composite tube. Each tube is attached to the inside of the bottom head by a partial penetration weld.

Internal surfaces of the vessel which are in contact with primary coolant are weld overlay with 0.125 inch minimum of stainless steel or Inconel. The exterior of the reactor vessel is insulated with canned stainless steel reflective sheets. The insulation is three inches thick and contoured to enclose the top, sides and bottom of the vessel. Provision for removability of the insulation is made for the portions covering the closure head and bottom head to provide access for Inservice Inspection.

5.4.2.1 Fabrication Processes

1. The use of severely sensitized stainless steel as a pressure boundary material has been prohibited and has been eliminated by either a select choice of material or by programming the method of assembly.

This restriction on the use of sensitized stainless steel has been established to provide the primary system with preferential materials suitable for:

   a. Improved resistance to contaminants during shop fabrication, shipment, construction and operation;

   b. Application in critical areas.

2. Minimum preheat requirements have been established for pressure boundary welds using low alloy weld material. Special preheat requirements have been added for stainless steel cladding of low stress areas. Preheat must be maintained until post weld heat treatment, except for overlay cladding where it may be lowered to ambient temperature under restrictive conditions. The purpose of placing limitations on preheat requirements is the addition of precautionary measures to decrease the probabilities of weld cracking by decreasing temperature gradients, lower susceptibility to brittle transformation, prevention of hydrogen embrittlement and reduction in peak hardness.

3. The threads of the control rod drive mechanism head adaptors and UHI adaptors as well as the surfaces of the guide studs are chrome plated to prevent possible galling of the mated parts.

4. At all locations in the reactor vessel where stainless steel and Inconel are joined, the final joining beads are Inconel weld metal in order to prevent cracking.

5. The location of full penetration weld seams in the upper closure head and bottom head are restricted to areas that permit accessibility during inservice inspection.

6. The modifications to the closure head for the UHI adaptors were performed in accordance with the requirements of Paragraph NB-4643, "Weld Repairs to Cladding After Final Postweld Heat Treatment," of the Summer 1972 Addenda to Section III of the ASME Boiler and Pressure Vessel Code. The partial penetration weld details were in accordance with Paragraph NB-3352, 4(d) and Figure NB-3352, 4-4(c) of the 1971 Edition ASME code. Figure 5.4.2-1 shows the weld groove geometry buttering configuration, and welding detail for the UHI adaptor attachment weld to the closure head. This weld detail was established to comply with the requirements of the three ASME code paragraphs listed above. The buttering will be a minimum of 1/8 inch thick and will consist of two layers using the half bead technique. The welding detail in Figure 5.4.2-1 shows the possible removal of a portion of the adaptor wall thickness for better welder accessibility to the narrow weld groove. The tube wall thickness is greatly oversized for rigidity reasons and this undercut will be restricted so it does not impinge on the required pressure thickness of the tube.

Principal design parameters of the reactor vessel are given in Table 5.4.2-1.

5.4.2.2 Protection of Closure Studs

Westinghouse refueling procedures typically require the studs, nuts and washers to be removed from the reactor closure and be placed in storage racks during preparations for refueling. The storage racks are then removed from the refueling cavity and stored at convenient locations on the containment operating deck prior to reactor closure removal and refueling cavity flooding. The stud holes in the reactor flange are sealed with special plugs before removing the reactor closure, thus preventing leakage of the borated refueling water into the stud holes. These procedures recognize that studs occasionally become stuck, at which time additional actions are required to protect the stud. In the event a closure stud cannot be removed prior to cavity flooding, the appropriate administrative measures shall be implemented to cover and seal the stud. Therefore, the reactor closure studs are never exposed to borated refueling cavity water. However, if it is determined that the closure stud is damaged beyond repair prior to removal, protective measures will only be required to preclude to borated refueling water from contacting the stud hole threads within the reactor vessel. Depending on the stud location, consideration must be made for the control of heavy loads and safe load paths (NUREG 0612).

5.4.3 Evaluation

5.4.3.1 Normal

Evaluation of normal stresses is discussed in Paragraph 5.2.1.4.
5.4.3.2 Fatigue Analysis Based on Transient Stresses

Fatigue analysis on transient stresses is discussed in Paragraph 5.2.1.4.

5.4.3.3 Thermal Stresses Due to Gamma Heating

The stresses due to gamma heating in the vessel wall are calculated by the vessel vendor and combined with the other design stresses. They are compared with the code allowable limit for mechanical plus thermal stress intensities to verify that they are acceptable. The gamma stresses are low and thus have a negligible effect on the stress intensity in the vessel.

5.4.3.4 Thermal Stresses Due to Loss of Coolant Accident (LOCA)

In the event of a large LOCA, the Reactor Coolant System rapidly depressurizes, and the loss of coolant may empty the reactor vessel. If the reactor is at normal operating conditions before the accident, the reactor vessel and closure head temperatures are approximately 550°F. If the plant has been in operation for some time, part of the reactor vessel is irradiated. At an early stage in the depressurization transient, the Emergency Core Cooling System (ECCS) rapidly injects cold coolant into the reactor vessel. This results in thermal stress in the vessel wall and closure head. To evaluate the effect of the stress, three possible modes of failure are considered in the vessel; ductile yielding, brittle fracture and fatigue.

Ductile Mode - The failure criterion used for this evaluation is that there shall be no gross yielding across the vessel wall using the material yield stress specified in Section III of the ASME Nuclear Power Plant Components Code. The combined pressure and thermal stresses during injection through the vessel thickness as a function of time have been calculated and compared to the material yield stress at the times during the safety injection transient. The results of the analyses showed that local yielding may occur only in approximately the inner 18 percent of the base metal and in the vessel cladding, complying with the above criterion.

Brittle Mode - The beltline region of the reactor vessel was chosen for analysis because the material adjacent to the centerline of the reactor core is subjected to the highest irradiation level and thus has the lowest end-of-life fracture resistance in the vessel. This analysis is performed assuming the variation effects of water temperature, heat transfer coefficients and fracture toughness as a function of time, temperature, and irradiation. Both a local crack effect and a continuous crack effect have been considered with the latter requiring the use of a rigorous finite element axisymmetric code. It is concluded from the analysis that if the NSSS sustains a large LOCA the integrity of the reactor pressure vessel would be maintained and the plant could be shutdown in an orderly manner.

Fatigue Mode - From the standpoint of fatigue, the region of the in-core instrumentation tube attachment welds to the vessel bottom head is the most sensitive region of the reactor vessel during a loss of coolant accident. This location will have the highest usage factor. The failure criterion used for the failure analysis is that of Section III of the ASME Boiler and Pressure Vessel Code. In this method the piece is assumed to fail once the combined usage factor at the most critical location for all transients applied to the vessel exceeds the core allowable usage factor of one. As a worst case

assumption, the incore instrument tubes and attachment penetration welds are considered to be quenched to the cooling water temperature while the vessel wall maintains its initial temperature before the start of the transient. The maximum possible pressure stress during the transient is also taken into account. This method of analysis is quite conservative and yields calculated stresses greater than would actually be experienced. The resulting usage factor for the instrument tube welds considering all the operating transients and including the safety injection transient occurring at the end of the plant life is below 0.2 which compares favorably with the code allowable usage factor of 1.0.

Since the closure head receives insignificant irradiation, it is evaluated in a ductile manner for LOCA. This analysis shows the closure head meets the applicable ASME code allowable limits.

It is concluded from the results of these analyses that the delivery of cold emergency core cooling water to the reactor vessel following a loss of coolant accident does not cause any loss of integrity of the vessel.

5.4.3.5 Stresses in UHI Adaptors

The UHI adaptor weld stress for normal and upset conditions, i.e., those anticipated during the course of plant life, was carried out in conformance with NB3337.3 of section III of the ASME Code. The weld stresses are evaluated for normal, upset, and faulted conditions. Emergency conditions were not evaluated since these transients are always less severe than those imposed by faulted conditions and do not constitute the limiting case for operability requirements as do upset conditions. A detailed stress analysis of the adaptors and head modification was performed by the reactor vessel supplier. This analysis was added as an addendum to the original reactor vessel stress report performed by the vessel vendor.

5.4.3.6 Heatup and Cooldown

Heatup and cooldown requirements for the reactor vessel material are discussed in Section 5.2.4.3.

5.4.3.7 Reactor Vessel Material Surveillance Program Requirements

In the surveillance programs, the evaluation of the radiation damage is based on pre-irradiation testing of Charpy V-notch and tensile specimens and post-irradiation testing of Charpy V-notch, tensile, and wedge opening loading (WOL) fracture mechanics test specimens. These programs are directed toward evaluation of the effect of radiation on the fracture toughness of reactor vessel steels based on the transition temperature approach and the fracture mechanics approach, and is in accordance with ASTM E185, "Recommended Practice for Surveillance Tests for Nuclear Reactor Vessels." ASTM E185-73 is the basis for the original surveillance program; however, removal and evaluation of surveillance capsules are in accordance with ASTM E185-82.

The reactor vessel surveillance program uses eight specimen capsules. The capsules are located in guide baskets welded to the outside of the thermal shield as shown in Figure 5.4.3-1 about 3 inches from the vessel directly opposite the center portion of the core. Sketches of an elevation and plan view showing the location and dimensional spacing of the capsules with relation to the core, thermal shield and vessel and weld seams are shown in Figures 5.4.3-2 and 5.4.3-3 respectively. The capsules can be removed when the vessel head is removed, and can be replaced when the internals are removed. The capsules contain reactor vessel steel specimens oriented in the major working direction and normal to the major working direction from the limiting SA-508 Class 2 shell forging located in the core region of the reactor and associated weld metal and heat affected zone metal. (As part of the

surveillance program, a report of the residual elements in weight percent to the nearest 0.01 percent was made for surveillance material base metal and as deposited weld metal. [8]) The eight capsules contain approximately 32 tensile specimens, 352 Charpy V-notch specimens (which include weld metal and heat affected zone material) and 32 WOL specimens. Dosimeters including Ni, Cu, Fe, Co-Al, Cd shielded Co-Al, Cd shielded Np-237 and Cd shielded U-238 are placed in filler blocks drilled to contain the dosimeters. The dosimeters permit evaluation of the flux seen by the specimens and vessel wall. In addition, thermal monitors made of low melting alloys are included to monitor temperature of the specimens. The specimens are enclosed in a tight fitting stainless steel sheath to prevent corrosion and ensure good thermal conductivity. The complete capsule is helium leak tested. Vessel material sufficient for at least 2 capsules will be kept in storage should the need arise for additional replacement test capsules in the program.

Four capsules (S, V, W, and X) contain the following specimens:

Material	No. of Charpys	No. of Tensiles	No. of WOLS
Limiting Forging*	8	-	-
Limiting Forging**	12	2	4
Weld Metal	12	2	-
Heat Affected Zone Metal	12	-	-

Four additional capsules (T, U, Y, and Z) contain the following specimens:

Material	No. of Charpys	No. of Tensiles	No. of WOLS
Limiting Forging*	8	-	-
Limiting Forging**	12	2	-
Weld Metal	12	2	4
Heat Affected Zone Metal	12	-	-

* Specimens oriented in the major working direction (Tangential).
** Specimens oriented normal to the major working direction (Axial).

The following dosimeters and thermal monitors are included in each capsule:

Dosimeters

Iron
Nickel
Copper
Cobalt-Aluminum (0.15% Co)
Cobalt-Aluminum (Cadmium shielded)
U-238 (Cadmium shielded)
Np 237 (Cadmium shielded)

Thermal Monitors

97.5% Pb, 2.5% Ag (approximately 579°F Melting Point)
97.5% Pb, 1.75% Ag, 0.75% Sn (approximately 590°F Melting Point)

The fast neutron exposure of the specimens occurs at a faster rate than that experienced by the vessel wall with the specimens being located between the core and the vessel and with the sequenced removal and reinsertion of capsules as noted in the tentative removal schedule. Since these specimens experience accelerated exposure and are actual samples from the materials used in the vessel, the NDTT measurements are representative of the vessel at a later time in life. Data from fracture toughness samples (WOL) are expected to provide additional information for use in determining allowable stresses for irradiated material.

The eight reactor vessel surveillance capsules were located at 4° and 40° as shown in Figure 5.4.3-3. Unit 1 original Capsules at Locations T, U, X, & Y were removed in accordance with the surveillance capsule withdrawal schedule. Unit 1 Specimens S & W were relocated to higher fluence locations, but were subsequently damaged during Unit 1 Cycle 20 operation and no longer exist. Capsule V was moved to Location U (140°) during the Unit 1 Cycle 22 refueling outage. Unit 2 original Capsules at Locations T, U, X & Y were removed in accordance with the surveillance capsule withdrawal schedule. Unit 2 Specimens S & W were moved to Locations T & U; however, the Specimen S was removed following Unit 2 Cycle 20 operation due to seating concerns of the as-found capsule. Reference 6 contains more details on the reactor Vessel Surveillance Program, including withdrawal schedules, specimen locations, and fluence values.

Correlations between the calculations and the measurements on the irradiated samples in the capsules, assuming the same neutron spectrum at the samples and the vessel inner wall, are described in 5.4.3.7.1 and have indicated good agreement. The calculation of the integrated flux at the vessel wall is conservative.

The anticipated degree to which the specimens will perturb the fast neutron flux and energy distribution will be considered in the evaluation of the surveillance specimen data. Verification and possible readjustment of the calculated exposure will be made by use of data on all capsules withdrawn.

Each specimen capsule upon removal after radiation exposure will be transferred to a post-irradiation test facility for disassembly of the capsule and testing of all specimens.

With the withdrawal of Capsule Y, Sequoyah Nuclear Plant (SQN) Units 1 and 2 fulfilled the surveillance capsule withdrawal recommendations contained in ASTM E185-73 for their 40 year end-of-life (EOL) (32 EFPY). To support the 20 year life extension for SQN Units 1 and 2, the capsules designated in Reference 6 have been relocated to higher lead factor locations.

Relocation of Unit 1 Capsule V and Unit 2 Capsule W places them at locations of higher fluence, to support future capsule withdrawal for irradiation assessments. One of these relocated capsules in each unit should be subsequently withdrawn from the reactor vessel and tested at the time when the accumulated neutron fluence of the capsule corresponds to not less than once or greater than twice the peak 60 year vessel fluence. Reference 6 provides the bases for capsule relocation and the withdrawal times recommended in support of plant life extension for both units.

For SQN Unit 1, the potential capsule withdrawal times associated with capsule relocation from the 4° to the 40° and 140° azimuthal location (from Reference 6) are:

Unit 1 Capsule Relocation Time	Capsule Time (EFPY) Corresponding to Vessel Life	
	60 Years of Operation (52 EFPY)	80 Years of Operation (72 EFPY)
EOC21	35.4	41.5
EOC22*	36.4	42.5
EOC23	37.3	43.4

These dates are based on the capsule fluence being equivalent to one times the peak vessel fluence at 60 years (2.66×10^{19} n/cm^2) as well as one times the peak vessel fluence at 80 years (3.56×10^{19} n/cm^2).

For SQN Unit 2, the potential capsule withdrawal times associated with capsule relocation from the 4° to the 40° and 140 °azimuthal location (from Reference 6) are:

Unit 2 Capsule Relocation Time	Capsule Time (EFPY) Corresponding to Vessel Life	
	60 Years of Operation (52 EFPY)	80 Years of Operation (72 EFPY)
EOC18	32.6	39.3
EOC19*	33.7	40.4
EOC20	34.7	41.4

These dates are based on the capsule fluence being equivalent to one times the peak vessel fluence at 60 years (2.57×10^{19} n/cm^2) as well as one times the peak vessel fluence at 80 years (3.52×10^{19} n/cm^2).

*Actual capsule relocation time

5.4.3.7.1 Measurement of Integrated Fast Neutron (E > 1.0 Mev) Flux at the Irradiation Samples

The use of passive neutron sensors such as those included in the internal surveillance capsule dosimetry sets does not yield a direct measure of the energy dependent neutron flux level at the measurement location. Rather, the activation or fission process is a measure of the integrated effect that the time- and energy-dependent neutron flux has on the target material over the course of the irradiation period. An accurate assessment of the average flux level, and hence, time integrated exposure (fluence) experienced by the sensors may be developed from the measurements only if the sensor characteristics and the parameters of the irradiation are well known. In particular, the following variables are of interest:

1) the measured specific activity of each sensor;

2) the physical characteristics of each sensor;

3) the operating history of the reactor;

4) the energy response of each sensor; and

5) the neutron energy spectrum at the sensor location.

In this section the procedures used to determine sensor specific activities, to develop reaction rates for individual sensors from the measured specific activities and the operating history of the reactor, and to derive key fast neutron exposure parameters from the measured reaction rates are described.

5.4.3.7.1.1 Determination of Sensor Reaction Rates

The specific activity of each of the radiometric sensors is determined using established ASTM procedures. Following sample preparation and weighing, the specific activity of each sensor is determined by means of a high purity germanium gamma spectrometer. In the case of the surveillance capsule multiple foil sensor sets, these analyses are performed by direct counting of each of the individual wires; or, as in the case of U-238 and Np-237 fission monitors, by direct counting preceded by dissolution and chemical separation of cesium from the sensor.

The irradiation history of the reactor over its operating lifetime is determined from plant power generation records. In particular, operating data are extracted on a monthly basis from reactor startup to the end of the capsule irradiation period. For the sensor sets utilized in the surveillance capsule irradiations, the half-lives of the product isotopes are long enough that a monthly histogram describing reactor operation has proven to be an adequate representation for use in radioactive decay corrections for the reactions of interest in the exposure evaluations.

Having the measured specific activities, the operating history of the reactor, and the physical characteristics of the sensors, reaction rates referenced to full power operation are determined from the following equation:

$$R = \frac{A}{N_0 F Y \sum_j \frac{P_j}{P_{ref}} C_j \left[1 - e^{-\lambda t_j}\right] e^{-\lambda t_d}}$$

where:

A = measured specific activity provided in terms of disintegrations per second per gram of target material (dps/gm).
R = reaction rate averaged over the irradiation period and referenced to operation at a core power level of P_{ref} expressed in terms of reactions per second per nucleus of target isotope (rps/nucleus).
N_0 = number of target element atoms per gram of sensor.
F = weight fraction of the target isotope in the sensor material.
Y = number of product atoms produced per reaction.
P_j = average core power level during irradiation period j (MW).
P_{ref} = maximum or reference core power level of the reactor (MW).
C_j = calculated ratio of ϕ(E> 1.0 MeV) during irradiation period j to the time weighted average ϕ(E> 1.0 MeV) over the entire irradiation period.
λ = decay constant of the product isotope (sec^{-1}).
t_j = length of irradiation period j (sec).
t_d = decay time following irradiation period j (sec).

and the summation is carried out over the total number of monthly intervals comprising the total irradiation period.

In the above equation, the ratio P_j/P_{ref} accounts for month-by-month variation of power level within a given fuel cycle. The ratio C_j is calculated for each fuel cycle and accounts for the change in sensor reaction rates caused by variations in flux level due to changes in core power spatial distributions from fuel cycle to fuel cycle. Since the neutron flux at the measurement locations within the surveillance capsules is dominated by neutrons produced in the peripheral fuel assemblies, the change in the relative power in these assemblies from fuel cycle to fuel cycle can have a significant impact on the activation of neutron sensors. For a single-cycle irradiation, C_j = 1.0. However, for multiple-cycle irradiations, particularly those employing low leakage fuel management, the additional C_j correction must be utilized in order to provide accurate determinations of the decay corrected reaction rates for the dosimeter sets contained in the surveillance capsules.

5.4.3.7.1.2 Corrections to Reaction Rate Data

Prior to using the measured reaction rates in the least squares adjustment procedure discussed in Section 5.4.3.7.1.3, additional corrections are made to the U-238 measurements to account for the presence of U-235 impurities in the sensors as well as to adjust for the build-in of plutonium isotopes over the course of the irradiation.

In addition to the corrections made for the presence of U-235 in the U-238 fission sensors, corrections are also made to both the U-238 and Np-237 sensor reaction rates to account for gamma ray induced fission reactions occurring over the course of the irradiation.

5.4.3.7.1.3 Least Squares Adjustment Procedure

Least squares adjustment methods provide the capability of combining the measurement data with the neutron transport calculation resulting in a Best Estimate neutron energy spectrum with associated uncertainties. Best Estimates for key exposure parameters such as neutron fluence (E> 1.0 MeV) or iron atom displacements (dpa) along with their uncertainties are then easily obtained from the adjusted spectrum. The use of measurements in combination with the analytical results reduces the uncertainty in the calculated spectrum and acts to remove biases that may be present in the analytical technique.

In general, the least squares methods, as applied to pressure vessel fluence evaluations, act to reconcile the measured sensor reaction rate data, dosimetry reaction cross-sections, and the calculated neutron energy spectrum within their respective uncertainties. For example,

$$R_j \pm \delta_{R_i} = \sum_g \left(\sigma_{ig} \pm \delta_{\sigma_{ig}} \right) \left(\phi_g \pm \delta_{\phi_g} \right)$$

relates a set of measured reaction rates, R_i, to a single neutron spectrum, ϕ_g, through the multigroup dosimeter reaction cross-section, σ_{ig}, each with an uncertainty δ.

The use of least squares adjustment methods in LWR dosimetry evaluations is not new. The American Society for Testing and Materials (ASTM) has addressed the use of adjustment codes in ASTM Standard E944, "Application of Neutron Spectrum Adjustment Methods in Reactor Surveillance" and many industry workshops have been held to discuss the various applications. For example, the ASTM-EURATOM Symposia on Reactor Dosimetry holds workshops on neutron spectrum unfolding and adjustment techniques at each of its bi-annual conferences.

The primary objective of the least squares evaluation is to produce unbiased estimates of the neutron exposure parameters at the location of the measurement. The analytical method alone may be deficient because it inherently contains uncertainty due to the input assumptions to the calculation. Typically these assumptions include parameters such as the temperature of the water in the peripheral fuel assemblies, bypass region, and downcomer regions, component dimensions, and peripheral core source. Industry consensus indicates that the use of calculation alone results in overall uncertainties in the neutron exposure parameters in the range of 15-20% (1σ).

The application of the least squares methodology requires the following input:

1. The calculated neutron energy spectrum and associated uncertainties at the measurement location.

2. The measured reaction rate and associated uncertainty for each sensor contained in the multiple foil set.

3. The energy dependent dosimetry reaction cross-sections and associated uncertainties for each sensor contained in the multiple foil sensor set.

For a given application, the calculated neutron spectrum is obtained from the results of plant specific neutron transport calculations applicable to the irradiation period experienced by the dosimetry sensor set. This calculation is performed using the benchmarked transport calculational methodology described in Section 5.4.3.7.2. The sensor reaction rates are derived from the measured specific activities obtained from the counting laboratory using the specific irradiation history of the sensor set to perform the radioactive decay corrections. The dosimetry reaction cross-sections and uncertainties that are utilized in LWR evaluations comply with ASTM Standard E1018, "Application of ASTM Evaluated Cross-Section Data File, Matrix E 706 (IIB)."

The uncertainties associated with the measured reaction rates, dosimetry cross-sections, and calculated neutron spectrum are input to the least squares procedure in the form of variances and covariances. The assignment of the input uncertainties also follows the guidance provided in ASTM Standard E 944.

5.4.3.7.2 Calculation of Integrated Fast Neutron (E> 1.0 MeV) Flux at the Irradiation Samples

A generalized set of guidelines for performing fast neutron exposure calculations within the reactor configuration, and procedures for analyzing measured irradiation sample data that can be correlated to these calculations, has been promulgated by the Nuclear Regulatory Commission (NRC) in Regulatory Guide 1.190, "Calculational and Dosimetry Methods for Determining Pressure Vessel Neutron Fluence" [Reference 1]. Since different calculational models exist and are continuously evolving along with the associated model inputs, e.g., cross-section data, it is worthwhile summarizing the key models, inputs, and procedures that the NRC staff finds acceptable for use in determining fast neutron exposures within the reactor geometry. This material is highlighted in the subsection of material that is provided below.

5.4.3.7.2.1 Calculation and Dosimetrv Measurement Procedures

The selection of a particular geometric model, the corresponding input data, and the overall methodology used to determine fast neutron exposures within the reactor geometry are based on the needs for accurately determining a solution to the problem that must be solved and the data/resources that are currently available to accomplish this task. Based on these constraints, engineering judgment is applied to each problem based on an analyst's thorough understanding of the problem, detailed knowledge of the plant, and due consideration to the strengths and weaknesses associated with a given calculational model and/or methodology. Based on these conditions, Regulatory Guide 1.190 does not recommend using a singular calculational technique to determine fast neutron exposures. Instead, RG-1.190 suggests that one of the following neutron transport tools be used to perform this work.

- Discrete Ordinates Transport Calculations

  a) Adjoint calculations benchmarked to a reference-forward calculation, or stand-alone forward calculations.

  b) Various geometrical models utilized with suitable mesh spacing in order to accurately represent the spatial distribution of the material compositions and source.

  c) In performing discrete ordinates calculations, RG-1.190 also suggests that a P_3 angular decomposition of the scattering cross-sections be used, as a minimum.

  d) RG-1.190 also recommends that discrete ordinates calculations utilize S_8 angular quadrature, as a minimum.

  e) RG-1.190 indicates that the latest version of the Evaluated Nuclear Data File, or ENDFIB, should be used for determining the nuclear cross-sections; however, cross-sections based on earlier or equivalent nuclear data sets that have been thoroughly benchmarked are also acceptable.

- Monte Carlo Transport Calculations

A complete description of the Westinghouse pressure vessel neutron fluence methodology, which is based on discrete ordinates transport calculations, is provided in Reference 2. The Westinghouse methodology adheres to the guidelines set forth in Regulatory Guide RG-1.190.

5.4.3.7.2.2 Plant-Specific Calculations

The most recent dosimetry analyses for both Sequoyah units, including the vessel fluence assessment that was made to support the Sequoyah 1.3% Uprate Program, were based on discrete ordinates transport calculations. All of these calculations were conducted in accordance with the guidelines that are specified in Regulatory Guide RG-1.190.

5.4.3.8 Capability for Annealing the Reactor Vessel

There are no special design features which would prohibit the onsite annealing of the vessel. If the unlikely need for an annealing operation was required to restore the properties of the vessel material opposite the reactor core because of neutron irradiation damage, a metal temperature of approximately 750°F maximum for a period of 168 hours maximum would be applied. This annealing operation would be performed with the use of a special electrical space heater assembly designed to raise the affected vessel area to the required temperature for the necessary holding period. This heater assembly will consist of an insulated vessel cover assembly below which is suspended the required space heaters positioned opposite the affected area of the reactor vessel shell. The heater assembly will contain provisions for sealing to the vessel flange, and waterproof electric connections. Hydraulic connections for emptying the reactor vessel of water after the assembly is in place are also required. A thermocouple assembly to monitor vessel metal temperature during annealing would also be included.

The reactor vessel materials surveillance program is adequate to accommodate the annealing of the reactor vessel. The remaining surveillance capsules at the time of annealing would be removed and given a thermal cycle equivalent to the annealing cycle. They would then be reinserted in their normal position between the core internals assembly and the reactor vessel wall. Subsequent testing of the fracture toughness specimens from the capsules would then reflect both the radiation environment before any annealing operation and after any annealing operation.

5.4.4 Tests and Inspections

The reactor vessel quality assurance program is located in Table 5.4.4-1.

5.4.4.1 Ultrasonic Examinations

1. During fabrication, in addition to the Design Code required straight beam ultrasonic examination, an angle beam examination of 100 percent of the plate material was performed to detect discontinuities that may go undetected by the straight beam examination.

2. The reactor vessel was examined after hydro-testing to provide a baseline map for use as a reference document in relation to later in-service examinations.

3. The UHI adaptor and attachment welds to the closure head received both straight beam and angle beam ultrasonic examination.

4. A special pre-service examination of the reactor vessel nozzles was conducted to evaluate the extent of underclad cracking. The examination utilized a 70° angle beam and 0° beam manual contact technique. All indications found were demonstrated to be acceptable in accordance with ASME Code Section XI criteria.

5.4.4.2 Penetrant Examinations

The partial penetration welds for the control rod drive mechanism head adaptors and UHI adaptors were examined by dye penetrant after the first layer of weld metal, after each 1/4 inch of weld metal, and the final surface. Bottom instrumentation tubes were examined by dye penetrant after each layer of weld metal. Core support block attachment welds were examined by dye penetrant after first layer of weld metal, and after each 1/2 inch of weld metal. This is required to detect cracks or other defects, lower the weld surface temperatures, cleanliness and prevent microfissures. All austenitic stainless steel clad surfaces were 100 percent liquid penetrant examined after the hydrostatic test.

5.4.4.3 Magnetic Particle Examination

1. All surfaces of quenched and tempered materials had the inside diameters inspected prior to cladding and the outside diameter 100 percent examined after hydro-testing. This serves to detect possible defects resulting from the forming and heat treatment operations.

2. The attachment welds for the vessel supports, lifting lugs and refueling seal ledge were examined after the first layer of weld metal and after each 1/2 inch of weld thickness. Where welds are back chipped, the areas were examined prior to welding.

5.4.4.4 Reactor Vessel Inservice Inspection

The Inservice Inspection Program is addressed in Section 5.2.8.

The welds in the following areas of the installed irradiated reactor vessel are available for ASME Section XI required inspections.

1. Vessel shell - The inside surface.

2. Primary coolant nozzles - The inside surface.

3. Vessel heads - The inside and outside surface.

   The lower head weld on each reactor pressure vessel is partially inaccessible for examination from the vessel inside diameter due to instrumentation tubes which penetrate the lower head. A 100 percent pre-service examination of the weld was conducted from the vessel outside diameter. This was accomplished by performance of a manual ultrasonic examination. A remote ultrasonic examination was conducted from the vessel inside diameter on all accessible areas of the weld. Accessible areas of the weld will be reexamined during the inservice intervals in accordance with Section XI of the ASME Boiler and Pressure Vessel Code.

4. Closure studs, nuts and washers.

5. Field welds between the reactor vessel nozzles, and the main coolant piping.

6. Vessel flange seal surface.

7. CRDM and UHI adaptors.

The design considerations which have been incorporated into the system design to permit the above examinations are as follows:

1. All reactor internals are completely removable. The tools and storage space required to permit these examinations are provided.

2. The closure head is stored dry on the reactor operating deck with the insulation capable of being temporarily removed during refueling to facilitate examinations.

3. Typically, reactor vessel studs, nuts and washers are removed to dry storage during refueling.

4. Removable covers are provided in the reactor cavity floor. The insulation covering the nozzle welds may be removed.

5. Irradiation specimen access holes are provided in the lower internals barrel flange to allow remote access to the reactor vessel internal surfaces between the flange and the nozzles without removal of the internals.

6. A removable manway cover is provided in the lower core support plate to allow access for examination of the bottom head without removal of the lower internals.

The reactor vessel presents access problems because of the radiation levels and remote underwater accessibility to this component. Because of these limitations on access to the reactor vessel, several steps have been incorporated into the design and manufacturing procedures in preparation for the periodic non-destructive examination which are required by Section XI of the ASME boiler and pressure vessel code. These are:

1. Shop ultrasonic examinations were performed on all internally clad surfaces to an acceptance and repair standards to assure an adequate cladding bond to allow later ultrasonic examination of the base metal from inside surface. The size of cladding bonding defect allowed was 3/4 of an inch in diameter.

2. The design of the reactor vessel shell in the core area is a clean, uncluttered cylindrical surface to permit future positioning of the examination equipment without obstruction.

3. After the shop hydrostatic testing, selected areas of the reactor vessel were ultrasonically examined and mapped to facilitate the Inservice Inspection Program. Vessel design data is in Table 5.4.2-1. Transients and anticipated number of cycles are in Table 5.2.1-1. The reactor vessel quality assurance program is in Table 5.4.4-1.

A total of eight surveillance capsules were originally installed at locations S, T, U. V, W, X, Y, and Z. Capsules at T, U, X, and Y have been removed and tested to fulfill the surveillance capsule withdrawal requirements contained in the 20 year License Extension, Unit 1 Capsule V was moved to Location U; Unit 2 Capsule W was moved to Location U.

5.5 COMPONENT AND SUBSYSTEM DESIGN

5.5.1 Reactor Coolant Pumps

5.5.1.1 Design Bases

The reactor coolant pump ensures an adequate core cooling flow rate and hence sufficient heat transfer to maintain a DNBR greater than 1.3 within the parameters of operation. The required net positive suction head is by conservative pump design always less than that available by system design and operation.

Sufficient pump rotation inertia is provided by a flywheel, in conjunction with the impeller and motor assembly, to provide adequate flow during coastdown. This flow following an assumed loss of pump power provides the core with adequate cooling.

The pump is capable of operation without mechanical damage at overspeeds up to and including 125 percent of normal speed.

The reactor coolant pump is shown in Figure 5.5.1-1. The reactor coolant pump design parameters are given in Table 5.5.1-1.

Code and material requirements are provided in Section 5.2.

5.5.1.2 Design Description

The reactor coolant pump is a vertical, single stage, centrifugal, shaft seal pump designed to pump large volumes of main coolant at high temperatures and pressures.

The pump assembly consists of three areas from bottom to top. They are the hydraulics, the shaft seals, and the motor.

1. The hydraulic section consists of an impeller, diffuser, casing, thermal barrier heat exchanger, lower radial bearing, bolting ring, motor stand, and pump shaft.

2. The shaft seal section consists of three devices. They are the number 1 controlled leakage, film riding face seal and the number 2 and number 3 rubbing face seals. The number 2 seal operation converts to a film riding seal as pressure increases. These seals are contained within the main flange and seal housing.

3. The motor section consists of a vertical solid shaft, squirrel cage induction type motor, an oil lubricated double Kingsbury type thrust bearing, two oil lubricated radial bearings, and a flywheel.

Attached to the bottom of the pump shaft is the impeller. The reactor coolant is drawn up through the impeller, discharged through passages in the diffuser, and out through the discharge nozzle in the side of the casing. Above the impeller is a thermal barrier heat exchanger which limits heat transfer between hot system water and seal injection water.

High pressure seal injection water is introduced through a connection on the thermal barrier flange and flows into the cavity between the main flange and thermal barrier. The injection water flows

upward to the radial bearing and into the seal while the remainder flows down through the thermal barrier labyrinth and past the cooling coils where it acts as a buffer to prevent RCS water from entering the radial bearing and seal section of the unit. The heat exchanger provides a means of cooling system water to an acceptable level in the event that seal injection flow is lost. The water lubricated journal-type pump bearing, mounted above the thermal barrier heat exchanger, has a self-aligning spherical seat.

The reactor coolant pump motor bearings are of conventional design. The radial bearings are the segmented pad type, and the thrust bearings are tilting pad Kingsbury bearings. All are oil lubricated. The lower radial bearing and the thrust bearings are submerged in oil, and the upper radial bearing is oil fed from an impeller integral with the thrust runner.

The motor is an air cooled, squirrel cage induction motor. The rotor and stator are of standard construction and are cooled by air. Multiple resistance temperature detectors are located throughout the stator to sense the winding temperature. The top of the motor consists of a flywheel and an anti-reverse rotation device.

Each of the reactor coolant pumps is equipped with vibration monitoring capabilities as provided by the Vibration and Loose Parts Monitoring System.

All parts of the pump in contact with the reactor coolant are austenitic stainless steel except for seals, bearings and special parts. Component cooling water is supplied to the two oil coolers on the pump motor and to the pump thermal barrier heat exchanger.

The pump shaft, seal housing, thermal barrier, bolting ring and motor stand can be removed from the casing as a unit without disturbing the reactor coolant piping. The flywheel is available for inspection by removing the cover.

The performance characteristic shown in Figure 5.5.1-2 is common to all of the fixed speed mixed flow pumps, and the "knee" at about 45 percent design flow introduces no operational restrictions, since the pumps operate at full flow.

5.5.1.3 Design Evaluation

5.5.1.3.1 Pump Performance

The reactor coolant pumps are sized to deliver flow at rates which equal or exceed the required flow rates. Initial RCS tests confirm the total delivery capability. Thus, assurance of adequate forced circulation coolant flow was provided prior to initial plant operation.

The Reactor Trip System ensures that pump operation is within the assumptions used for loss of coolant flow analyses, which also assures that adequate core cooling is provided to permit an orderly reduction in power if flow from a reactor coolant pump is lost during operation.

An extensive test program has been conducted for several years to develop the controlled leakage shaft seal for pressurized water reactor applications. Long term tests were conducted on less than full scale prototype seals as well as on full size seals. Operating plants continue to demonstrate the satisfactory performance of the controlled leakage shaft seal pump design.

The support of the stationary member of the number 1 seal ("seal ring") is such as to allow large deflections, both axial and tilting, while still maintaining its controlled gap relative to the seal runner. Even if all the graphite were removed from the pump bearing, the shaft could not deflect far enough to cause opening of the controlled leakage gap. The "spring-rate" of the hydraulic forces associated with the maintenance of the gap is high enough to ensure that the ring follows the runner under very rapid shaft deflections.

Testing of pumps with the number 1 seal entirely removed (full reactor pressure on the number 2 seal) shows that relatively small leakage rates would be maintained for long periods of time (approximately 100 hours) even if the number 1 seal fails entirely. The plant operator is warned of this condition by the increase in number 1 seal leakoff and has time to close this line, and to conduct a safe plant shutdown without significant leakage of reactor coolant to the containment. Thus, it may be concluded that gross leakage from the pump does not occur, even if the number 1 seal were to suffer physical damage.

A loss of off-site power will cause a temporary stoppage in the supply of injection flow to the pump seals and the cooling water for seal and bearing cooling. The emergency diesel generators are started automatically due to loss of off-site power so that seal water injection flow and component cooling flow are automatically restored.

5.5.1.3.2 Coastdown Capability

It is important to reactor operation that the reactor coolant continues to flow for a short time after reactor trip. In order to provide this flow in a station blackout condition, each reactor coolant pump is provided with a flywheel. Thus, the rotating inertia of the pump, motor and flywheel is employed during the coastdown period to continue the reactor coolant flow. Flow coastdown curves are shown in Subsection 15.2.

The pump is designed for the safe shutdown earthquake. Hence, it is concluded that the coastdown capability of the pumps is maintained even under the most adverse case of a blackout coincident with the safe shutdown earthquake.

5.5.1.3.3 Flywheel Integrity

Integrity of the reactor coolant pump flywheel is discussed in Subsection 5.2.6.

5.5.1.3.4 Bearing Integrity

The design requirements for the reactor coolant pump bearings are primarily aimed at ensuring a long life with negligible wear, so as to give accurate alignment and smooth operation over long periods of time. To this end, the surface-bearing stresses are held at a very low value, and even under the most severe seismic transients do not begin to approach loads which cannot be adequately carried for short periods of time.

Because there are no established criteria for short time stress-related failures in such bearings, it is not possible to make a meaningful quantification of such parameters as margins to failure, safety factors, etc. A qualitative analysis of the bearing design, embodying such considerations, gives assurance of the adequacy of the bearing to operate without failure.

Low oil level in the motor bearings actuates an alarm in the control room. Motor bearings contain an embedded temperature detector, and so initiation of failure, separate from loss of oil, is indicated and alarmed in the control room as a high bearing temperature. Confirmed high bearing temperature requires pump shutdown. Even if these indications were ignored, and the bearing proceeded to failure, the low melting point of Babbitt metal on the pad surfaces ensures that no sudden seizure of the bearing would occur. In this event the motor continues to drive, as it has sufficient reserve capacity to continue to operate, even under such conditions. However, it demands excessive currents and shut down will eventually result from current demand.

5.5.1.3.5 Locked Rotor

It may be hypothesized that the pump impeller might severely rub on a stationary member and then seize. Analysis has shown that under such conditions, assuming instantaneous seizure of the impeller, the pump shaft fails in torsion just below the coupling to the motor, disengaging the flywheel and motor from the shaft. This constitutes a loss of coolant flow in the loop. Following such a postulated seizure, the motor continues to run without any overspeed, and the flywheel maintains its integrity, as it is still supported on a shaft with two bearings.

There are no other credible sources of shaft seizure other than impeller rubs. Any seizure of the pump bearing is precluded by graphite in the bearing. Any seizure in the seals results in a shearing of the anti-rotation pin in the seal ring. The motor has adequate power to continue pump operation even after the above occurrences. Indications of pump malfunction in these conditions are initially by high temperature signals from the bearing water temperature detector, and excessive number 1 seal leakoff indications respectively. Following these signals, pump vibration levels can be checked. Excessive vibration indicates mechanical trouble and the pump can be shut down for investigation.

5.5.1.3.6 Critical Speed

It is considered desirable to operate below first critical speed, and the reactor coolant pumps are designed in accordance with this philosophy. This results in a shaft design which, even under the most severe postulated transient, gives very low values of actual stress.

Both the damped and lateral natural frequencies are determined by establishing a number of shaft sections and applying weights and moments of inertia for each section bearing spring and damping data. The torsional natural frequencies are similarly determined. The lateral and torsional natural frequencies are greater than 120 percent and 110 percent of the running speed.

5.5.1.3.7 Missile Generation

Each component of the pump is analyzed for missile generation. Any fragments of the motor rotor would be contained by the heavy stator. The same conclusion applies to the pump impeller because the small fragments that might be ejected would be contained by the heavy casing.

5.5.1.3.8 Pump Cavitation

The minimum net positive suction head required by the reactor coolant pump at operating conditions is approximately 170 ft. head (approximately 85 psi). In order for the controlled leakage seal to operate correctly, it is necessary to have a minimum differential pressure of approximately 200 psi across the seal and a minimum of 325 psi pressure in the primary loop before the reactor coolant pump may be operated. At this pressure the net positive suction head required is exceeded.

5.5.1.3.9 Pump Overspeed Considerations

For turbine trips, the reactor coolant pumps are maintained energized to prevent any pump overspeed condition.

The RCPs at 120 percent overspeed is evaluated in the thermal-hydraulic design (subsection 4.4.2.7).

5.5.1.3.10 Anti-Reverse Rotation Device

Each of the reactor coolant pumps is provided with an anti-reverse rotation device in the motor. This anti-reverse mechanism consists of multiple pawls mounted on the outside diameter of the flywheel, a serrated ratchet plate mounted on the oilpot, a spring return for the ratchet plate, and three shock absorbers.

After the motor has come to a stop, one pawl engages the ratchet plate and, as the motor tends to rotate in the opposite direction, the ratchet plate also rotates until stopped by the shock absorbers. The rotor remains in this position until the motor is energized again. After the motor has come up to speed, the ratchet plate is returned to its original position by the spring return.

When the motor is started, the pawls drag over the ratchet plate until the motor reaches approximately 80 revolutions per minute. At this time, centrifugal forces acting on the pawls, are sufficient to lift and hold the pawls in the elevated position until the speed falls below the above value. Considerable shop testing and plant experience with the design of these pawls has shown a high reliability of operation.

5.5.1.3.11 Shaft Seal Leakage

Leakage along the reactor coolant pump shaft is controlled by three shaft seals arranged in series such that reactor coolant leakage to the containment is essentially zero. Charging flow is directed to each reactor coolant pump via a seal water injection filter. The flow splits and a portion enters the Reactor Coolant System and the thermal barrier cooler cavity. The remainder of the flow flows up the pump shaft (cooling the lower bearing) and leaves the pump via the number 1 seal where its pressure is reduced to close to the volume control tank pressure.

Number 1 seal leakoff flow is normally $\geq$0.2 gpm but may be reduced after seal maintenance provided some flow can be verified. The number 1 seal leakoff from each pump seal assembly is piped to a common manifold and then via a seal water filter through a seal water heat exchanger where the temperature is reduced to about that of the volume control tank. Leakage past the number 1 seal provides a constant pressure on the number 2 seal. A standpipe is provided to assure a backpressure of approximately 7 feet of water on the number 2 seal and warn of excessive number 2 seal leakage. The first outlet from the standpipe has an orifice to permit normal number 2 seal leakage to flow to the reactor coolant drain tank; excessive number 2 leakage results in a rise in the standpipe level, alarm in the MCR, and eventual overflow to the reactor coolant drain tank (RCDT) via a second overflow connection. Leakage from the number 3 seal flows to the containment floor and equipment drain sump.

5.5.1.3.12 Spool Piece

The application of a removable spool piece in the Reactor Coolant Pump shaft serves to facilitate the inspection and maintenance of the pump seal system without breaking any of the fluid, electrical or instrumentation connections to the motor, without removal of the motor, and without affecting the pump motor alignment.

Thus it serves to reduce plant downtime for pump maintenance, and also to reduce personnel radiation exposure due to the reduced time in the proximity of the primary coolant loop. (See Figure 5.5.1-3.)

5.5.1.4 Tests and Inspections

Unit 1 RCP support feet are integral cast with the casing to eliminate a weld region. Unit 2 has 3 RCPs with integrally welded pump feet and one integrally cast.

The design enables disassembly and removal of the pump internals for usual access to the internal surface of the pump casing.

Inservice Inspection is discussed in Subsection 5.2.8.

The reactor coolant pump quality assurance program is given in Table 5.5.1-2.

Electroslag Welding

Reactor coolant pump casings fabricated by electroslag welding were qualified as follows:

1. The electroslag welding procedure employing two and three wire technique was qualified in accordance with the requirements of the ASME B&PV Code Section IX and Code Case 1355 plus supplementary evaluations as requested by WNES-PWRSD. The following test specimens were removed from an 8-inch thick and from a 12-inch thick weldment and successfully tested for both the 2 wire and the 3 wire techniques, respectively. They are:

    a. Two wire electroslag process - 8 inch thick weldment

        i. 6 Transverse Tensile Bars - 750°F post weld stress relief

        ii. 12 Guided Side Bend Test Bars

    b. Three wire electroslag process - 12 inch thick weldment

        i. 6 Transverse Tensile bars - 750°F post weld stress relief

        ii. 17 Guided Side Bend Test Bars

        iii. 21 Charpy Vee Notch Specimens

        iv. Full section macroexamination of weld and heat affected zone

v. Numerous microscopic examinations of specimens removed from the weld and heat affected zone regions

vi. Hardness survey across weld and heat affected zone

c. A separate weld test was made using the 2 wire electroslag technique to evaluate the effects of a stop and restart of welding by this process. This evaluation was performed to establish proper procedures and techniques as such an occurrence was anticipated during production applications due to equipment malfunction, power outages, etc. The following test specimens were removed from an 8 inch thick weldment in the stop-restart-repaired region and successfully tested. They are:

i. 2 Transverse Tensile Bars - as welded

ii. 4 Guided Side Bend Test Bars

iii. Full section macroexamination of weld and heat affected zone

d. All of the weld test blocks in (a), (b), and (c) above were radiographed using a 24 Mev Betatron. The radiographic quality level as defined by ASTM E-94 was between one half of 1 percent and 1 percent. There were no discontinuities evident in any of the electroslag welds.

i. The casting segments were surface conditioned for 100 percent radiographic and penetrant inspection. The radiographic acceptance standards were ASTM E-186 severity level 2 except no category D or E defects were permitted for section thickness up to 4-1/2 inches and ASTM E-280 severity level 2 for section thickness greater than 4-1/2 inches. The penetrant acceptance standards were ASME B&PV Code Section III, paragraph N-627.

ii. The edges of the electroslag weld preparations were machined. These surfaces were penetrant inspected prior to welding. The acceptance standards were ASME B&PV Code Section III, paragraph N-627.

iii. The completed electroslag weld surfaces were ground flush with the casting surface. Then, the electroslag weld and adjacent base material were 100 percent radiographed in accordance with ASME Code Case 13355. Also, the electroslag weld surfaces and adjacent base material were penetrant inspected in accordance with ASME B&PV Code Section III, paragraph N-627.

iv. Weld metal and base metal chemical and physical analyses were determined and certified.

v. Heat treatment furnace charts were recorded and certified.

<u>In-Process Control of Variables</u>

There are many variables that must be controlled in order to maintain desired quality welds. These, together with an explanation of their relative importance are as follows:

Heat Input vs Output

The heat input is determined by the product of volts times current and they are measured by voltmeters and ammeters which are considered accurate, as they are calibrated every 30 days. During any specific weld these meters are constantly monitored by the operators.

The ranges specified are 500-620 amperes and 44-50 volts. The current amperage variation, even though it is less than ASME allows by Code Case 1355, is necessary for several reasons:

1. The thickness of the weld is in most cases the reason for changes.

2. The weld gap variation during the weld cycle will also require changes. For example, the procedure qualifications provide for welding thickness from 5 inches to 11 inches with two wires. The current and voltage are varied to accommodate this range.

3. Also, the weld gap is controlled by spacer blocks. These blocks must be removed as the weld progresses. Each time a spacer block is removed there is chance of the weld gap decreasing by as much as 1/4-inch or increasing perhaps as much as 1/4-inch. In either case, a change in current may be necessary.

4. The heat output is controlled by the heat sink of the section thickness and the metered water flow through the water cooled shoes. The nominal temperature of the discharged water is 100°F.

Weld Gap Configuration

As previously mentioned, the weld gap configuration is controlled by 1-1/4 inch spacer blocks. As these blocks are removed, there is the possibility of gap variation. It has been found that a variation from 1-inch to 1-3/4 inches is not detrimental to weld quality as long as the current is adjusted accordingly.

Flux Chemistry

The flux used for welding is Acros BV-1 Vertomax. This is a neutral flux whose chemistry is specified by Acros Corporation. The molten slag is kept at a nominal depth of 1-3/4 inches and may vary in depth by plus or minus 3/8 inch without affecting the weld. This is measured by a stainless steel dipstick.

Weld Cross Section Configuration

It is noted that the higher the current or heat input and the lower the heat output that the dilution of weld metal with base metal is greater, causing a more round barrel-shaped configuration as compared to welding with less heat input and higher heat output. This would cut the amount of dilution to provide a more narrow barrel-shaped configuration. This is also a function of section thicknesses; the thinner the section, the more round the pattern that is produced.

Welder Qualification

Welder qualification in accordance with ASME B&PV Code, Section IX rules (Table Q24.1) is required, using transverse side bend test specimens.

5.5.2 Steam Generator

5.5.2.1 Design Bases

The design data for the replacement steam generators are given in Table 5.5.2-1. The design sustains transient conditions given in Chapter 3. Estimates of radioactivity levels anticipated in the secondary side of the steam generators during normal operation, and the bases for the estimates are given in Chapter 11. Rupture of a steam generator tube is discussed in Chapter 15. Secondary safety relief valves design data is given in Section 10.3.2.1.

The internal moisture separation equipment for the replacement steam generators (RSGs) is designed to ensure that moisture carryover does not exceed 0.10 percent by weight under the following conditions:

1. Steady state operation up to 100 percent of full load steam flow, with water at the normal operating level.

2. Loading or unloading at a rate of five percent of full power steam flow per minute in the range from 15 percent to 100 percent of full load steam flow.

3. A step load change of ten percent of full power in the range from 15 percent to 100 percent full load steam flow.

The steam generator tubesheet complex for the RSGs meets the stress limitations and fatigue criteria specified in the ASME code Section III as well as emergency condition limitations. Codes and materials requirements of the steam generator are given in Section 5.2.

The steam generator design maximizes integrity against hydrodynamic excitation and vibration failure of the tubes for plant life.

The water chemistry in the reactor side is selected to provide the necessary boron content for reactivity control and to minimize corrosion of Reactor Coolant System (RCS) surfaces. The water chemistry of the steam side is consistent with the Steam Generator Owners' Group EPRI report, "PWR Secondary Water Chemistry Guidelines", revision 1, dated June 1984, or subsequent revisions as they are deemed appropriate.

5.5.2.2 Design Description

Original Steam Generator (OSG) (Historical)

The OSG in Figure 5.5.2-1a is a vertical shell and U-tube evaporator with integral moisture separating equipment. The reactor coolant flows through the inverted tubes, entering and leaving through the nozzles located in the hemispherical bottom head of the steam generator. The head is divided into inlet and outlet chambers by a vertical partition plate extending from the head to the tube sheet. Manways are provided for access to both sides of the divided head. Steam is generated on the shell side and travels through swirl vanes and moisture separators to the outlet nozzle at the top of the vessel. The unit is primarily carbon steel. The heat transfer tubes and the divider plate are Inconel and the interior surfaces of the reactor coolant channel heads and nozzles are clad with austenitic stainless steel. The primary side of the tube sheet is weld clad with Inconel.

Feedwater flows directly into the annulus formed by the shell and tube bundle wrapper before entering the boiler section of the steam generator. Subsequently, water-steam mixture flows upward through the tube bundle and into the steam drum section. A set of centrifugal moisture separators, located above the tube bundle, removes most of the entrained water from the steam. Steam dryers are employed to increase the steam quality to a minimum of 99.75 percent (0.25 percent moisture). The moisture separators recirculate the separated water which mixes with feedwater as it passes through the annulus formed by the shell and tube bundle wrapper.

The steam drum has two access openings for inspection and maintenance of the dryers, which can be disassembled and removed through the opening.

Replacement Steam Generator (RSG)

The RSG is similar in design to the original steam generator and is shown in Figure 5.5.2-1b. Steam is generated on the shell side and travels through primary centrifugal moisture separators and secondary hook vane dryers to the outlet nozzle at the top of the vessel. The unit is primarily low alloy steel. The heat transfer tubes and the divider plate are nickel alloy 690 and the interior surfaces of the reactor coolant channel heads and nozzles are clad with stainless steel. The primary side of the tubesheet is clad with nickel alloy weld material.

A set of centrifugal moisture separators, located above the tube bundle, removes most of the entrained water from the steam. Steam dryers are employed to increase the steam quality to a minimum of 99.9 percent (0.10 percent moisture). Water from the separation equipment mixes with feedwater and is recirculated through the evaporator section via the annulus formed by the shell and tube bundle wrapper. The steam drum has two access openings for inspection and maintenance of the steam separation equipment.

5.5.2.3 Design Evaluation

5.5.2.3.1 Forced Convection

The limiting case for heat transfer capability is the "Nominal 100 Percent Design" case. The steam generator effective heat transfer coefficient is based on the coolant condition temperature and flow for this case, and includes a conservative allowance for tube fouling. Adequate tube area is selected to ensure that the full design heat removal rate is achieved.

5.5.2.3.2 Natural Circulation Flow

Upon loss of power to the reactor coolant pumps, coolant flow necessary for core cooling and the removal of residual heat is maintained by natural circulation in the reactor coolant loops. The natural circulation flow with original steam generators was calculated by a digital code for the conditions of equilibrium flow and maximum loop flow impedance. The model used has given results within 15 percent of the measured flow values obtained during natural circulation tests conducted at the Yankee-Rowe plant and has also been confirmed at San Onofre, Connecticut Yankee and the Ginna Nuclear Power Plants. The natural circulation capability of Sequoyah Plant with original steam generators was confirmed through testing at the Sequoyah Plant. An analysis performed by Framatome ANP shows that the natural circulation flow is marginally higher with the replacement steam generators.

Tube and tube sheet stress analyses of the steam generator are given in Section 5.2.

Calculations confirm that the steam generator tube sheet will withstand the loading (which is quasi-static rather than a shock loading) caused by loss of reactor coolant.

5.5.2.3.3 Corrosion

The Replacement Steam Generator Tube material is thermally-treated Ni-Cr-Fe Alloy 690.

5.5.2.3.3.1 Original Steam Generator (Historical)

No significant general corrosion of the Inconel tubing of the original steam generator is expected during the lifetime of the unit. Corrosion tests show a "worst case" rate of 15.0 mg/dm^2 in the 2000 hour test under simulated reactor coolant chemistry conditions. Conversion of this rate to a 40 year plant life gives a corrosion loss of 1.3 x 10^{-3} inch which is insignificant compared to the minimum wall thickness of the steam generator tubes.

Comparable tests with Inconel-600 exposed to simulated steam generator secondary side water chemistry have shown equally low general corrosion rates. Testing to investigate the susceptibility of heat exchanger construction materials to stress corrosion in caustic and chloride aqueous solutions has indicated that Inconel-600 has excellent resistance to general and pitting type corrosion in severe operation water conditions, hence its selection for use in the steam generator. As discussed above, Inconel-600 is compatible with both the primary and secondary coolant. Laboratory tests have shown the general corrosion rate of Inconel-600 when subjected to both primary and secondary coolant conditions to be insignificant when compared to the nominal tube wall thickness. Many reactor years of successful operation have shown the same low general corrosion rates in operating steam generators.

Operating experience, however, has revealed areas of localized corrosion where the corrosion rates were significantly greater than the low general corrosion rates. Both intergranular corrosion and tube wall thinning were experienced in localized areas, although not at the same location or under the same environmental conditions (water chemistry and sludge composition). These localized areas of corrosion posed no threat to the public health and safety but were of concern because of their possible effect on plant availability.

Therefore, to eliminate these localized areas of corrosion for long term operation of the unit, it was decided that the use of phosphates for steam generator chemistry control would be eliminated. Steam generator corrosion control and secondary side water chemistry is maintained by All Volatile Treatment (AVT) with any combination of hydrazine, ammonia, morpholine, ethanolamine, or other similar organic amines to control at temperature pH in the steam cycle. Treatment programs are compatible and may be overlapped or switched at any time. The availability of compatible treatment programs allows the flexibility to directly compare program performance and utilize plant operating experience as the basis for program selection. In addition, Boric Acid is introduced during heatup and power operations to mitigate the potential for secondary side intergranular attack and denting.

Ammonia/Hydrazine Treatment - The All Volatile Treatment (AVT) control program (ammonia for pH control, hydrazine for oxygen scavenging) will minimize the possibility for recurrence of the tube wall thinning phenomenon, since successful AVT operation requires maintenance of low concentrations of

impurities in the steam generator water. This reduces the potential for formation of highly concentrated solutions in low flow zones. By restriction of the total alkalinity in the steam generator and prohibition of extended operation with free alkalinity, the AVT program will minimize the recurrence of intergranular corrosion in localized areas due to excessive levels of free caustic. Laboratory testing has shown that the Inconel-600 tubing is compatible with the AVT environment.

Organic Amine/Hydrazine Treatment - Organic Amines, in conjunction with hydrazine, have been used successfully at numerous domestic and foreign utilities as a pH control additive. In these applications, organic amines reduce erosion-corrosion in two-phase regions, since they are less volatile than ammonia and provide a higher liquid phase pH in wet steam regions. A benefit expected with organic amines pH control is a reduction in steam generator sludge accumulations, lower than would be expected with just ammonia treatment. Organic amines provide better two-phase pH control, which reduces corrosion product formation, resulting in less corrosion product formation and transport to the steam generators, minimizing sludge accumulation. Experience and testing documented by Westinghouse and EPRI demonstrates morpholine's acceptability as a secondary side water treatment additive (References 5.0 and 6.0). Additionally, Westinghouse has provided a Sequoyah specific evaluation documenting compatibility of morpholine with secondary side materials and its usefulness as a secondary side chemical treatment additive (Reference 5).

Ethanolamine - This chemical favorably distributes itself into the water phase of wet steam cycles, which makes it effective as cycle pH additive. In addition, ethanolamine has a high basic strength at elevated temperatures, which reduces the quantity of the amine required to provide protection. Tests have indicated that ethanolamine can reduce corrosion product transport with little negative effect on polishers (Reference 6).

5.5.2.3.3.2 Secondary Side Chemical Treatment

Dimethylamine - For Unit 1 and Unit 2 RSG's Dimethylamine (DMA) has a high basicity for "at temperature" pH control in the steam cycle, but will not significantly decrease condensate polisher run times. DMA has other characteristics such as anti-scaling and anti-fouling properties, and inhibition of silica formation that makes it desirable as a chemical additive in systems that have no copper based materials. DMA acts as a solvent to copper and copper oxides and will remove them from surfaces and surface deposits so they can be removed by steam generator blowdown.

A comprehensive program of steam generator inspections, including the requirements of Regulatory Guide 1.83, will insure detection and correction of any unanticipated degradation that might occur in the steam generator tubing.

5.5.2.3.4 Flow Induced Vibration

In the design of the Westinghouse RSGs, consideration has been given to the possibility of degradation of tubes due to mechanical or flow induced vibration. This consideration includes detailed analyses of the tube support system as well as an extensive research program with tube vibration model testing.

The primary cause of tube vibration in a steam generator is the propensity for the tubes to extract energy from the secondary fluid flow and convert it into tube motion. The extent of movement experienced by the tubes is dependent on the nature of the flow regime and the approach angle of the flow with regard to the tube span orientation. For vibration assessment purposes, in a typical inverted U-tube steam generator there are four types of secondary flow.

These are:

1. Entrance Cross-Flow - This is either subcooled or saturated liquid (recirculated water mixed with feedwater from the downcomer) cross-flow which occurs at the secondary face of the tubesheet on both the hot side and cold side.

2. Axial Flow - This flow can vary from subcooled to saturated liquid two-phase flow depending on elevation in the steam generator tube bundle. The direction of flow is parallel to the tube axis and this type of flow is the predominate flow in the unit.

3. Two-Phase Cross-Flow (Exit Region) - This type of flow exists for the tubes in the U-bend region of the tube bundle. The effects of this flow are similar to those produced by "entrance cross-flow" except that due to lower density, the energy available to the tubes is not as great.

4. Mixed Flow - This type of flow is a combination of axial flow and cross-flow which could exist in two distinctly different situations.

    a. Oblique Flow Across Straight Tubes - This could occur in regions of flow direction change such as directly above the recirculating entrance region.

    b. Unidirectional Flow Across Curved Tubes - This occurs in the U-bend area of the tubes.

Since the problem of flow induced vibration in the identified regions is of significant concern in the design of shell and tube heat exchangers, Westinghouse has given consideration to the experimental evaluation of the behavior of tube arrays under cross flow. The vibration analysis of the RSG tubes and tube supports is based on the following:

i. Full scale parametric flow test data.

ii. Multi-span dynamic response test data.

iii. Both general and local shell-side flow distribution analysis.

iv. State-of-the-art flow induced vibration analysis techniques, including Appendix N of ASME Code Section III.

The test data described above provided the basis for determining acceptable shell side fluid velocities in the most critical regions of the tube bundle which are the fluid entrance and fluid exit regions. Based on the test data and results from the shell side flow distribution analyses, the design tube support spacing has been shown to have conservative design margins against the onset of fluid elastic instability. The RSG design configuration indicates tube vibration stability ratios (i.e., the effective cross-flow velocity / fluid-elastic critical cross-flow velocity) well below the theoretical allowable of 1.0 and less than or equal to the conservative design requirement of 0.75.

Displacements due to random turbulent excitation of the RSG tubing based on the turbulent buffeting methodology of Appendix N of Section III of the ASME Code are well below the design goal of 10 mils. Reliable methods for calculating tube wear are not available for stable flow vibrations at this level of displacement. Experimental tube vibration data indicate that tube wear is not significant for vibration displacements less than 10 mils.

Additionally, the Sequoyah plant technical specification defines the SG tube repair limit as 40 percent through-wall degradation or 0.0168 inches. Historically and throughout the industry, this repair limit has been determined from bounding values of non-destructive examination sizing uncertainty and degradation growth rate from a structural limit in conjunction with a conservative safety margin. The repair limit is defined such that the performance criteria for structural and leakage integrity will be met at the end of an interval between inspections with this reduction in tube wall thickness.

The structural effects of vibration have been given consideration and the stress limitations for each category in the ASME Code have been met. The tube stresses due to flow induced vibrations were determined to be less than 1.0 kips per square inch, which is less than the lower bound fatigue stress limit. Therefore, there will be no structural or fatigue damage resulting from flow induced vibration in the RSGs.

Finally, it should be noted that successful operational experience with several steam generator designs with similar tube support structures has given confidence in the overall approach to address flow induced vibration in the RSG tube support design.

5.5.2.4 Tests and Inspections

The steam generator quality assurance program during construction is given in Table 5.5.2-2.

Radiographic examination and acceptance standards were in accordance with the requirements of Section III of the ASME code.

Liquid penetrant examination was performed on weld deposited tube sheet cladding, channel head cladding, tube-to-tube sheet weldments, and weld deposit cladding.

Liquid penetrant examination and acceptance standard were in accordance with the requirements of Section III of the ASME code.

Magnetic particle examination was performed on the tube sheet forging, channel head casting, nozzle forgings, and the following weldments:

l. Nozzle to shell

2. Support brackets

3. Instrument connections (primary and secondary)

4. Temporary attachments after removal

5. All accessible pressure containing welds after hydrostatic test.

Magnetic particle examination and acceptance standard were in accordance with requirements of Section III of the ASME code.

An ultrasonic examination was performed on the tube sheet forging, tube sheet cladding, secondary shell and heat plate and nozzle forgings.

The heat transfer tubing was subjected to eddy current examination.

Hydrostatic tests were performed in accordance with Section III of the ASME code. In addition, the heat transfer tubes were subjected to a hydrostatic test pressure prior to installation into the vessel which is not less than 1.25 times the primary side design pressure multiplied by the ratio of the material allowable stress at the testing temperature.

Manways are to provide access to both the primary and secondary sides.

Regulatory Guide 1.83, "Inservice Inspection of Pressurized Water Reactor Steam Generator Tubes," provides recommendations concerning the inspection of tubes, which cover inspection equipment,

baseline inspections, tube selection, sampling and frequency of inspection, methods of recording and required actions based on findings. The minimum requirements for inservice inspection of steam generators are established as part of the technical specifications.

5.5.3 Reactor Coolant Piping

5.5.3.1 Design Bases

The Reactor Coolant System (RCS) piping is designed and fabricated to accommodate the system pressures and temperatures attained under all expected modes of plant operation or anticipated system interactions.

Materials of construction are specified to minimize corrosion/erosion and ensure compatibility with the operating environment.

The piping in the RCS pressure boundary is Safety Class 1. See FSAR Section 3.2 for applicable codes for design, fabrication, inspection, and testing of the RCS pressure boundary.

5.5.3.2 Design Description

Principal design data for the reactor coolant piping material is given in Table 5.2.3-1.

The RCS loop piping is specified in the smallest sizes consistent with system requirements. In general, high fluid velocities are used to reduce piping sizes. This design philosophy results in the reactor inlet and outlet piping diameters given in Figure 5.1-1. The line between the steam generator and the pump suction is larger to reduce pressure drop and improve flow conditions to the pump suction.

The reactor coolant piping and fittings which made up the loops are austenitic stainless steel. There will be no electroslag welding on these components. All smaller piping which comprise part of the RCS boundary, such as the pressurizer surge line, spray and relief line, loop drains and connecting lines to other systems are also austenitic stainless steel. The nitrogen supply line for the pressurizer relief tank is stainless steel. All joints and connections are welded except for the pressurizer code safety valves, pressurizer relief valves, refueling disconnects, and flow orifice elements, where flange joints are used. Flanges are also used for selected vents, drains, and other lower class connections as shown on drawings.

Thermal sleeves are installed at points in the system where high thermal stresses could develop due to rapid changes in fluid temperature during normal operational transients. These points include:

1. Charging connections at the primary loop from the Chemical and Volume Control System.

2. Return line connections from the Residual Heat Removal System at the reactor coolant loops 1 and 4.

3. Both ends of the pressurizer surge line.

4. Pressurizer spray line connection at the pressurizer.

Thermal sleeves are not provided for the remaining injection connections of the Emergency Core Cooling System since these connections are not in normal use.

All piping connections from auxiliary systems are made above the horizontal centerline of the reactor coolant piping, with the exception of:

1. Residual heat removal pump suction, which is 45° down from the horizontal centerline. This enables the water level in the RCS to be lowered in the reactor coolant pipe (midloop operation) while continuing to operate the Residual Heat Removal System.

2. Loop drain lines and the connection for temporary level measurement of water in the RCS during refueling and maintenance operation.

3. The differential pressure taps for flow measurement are downstream of the steam generators on the first 90° elbow. The tap arrangement is discussed in the instrumentation section of this description.

4. Fast response resistance temperature detector thermowells on the RCS hot legs and the reactor vessel level system connections.

Penetrations into the coolant flow path are limited to the following:

1. The pressurizer spray line inlet connections extend into the cold leg piping in the form of a scoop so that the velocity head of the reactor coolant loop flow adds to the spray driving force.

2. The reactor coolant sample system taps protrude into the main stream to obtain a representative sample of the reactor coolant.

3. Fast response resistance temperature detector hot leg thermowells are installed in scoops which extend into the reactor coolant pipes.

4. The wide range temperature detectors are located in resistance temperature detector wells that extend into the reactor coolant pipes.

5. Fast response resistance temperature detector thermowells that extend into the cold leg piping.

The Reactor Control and Protection System narrow range temperature detectors are located in separate thermowells in each reactor coolant loop hot and cold leg. Three hot leg scoops extend into the flow path at locations 120-degrees apart in the cross sectional plane of the reactor coolant hot leg. A resistance temperature detector thermowell is installed in each of these hot leg scoops. Two resistance temperature detector thermowells extend directly into the flow path (no scoops) in a cross sectional plane of the cold leg. One thermowell is installed at the top of the cold leg (and another thermowell is installed approximately 45 degrees from the top thermowell.

The RCS piping includes those sections of piping interconnecting the reactor vessel, steam generator, and reactor coolant pump. It also includes the following auxiliary and connecting piping:

1. Charging line and alternate charging line from the isolation valve up to the branch connections on the reactor coolant loop.

2. Letdown line from the branch connection on the reactor coolant loop to the isolation valve.

3. Pressurizer spray lines from the reactor coolant cold legs to the spray nozzle on the pressurizer vessel.

4. Residual heat removal lines to or from the reactor coolant loops up to the designated isolation or check valve.

5. Safety injection lines from the designated isolation or check valve to the reactor coolant loops.

6. Accumulator lines from the designated isolation or check valve to the reactor coolant loops.

7. Loop fill, loop drain, sample, and instrument lines from the designated isolation valve or 3/8" restrictive orifice to the reactor coolant loops and pressurizer.

8. Pressurizer surge line from one reactor coolant loop hot leg to the pressurizer vessel inlet nozzle.

9. Resistance temperature detector scoop element, pressurizer spray scoop, sample connection with scoop, reactor coolant temperature element installation boss, and the temperature element well itself.

10. All branch connection nozzles attached to reactor coolant loops.

11. Pressure relief lines from nozzles on top of the pressurizer vessel up to and through the power-operated pressurizer relief valves and pressurizer safety valves.

12. Seal injection water and labyrinth differential pressure lines from the reactor coolant pump to the designated isolation or check valve.

13. Excess letdown line from the branch connection on the reactor coolant loop to the 3/8" I.D. flow restrictor.

14. Auxiliary spray line from the isolation valve to the pressurizer spray line header.

Details of the materials of construction and codes used in the fabrication of reactor coolant piping and fittings are discussed in Section 5.2.2.

5.5.3.3 Design Evaluation

Piping load and stress evaluation for normal operating loads, seismic loads, blowdown loads, and combined normal, blowdown and seismic loads is discussed in Section 5.2.2.

5.5.3.3.1 Material Corrosion Erosion Evaluation

The water chemistry is selected to minimize corrosion. A periodic analysis of the coolant chemical composition is performed to verify that the reactor coolant quality meets the specifications.

An upper limit of about 50 feet per second is specified for internal coolant velocity to avoid the possibility of accelerated erosion. All pressure containing welds out to the second valve or flow restrictor that delineates the reactor coolant pressure boundary are available for examination with removable insulation.

Components with stainless steel will operate satisfactorily under normal plant chemistry conditions in pressurized water reactor systems, because chlorides, fluorides, and particularly oxygen, are controlled to very low levels.

Periodic analysis of the coolant chemical composition is performed to monitor the adherence of the system to desired reactor coolant water quality listed in Table 5.2.3-3. Maintenance of the water quality to minimize corrosion is accomplished using the Chemical and Volume Control System and sampling system which are described in Chapter 9.

5.5.3.3.2 Sensitized Stainless Steel

Sensitized stainless steel is discussed in Subsection 5.2.5.

5.5.3.3.3 Contaminant Control

Contamination of stainless steel and Inconel by copper, low melting temperature alloys, mercury and lead is prohibited. Thread lubricants other than colloidal graphite in isopropanol (or Westinghouse PWRSD approved equivalent provided the requirements of TVA internal procedures which control the chemical content of the material used for thread lubricant or sealant are met) shall not be used in plant systems.

Prior to application of thermal insulation on the austenitic stainless steel surfaces for the first time, these surfaces are cleaned and analyzed to a halogen limit of 0.08 mg Cl/dm^2 and 0.08 F/dm^2.

5.5.3.4 Tests and Inspections

The Reactor Coolant System piping quality assurance program is given in Table 5.5.3-1. Inservice inspection is discussed in Section 5.2.8.

5.5.4 Main Steam Line Flow Restrictors

The Main Steam System is not part of the RCS pressure boundary in a PWR. Refer to Sections 6.2.1, 10.3, and 15.4.2 for a discussion on the main steam flow restrictions.

5.5.5 Main Steam Line Isolation System

Since the main steam lines in the Sequoyah Units are not part of the reactor coolant pressure boundary, as in a BWR, the requirement for a discussion of the isolation of the main steam lines in this section of the report is not applicable. For details of the main steam line isolation, see Section 10.3.

5.5.6 Reactor Core Isolation Cooling System

The requirement is for BWR units, and is not applicable to the Sequoyah Units.

5.5.7 Residual Heat Removal System

5.5.7.1 Design Bases

Residual Heat Removal System design parameters are listed in Table 5.5.7-1.

The Residual Heat Removal System is designed to remove heat from the core and reduce the temperature of the Reactor Coolant system (RCS) during the second phase of plant cooldown. During the first phase of cooldown, the temperature of the RCS is reduced by transferring heat from the RCS to the Steam and Power Conversion System through the use of the steam generators.

The Residual Heat Removal System can be placed in operation approximately four hours after reactor shutdown when the temperature and pressure of the RCS are approximately 350°F and 380 psig, respectively. Assuming that two heat exchangers and two pumps are in service and that each heat exchanger is supplied with component cooling water at design flow and temperature, the Residual Heat Removal System is designed to reduce the temperature of the reactor coolant from 350°F to 140°F within 29 hours following Residual Heat Removal System initiation. The heat load handled by the Residual Heat Removal System during the cooldown transient includes residual and decay heat from the core and reactor coolant pump heat. The design heat-load is based on the decay heat fraction that exists at the time of the cooldown.

5.5.7.2 System Description

The Residual Heat Removal System as shown in Figure 5.5.7-1 consists of two residual heat exchangers, two residual heat removal pumps, and the associated piping, valves, and instrumentation necessary for operational control. The inlet line to the Residual Heat Removal System is connected to the hot leg of reactor coolant loop No. 4, while the return lines are connected to the cold legs of each of the reactor coolant loops. These return lines are also the Emergency Core Cooling System low head injection lines. (See Figure 6.3.2-1.)

The RHR pump logic is shown in Figures 5.5.7-2. The Residual Heat Removal System suction line is isolated from the Reactor Coolant System by two motor-operated valves in series and a relief valve, all located inside the containment. The motor-operated valves cannot be opened unless all of the following conditions are satisfied:

1. The RWST suction valve (FCV-63-1) is closed.

2. The containment sump isolation valve in that train is closed (FCV-63-72 or 73).

3. The RCS pressure is less than approximately 380 psig.

4. An administrative lock at valve motor breaker is released (i.e., not less than 350°F) and power is energized.

The RHR pump suction valve is located in the pump room and is interlocked with the respective train containment sump isolation valve. The pump suction valve cannot be opened unless all of the following conditions are satisfied:

1. The containment sump valve in that train is closed (FCV-63-72/73).

2. The ECCS recirculation valve (FCV-63-8) is closed.

3. The RHR spray valve in that train is closed (FCV-72-40 or 41).

The cold leg discharge lines are isolated from the Reactor Coolant System by two check valves located inside the containment and by a normally open motor-operated valve located outside the containment. These valves are shown as part of the Emergency Core Coolant System in Figure 6.3.2-1 and described in Section 6.3.

The environmental qualification of the electric valve operators for these systems that are located within the primary containment is given in Section 3.11.

In the unlikely event that a suction valve to the RCS failed to open, the position indication lights are available in the MCR. An operator can enter the containment and, utilizing the valve handwheel, open the valve manually or the unit can be cooled and maintained at an intermediate hot shutdown temperature utilizing the Steam Generator.

During Residual Heat Removal operation, reactor coolant flows from the RCS to the residual heat removal pumps, through the tube side of the residual heat exchangers, and back to the RCS. The heat is transferred to the component cooling water circulating through the shell side of the residual heat exchangers.

Coincident with operation of the Residual Heat Removal System, a portion of the reactor coolant flow may be diverted from downstream of the residual heat exchangers to the Chemical and Volume Control System low pressure letdown line for cleanup and/or pressure control. By regulating the diverted flow rate and the charging flow, the RCS pressure may be controlled. Pressure regulation is necessary to maintain the pressure range dictated by the fracture prevention criteria requirements of the reactor vessel and by the number 1 seal differential pressure and net positive suction head requirements of the reactor coolant pumps.

The RCS cooldown rate is manually controlled by regulating the reactor coolant flow through the tube side of the residual heat exchangers. A line containing a flow control valve bypasses the residual heat exchangers and is used to control the bypass flow and total return flow to the Reactor Coolant System. Instrumentation is provided to monitor system pressure, temperature and total flow.

The Residual Heat Removal System is also used for filling the refueling cavity before refueling. After refueling operations, water is pumped back to the refueling water storage tank until the water level is brought down to the flange of the reactor vessel. The remainder of the water is removed via a drain connection at the bottom of the refueling canal.

When the Residual Heat Removal System is in operation, the water chemistry is the same as that of the Reactor Coolant. Provision is made for the Sampling System to extract samples downstream of the residual heat exchangers. A local sampling point is also provided on each residual heat removal train between the pump and heat exchanger.

The Residual Heat Removal System functions in conjunction with the Emergency Core Coolant System (ECCS). The use of the Residual Heat Removal System as part of the ECCS is more completely described in Section 6.3.

5.5.7.2.1 Component Description

The materials used to fabricate Residual Heat Removal System components are in accordance with the applicable code requirements. All parts of components in contact with borated water are fabricated or clad with austenitic stainless steel or equivalent corrosion resistant material.

Component codes and classifications are given in Section 3.2 and component parameters are listed in Table 5.5.7-2.

Residual Heat Removal Pumps

Two pumps are installed in the Residual Heat Removal System. The two pumps are vertical, centrifugal units with mechanical seals on the shafts. All pump surfaces in contact with reactor coolant are austenitic stainless steel or equivalent corrosion resistant material. The pumps are sized to deliver reactor coolant flow through the residual heat exchangers to meet the plant cooldown requirements. The use of two pumps assures that cooling capacity is only partially lost should one pump become inoperative.

The residual heat removal pumps have mini-flow lines and valves, which must open, for pump protection during ECCS operation when RCS pressure is above the pump shutoff head. The valves must also open when testing or running the pumps on mini-flow. The mini-flow valves must close when flow increases to ensure sufficient ECCS delivery to the core. The mini-flow valves are opened or closed by their respective flow switches when the pumps are running. The flow switches, which sense differential pressure across an orifice plate at the discharge of the pumps, automatically control the mini-flow valves.

The RHR system has a check valve downstream of each RHR pump miniflow line which functions to preclude the possibility of pump-to-pump interaction when both RHR pumps are operating in the ECCS mode on miniflow. These check valves were the result of the corrective actions for NRC Bulletin 88-04, "Potential Safety-Related Pump Loss."

Pump discharge header pressure is indicated in the MCR. An alarm on high pressure is provided in the MCR.

Residual Heat Exchangers

Two residual heat exchangers are installed in the system. The heat exchangers design is based on heat load and temperature differences between reactor coolant and component cooling water existing twenty hours after reactor shutdown when the temperature difference between the two systems is small.

The installation of two heat exchangers assures that the heat removal capacity of the system is only partially lost if one heat exchanger becomes inoperative.

The residual heat exchangers are of the shell and U-tube type. Reactor coolant circulates through the tubes, while component cooling water circulates through the shell. The tubes are welded to the tube sheet to prevent leakage of reactor coolant.

Residual Heat Removal System Valves

Valves that perform a modulating function are equipped with two sets of packings and an intermediate leakoff connection that discharges to the drain header. Some valves may have their leakoff line connections plugged after packing has been upgraded with graphite packing rings. These new configurations and materials provide improved sealing abilities to reduce the possibilities of stem leakage.

Manual and motor operated valves have backseats to facilitate repacking and to limit stem leakage when the valves are open. Leakage connections are provided where required by valve size and fluid conditions.

The suction isolation valves from the RCS are manually actuated motor operated valves which are closed during normal operation with their power removed to prevent opening. These valves are opened during residual heat removal operations. Operator action is required to close these valves during plant heatup to protect the system from overpressurization. An alarm is provided in the main control room to alert the operator of increasing RHR pressure approaching the RHR system design pressure. Additionally during normal plant operation when the suction valves are closed, if one of the suction isolation valves is moved from the closed position, the alarm will also be activated.

5.5.7.2.2 System Operation

Reactor Startup

Generally, while at cold shutdown, decay heat from the reactor core is being removed by the Residual Heat Removal System. The number of pumps and heat exchangers in service depends upon the heat load at the time.

At initiation of the plant startup, the RCS is completely filled, and the pressurizer heaters are energized. The Residual Heat Removal System is operating and is connected to the Chemical and Volume Control System via the low pressure letdown line to control reactor coolant pressure. During this time, the Residual Heat Removal System acts as an alternate letdown path. The manual valves downstream of the residual heat exchangers leading to the letdown line of the Chemical and Volume Control System are opened. The pressure control valve in the letdown line of the Chemical and Volume Control System is then manually adjusted in the control room to control letdown flow and the system pressure. This letdown flow allows RCP seal injection flow and constant PRZ level.

A pressurizer bubble is formed, then the reactor coolant pumps are started.

Indication of steam bubble formation is provided in the control room by pressurizer level indication. The Residual Heat Removal System is then isolated from the RCS and the system pressure is controlled by normal letdown and the pressurizer spray and pressurizer heaters. RCP operation provides the energy to heat up the RCS.

Power Generation and Hot Standby Operation

During power generation and hot standby operation, the Residual Heat Removal System is not in service but is aligned for operation as part of the ECCS as described in Section 6.3.

Reactor Cooldown

The initial phase of reactor cooldown is accomplished by transferring heat from the RCS to the Steam and Power Conversion System through the use of the steam generators.

When the reactor coolant temperature and pressure are reduced to approximately 350°F and 380 psig, approximately four hours after reactor shutdown, the second phase of cooldown can be started by placing the Residual Heat Removal System in operation.

The rate of heat removal from the reactor coolant is manually controlled by regulating the coolant flow through the residual heat exchangers. By adjusting the control valves downstream of the residual heat exchangers the mixed mean temperature of the return flows is controlled. Coincident with the manual adjustment, the heat exchanger bypass valve is regulated to give the required total flow.

The reactor cooldown rate is limited by RCS equipment cooling rates based on allowable stress limits, as well as the operating temperature limits of the Component Cooling System. As the reactor coolant temperature decreases, the reactor coolant flow through the residual heat exchangers is increased by adjusting the control valve in each heat exchanger's tube-side outlet line.

Pressure control is accomplished by regulating the charging flow rate and the rate of letdown from the Residual Heat Removal System to the Chemical and Volume Control System.

After the reactor coolant pressure is reduced and the temperature is 140°F or lower, the RCS may be opened for refueling.

Reduced Inventory and Midloop Operation

RHR cooling capability continues during cold shutdown and refueling conditions. This includes times when the RCS level is reduced to below the reactor vessel flange and into the midloop region. Procedural controls are provided to establish the proper relationship between RHR flow and reactor vessel level to avoid RHR pump cavitation and loss of RHR cooling.

Refueling

The residual heat removal pumps can be utilized during refueling to pump borated water from the refueling water storage tank to the refueling cavity.

The reactor vessel head is lifted. The refueling water from the RWST is then pumped into the reactor vessel through the normal Residual Heat Removal System return lines and into the refueling cavity through the open reactor vessel.

During refueling, the Residual Heat Removal System is normally maintained in service with the number of pumps and heat exchangers in operation as required by the heat load.

Following refueling, the residual heat removal pumps are used to drain the refueling cavity to the top of the reactor vessel flange by pumping water from the Reactor Coolant System to the refueling water storage tank.

In the event of spurious closure of one of the isolation valves in the Residual Heat Removal suction line, the redundant flow indicators, provided on both of the Residual Heat Removal injection lines to the Reactor Coolant system cold legs, would provide the operator with indication in the main control room of a loss of Residual Heat Removal flow. Also, there will be annunciation provided in the main control room which will alarm in the event of a low-flow condition to either Residual Heat Removal pump when running.

5.5.7.3 Design Evaluation

5.5.7.3.1 System Availability and Reliability

The system is provided with two residual heat removal pumps and two residual heat exchangers arranged in separate flow paths. If one of the two pumps or one of the two heat exchangers is not operable, safe cooldown of the plant is not compromised; however, the time required for cooldown is extended. The two separate flow paths provide redundant capability of meeting the safeguards function of the Residual Heat Removal System.

To assure reliability, the two residual heat removal pumps are connected to two separate electrical buses so that each pump receives power from a different source. If a total loss of off-site power occurs while the system is in service, each bus is automatically transferred to a separate emergency diesel power supply.

5.5.7.3.2 Leakage Provisions and Activity Release

In the event of a Loss Of Coolant Accident (LOCA), fission products may be recirculated through part of the Residual Heat Removal System exterior to the containment. If the residual heat removal pump seal should fail, the water would spill out on the floor in a shielded compartment. Each pump is located in a separate, shielded room. If one of the rooms is flooded, this would have no effect on the other since there are no interconnections.

5.5.7.3.3 Overpressurization Protection

The inlet line to the Residual Heat Removal System is equipped with a pressure relief valve sized to mitigate the heat input and mass input transients as described in Section 5.2.2.4.2 for the purposes of protecting the RHR system given administrative controls as described below.

There are two sets of requirements to ensure that the RHR system is not over pressurized above the code allowable. These restrictions exist when RHR is connected to the RCS and the Rx head is installed. These requirements ensure that the pressure in the RHR system can be maintained as the relief valve setpoint upstream of the RHR pumps. For heat input transients as defined in Section 5.2.2.4.2 there are restrictions on the operation of RCP(s). For $0<T_{RCS}<200$ at least one RCP should be running before temperature reaches 200°F. For $200<T_{RCS}<300$ if all RCPs are lost and one is to be restarted then the pressurizer level must be less than or equal to 65 percent. For $T_{RCS}>300$ if all RCPs are lost they cannot be restarted. For mass input transients there are restrictions on the operation of CCPs and SI pumps: (1) no more than one CCP can be capable of injecting or before placing two CCPs in operation for the purposes of swapping CCPs, the RCS cannot be water solid and (2) no SI pump can be capable of injection. When P_{RHR} exceeds 600 psig downstream of RHR pumps, the RHR pressure must be lowered or the RHR system isolated. There is annunciation of the discharge side of the RHR pumps which indicate high pressure. Upon receipt of this annunciation, the pressure in the RHR system will be monitored to ensure that the condition described is not exceeded.

Each discharge line to the RCS is equipped with a pressure relief valve to relieve the maximum credible back-leakage through the valves separating the Residual Heat Removal System from the RCS. These relief valves are located in the ECCS (see Figure 6.3.2-1). The design of the Residual

Heat Removal System includes two isolation valves in series on the inlet line between the high pressure RCS and the lower pressure Residual Heat Removal System. These valves are motor operated and are closed during normal operation with their actuator power removed to prevent inadvertent opening. When these valves are opened for residual heat removal operation or in the event of isolation valves leaking during normal operation, there is an annunciation provided in the Main Control Room which will alarm in the event of a high pressure on suction side of the RHR pumps. Additionally, this annunciator will also alarm if one of the isolation valves is not closed during normal plant operation. These interlocks are discussed in more detail in subsection 7.6.2.

5.5.7.3.4 Shared Function

The safety function performed by the Residual Heat Removal System is not compromised by its normal function which is normal plant cooldown. The valves associated with the Residual Heat Removal System are normally aligned to allow immediate use of this system in its safeguard mode of operation. The system has been designed in such a manner that two redundant flow circuits are available, assuring the availability of at least one train for safety purposes.

The normal plant cooldown function of the Residual Heat Removal System is accomplished through a suction line arrangement which is independent of any safeguards function. The normal cooldown return lines are arranged in parallel circuits and are utilized also as the low head safeguards injection

lines to the RCS. Utilization of the same return circuits for safeguards as well as for normal cooldown lends assurance to the proper functioning of these lines for safeguards purposes.

5.5.7.3.5 Radiological Considerations

The highest radiation levels experienced by the Residual Heat Removal System are those which would result from a loss of coolant accident. Following a loss of coolant accident, the Residual Heat Removal System is used as a part of the ECCS. During the recirculation phase of emergency core cooling, the Residual Heat Removal System is designed to provide long term cooling by pumping water from the containment sump, cooling it, and returning it to cool the core and containment.

Since, except for some valves and piping, the Residual Heat Removal System is located outside the containment, most of the system is not subjected to the high levels of radioactivity in the containment post-accident environment.

The post accident operation of the Residual Heat Removal System does not involve a radiation hazard for the operators since the system is controlled remotely from the control room. If maintenance of the system is necessary, the portion of system requiring maintenance is isolated by remotely operated valves and/or manual valves with operator or handwheel extensions which allow operation of the valves from a shielded location. The isolated piping may be drained and flushed before maintenance is performed if required.

5.5.7.4 Tests and Inspections

Periodic visual examination and preventive maintenance are conducted during plant operations in accordance with approved plant maintenance program procedures. Inservice Inspection is discussed in subsection 5.2.8.

The instrumentation channels for the residual heat removal pump flow instrumentation devices are calibrated when periodic checks indicate that recalibration is necessary. Due to the role the Residual Heat Removal System has in sharing components with the ECCS, the residual heat removal pumps are tested as a part of the Emergency Core Cooling System testing program (see Subsection 6.3.4).

5.5.8 Reactor Coolant Cleanup System

The Chemical and Volume Control System provides reactor coolant cleanup and is discussed in Section 9.3. The radiological considerations are discussed in Chapter 11.

5.5.9 Main Steam Line and Feedwater Piping

For details of the main steam lines and feedwater piping, see Sections 10.3 and 10.4, respectively.

5.5.10 Pressurizer

5.5.10.1 Design Bases

The general configuration of the pressurizer is shown in Figure 5.5.10-1. The design data of the pressurizer are given in Table 5.5.10-1. Codes and material requirements are provided in Section 5.2.

5.5.10.1.1 Pressurizer Surge Line

The surge line is sized to limit the pressure drop between the Reactor Coolant System (RCS) and the safety valves with design discharge flow from the safety valves. Over pressure of the RCS does not exceed 110 percent of the maximum allowable pressure.

The surge line and the thermal sleeves at each end are designed to withstand the thermal stresses resulting from volume surges which occur during operation.

The pressurizer surge line is qualified for the thermal stratification phenomena which occurs during normal heatup and cooldown of the reactor coolant system as identified in NRC Bulletin 88-11. Qualification is documented in Reference 9.

5.5.10.1.2 Pressurizer

The volume of the pressurizer is equal to, or greater than, the minimum volume of steam, water, or total of the two which satisfies all of the following requirements:

1. The combined saturated water volume and steam expansion volume is sufficient to provide the desired pressure response to programmed system volume changes during credible (Condition II) transients.

2. The water volume is sufficient to prevent the heaters from being uncovered during a step load increase of ten percent of full power.

3. The steam volume is large enough to accommodate the surge resulting from the design step load reduction at full load, with reactor control system, power operated relief valves and steam dump operation, without the water level reaching the high level reactor trip point or high pressurizer pressure reactor trip.

4. The pressurizer does not empty following reactor trip and turbine trip.

5. The safety injection signal is not activated during reactor trip and turbine trip for design transients (Condition II).

5.5.10.2 Design Description

5.5.10.2.1 Pressurizer Surge Line

The pressurizer surge line connects the pressurizer to one reactor hot leg. The line enables continuous coolant volume and pressure adjustments between the RCS and the pressurizer.

5.5.10.2.2 Pressurizer

The pressurizer is a vertical, cylindrical vessel with essentially hemispherical top and bottom heads constructed of carbon steel, with austenitic stainless steel cladding on all surfaces exposed to the reactor coolant.

The surge line nozzle and removable electric heaters are installed in the bottom head. The heaters are removable for maintenance or replacement. A thermal sleeve is provided to minimize stresses in

the surge line nozzle. A screen at the surge line nozzle and baffles in the lower section of the pressurizer prevent insurge of relatively cool water from flowing directly to the steam/water interface, and assists in mixing.

Spray line nozzles and relief and safety valve connections are located in the top head of the vessel. Spray flow is modulated by two automatically controlled air operated valves. The spray valves also can be operated manually from the control room. Manual auxiliary spray is also provided from the CVCS.

A small continuous spray flow through a manual bypass valve around the power operated spray valves provide some mixing of the resident pressurizer liquid with the reactor coolant and to provide chemical mixing and reduce thermal shock to spray piping and nozzle during spray cycles.

During an outsurge from the pressurizer, flashing of water to steam and generation of steam by automatic actuation of the heaters keep the pressure above the low pressurizer pressure reactor trip set point. During insurges from the Reactor Coolant System, which result from normal load transients, the spray system, which is fed from two cold legs, condenses steam in the vessel to prevent the pressurizer pressure from reaching the reactor trip setpoint. Heaters are energized on high water level during insurge to heat the sub-cooled surge water that enters the pressurizer from the reactor coolant loop.

Pressurizer Support

The skirt type support is attached to the lower head and extends for a full 360° around the vessel. The lower part of the skirt terminates in a bolting flange with bolt holes for securing the vessel to its foundation. The skirt type support is provided with ventilation holes around its upper perimeter to assure free convection of ambient air past the heater connector ends for cooling.

Pressurizer Instrumentation

Refer to Chapter 7 for details of the instrumentation associated with pressurizer pressure, level, and temperature.

Spray Line Temperatures

Temperatures in the two spray lines are indicated in the MCR. Alarms are actuated by low spray water temperature which could indicate insufficient flow in the spray lines.

Safety and Relief Valve Discharge Temperatures

Temperatures in the pressurizer safety and relief valve discharge lines are indicated in the MCR. An increase in a discharge line temperature could be an indication of leakage through the associated valve.

5.5.10.3 Design Evaluation

5.5.10.3.1 System Pressure

Whenever a steam bubble is present within the pressurizer, Reactor Coolant System pressure is maintained by the pressurizer. Analyses indicate that proper control of pressure is maintained for the operating conditions.

A safety limit has been set to ensure that the RCS pressure does not exceed the maximum transient value allowed under the ASME code, Section III, and thereby assure continued integrity of the RCS boundary. Evaluation of plant conditions of operation which follow indicate that this safety limit is not reached.

During startup and shutdown, the rate of temperature change is controlled by the operator. When the reactor core is shut down, the maximum heatup rate by pump energy, as controlled by the operator, is limited by the installed pressurizer electrical heating capacity. This heatup rate takes into account the continuous spray flow provided to the pressurizer.

If the pressurizer is filled with water, i.e., near the end of the second phase of plant cooldown and during initial system heatup, RCS pressure is maintained by the Chemical and Volume Control System with letdown from the Residual Heat Removal System.

5.5.10.3.2 Pressurizer Performance

The pressurizer has a minimum internal volume of 1800 cubic feet. The normal operating water volume at full load conditions is 60 percent of the minimum free internal vessel volume. Under part load conditions, the water volume in the vessel is reduced for proportional reductions in plant load to 25 percent of free vessel volume at zero (0) power level. The various plant operating transients are analyzed to assure that the design pressure is not exceeded with the pressurizer design parameters as given in Table 5.5.10-1.

5.5.10.3.3 Pressure Set Points

The RCS design and operating pressure together with the safety, power relief and pressurizer spray valves set points, and the protection system setpoint pressures are listed in Section 5.2, Table 5.2.2-2. The design pressure allows for operating transient pressure changes. The selected design margin considers core thermal lag, coolant transport times and pressure drops, instrumentation and control response characteristics, and system relief valve characteristics.

5.5.10.3.4 Pressurizer Spray

Two separate, automatically controlled spray valves with remote manual overrides are used to control pressurizer spray. In parallel with each spray valve is a manual throttle valve which permits a small continuous flow through both spray lines to reduce thermal stresses and thermal shock when the spray valves open, and to help maintain uniform water chemistry and temperature in the pressurizer. Temperature sensors with low alarms are provided in each spray line to alert the operator to insufficient bypass flow. The layout of the common spray line piping to the pressurizer forms a water seal which prevents steam buildup back to the control valves. The spray rate is selected to prevent the pressurizer pressure from reaching the operating set point of the power relief valves during a step reduction in power level of ten percent of full load. In the case that one of the two automatically controlled spray valves is out of service or inoperable, analysis has determined a ten percent step load decrease transient will not challenge the operating set point of the pressurizer power relief valves.

The pressurizer spray lines and valves are large enough to provide adequate spray using as the driving force the differential pressure between the surge line connection in the hot leg and the spray line connection in the cold leg. The spray line inlet connections extend into the cold leg piping in the

form of a scoop so that the velocity head of the reactor coolant loop flow adds to the spray driving force. The spray lines are connected to loops 1 and 2 to ensure spray flow in the event one RCP is not operating. The line may also be used to assist in equalizing the boron concentration between the reactor coolant loops and the pressurizer.

A flow path from the Chemical and Volume Control System to the pressurizer spray line is also provided. This additional facility provides auxiliary spray to the vapor space of the pressurizer during cooldown if the reactor coolant pumps are not operating. The thermal sleeves on the pressurizer spray connection and the spray piping are designed to withstand the thermal stresses resulting from the introduction of cold spray water.

5.5.10.3.5 Pressurizer Design Analysis

The occurrences for pressurizer design cycle analysis are defined as follows:

1. The temperature in the pressurizer vessel is always, for design purposes, assumed to equal saturation temperature for the existing pressurizer pressure, except in the steam space following a pressure increase. In this case, the temperature of the steam space will exceed the saturation temperature since an isentropic compression is assumed.

   The only exception of the above occurs when the pressurizer is completely filled with liquid during plant startup and cooldown.

2. The temperature shock on the spray nozzle is assumed to equal the temperature of the nozzle minus the cold leg temperature and the temperature shock on the surge nozzle is assumed to equal the pressurizer water space temperature minus the hot leg temperature.

3. Pressurizer spray is assumed to be initiated instantaneously to its design flow rate as soon as the RCS pressure increases above 2275 psia.[1] Spray is assumed to be terminated as soon as the RCS pressure falls below 2275 psia unless otherwise noted.

4. Unless otherwise noted, pressurizer spray is assumed to be initiated once per occurrence of each transient condition. The pressurizer surge nozzle is also assumed to be subject to one temperature transient per transient condition, unless otherwise noted.

5. Each Condition II (Upset Condition) transient results in a reactor trip. At the conclusion of these transients the RCS, including pressurizer, is assumed to return to no-load conditions, with pressure and temperature changes controlled within normal limits.

6. For design purposes, the following assumptions are made with respect to Condition III (Emergency Conditions) and Condition IV (Faulted Conditions) transients.

   a. The plant eventually reaches cold shutdown conditions in the following cases:

---

[1]Spray is assumed to be at maximum rate instantaneously upon exceeding setpoint.

i. Small Loss-of-Coolant Accident (LOCA) - Condition III
ii. Small Steam Break - Condition III
iii. Reactor Coolant Pipe Break (Large LOCA) - Condition IV
iv. Large Steam Line Break - Condition IV

After the transients are completed, cooldown to the cold shutdown conditions is controlled by the operator, maintaining pressure and temperature changes within allowable limits in so far as possible.

b. For the other Conditions III and Condition IV transients, the plant goes to hot shutdown until the condition of the plant is determined. It is then brought either to no-load conditions or to cold shutdown conditions, with pressure and temperature changes controlled within allowable limits.

7. Temperature changes occurring as a result of pressurizer spray are assumed to be instantaneous. Temperature changes occurring on the surge nozzle are also assumed to be instantaneous.

8. Whenever spray is initiated in the pressurizer, the pressurizer water level should be assumed to be at the no-load level. This is conservative, as it maximizes the pressurizer wall area exposed to the spray.

5.5.10.4 Tests and Inspections

The pressurizer is designed and constructed in accordance with ASME Section III.

Peripheral support rings are furnished for the removable insulation modules.

The pressurizer quality assurance program is given in Table 5.5.10-2.

5.5.11 Pressurizer Relief Tank

5.5.11.1 Design Bases

Design data for the pressurizer relief tank are given in Table 5.5.11-1. Codes and materials of the tank are given in Section 5.2.

The tank design is based on the requirement to condense and cool a discharge of pressurizer steam equal to 110 percent of the volume above the full power pressurizer water level setpoint. The tank is not designed to accept a continuous discharge from the pressurizer. The volume of water in the tank is capable of absorbing the heat from the assumed discharge, assuming an initial temperature of 132°F. If the temperature in the tank rises above 132°F during plant operation, the tank can be cooled by spraying in cool water and draining out the warm mixture to the holdup tanks in the Chemical and Volume Control System (CVCS) or to either the floor drain collector tank or tritiated drain collector tank in the Waste Disposal System as required.

5.5.11.2 Design Description

Discharge from smaller relief valves located inside and outside the containment is also piped to the pressurizer relief tank. These smaller relief valves are specific to the Residual Heat Removal,

Safety Injection, Containment Spray and Chemical Volume Control Systems. The tank normally contains water and a predominantly nitrogen atmosphere; however, provision is made to permit the gas in the tank to be periodically analyzed to monitor the concentration of hydrogen and/or oxygen.

By means of its connection to the Waste Processing System, the pressurizer relief tank provides an additional means for removing any noncondensable gases from the Reactor Coolant system which might collect in the pressurizer vessel.

Steam from the pressurizer safety and relief valves is discharged into the pressurizer relief tank through a sparger pipe under the water level. This condenses and cools the steam by mixing it with water that is near ambient temperature. The tank is equipped with an internal spray and a drain which are used to cool the tank following a discharge. A flanged nozzle is provided on the tank for the pressurizer discharge line connection.

5.5.11.2.1 Pressurizer Relief Tank Level

The pressurizer relief tank level is indicated in the MCR with high and low level alarms.

5.5.11.2.2 Pressurizer Relief Tank Water Temperature

The temperature of the water in the pressurizer relief tank is indicated in the MCR, and a high temperature alarm informs the operator that cooling of the tank contents may be required.

5.5.11.3 Design Evaluation

The PRT design is based on the requirement to condense and cool a discharge of pressurizer steam equal to 110 percent of the volume above the full-power pressurizer water level set-point.

The steam volume requirement is approximately the amount of steam that would be discharged from the pressurizer safety valves and relief valves if the plant were to suffer a complete loss of load accompanied by a turbine trip without an immediate reactor trip. A reactor trip is assumed to be initiated slightly later by high pressurizer water level.

The rupture discs on the relief tank have a relief capacity equal to the combined capacity of the pressurizer safety valves. The tank design pressure is twice the calculated pressure resulting from the maximum design safety valve discharge described above. The tank and rupture discs holders are also designed for full vacuum to prevent tank collapse if the contents cool following a discharge without nitrogen being added.

The discharge piping from the safety and relief valves to the relief tank is sufficiently large to prevent backpressure at the safety valves from exceeding 20 percent of the set point pressure at full flow.

5.5.12 Valves

5.5.12.1 Design Bases

As noted in Section 5.2, for all valves out to and including the second valve normally closed or capable of automatic or remote closure, valve closure time is such that for any postulated component failure outside the system boundary, the loss of reactor coolant would not prevent orderly reactor shutdown and cooldown assuming makeup is provided by normal makeup systems. Normal makeup systems are those systems normally used to maintain reactor coolant

inventory under respective conditions of start-up, hot standby, operation or cooldown. For a check valve to qualify as the system boundary, it must be located inside the primary containment boundary.

Construction materials are specified to minimize corrosion/erosion and to ensure compatibility with the environment.

Valves are designed and fabricated in accordance with ANSI B16.5, MSS-SP-66 and ASME Section III, 1968 Edition. Leakage is minimized to the extent practicable by design.

Design parameters for the Reactor Coolant System (RCS) boundary valves are given in Table 5.5.12-1.

5.5.12.2 Design Description

All valves in the RCS which are in contact with the coolant are constructed primarily of stainless steel. Other materials in contact with the coolant, such as for hard surfacing and packing, are special materials.

RCS manual or motor-operated valves, 3 inches or larger, and throttling control valves, regardless of size, may have double-packed stuffing boxes and intermediate leakoff connections. Some valves may have their leakoff line connections plugged after packing has been upgraded with graphite packing rings. These new configurations and materials provide improved sealing abilities to reduce the possibilities of stem leakage.

For valves normally containing radioactive fluid and operating above 212°F, leakoff connections, when used, are piped to a closed collection system so leakage to the atmosphere is essentially zero.

Gate valves at the Engineered Safety Features interface are either wedge design or parallel disc and are essentially straight through. The wedge may be either split or solid. All gate valves have backseat and outside screw and yoke. Globe valves, "T" and "Y" style are full ported with outside screw and yoke construction. Check valves are spring loaded lift piston types for sizes 2 inches and smaller, and swing type for sizes 3 inches and larger. All check valves which contain radioactive fluid are stainless steel or equivalent corrosion resistant material and do not have body penetrations other than the inlet, outlet and bonnet. The check hinge is serviced through the bonnet.

The accumulator check valve is designed with a low pressure drop configuration with all operating parts contained within the body. The disc has limited rotation to provide a change of seating surface and alignment after each valve opening.

The isolation valves between the accumulators and the reactor coolant system boundary are provided with interlocks that meet the intent of IEEE-279 and assure automatic valve opening when reactor coolant system pressure exceeds a specified pressure or on a safety injection signal. These interlocks are discussed in detail in Section 6.3.2.

5.5.12.3 Design Evaluation

Stress analysis of the reactor coolant loop/support system, discussed in Section 3.7 and 5.2, assure acceptable stresses for all valves in the reactor coolant pressure boundary under every anticipated condition.

Reactor coolant chemistry parameters are specified to minimize corrosion. Periodic analysis of coolant chemical composition ensure that the reactor coolant meets these specifications. The upper-limit coolant velocity of about 50 feet per second precludes accelerated corrosion.

Valve leakage is minimized by design features as discussed above.

All Reactor Coolant System boundary valves required to perform a safety function, during the short term recovery from transients or events considered in the respective operating condition categories, will operate in less than or equal to 10 seconds (except for PORV block valves, which have a longer allowed stroke time).

5.5.12.4 Tests and Inspections

Pressure tests, seat leakage tests, and operation tests are performed on reactor coolant boundary valves as required by ASME Section XI, and the SQN Technical Specifications. No further test program is considered necessary.

There are no full-penetration welds within valve body walls. Valves are accessible for disassembly and internal visual inspection.

Inservice inspection is discussed in Subsection 5.2.8.

5.5.13 Safety and Relief Valves

5.5.13.1 Design Bases

The combined capacity of the pressurizer safety valves is designed to accommodate the maximum surge resulting from complete loss of load. This objective is met without reactor trip or any operator action provided that the steam safety valves open as designed when steam pressure reaches the steam-side safety valve setting.

The power-operated pressurizer relief valves operate below the fixed high pressure reactor trip setpoint to limit pressurizer pressure.

5.5.13.2 Design Description

The pressurizer safety valves are totally enclosed pop type. The valves are spring loaded, self activated and with back pressure compensation features.

The 6 inch pipe connecting each pressurizer nozzle to its respective code safety valve, is shaped in the form of a loop seal. Any condensate forming in the loop seal, as a result of normal heat losses, is continuously drained back to the pressurizer. If the pressurizer pressure exceeds the set pressure of the safety valves, they start lifting, and steam discharges during the actuation period.

The relief valves are quick-opening and operated automatically or by remote control. Remotely operated block valves are provided to isolate the power operated relief valves if necessary.

Temperatures in the pressurizer safety and relief valve discharge lines are indicated in the MCR. An increase in a discharge line temperature could be an indication of leakage through the associated valve.

Design parameters for the pressurizer spray control, safety, and power relief valves are given in Table 5.5.13-1.

5.5.13.3 Design Evaluation

The pressurizer safety valves prevent reactor coolant system pressure from exceeding 110 percent of system design pressure, in compliance with the ASME Nuclear Power Plant Components Code, Section III. Design of the safety valves accounts for the pressure drop between the reactor coolant pump discharge and the most remote safety valve. These valves attain full lift prior to reaching 3 percent above set pressure.

The pressurizer power-operated relief valves prevent actuation of the reactor high-pressure trip for all design transients up to and including the design step load decrease with steam dump but without reactor trip. The relief valves also limit undesirable opening of the spring-loaded safety valves.

5.5.13.4 Tests and Inspections

The safety and relief valves are subjected to pressure tests, seat leakage tests, operational tests, and inspections, as required. These tests assure that the valves will operate as designed.

There are no full penetration welds within the valve body walls. Valves are accessible for disassembly and internal visual inspection.

5.5.14 Component Supports

5.5.14.1 Design Bases

Component supports allow virtually unrestricted lateral thermal movement of the loop during normal plant operation and provide restraint to the loops and components during accident conditions. The loading combinations, design stress limits are discussed in Paragraph 5.2.1.2. Material properties are discussed in Subsection 5.2.3. Support design is in accordance with "Specifications for Design, Fabrication and Erection of Structural Steel for Buildings," American Institute of Steel Construction, 1969 Edition. The design maintains the integrity of the reactor coolant system boundary for normal and accident conditions and satisfies the requirements of the piping code. Piping and supports stress analyses are presented in Paragraphs 5.2.1.2 and 5.2.1.3.

5.5.14.2 Description

The support structures are of welded steel construction and are either a linear type or plate and shell type. Vessel skirts and saddles are fabricated from plate and shell elements to accommodate a biaxial stress field. Linear supports are tension and compression struts, beams and columns. Attachments are of integral and non-integral types. Integral attachments are welded, cast or forged to the pressure boundary component by lugs, shoes, rings and skirts. Non-integral attachments are bolted, pinned, or bear on the pressure boundary component. By means of sliding joints, clamps, cradles, saddles, or straps the non-integral supports transmit loads to integral supports.

The supports permit unrestrained thermal growth of the supported systems but restrain vertical, lateral, and rotational movement resulting from seismic and pipe break loadings. This is accomplished using pin ended columns for vertical support and girders, bumper pedestals, hydraulic snubbers, and tie-rods for lateral support.

Shimming and grouting enable adjustment of all support elements during erection to achieve correct fit up and alignment. Final setting of equipment is by shim and grouting at the concrete-steel support interface rather than at the equipment-support interface.

Vessel

Supports for the reactor vessel (Figure 5.5.14-1) are individual aircooled rectangular box structures beneath the vessel nozzles bolted to the primary shield wall concrete. Each box structure consists of a horizontal top plate that receives loads from the reactor vessel shoe, a horizontal bottom plate supported by and transferring loads to the primary shield wall concrete, and connecting vertical plates. The supports are air cooled with a design inlet air temperature of 130°F.

Steam Generator

The lower supports for the steam generator (Figure 5.5.14-2) consists of (1) four vertical pin-ended columns bolted to the bottom of the steam generator support pads, and (2) lateral support girders and pedestals that bear against horizontal bumper blocks bolted to the side of the generator support pads. The upper lateral steam generator support consists of a ring girder around the generator shell connected to hydraulic snubbers on the reactor vessel side and supported by struts on other sides to transmit lateral loads to the building concrete. Loads are transferred from the equipment to the ring girder by means of a number of bumper blocks between the girder and generator shell.

Pump

The reactor coolant pump supports (Figure 5.5.14-3) consist of three pin-ended structural steel columns and three lateral tie bars. A large diameter bolt connects each column and tie rod to a pump support pad.

Pressurizer

The pressurizer (Figure 5.5.14-4) is supported at its base by bolting the flange ring to the supporting concrete slab. In addition upper lateral internal support is provided near the vessel center of gravity by four "V frames" extending horizontally from the compartment walls and bearing against the vessel lugs.

Piping

In original construction of Unit 1 and Unit 2, the reactor coolant loop (RCL) piping contained three pipe thrust blocks attached to the internal concrete structure, functioning as the RCL support system. These were located on the crossover leg pipe, one at each end of the horizontal run (Figure 5.5.14-5), and the other at the vertical run on the steam generator side. As a result of the Unit 1 and Unit 2 steam generator replacements, the RCL piping for both Unit 1 and Unit 2 does not contain any component supports or whip restraints.

5.5.14.3 Evaluation

Detailed evaluation ensures the design adequacy and structural integrity of the RCL and the Primary Equipment Supports System. This detailed evaluation is made by comparing the analytical results with established criteria for acceptability. Structural analyses are performed to demonstrate design adequacy for safety and reliability of the plant in case of a large or small seismic disturbance and/or loss-of-coolant accident conditions. Loads which the system is expected to encounter often during its lifetime (thermal, weight, pressure, and operational basis earthquake) are applied and stresses are compared to allowable values as described in Paragraph 5.2.1.2 and 5.2.1.3.

The safe shutdown earthquake (SSE) and design basis loss-of-coolant accident (LOCA) resulting in a rapid depressurization of the system, are required design conditions for public health and safety.

For SSE and LOCA loadings, the basic criteria ensure that the severity will not be increased, thus maintaining the system for a safe shutdown condition.

The rupture of a reactor coolant loop pipe will not violate the integrity of the unbroken leg of the loop. To ensure the integrity and stability of the RCL support system and a safe shutdown of the system under LOCA and the worst combined (Normal + SSE + LOCA) loadings, the stresses in the unbroken piping to broken loop as well as those in the unbroken loop piping and the supports system are analyzed.

The results of design analysis are provided in Paragraph 5.2.1.2 and 5.2.1.3.

5.5.14.4 Tests and Inspections

The design and fabrication is specified in accordance with the AISC Specifications for the "Design, Fabrication, and Erection of Structural Steel for Buildings," 1969 Edition and applicable portions of the ASME Boiler and Pressure Vessel Code. Welder Qualifications, Welding Procedures, and Inspection of Welded Joints is specified to be in accordance with Section IX of the ASME Code.

5.5.15 Reactor Coolant System Head Vents (RCSHVs)

Design Basis

The basic function of the Reactor Coolant System Head Vent (RCSHV) is to remove noncondensable gases or steam from the reactor vessel head. This system is designed to mitigate a possible condition of inadequate core cooling or impaired natural circulation resulting from the accumulation of noncondensable gases in the Reactor Coolant System (RCS).

This system may also be used as a backup RCS letdown flowpath to prevent filling the pressurizer solid after the reactor is tripped with normal and excess letdown unavailable.

General Description

The RCSHV is designed to remove noncondensable gases or steam from the reactor coolant system via remote manual operation from the control room. The piping is connected above the reactor vessel to one of the capped injection lines previously used for the Upper Head Injection System and is routed to the pressurizer relief tank. The socket welded connection to the cap contains a 3/8 inch orifice which would serve to limit the blowdown from a break in the RCSHV piping to within the capacity of the normal makeup system. The system is designed to vent a volume of noncondensables, such as hydrogen, from the reactor vessel in a reasonable amount of time to preclude increased accumulation.

The RCSHV piping consists of one flow path with redundant valves with identical bypass valves in parallel. The venting operation uses only one of the parallel valves at any one time.

The active portion of the RCSHVs consists of four one-inch solenoid operated valves. The inboard solenoid isolation valves are open/close isolation valves. The outboard throttle valves are remotely operated and capable of regulating the flow rate through the system. With two valves in series in the flow path, the possibility of reactor coolant pressure boundary leakage is minimized. The two parallel isolation valves are powered by two different vital power supplies. The isolation valves are fail

closed, normally closed active valves. Similarly, the throttle valves are powered by two different vital power supplies. They are also fail closed normally closed valves. The isolation and throttle valves are included in the Westinghouse valve operability program which is an acceptable alternative to Regulatory Guide 1.48. These valves will be qualified to IEEE-323-1974, -344-1975, -382-1972.

If one single active failure prevents a venting operation, the redundant parallel valve is available for venting. Similarly the two redundant valves provide a single failure method of closing the vent system. With two valves in series, the failure of any one valve or power supply will not inadvertently open a vent path. Thus, the combination of safety grade train assignments and valve failure modes will not prevent vessel head venting nor venting isolation with any single active failure. Therefore, the single failure capability to vent the reactor vessel head exceeds the requirements to NUREG-0737 since the system is also a backup to the pressurizer vent path (PORVs) and vice-versa. As such, a total failure of the RCSHV to open could be rectified by pressurizer venting. This same reasoning can also be applied to reduction in the capacity of one vent path since the parallel path would be available to increase the venting rate. Therefore, failure or partial opening of one control valve can be supplemented by opening the parallel head vent control valve or by using the pressurizer vent system.

In addition to the preceeding single failure system valve arrangement, all valves are normally closed. This eliminates the possibility of an open flow path due to the spurious movement of one valve. As such, power lockout to any valve is not considered necessary.

In addition to the RCSHV valves being controlled from the control room, the isolation valves also have stem position switches, such that the position may be monitored by status lights. The throttle valve position is monitored by an independent valve position feedback signal.

Therefore, the system provides for venting the reactor vessel head by using only safety grade equipment. From the orifice to the discharge of the throttle valves, all equipment is designed and fabricated in accordance with the ASME, Section III, Class 2 requirements. The remainder of the piping is non-nuclear safety. The RCSHV satisfies applicable requirements and industry standards including the ASME Code classification , safety classification, single-failure criteria, and environmental qualification.

5.6 INSTRUMENTATION APPLICATION

Process control instrumentation is provided for the pressurizer and RCS loops (including the reactor coolant pump motors). Residual Heat Removal System instrumentation is discussed in sections 6.3 and 7.6. The safety-related display instrumentation for Post Accident Monitoring is discussed in Section 7.5. Instrument locations for the RCS are shown in the Figure 5.1-1. Functional diagrams involving RCS instrument applications are provided in Section 7.1. This instrumentation provides input signals for the Protection System and Control Systems as follows:

1. Provide input to the Reactor Trip System for reactor trips as follows:

   a. Overtemperature ΔT

   b. Overpower ΔT

   c. Low pressurizer pressure

   d. High pressurizer pressure

   e. High pressurizer water level

   f. Low primary coolant flow

   Provide input to the Engineered Safety Features Actuation System (ESFAS) as follows:

   a. Pressurizer low pressure

3. Furnish input signals to non-safety related systems, such as the Plant Control Systems (or the Distributed Control System (DCS)) and surveillance circuits so that:

   a. Reactor coolant average temperature (Tavg) will be maintained within prescribed limits.

   b. Pressurizer level control, using Tavg to program the setpoint.

   c. Pressurizer pressure will be controlled within specified limits.

   d. Steam dump control, using Tavg control, will accommodate sudden loss of generator load.

   e. Information is furnished to the control room operator and at local stations for monitoring.

The following is a functional description of the system instrumentation. Unless otherwise stated, all indicators, recorders and alarm annunciators are located in the main control room.

1. Temperature Measuring Instrumentation

   a. Narrow Range Cold and Hot Leg Temperature (RTDs)

      Separate thermowells (three in each hot leg and two in each cold leg) are provided so that individual temperature signals may be developed for use in the Reactor Control and Protection System. The hot leg temperature for each loop is measured by three fast-response, narrow-range RTDs mounted in thermowells which extend into the flow stream at locations 120 degrees apart in the cross-sectional plane of the hot leg. A hole is drilled through the end of each scoop so that water will flow in through the holes in the leading edge of the scoop, past the RTD, and out through the end hole.

The cold leg temperature is obtained for each loop by two fast response narrow-range RTDs mounted in thermowells placed in each cold leg at the discharge of the reactor coolant pump. These thermowells are located as follows: one located at the top center line of the cold leg and the other 45 degrees (clockwise for Unit 1 and counter-clockwise for Unit 2) from the top as viewed from the reactor coolant pump towards the reactor vessel.

Signals from these instruments are used to compute the reactor coolant ΔT (temperature of the hot leg, Thot, minus the temperature of the cold leg, Tcold) and an average reactor coolant temperature (Tavg). The Tavg for each loop is indicated in the main control room.

b. Wide Range Cold Leg and Hot Leg Temperatures

Temperature detectors, located in the thermometer wells in the cold and hot leg piping of each loop, supply signals to wide range temperature recorders. This information is used by the operator to control coolant temperature during startup and shutdown.

c. Pressurizer Temperature

There are two temperature detectors in the pressurizer, one in the steam phase and one in the water phase. Both detectors supply signals to temperature indicators and high-temperature alarms. The steam phase detector, located near the top of the pressurizer, can be used during startup to determine water temperature when the pressurizer is completely filled with water. The water phase detector, located at an elevation near the center of the heaters, can be used during cooldown when the steam phase detector response is slow due to poor heat transfer.

d. Surge Line Temperature

This detector supplies a signal for a temperature indicator and a low-temperature alarm. Low temperature could be an indication that the continuous spray rate is too small.

e. Safety and Relief Valve Discharge Temperatures

Temperatures in the pressurizer safety and relief valve discharge lines are measured and indicated. An increase in a discharge line temperature is an indication of operation or leakage through the associated valve.

f. Spray Line Temperatures

Temperatures in the spray lines, one from each of two loops are measured and indicated. Alarms from these signals are actuated by low spray water temperature which could indicate insufficient flow in the spray lines.

g. Pressurizer Relief Tank Water Temperature

The temperature of the water in the pressurizer relief tank is indicated, and an alarm actuated by high temperature informs the operator that cooling of the tank contents may be required.

h. Reactor Vessel Flange Leakoff Temperature

The temperature in the leakoff line from the reactor vessel flange O-ring seal connections is indicated. An increase in temperature above ambient may be an indication of O-ring seal leakage. High temperature actuates an alarm.

i. Reactor Coolant Pump Motor Temperature Instrumentation

i. Thrust Bearing Upper and Lower Shoes Temperature:

Resistance temperature detectors are provided with one located in one shoe of the upper and one in one shoe of the lower thrust bearing. These RTDs provide a signal to the plant computer.

ii. Stator Winding Temperature:

The stator windings contain multiple resistance-type detectors, at least two per phase, imbedded in the windings. A signal from one of these detectors is monitored by the plant computer which actuates a high temperature alarm.

iii. Upper and Lower Bearing Temperature:

Resistance temperature detectors are located one in one shoe of the upper and one in one shoe of the lower radial bearings. These RTDs provide a signal to the plant computer.

2. Flow Indication

a. Reactor Coolant Loop Flow

Flow is monitored by three differential pressure measurements at a piping elbow tap in each reactor coolant loop. These measurements, on a two-out-of-three coincidence circuit, provide a loss of flow signal to the reactor protection system.

3. Pressure Indication

a. Pressurizer Pressure

Four pressurizer pressure transmitters provide signals for individual indicators in the main control room, actuation of a low pressure trip, a high pressure trip, safety injection initiation and for safety injection signal unblock during plant startup. The four pressure signals provide input into two independent DCS processor controllers. The DCS selects the median-low signal to be used in each of the independent processors for control to preclude a single input signal failure from causing a plant upset. This median-low signal is used for display on the pressure recorder.

The median-low signal is also used by a three mode pressure controller along with a reference signal, or pressure setpoint, contained within the DCS. The lower portion of the controller's output range operates the pressurizer heaters. For normal operation, a small group of heaters is controlled by variable power to maintain the pressurizer operating pressure. If the pressure error signal falls towards the bottom of the variable heater control range, additional pressurizer heaters are turned on.

The upper portion of the controller's output range operates the pressurizer spray valves and one PORV. The spray valves are proportionally controlled in a range above normal operating pressure with spray flow increasing as pressure rises. If the pressure rises significantly above the proportional range of the spray valves, one PORV (interlocked with a separate and independent DCS processing group to prevent spurious operation) is opened. A further increase in pressure will actuate a high pressure reactor trip signal. The second PORV will also actuate due to high pressurizer pressure determined by the median low pressure signal in the two independent DCS processor controllers to prevent its spurious operation.

b. Reactor Coolant Loop Pressures

Reactor coolant loop pressure is measured at the locations shown on Figure 5.1-1 and indicated in the MCR. RCS pressure is also used in the RVLIS.

c. Pressurizer Relief Tank Pressure

Pressurizer relief tank pressure instrumentation is provided and indicated in the MCR.

d. Reactor Coolant Pump Motor Oil

i. Oil Lift Switch

A dual purpose switch is provided on the high pressure oil lift system. Upon low oil pressure the switch will actuate an alarm on the main control board. In addition, the switch is part of an interlock system that will prevent starting of the pump until the oil lift pump is started manually prior to starting the reactor coolant pump motor.

ii. Lower Oil Reservoir Liquid Level

A level switch is provided in the motor lower radial bearing oil reservoir. The switch will actuate a high / low level alarm in the MCR.

iii. Upper Oil Reservoir Liquid Level

A level switch is provided in the motor upper radial bearing and thrust bearing oil reservoir. The switch will actuate a high / low level alarm in the MCR.

4. Liquid Level Indication

a. Pressurizer Level

Three pressurizer liquid level transmitters provide signals for use in the Reactor Control and Protection System, the Emergency Core Cooling System and the Chemical and Volume Control System. The transmitters provide a high water level alarm and input for a reactor trip. The transmitters also provide independent low water level signals that will activate an alarm. Each transmitter has a level indicator that is located in the MCR.

The three level transmitters provide input signals into the two separate and independent DCS processors that utilize the median signal for control and indication functions as follows:

i. One DCS processing group provides the median level signal that is displayed on a level recorder located in the MCR.

ii. Each DCS processing group will actuate an alarm when level falls to a fixed level setpoint. The same signal will trip the pressurizer heaters "off" and close the letdown line isolation valves.

iii. One DCS processor supplies a signal to the pressurizer liquid level controller (also contained within DCS) for charging flow control and also initiation of a low flow (hi demand) alarm. This signal is also compared to the reference level and actuates a high level alarm and turns on pressurizer backup heaters if the actual level exceeds the allowed reference level band. If the actual level is lower than the allowed reference level band, a low alarm is actuated.

A fourth independent pressurizer level transmitter that is calibrated for low temperature conditions, provides water level indication during startup, shutdown and certain refueling operations.

b. Pressurizer Relief Tank Level

The pressurizer relief tank level transmitter supplies a signal for an indicator and high and low level alarms.

5. RCS Midloop and Reduced Inventory Instrumentation for Generic Letter 88-17

Midloop operation exists when the fluid level in the RCS is below the top of the hot legs. Reduced Inventory operation exists when the fluid level in the RCS is three feet below the Reactor Vessel flange. Specific temperature and level instrumentation requirements are:

At least two independent, continuous temperature indications representative of core exit conditions are required when the reactor vessel head is in place with irradiated fuel in the vessel. These independent temperature indications must be periodically monitored.

At least two independent, continuous RCS water level indications must be periodically checked and recorded or automatically monitored and alarmed in the control room. Two independent permanent level systems are capable of monitoring RCS level during midloop operation. The Ultrasonic Level Monitoring System (ULMS) can operate in midloop and has main control room indication which includes high and low level alarms. The Liquid Level Gauge (LLG) has main control room indication which includes high and low level alarms. The LLG is a multi-channel instrument that can operate in midloop and reduced inventory conditions. Other instrumentation can be utilized for level indication when controlled by established procedures (e.g. modified RVLIS, temporary pressure transmitters, temporary sightglass).

Procedures are provided to address loss of decay heat removal when the RCS is in a reduced inventory condition to include the following:

a) A predetermined action plan for establishing containment closure.

b) Operations cognizant of all open containment penetrations during reduced inventory conditions, and appropriate notice will be given to initiate closure actions following a loss of RHR.

c) Provide environmental monitoring for closure activities as appropriate.

d) Maintain availability of one train of hydrogen igniters and one air return fan, and guidance will be provided on their use.

e) Outage activities will be planned and scheduled to avoid perturbations to the RCS or the RHR system while the RCS is in reduced inventory condition and to provide for increased monitoring and enhanced communication if these activities cannot be avoided.

f) Two available or operable means to add inventory to the RCS at all times will be maintained, and guidance will be provided for use of these standby sources in the event of a loss of RHR in a reduced inventory condition.

g) Adequate RCS hot-side ventilation will be provided before installing each hot leg nozzle dam or when there is cold-side opening.

The RCS design and operating pressure together with the safety, PORV and pressurizer spray valve setpoints, and the protection system setpoint pressures are listed in Table 5.2.2-2. The design pressure allows for operating transient pressure changes. The selected design margin considers core thermal lag, coolant transport times and pressure drops, instrumentation and control accuracy and response characteristics, and system relief valve characteristics.

6.0 ENGINEERED SAFETY FEATURES

6.1 GENERAL

The engineered safety features provided for each unit include sufficient redundancy of components and power sources to prevent undue risk to public health and safety under the conditions of a hypothetical design basis accident.

The systems provided are summarized below:

1. The steel containment vessel provides a highly reliable barrier against the escape of fission products. All vessel penetrations with gasket or bellows sealed components are provided with double containment which is available for periodic leak testing. Pipes or ducts penetrating the containment which could become potential paths for leakage to the environment following a loss of coolant accident are provided with isolation valves.

   Containment penetrations are designed to prevent leakage from the containment and testable penetrations can be pressurized to values above containment design pressure for leak rate testing.

2. The Emergency Core Cooling System protects the fuel cladding following a loss of coolant accident by providing a timely and adequate supply of borated water to the Reactor Coolant System and, ultimately, the reactor core. The Emergency Core Cooling System provides high head (safety injection pumps and centrifugal charging pumps) injection, low head (residual heat removal pumps) injection and accumulator injection immediately following an accident. Low head/high head recirculation is used in the long-term recovery period.

3. The Containment Spray System provides a spray of cool, borated water to the containment atmosphere. The spray acts as an extended term method of condensing steam after all the ice in the ice condenser has melted. The spray system includes heat exchangers, which, in conjunction with the residual heat removal heat exchangers act as heat sinks for core residual heat.

4. The shield building and auxiliary building provide the necessary shielding for normal and emergency conditions and, in addition, provide a secondary barrier to fission products leaking from the primary containment vessel. This barrier, with the Emergency Gas Treatment System and Auxiliary Building Gas Treatment System, reduces the affect of such leakage by providing holdup time for decay and by collecting the leakage for filtration.

5. The Ice Condenser System provides borated ice to absorb the thermal energy released in the event of a LOCA or HELB to limit the peak pressure and temperature in the containment. The borated solution formed by meltdown of the ice absorbs and retains iodine released during the accident and prevents dilution of the borated water injected from the refueling water storage tank and accumulators. This solution also contributes to the inventory of water used for long-term heat removal from the reactor core and containment atmosphere.

6. Combustible gas is controlled inside primary containment by the Hydrogen Recombiners and Hydrogen Mitigation System.

6.0 ENGINEERED SAFETY FEATURES

7. The Air Return Fans enhance the performance of the Ice Condenser and Containment Spray Systems by circulating air/steam from upper containment to lower containment for another pass through the ice condenser back to upper containment.

8. The Main Control Room Habitability System provides HVAC for the control room and ensures 10CFR50 GDC 19 operator dose limits are met.

9. The Auxiliary Feedwater System supplies, in the event of a loss of the main feedwater supply, sufficient feedwater to the steam generators to remove primary system stored and residual core energy.

A primary containment Vacuum Relief System is also provided to limit external pressure on the free standing containment vessel by allowing air flow from the annulus into the upper containment. The system serves to mitigate events that challenge the integrity of a fission product barrier (primary containment) and therefore performs a *specified safety function* as defined by 10 CFR 50.36(c)(2)(ii). However, because it does not mitigate the consequences of an accident, it does not meet the definition of an Engineered Safety Feature.

6.2 CONTAINMENT SYSTEMS

6.2.1 Containment Functional Design

6.2.1.1 Design Basis

6.2.1.1.1 Primary Containment Design Basis

The containment is designed to assure that an acceptable upper limit of leakage of radioactive material is not exceeded under design basis accident conditions. For purposes of integrity, the containment may be considered as the Containment Vessel and Containment Isolation System. This structure and system are directly relied upon to maintain containment integrity. The Emergency Gas Treatment System and Reactor Building function to keep out-leakage minimal (the Reactor Building also serves as a protective structure), but are not factors in determining the design leak rate.

The containment is specifically designed to meet the intent of the applicable General Design Criteria listed in Section 3.1. This Subsection 6.2.1, Chapter 3 and other portions of Chapter 6 present information showing conformance of design of the containment and related systems to these criteria.

The ice condenser is designed to limit the containment pressure below the design pressure for all reactor coolant pipe break sizes up to and including a double-ended severance. Characterizing the performance of the ice condenser requires consideration of the rate of addition of mass and energy to the Containment as well as the total amounts of mass and energy added. Analyses have shown that the accident which produces the highest blowdown rate into an ice condenser containment will result in the maximum containment pressure rise; that accident is the double-ended severance of a reactor coolant pipe. The design basis accident is therefore defined to be the double-ended severance of a reactor coolant pipe. Post-blowdown energy releases can also be accommodated without exceeding containment design pressure.

The functional design of the containment is based upon the following accident input source term assumptions and conditions:

1. The design basis blowdown energy of 334.6 x 10^6 BTU and mass of 543,300 lb put into the containment.

2. A core power of 3455 MWt (plus 0.7%) used for decay heat generation.

3. The minimum Engineered Safety Features are (i.e., the single failure criterion applied to each safety system) comprised of the following:

    a. The ice condenser which condenses steam generated during a LOCA, thereby limiting the pressure peak inside the containment (see Section 6.5).

    b. The Containment Isolation System which closes those fluid penetrations not serving accident-consequence limiting purposes (see Subsection 6.2.4).

    c. The Containment Spray System which sprays cool water into the containment atmosphere, thereby limiting the pressure peak (particularly in the long term - see Subsection 6.2.2).

d. The Emergency Gas Treatment System (EGTS) which produces a slightly negative pressure within the annulus, thereby precluding out-leakage and relieving the post-accident thermal expansion of air in the annulus (see Subsection 6.2.3).

e. The Air Return Fans which return air to the lower compartment (see Section 6.6).

Table 6.2.1-1 provides general information about containment design parameters.

Consideration is given to subcompartment differential pressure resulting from a design basis accident in Section 3.8, Containment Interior Structure Structural Analysis, and in Subparagraph 6.2.1.3.3, Containment Pressure Transient - Short Term Analysis. If a design basis accident were to occur due to a pipe rupture in these relatively small volumes, the pressure would build up at a faster rate than in the Containment, thus imposing a differential pressure across the wall of these structures.

Parameters affecting the assumed capability for post-accident pressure reduction are discussed in Subparagraph 6.2.1.3.4, Containment Pressure Transient - Long Term Analysis.

Three events have a potential for generating an external pressure on the Containment Vessel:

1. Rupture of a process pipe where it passes through the annulus.

2. Inadvertent Containment Spray System initiation during normal operation.

3. Inadvertent air return fan operation during normal operation.

The design of the guard pipe portion of hot penetrations (subsection 6.2.4) is such that any process pipe leakage in that area is returned to the containment. All process piping which has potential for annulus pressurization upon rupture is routed through hot penetrations.

FSAR Section 3.8 describes the structural design of the containment vessel. The containment vessel is designed to withstand a net external pressure of 0.5 psi. The Vacuum Relief System (Subsection 6.2.6) is designed to prevent the net external design pressure from being exceeded by inadvertent containment spray initiation and/or inadvertent air return fan operation.

Therefore, the containment vessel is designed to withstand the maximum expected net external pressure in accordance with ASME Pressure and Vessel Code Section III paragraph NE-7116.

6.2.1.1.2 Secondary Containment Design Bases

The design bases for the secondary containment system were devised to assure that an effective barrier will exist for airborne fission products that may leak from the primary containment during a loss-of-coolant accident (LOCA). Within the scope of these design bases are requirements that influence the size, structural integrity, and leak tightness of the secondary containment enclosure. Specifically, these include a capability to: (a) Maintain an effective barrier for gases and vapors that may leak from the primary containment during all normal and abnormal events; (b) Delay the release of any gases and vapors that may leak from the primary containment during a LOCA; (c) Allow gases and vapors that may leak through the primary containment during a LOCA to flow into the contained air volume within the secondary

containment where it will be diluted, held up, and filtered prior to being released to the environs (see Subsection 6.2.3.1 for the EGTS and ABGTS Air Cleanup Subsystems Design Bases); (d) Bleed to the annulus secondary containment each air-filled containment penetration enclosure which extends beyond the shield building and that is formed by automatically actuated isolation valves; and (e) Maintain an effective barrier for airborne radioactive contaminants, gases and vapors originating in the auxiliary building during all normal and abnormal events.

6.2.1.2 System Design

6.2.1.2.1 Primary Containment System Design

The Containment consists of a Containment Vessel and a separate Reactor Shield Building enclosing the Containment Vessel and annulus. The Containment Vessel is a freestanding, welded steel structure with a vertical cylinder, hemispherical dome, and a flat circular base that provides Primary Containment. The Reactor Shield Building is a reinforced concrete structure similar in shape to the Containment Vessel that protects the containment Vessel from external events. The design of these structures is described in Section 3.8.

The design pressure, temperature, and methods used to ensure integrity of the Containment internal structures and sub-compartments from accident pressure pulses are described in Section 3.8.

The type of Containment used for the Sequoyah Nuclear Plant was selected for the following reasons:

1. The Ice Condenser Containment can accept large amounts of energy and mass inputs and maintain low internal pressures and leakage rates. A particular advantage of the ice condenser is its passive actuation not requiring an actuation system signal.

2. The Containment combines the required integrity, compact size, and a carefully considered advanced design desirable for a nuclear plant.

3. The double-enclosure concept affords minimal interaction between the Containment Vessel (leakage barrier) and the Reactor Building (protected structure); a margin of conservatism in leakage rate from the use of two structures and the EGTS; and a reduction of gaseous and particulate radioactive release due to annulus mixing and holdup prior to filtering and release.

6.2.1.2.2 Secondary Containment System Design

Two secondary containment barriers are provided at the Sequoyah Nuclear Plant. One of these is formed by the Reactor Shield Building that surrounds the steel primary containment vessel. The other secondary containment barrier is the Auxiliary Building structure that encloses all equipment in the building that may handle, collect or store radioactive materials during normal operation or during accidents.

1. Reactor Shield Building Secondary Containment Enclosure (Annulus)

The principal components that function collectively to form a secondary containment barrier around the steel primary containment vessel are the Shield Building itself, the Shield Building penetration seals, the isolation valves installed in the penetrations to the Shield Building, and the Shield Building penetration leakoff facilities.

Structure

The Reactor Shield Building is a reinforced concrete structure that encloses the reactor steel primary containment structure. It has a circular horizontal cross section and a shallow domed roof. The vertical center line of this building is also the vertical center line of the steel primary containment vessel. The inside diameter of this building was sized to provide an annular shaped air space between the two reactor enclosures that is five feet wide. The total enclosed free air space between the two enclosures is about 375,000 cubic feet. Additional data on the Shield Building is provided in Section 3.8 and in Table 6.2.1-2. Testing is performed in accordance with the Technical Specifications to ensure compliance with in-leakage limits.

Penetrations

To ensure that the shield building provides a nearly leak tight enclosure for the primary containment structure, all openings in the shield building penetrations are sealed. Typical mechanical piping or ventilation penetrations are equipped with a flexible membrane seal and are discussed further in subsection 6.2.1.3.2. The primary containment personnel hatch passes through the shield building and opens directly to the auxiliary building. This opening in the shield building wall is handled as an ordinary piping penetration and is provided with a flexible, double membrane shield as shown in Figure 3.8.2-11 (see Section 3.8). Personnel and equipment access doors to the secondary containment are treated as special cases and are provided with resilient seals. (See Subsection 3.8.4 for a description of the personnel access doors and Subsection 3.8.1 for a description of the equipment access doors.)

Air filled lines which must be isolated by automatic valve actuation and which penetrate both the primary containment and the secondary building are considered more likely to pass airborne radioactivities than other lines. Therefore these lines are provided with a third isolation valve outside the secondary containment for additional leak protection. This single, third valve is tied into both train A and B actuation signals and power. Electronic buffering prevents an electrical failure in one train from affecting the performance of the other. To enhance the effectiveness of the third isolation valve as a barrier to leakage, the enclosed volume between the second and third isolation valves is opened to the annulus during isolation. Opening this enclosed space to the annulus is accomplished with leakoff lines as shown in Figure 6.2.1-2 (Typical Purge Penetration Arrangement). When an isolation valve is closed, the leak-off allows the negative pressure in the annulus to include this small volume, and leakage from the primary containment outward or leakage from the Auxiliary Building inward will be drawn into the annulus for processing. The lines provided with this feature are those for the primary containment purge supply and exhaust and the lower compartment pressure relief.

Electrical penetrations are of either a cable tray/cable sleeve type or a conduit type. For cable tray/cable sleeve patterns, silicone room temperature vulcanizing (RTV) foam is used as the sealant around cables and openings within the cable sleeves. In conduit penetrations, the interstitial spaces between cables and conduit or conduit walls are filled with RTV silicone rubber or Chico Type A cement as the sealant over a portion of the length of the penetration.

2. Auxiliary Building Secondary Containment Enclosure

Structure

The auxiliary building is a conventional reinforced concrete structure located between the reactor buildings and the control building as shown in Figures 1.2.3-1 through 1.2.3-9. Its basic functions are to house support and safety equipment for the primary system and to provide an isolation barrier during certain postulated accidents involving airborne radioactive contamination. Certain of the building's interior and exterior walls, floor slabs, and a part of its roof form the isolation barrier, which is shown as a heavy bolded line on drawing series 46W501. The enclosed volume is about 3.5 x 10^6 cubic feet. The only openings in the isolation barrier are sealed mechanical and electrical penetrations, normally locked-closed doors, or airlocks. The building itself is by design and construction leak tight. Additional structural data on the auxiliary building is provided in Subsection 3.8.4.

The accident situations for which the auxiliary building isolation barrier will serve as a containment barrier are those involving irradiated fuel within the confines of the building and spills or leaks of radioactive materials from tanks and process lines inside the building. During a LOCA, any through-the-line leakage from primary containment into the auxiliary building will bypass the shield building annulus, in this case, the ABSCE will serve as part of the secondary containment enclosure.

Penetrations

Mechanical and electrical penetration seals in the isolation barrier will be similar to those for the shield building. See Subsection 6.2.1 for design details. Other potential leakage paths into the auxiliary building will be ventilation openings and equipment and personnel access points. Testing is performed in accordance with the Technical Specifications to ensure compliance with pressure limits.

All auxiliary building ventilation supply and exhaust ducts are provided with two low leakage isolation dampers in series. These two isolation dampers are heavy duty with resilient seals along the blade edges. Where practical, one damper in each pair is located inboard and one outboard of the containment barrier. The dampers fail in the closed position upon loss of power.

All normally used entrances and exits into the ABSCE for both equipment and personnel are through air locks during power operation. The air lock locations are shown in figures found in Section 1.2.3. The doors in each air lock are electrically interlocked such that only one side of the air lock can be opened at a time. As a safety precaution, an interlock defeat switch is provided to allow emergency egress should either side of the air lock be blocked open in an accident.

A special case is the interlock system for the large exterior door to the railway loading area. The large door is treated as one side of the air lock and either the two doors leading to the fuel handling area or the railway access hatch covers above can act as the other side of the lock. When the large railroad door is open, neither of the doors to the fuel handling area nor the access hatches above can be opened, and when either of these two doors and either of the access hatches above are open, the large railway access door cannot be opened. The railway access doors and hatches are described in Subsection 3.8.4.

6.2.1.3 Design Evaluation

The design basis for containment pressure transients has been revised for Sequoyah. This design basis is documented in WCAP 12455, Revision 1 (Reference 72). Since the pressure transient for Sequoyah is limited by the minimum safeguards condition, the documentation for the minimum safeguards cases presented in Section 6.2.1.3 are based on the above referenced WCAP.

6.2.1.3.A Sensitivity to Containment Spray Heat Exchanger Tube Plugging

LOCA Containment Integrity containment pressure calculations have been completed to assess the effect of containment spray heat exchanger tube plugging on containment response. The limiting pressure transient for Sequoyah documented in WCAP 12455, the Double-ended Pump Suction Minimum Safeguards case, was addressed. Documentation of the minimum safeguards case is presented in Section 6.2.1.3. This analyses supports a heat exchanger tube plugging limit of 13.3 percent.

6.2.1.3.1 Primary Containment Evaluation

1. The primary containment's leak tightness does not depend on the operation of any continuous monitoring or compressor system. The leak testing of the primary containment and its isolation system is discussed in Section 6.2.1.4.1 and 6.2.1.4.2.

2. The acceptance criteria for the leak tightness of the primary containment are such that at containment design pressure, there is a 25% margin between the acceptable maximum leakage rate and the maximum permissible leakage rate.

3. Reduced inventory/mid-loop requirements dictate to reasonably assure that containment closure can be achieved when core uncovery could result from a loss of RHR coupled with the inability to initiate alternate cooling or addition of water to RCS inventory.

6.2.1.3.2 Secondary Containment Evaluation

The secondary containment enclosures were designed to provide a positive barrier to all potential primary containment leakage pathways during a LOCA and to radioactive contaminants released in accidental spills and fuel handling accidents that may occur in the auxiliary building. In a LOCA, the shield building containment enclosure provides the barrier to airborne primary containment leakage from air-filled automatic isolating penetrations, and the auxiliary building provides a barrier to through-the-line leakage which can potentially become airborne.

1. Shield Building

   Structure

   The building construction employs monolithic pours of concrete. This approach for structures of this type produces a very low leakage barrier. The low leakage characteristics of this barrier help to reduce the rate at which filtered annulus air must be released to maintain the enclosed volume at a negative pressure. This factor contributes significantly to keeping the exclusion area boundary and the low population zone (LPZ) dosage levels within 10 CFR 100 guidelines.

The size of the annular region between the primary containment and the shield building assures a residence time for all leakage into the annulus. The residence time will average about 90 minutes and is a significant factor in reducing exclusion area boundary and LPZ dosages. The accident dosage analyses is given in Subsection 15.4.1 and Appendix 15B.

Penetrations

The shield building wall is provided with more than 200 penetrations to accommodate mechanical equipment piping, cable trays, and electrical conduit which leave and enter the shield building. Leakage through the shield building wall when the annulus is at a negative pressure is expected to be restricted almost entirely to openings in these penetrations. The design thus assures that penetration leakage will not exceed predetermined quantities. Such a capability ensures that the inleakage will be sufficiently low to keep the dose contributions at the exclusion area boundary and to the LPZ within 10 CFR 100 guidelines.

Openings in mechanical piping penetrations are sealed typically with a combination of silicone room temperature vulcanizing (RTV) foam, slygard 170 silicone elastomer, a flexible membrane boot type on the inside and/or outside of the shield wall, welded plates, or single gaskets which are designed to withstand the combinations of shield building and piping movements in the SSE and retain their functional integrity. In addition, seals at or below elevation 724.0 in buildings subject to flooding are designed to be water tight for flood static head and surge forces. All seals, where possible, are installed outside the shield building such that whether during normal operation, accidents, or flood, the differential pressures will tend to enhance the tightness of the seal. The Shield Building penetration seal materials have been selected to sustain the integrated doses for 40 years normal plant operation and LOCA/HELB events.

Cables routed in cable trays pass through the shield building wall through rectangular cable sleeve penetrations. The single interior metal barrier plate of the penetration assembly, containing the metal cable sleeves, effectively seals most of the open space within the wall opening for cable trays. The sealant material installed around cables within the cable sleeves is silicone RTV (room temperature vulcanizing) foam and RTV silicone rubber is installed around cables within conduits. The seals are designed to withstand the SSE and retain their integrity. Electrical penetration seals are allowed twice the leakage of mechanical seals to provide sufficient margin in meeting the total allowable shield building leakage requirements.

At or below elevation 724.0, Chico Type A sealant is installed around cables within conduit and RTV silicone is used to seal capped conduit penetrations. The seals are designed to withstand the SSE and retain their integrity, as well as withstand hydrostatic forces generated by the Design Basis Flood.

Fire protection requirements for penetrations are discussed in the Fire Protection Report (see 9.5.1).

The personnel and equipment access doors to the shield building are designed with heat resistant, resilient seals which reduce their leakage to allowable values as stated. These doors are designed to retain their structural integrity and leak tightness during a SSE as described in Subsections 3.8.1 and 3.8.4.

The fuel transfer tubes penetrate the primary and secondary containment on their way to the auxiliary building. Each transfer tube has a blind flange on the inboard side of primary containment equipped with double 0-rings and a pressure test connection between the 0-rings. The valve in the auxiliary building end of the transfer tube serves as the secondary containment isolation valve. The inner space between the primary containment flange and the isolation valve is bled to the annulus so that any leakage into the tube from primary containment or the auxiliary building flows into the annulus. The bleed line is routed above the maximum refueling pool water level to preclude accidental spills of refueling water.

2. Auxiliary Building

Structure

The entire auxiliary building including walls, roof and interior partitions is constructed by consecutive monolithic pours of concrete. This method of assembly produces structure with very low leakage characteristics. The portions of the building chosen to constitute the isolation barrier were selected such that all sources of potential contamination are completely enclosed. Therefore, the structure utilized to form the auxiliary building containment envelope will function effectively as a barrier to the release of unprocessed auxiliary building air to the environs. This same structure will also help to reduce inleakage into the auxiliary building containment envelope during accidents to levels easily accommodated by the ABGTS.

Penetrations

Seals for mechanical penetrations are a flexible membrane type or single gaskets. They are designed to withstand auxiliary building and piping movements on the SSE and retain their structural integrity. All seals, where possible, are designed such that whether during normal operation or accidents, the differential pressures will tend to enhance the tightness of the seal. Sealing methods for electrical penetrations are similar to those for the shield building electrical penetrations.

The ventilation duct isolation dampers are double-tracked with one inside and one outside the containment barrier for physical separation where practical. The dampers have resilient blade end and blade edge seals which will retain their functional characteristics indefinitely over the operational temperature extremes. The motor operators for these dampers have been sized to tightly close the damper blades against their resilient seals. The entire damper and motor operator assembly is designed to operate during and after the SSE.

Fire protection requirements for penetrations are discussed in the Fire Protection Report (see 9.5.1).

6.2.1.3.3 Containment Pressure Transients - Short Term Analysis

Description of Analysis

Calculating pressure and temperature transients following a loss of coolant accident is a three-step process involving the computer codes and a calculation for the compression ratio.

During the first few seconds of the blowdown period of the reactor coolant system, the TMD computer code (References 14 and 15) with unaugmented critical flow and the Y compressibility factor is used to calculate pressure and temperature transients. It is during this period that the peak transient pressures, differential pressures, temperature and blowdown loads occur.

The containment pressure at or near the end of blowdown is calculated by the containment compression ratio analysis described in Subparagraph 6.2.1.3.4. Although the TMD code can be run to the end of the blowdown, this is not normally done, because the TMD code assumptions, such as no structural heat sinks and no containment sprays, become important in a long transient. The TMD code can conservatively compute the RCS blowdown transient.

The LOTIC code (References 18 and 30) does not calculate containment pressure during the RCS blowdown. The containment pressure calculation in LOTIC begins after blowdown.

At the end of the blowdown phase, the containment pressure is inputted at the compression ratio value. The containment upper and lower compartment temperatures are calculated based on this compression. These temperatures are not necessarily the same as that predicted by the TMD code.

During the blowdown phase, LOTIC computer code goes through an initialization calculation computing ice mass, sump temperatures, and heat sink temperatures. After the initialization calculation, the LOTIC code calculates the pressure and temperature during the depressurization and long-term periods. An explanation of the method of calculation employed is given in Subparagraph 6.2.1.3.4.

Introduction

The basic performance of the Ice Condenser Reactor Containment System has been demonstrated for a wide range of conditions by the Waltz Mill Ice Condenser Test Program (Reference 29). These results have shown the capability and reliability of the Ice Condenser Concept to limit the containment pressure rise subsequent to a hypothetical loss-of-coolant accident.

To supplement this experimental proof of performance, a mathematical model has been developed to simulate the ice condenser pressure transients. This model, encoded as computer program TMD (Transient Mass Distribution), provides a means for computing pressures, temperatures, heat transfer rates, and mass flow rates as a function of time and location throughout the containment. This model is used to compute pressure differences on various structures within the containment as well as the distribution of steam flow as the air is displaced from the lower compartment. Although the TMD code can calculate the entire blowdown transient, the peak pressure differences on various structures occur within the first few seconds of the transient.

Analytical Models - (No Entrainment)

The mathematical modeling in TMD is similar to that of the SATAN blowdown code in that the analytical solution is developed by considering the conservation equations of mass, momentum and energy and the equation of state, together with the control volume technique for simulating spatial variation. The governing equations for TMD are given in Reference 14.

The moisture entrainment modifications to the TMD code is discussed, in detail, in Reference 15. These modifications comprise of incorporating the additional entrainment effects into the momentum and energy equations.

As part of the review of the TMD code, additional effects are considered. Changes to the analytical model required for these studies are described in Reference 15.

These studies consist of:

1. Spatial acceleration effects in ice bed,
2. Liquid entrainment in ice beds,
3. Upper limit on sonic velocity,
4. Variable ice bed loss coefficient,
5. Variable door response,
6. Wave propagation effects.

Experimental Verification

The performance of the TMD code was verified against the 1/24th scale air tests and Waltz Mill tests. For the 1/24th scale model the TMD code was utilized to calculate flow rates to compare against experimental results. The effect of increased nodalization was also evaluated. The details of the information are given in Reference 14. The Waltz Mill test comparisons involved a reexamination of test data. In conducting the reanalysis, representation of the Waltz Mill test was reviewed with regard to parameters such as loss coefficients and blowdown time history.

The TMD code uses a mixed element model with thermal equilibrium between the air, steam and water. This model is conservative and predicts Waltz Mill test results. See Reference 21 for details.

Application to Plant Design (General Description)

As described in Reference 15, the control volume technique is used to spatially represent the containment. The containment is divided into 50 elements to give detailed representation of the local pressure transient on the containment shell and internal concrete structures. This division of the containment is similar for all ice condenser plants.

The Sequoyah plant containment has been divided into 50 elements or compartments as shown in Figures 6.2.1-4, 6.2.1-5, 6.2.1-6 and 6.2.1-7. The interconnection between containment elements in the TMD code is shown schematically in Figure 6.2.1-8. Flow resistance and inertia are lumped together in the flow paths connecting the elements shown. The division of the lower compartments into 6 volumes occurs at the points of greatest flow resistance, i.e., the four steam generators, pressurizer and refueling cavity.

Each of these lower compartment sections delivers flow through doors into a section behind the doors and below the ice bed. Each vertical section of the ice bed is, in turn, divided into three elements. The upper plenum between the top of the ice bed and the upper doors is represented by an element. Thus, a total of thirty elements (elements 7 through 24 and 38 through 49) are used to simulate the ice condenser. The six elements at the top of the ice bed between bed and upper doors deliver to element number 25 the upper compartment. Note that cross flow in the ice bed is not accounted for in the analysis; this yields the most conservative results for the particular calculations described herein. The upper reactor cavity (element 33) is connected to the lower compartment volumes and provides cross flow for pressure equalization of the lower compartments. The less active compartments, called dead-ended compartments (elements 26 through 32 and 34 through 37) outside the crane wall are pressurized by ventilation openings through the crane wall into the fan compartments.

For each element in the TMD network the volume, initial pressure and initial temperature conditions are specified. The ice condenser elements have additional inputs of mass of ice, heat transfer area and condensate layer length. For each flow path between elements flow resistance is specified as a loss coefficient "K" or a friction loss "$f\frac{L}{D}$" or a combination of the two based on the flow area specified between elements. Friction factor, friction factor length and hydraulic diameter are specified for the friction loss. The code input for each flow path is the flow path length used in the momentum equation. In addition the ice condenser loss coefficients have been based on the 1/4 scale tests without inlet door port rounding which is representative of the ice condenser geometry. The test loss coefficient includes basket roughness effects and intermediate and top deck pressure losses. To better represent short term transients effects, the

opening characteristics of the lower, intermediate and top deck ice condenser doors have also been modeled in the TMD code. The containment geometric data for the elements and flow paths used in the TMD code is confirmed to agree with the actual design by the utility and Westinghouse. An initial containment pressure of 0.3 psig was assumed in the analysis. Initial containment pressure variation about the assumed 0.3 psig value has only a slight effect on the initial pressure peak and the compression ratio pressure peak.

The reactor coolant blowdown rates used in these cases are based on the SATAN analysis of a double-ended rupture of either a hot or cold leg reactor coolant pipe utilizing a discharge coefficient of 1.0. The blowdown analysis has been presented in Subparagraph 6.2.1.3.6.

Analyses have been conducted implementing unaugmented critical flow correlations. Results of the analyses for the Sequoyah Plant are presented in Table 6.2.1-3. The short term peak pressures and peak differential pressures occur within 1.0 second of the blowdown. A number of analyses have been performed. The analysis were performed using the following assumptions and correlations:

1. Flow was limited by the unaugmented critical flow correlation.

2. The TMD variable volume door model, which accounts for changes in the volumes of TMD elements as the door opens, was implemented.

3. The heat transfer calculation used was based on performance during the 1973-1974 Waltz Mill test series. A higher value of the ELJAC parameter has been used and an upper bound on calculated heat transfer coefficients has been imposed. (See Reference 19).

4. One hundred percent moisture entrainment was assumed.

5. The Y compressibility factor was assumed.

The analyses consisted of DECL and DEHL breaks in TMD compartments 1 through 6. Figures 6.2.1-9 and 6.2.1-10 are representative of the upper and lower compartment pressure transients that result from a hypothetical double-ended rupture of a reactor coolant pipe for the worst possible location in the lower compartment of the containment; i.e., hot leg and cold leg breaks in element 1.

<u>Initial Pressure Peaks (Assuming unaugmented flow</u>)

The worst case lower compartment breaks (in TMD elements 1-6) are the result of a double-ended guillotine break of a main reactor coolant line. The breaks occur either on the hot leg or cold leg side.

Results of the analysis for the Sequoyah Plant are presented in Table 6.2.1-3. The peak pressures and peak differential pressures resulting from hot and cold leg reactor coolant pipe breaks in each of the six lower compartment control volumes were calculated.

Table 6.2.1-3 presents the maximum calculated pressure peak for the lower compartment elements resulting from hot and cold leg double ended pipe breaks. Generally, the maximum peak pressure within a lower compartment element results when the pipe break occurs in that element. A cold leg break in the element 1 creates the highest pressure peak, also in element 1, of 15.7 psig.

Table 6.2.1-3 also presents the maximum calculated peak pressure in each of the ice condenser sections resulting from any pipe break location. The maximum peak pressure in each of the ice condenser sections is found in the lower plenum element of the section. The peak pressure was calculated to be 11.7 psig in element 40.

Table 6.2.1-3 also presents the maximum calculated differential pressure across the operating deck (divider barrier) between the lower compartment elements and the upper compartment. These values are approximately the same as the maximum calculated differential pressure across the lower crane wall between the lower compartment elements and the dead ended volumes surrounding the lower compartment. The peak differential pressure of 14.9 psi was calculated to be between elements 1 and 25 for a hot leg break.

Table 6.2.1-3 also presents the maximum calculated differential pressures across the upper crane wall between the upper ice condenser elements and the upper compartment. The peak differential of 8.2 psi pressure was calculated to be between element 7-8-9 and 25 and elements 22-23-24 and 25 for a hot leg pipe break.

Initial Pressure Peaks (Assuming a 15% reduction in flow area through the ice condenser)

An additional analysis (see Reference 66) has been performed to determine the effect on short-term containment pressure from a 15% reduction in the flow area through the ice condenser. This analysis was performed to document the effect of the maximum flow area reduction normally expected due to frost and ice accumulation during the course of an operating cycle on the subcompartment pressurization analysis. This 15% flow blockage analysis employs the same assumptions and methods as in the base analysis described above with the exception that a 15% uniform flow area reduction is modeled. This 15% reduction in flow area corresponds to a 6.15 ft^2 reduction in the free flow area of 41.02 ft^2 used for the flow area through each bay of the ice condenser at the elevation of a lattice frame. This flow area was modeled as existing over the entire length of the ice baskets. The breaks which resulted in the highest peak and differential pressures were examined as in the base case analysis discussed above and included a DECL and a DEHL break in element 1. The limiting differential pressures from this analysis are reported in Table 6.2.1-4. The peak short-term containment pressure for the 15% flow blockage analysis was calculated to be 11.9 psig in element 40.

Sensitivity Studies

A series of TMD runs for the D. C. Cook Plant investigated the sensitivity of peak pressures to variations in individual input parameters for the design basis blowdown rate and 100% entrainment. This analysis used a DEHL break in element 6 of the Cook Plant. Table 6.2.1-5 presents the results of this sensitivity study.

The humidity level in the Sequoyah containment at the time of a design basis accident, a double-ended hot leg break in compartment 1, has no significant effect on the initial pressure transient. The difference between peak operating deck pressure differentials calculated by TMD for 100% initial relative humidity and zero initial humidity is less than 0.5%.

Choked Flow Characteristics

The data in Figure 6.2.1-11 illustrate the behavior of mass flow rate as a function of upstream and downstream pressures, including the effects of flow choking. The upper plot shows mass flow rate as a function of upstream pressure for various assumed values of downstream

pressure. For zero back pressure (P_d = 0), the entire curve represents choked flow conditions with the flow rate approximately proportional to upstream pressure, P_u. For higher back pressure, the flow rates are lower until the upstream pressure is high enough to provide choked flow. After the increase in upstream pressure is sufficient to provide flow choking, further increases in upstream pressure cause increases in mass flow rate along the curve for P_d = 0. The key point in this illustration is that flow rate continues to increase with increasing upstream pressure, even after flow choking conditions have been reached. Thus choking does not represent a threshold beyond which dramatically sharper increases in compartment pressures could be expected because of limitations on flow relief to adjacent compartments.

The phenomenon of flow choking is more frequently explained by assuming a fixed upstream pressure and examining the dependence of flow rate with respect to decreasing downstream pressure. This approach is illustrated for an assumed upstream pressure of 30 psia as shown in the upper plot with the results plotted vs. downstream pressure in the lower plot. For fixed upstream conditions, flow choking represents an upper limit flow rate beyond which further decreases in back pressure will not produce any increase in mass flow rate.

6.2.1.3.4 Containment Pressure Transient - Long Term Analysis

Introduction

Early in the ice condenser development program it was recognized that there was a need for computer modeling of ice condenser containment performance. It was realized that the model would have to have capabilities comparable to those of the dry containment (COCO) model. These capabilities would permit the model to be used to solve problems of containment design and optimize the containment and safeguards systems. This has been accomplished in the development of the LOTIC code. (See Reference 18). Another computer code, MONSTER, with capabilities comparable to those of the LOTIC code has been developed to solve similar containment design problems. (See Reference 63.)

Method of Solution

The model of the containment for the LOTIC computer code consists of five distinct control volumes, the upper compartment, the lower compartment, the portion of the ice bed from which the ice has melted, the portion of the ice bed containing unmelted ice, and the dead ended compartment. The ice condenser control volume with unmelted and melted ice is further subdivided into six subcompartments to allow for maldistribution of break flow to the ice bed.

The conditions in these compartments are obtained as a function of time by the use of fundamental equations solved through numerical techniques. These equations are solved for three distinct phases in time. Each phase corresponds to a distinct physical characteristic of the problem. Each of these phases has a unique set of simplifying assumptions based on test results from the ice condenser test facility. These phases are the blowdown period, the depressurization period, and the long term period.

Blowdown Period

This phase coincides with the blowdown of the reactor coolant system. During this phase no attempt is made to calculate the pressure, flow, and temperature transients in the containment in the LOTIC code. Instead, this complicated analysis is accomplished with the TMD code, a code created specifically for this short term analysis (discussed in 6.2.1.3.3). The pressure and

temperatures in the containment are held constant during this phase. Input values are determined from TMD analyses and compression ratio calculations. Physically, tests at the ice condenser Waltz Mill Test facility have shown that this phase represents that period of time in which the lower compartment air and a portion of the ice condenser air are displaced and compressed into the upper compartment and the remainder of the ice condenser. (The initial pre-blowdown atmosphere in the dead ended compartment is retained at that time.) The code represents this phenomenon through the use of an input value for the fraction of the ice bed which retains air during this phase. This fraction, determined from test data, is also used to establish the volumes of the two ice condenser control volumes, which are held constant during this phase.

The temperatures in the upper and lower compartments are calculated from the input pressure. The portions of the containment which are primarily air-filled, i.e., the dead ended compartment and a portion of the ice bed, are assumed to be at upper compartment temperature during this phase. Deck leakage considerations resulted in consideration of the upper compartment atmosphere as saturated, at this temperature.

Depressurization Period

This phase of the analysis corresponds to the period of time between the end of blowdown and the establishment of a circulation flow between the control volumes. During this phase, the noncondensable nitrogen blowdown from the accumulator occurs, the decay heat boiloff is initiated, and the engineered safeguards come into operation. Maximum decay heat boiloff is achieved by assuming that the safety injection system is disabled to the point that only enough water is delivered to the core to replace the water boiled, and the remaining safety injection is spilled to the sump, (although varying degrees of SIS effectiveness can be simulated). The engineered safeguards which are initiated in this phase are the return fan, the safety injection system, and the spray system. During this phase the spray systems and safety injection system take water from the refueling water storage tank and pump it into the containment. The models for the spray system and heat exchangers are discussed in Subparagraph 6.2.1.3.4. At the beginning of this phase the blowdown ice melt is computed using the blowdown energy. This result is used to compute the actual volume of the melted out portion of the ice condenser, which is used to change the ice condenser volumes from the compressed value associated with the air displacement in the blowdown phase, to the actual value computed from the ice melt. As soon as the return fan is started, the dead ended compartment begins to undergo a conversion to upper compartment atmosphere. This continues until all the dead ended compartment atmosphere has been converted to upper compartment. It is also possible to select an input option in the code such that the dead ended compartment is always treated as upper compartment volume.

As soon as return fan flow is initiated, the lower compartment begins to fill with an air/steam mixture composed of the upper/dead ended compartment air from the fan flow and decay heat boiloff steam. This steam air mixture displaces the previous steam atmosphere of the lower compartment through the ice bed, like the motion of a piston. As this occurs the code calculates the conditions in the upper and lower compartment from the compartment conditions and the spray and flow characteristics. This phase of the analysis ends when the air/steam mixture fills both the lower compartment and the melted out portion of the ice bed.

Long Term

This phase of the analysis begins as soon as the circulation of air through the containment has been established and continues until the problem is terminated. The major occurrences during

this phase are recirculation and ice meltout. Recirculation occurs when the refueling water storage tank has reached its low level and the level in the containment sump has reached high level. At this time the safety injection and spray system begin drawing from the active sump instead of the refueling water storage tank (the two sump model is discussed in Sub- paragraph 6.2.1.3.4). The spray system flow continues to be routed through the spray heat exchanger during this period, and the safety injection and residual spray flows are routed through the residual heat exchanger.

Meltout occurs when there is no longer enough ice in the ice bed to prevent steam from flowing directly from the lower compartment to the upper compartment. As long as there is more than a foot of ice in the ice compartment, the temperatures in the two ice compartment control volumes remain at different constant values which were determined from Waltz Mill test data. When the ice in a subcompartment of the ice bed volume is gone, the subcompartment is assumed to contain lower compartment atmosphere. (Due to maldistribution which is input to the code, the sub-compartments may melt in a sequenced manner rather than simultaneously.) During the long term phase the fan flow from the upper compartment and the flow out of the lower compartment are assumed to be at the respective compartment temperatures.

Primary Assumptions

The most significant simplification of the problem is the assumption that the total pressure in the containment is uniform. This assumption is justified by the fact that after the initial blowdown of the reactor coolant system, the remaining mass and energy released from this system into the containment are small and very slowly changing. The resulting flow rates between the control volumes will also be relatively small. These small flow rates then are unable to maintain significant pressure differences between the compartments.

In the control volumes, which are always assumed to be saturated, steam and air are assumed to be uniformly mixed and at the control volume temperature. When the air return fan is in operation, the fan flow and the reactor coolant system boiloff are mixed before entering the lower compartment. The air is considered a perfect gas, and the thermodynamic properties of steam are taken from the ASME steam table (1975 version).

The condensation of steam is assumed to take place in a condensing node which is located, for the purpose of calculation, between the two control volumes in the ice condenser compartment. The exit temperature of the air leaving this node is set equal to the temperature of the ice filled control volume of the ice storage compartment. Lower compartment exit temperature is used if the ice bed section is melted.

Compression Ratio Analysis

As blowdown continues following the initial pressure peak from a double ended cold leg break, the pressure in the lower compartment again increases, reaching a peak at or before the end of blowdown. The pressure in the upper compartment continues to rise from beginning of blowdown and reaches a peak which is approximately equal to the lower compartment pressure. After blowdown is complete, the steam in the lower compartment continues to flow through the doors into the ice bed compartment and is condensed.

The primary factor in producing this upper containment pressure peak and therefore, in determining design pressure, is the displacement of air from the lower compartment into the

upper containment. The ice condenser quite effectively performs its function of condensing virtually all the steam that enters the ice beds. Essentially, the only source of steam entering the upper containment is from leakage through the drain holes and other leakage around crack openings in hatches in the operating deck separating the lower and upper portions of the containment building.

A method of analysis of the compression peak pressure was developed based on the results of full-scale section tests. This method consists of the calculation of the air mass compression ratio, the polytropic exponent for the compression process, and the effect of steam bypass through the operating deck on this compression.

The compression peak pressure in the upper containment for the Sequoyah plant design is calculated to be 7.18 psig (for an initial air pressure of 0.3 psig). This compression pressure includes the effect of a pressure increase of 0.4 psi from steam bypass and also for the effects of the dead-ended volumes. The nitrogen partial pressure from the accumulators is not included since this nitrogen is not added to the containment until after the compression peak pressure has been reduced, which is after blowdown is completed. This nitrogen is considered in the analysis of pressure decay following blowdown as presented in the long term performance analysis using the LOTIC code. In the following sections, a discussion of the major parameters affecting the compression peak will be discussed. Specifically they are: air compression, steam bypass, blowdown rate and blowdown energy.

Air Compression Process Description

The volumes of the various containment compartments determine directly the air volume compression ratio. This is basically the ratio of the total active containment air volume to the compressed air volume during blowdown. During blowdown air is displaced from the lower compartment and compressed into the ice condenser beds and into the upper containment above the operating deck. It is this air compression process which primarily determines the peak in-containment pressure, following the initial blowdown release. A peak compression pressure of 7.18 psig is based on the Sequoyah Plant design compartment volumes shown in Table 6.2.1-6.

Methods of Calculation and Results

Full Scale Section Tests

The actual Waltz Mill test compression ratios were found by performing air mass balances before the blowdown and at the time of the compression peak pressure, using the results of three special full-scale section tests. These three tests were conducted with an energy input representative of the plant design.

In the calculation of the mass balance for the ice condenser, the compartment is divided into two sub-volumes; one volume representing the flow channels and one volume representing the ice baskets. The flow channel volume is further divided into four sub-volumes, and the partial air pressure and mass in each sub-volume is found from thermocouple readings that the air is saturated with steam at the measured temperature. From these results, the average temperature of the air in the ice condenser compartment is found, and the volume occupied by the air at the total condenser pressure is found from the equation of state.

The compression ratio can then be calculated for the three full-scale section tests. From the results of the air mass balances, it was found that air occupied approximately 64.5% of the ice condenser compartment volume at the time of peak compression.

The final compression volume includes the volume of the upper compartment as well as part of the volume of air in the ice condenser. The results of the full-scale section tests (Figure 6.2.1-12) show a variation in steam partial pressure from 100% near the bottom of the ice condenser to essentially zero near the top. The thermocouples and pressure detectors confirm that at the time when the compression peak pressure is reached steam occupies less than half of the volume of the ice condenser. The analytical model used in defining the containment pressure peak uses upper compartment volume plus 64.5 percent of the ice condenser air volumes as the final volume. This 64.5% value was determined from appropriate test results.

The calculated volume compression ratios are shown in Figure 6.2.1-13, along with the compression peak pressures for these tests. The compression peak pressure is determined from the measured pressure, after accounting for the deck leakage contribution. From the results shown in Figure 6.2.1-13, the polytropic exponent for these tests is found to be 1.13.

Plant Case

For the Sequoyah design, the volume compression ratio, not including the upper plenum as part of the ice condenser and not accounting for dead-ended volume effect, was calculated from Table 6.2.1-6. The peak compression pressure, based on an initial containment pressure of 15.0 psia, was then found to be 21.88 psia or 7.18 psig.

This peak compression pressure includes a pressure increase of 0.4 psi from steam bypass through the deck (see Subparagraph 6.2.1.3.5). The effect of the dead-ended compartment volumes is to trap additional air and thus reduce the compression ratio and the above calculated peak pressure.

Sensitivity To Blowdown Energy

The sensitivity of the upper and lower compartment peak pressure versus blowdown rate as measured from the 1974 Waltz Mill Tests is shown in Figure 6.2.1-14. This figure shows the magnitude of the peak pressure versus the amount of energy released in terms of percentage of RCS energy release rate. Percent energy blowdown rate was selected for the plot because energy flow rate more directly relates to volume flow rate and therefore pressure. There are two important effects to note from the peak upper compartment pressure versus blowdown rate. One, the magnitude of the final peak pressure in the upper compartment is low (about 9 psig) for the plant design DECL blowdown rate; two, even an increase in this rate up to 141 percent of the blowdown energy rate produces only a small increase in the magnitude of this peak pressure (about 1 psi). The major factor setting the peak pressure reached in the upper compartment is the compression of air displaced by steam from the lower compartment into the upper compartment. The lower compartment initial peak pressure shows a relatively low peak pressure of 12.9 psig for the design basis DECL blowdown rate, and even a substantial increase in blowdown energy rate (141 percent reference initial DECL) would cause an increase in initial peak pressure of only 3 psi. The peak pressure in the lower compartment is due mainly to flow resistance caused by displacement of air from the lower compartment into the upper compartment.

For a further discussion, see Section 5 of Reference 21.

Containment Pressure Calculation

The following are the major input assumptions used to calculate the containment transients for the pump suction pipe rupture cases with the steam generators considered as an active heat source for the Sequoyah Nuclear Station Containment:

1. Minimum containment safeguards are employed in all calculations, e.g., one of two spray pumps and one of two spray heat exchangers; one of two RHR pumps and one of two RHR heat exchangers providing flow to the core; one of two safety injection pumps and one of two centrifugal charging pumps; and one of two air recirculation fans.

2. Initial ice weight in the ice condenser as specified in Table 6.2.1-1.

3. The Blowdown, Reflood, and Post-Reflood mass and energy releases described in Section 6.2.1.3.6 are used.

4. Blowdown and post-blowdown ice condenser drain temperature of 190°F and 130°F were used. (These numbers are based on the long-term Waltz Mill ice condenser test data described in Reference 21).

5. Nitrogen from the accumulators in the amount of 3676 lbs. is included in the calculations. Additionally, hydrogen from post-LOCA sources of approximately 94 lbs. two hours after event initiation is included in the calculations.

6. The air recirculation fan is assumed to be effective, approximately 10 minutes after the transient is initiated.

7. Essential service water temperature of 87°F is used on the spray heat exchanger and the component cooling heat exchanger.

8. Even distribution of steam flow into the ice bed is assumed.

9. No ice condenser bypass is assumed. (This assumption depletes the ice in the shortest time and is thus conservative.)

10. The initial conditions in the containment are a temperature of 100°F in the lower and dead-ended volumes, a temperature of 15°F in the ice condenser, and a temperature of 85°F in the upper volume. All volumes are at a pressure of 0.3 psig and a 10% relative humidity, except for the ice condenser which is at a 100% relative humidity.

11. The pump flows vs. time given in Table 6.2.1-7 were used.

12. A residual spray of 1277 gpm is assumed at 1 hour into the accident. Residual heat removal pump and spray pump take suction from the sump, after 1691 seconds, and 3113 seconds respectively.

13. Containment structural heat sinks are assumed with conservatively low heat transfer rates.

14. The Containment compartment volumes were based on the following: Upper Compartment 651,000 ft^3; Lower Compartment 248,500 ft^3; and Dead-Ended Compartment 129,900 ft^3.

15. The operation of one containment spray heat exchanger (UA = 2.953 $*$ 10^6 Btu/hr-°F), for containment cooling and the operation of one RHR heat exchanger (UA = 1.402 *10^6 Btu/hr-°F) for core cooling. The component cooling heat exchanger was modeled at 2.793 $*$ 10^6 Btu/hr-°F. All heat exchangers were modeled as strictly counterflow heat exchangers.

16. The air return fan returns air at a rate of 40,000 cfm from the upper to the lower compartment.

17. An active sump volume of 38,400 ft^3 is used.

18. 102% of 3411 MWt (i.e., 100.7% of 3455 MWt) power is used in the calculations.

19. Subcooling of ECC water from the RHR heat exchanger is assumed.

20. Nuclear service water flow to the containment spray heat exchanger was modeled as 3400 gpm. Also the nuclear service water flow to the component cooling heat exchanger was modeled as 4000 gpm.

21. The decay heat curve used to calculate mass and energy releases after steam generator equilibration is presented in Table 6.2.1-8.

The minimum time at which the RHR pumps can be diverted to the RHR sprays is specified in the plant operating procedures as 60 minutes after the accident.

Structural Heat Removal

Provision is made in the containment pressure analysis for heat storage in interior and exterior walls. Each wall is divided into a number of nodes. For each node, a conservation of energy equation expressed in finite difference forms accounts for transient conduction into and out of the node and temperature rise of the node for the containment structural heat sinks used in the analysis. The heat sink and material property data used are found in Table 6.2.1-32.

The heat transfer coefficient to the containment structure is based primarily on the work of Tagami (Reference 77). When applying the Tagami correlations, a conservative limit was placed on the lower compartment stagnant heat transfer coefficients. They were limited to a steam-air ratio of 1.4 according to the Tagami correlation. The imposition of this limitation is to restrict the use of the Tagami correlation within the test range of steam-air ratios where the correlation was derived.

With these assumptions, the heat removal capability of the containment is sufficient to absorb the energy releases and still keep the maximum calculated pressure below the design pressure.

Analysis Results

The results of the analysis shows that the maximum calculated containment pressure is 11.44 psig, for the double-ended pump suction minimum safeguards break case. This pressure. peak occurs at approximately 7068 seconds, with ice bed meltout at approximately 3367 seconds.

The following plots show the containment integrity transient, as calculated by the LOTIC-1 code.

Table 6.2.1-10	Energy accounting at time of ice melt and peak pressure

Relevant Acceptance Criteria

The LOCA mass and energy analysis has been performed in accordance with the criteria shown in the Standard Review Plan (SRP) section 6.2.1.3. In this analysis, the relevant requirements of General Design Criteria (GDC) 50 and 10 CFR Part 50 Appendix K have been included by confirmation that the calculated pressure is less than the design pressure, and because all available sources of energy have been included. These sources include: reactor power, decay heat, core stored energy, energy stored in the reactor vessel and internals, metal-water reaction energy, and stored energy in the secondary system.

The containment integrity peak pressure analysis has been performed in accordance with the criteria shown in the SRP section 6.2.l.1.b, for ice condenser containments. Conformance to GDC's 16, 38, and 50 is demonstrated by showing that the containment design pressure is not exceeded at any time in the transient. This analysis also demonstrates that the containment heat removal systems function to rapidly reduce the containment pressure and temperature in the event of a LOCA.

Conclusions

Based upon the information presented in this report, it may be concluded that operation with an initial ice weight of 1.916 million pounds for the Sequoyah Nuclear Plant is acceptable. Operation with an initial ice mass of 1.916 million pounds results in a calculated peak containment pressure of 11.44 psig, as compared to the design pressure of 12.0 psig. Thus, the most limiting case has been considered, and has been demonstrated to yield acceptable results.

Mark-BW17 Fuel Evaluation

The effect of transitioning to and loading Mark-BW17 fuel on the previously discussed analysis results, which utilized Westinghouse fuel, was evaluated. The important aspects of the fuel change that have the possibility of impacting the analysis include the changes in the flow characteristics past the fuel, the RCS operating T_{avg}, the core-stored energy and fuel-heat capacity, and the decay heat.

There are very small deviations in flow characteristics past the fuel. However, for an ice condenser design, since the peak pressure occurs late in the transient, well after the ice bed has melted out, the single effect of small deviations in flow is insignificant relative to analysis results. Total energy content, or total energy available for release to containment, is significant, which remains unchanged. The RCS T_{avg} remains at 578.2°F.

For the reload core, there is no difference in the mechanical heat capacity of the fuel; however, the core stored energy has increased slightly. The increase was evaluated, and it was determined to have an increased energy effect of 132,000 BTUs. However, the Tech-Spec ice mass based on the Reference 72 analysis contains an additional 384 Lbms of ice due to roundoff. The increase in core stored energy is offset by the roundoff in the Tech-Spec operational limit. Therefore, the Reference 72 analysis bounds operation with reloads having up to 96 fresh Mark-BW17 fuel assemblies.

The metric tons of Uranium, the enrichment, and the fuel reload cycle utilized in the current analysis remain bounding for the B&W fuel. Therefore, the Sequoyah-specific decay heat curve remains bounding.

In summary, the effect of including Mark-BW17 Fuel on the current LOCA M&E and the containment integrity analysis has been evaluated. It has been concluded that the current analysis results remain bounding.

HTP Fuel Evaluation

The inputs/features that are of primary importance in containment analyses are evaluated individually below for operation with Advanced W17 HTP fuel:

- Initial system mass inventory and energy content
- break mass and energy release rates
- structural inputs such as compartment volumes and containment structure mass
- structural heat content and decay heat
- safety systems that include containment sprays, fans, and the ice condenser

The effect of Advanced W17 HTP fuel on initial system inventory and energy content, break flows, and containment structural and safety system inputs used in containment analyses were evaluated. The Advanced W17 HTP fuel has been shown to have no significant effect on these inputs. Existing containment analyses, therefore, remain applicable with the implementation of the Advanced W17 HTP fuel.

There is a minor increase to the LBLOCA long-term containment temperature profile when coupled with loss of downstream dam (670’ to 639’ elevation). The loss of dam event gradually reduces the river head which in turn eventually decreases ERCW flow approximately 7%. For this scenario, long-term containment cooling begins after the reservoir level has decreased below the minimum analysis elevation 670’; this time is more than 2 hours after the peak containment temperature and pressure have already occurred. The increase in long-term containment temperature is estimated to be 3°F (based on the design input to the 1988 UHS technical specification change). The 3°F increase should only be applied to the temperatures shown in Figures 6.2.1-16 and 6.2.1-17 after approximately 10E3 seconds.

6.2.1.3.5 Effect of Steam Bypass

The sensitivity of the compression peak pressure to deck bypass is shown in Figure 6.2.1-22, which shows that an increase in deck bypass area of 50 percent would cause an increase of about 0.2 psi in final peak compression pressure. Also, it is important to note that the plant final peak compression pressure of 7.18 psig already includes a contribution of 0.4 psi from the plant deck bypass area of 5 ft^2.

This effect of deck leakage on upper containment pressure has been verified by a series of four special, full-scale section tests. These tests were all identical except different size deck leakage areas were used.

The results of these tests are given in Figure 6.2.1-23 which includes two curves of test results. Each curve shows the difference in upper compartment pressure between one test and another resulting from a difference in deck leakage area. One curve shows the increase in upper compartment pressure at the end of the boiler blowdown (after the compression peak pressure, at about 50 seconds in these tests), and the second curve shows the increase in upper compartment peak pressure (at about 10 seconds in these tests). It should be noted that the pressure at the end of the blowdown is less than the peak compression ratio pressure occurring at about 10 seconds for reference blowdown test.

The containment pressure increase due to deck leakage is directly proportional to the total amount of steam leakage into the upper compartment, and the amount of this steam leakage is, in turn, proportional to the amount of steam released from the boiler, less the inventory of steam remaining in the lower compartment. Notably, the increase in upper compartment compression peak pressure is substantially less than the upper compartment pressure increase at the end of blowdown, because the peak compression pressure occurs before the boiler has released all of its energy, and measured increase in peak compression pressure due to increased deck leakage,

is proportionately reduced. For the case of the plant design, the final peak compression pressure is conservatively assumed to occur when the reactor coolant system release is 75 percent of its total energy. This value is selected as a reference value, based on the results of a number of tests conducted with different blowdown rates and total energy releases, as shown in Figure 6.2.1-24. The actual deck leakage coefficient is therefore,

$$\frac{\Delta P_3}{A_{deck}} = 0.107 \times 0.75 = 0.080 \text{ psi/ft}^2$$

The divider barrier including the enclosures over the pressurizer, steam generators and reactor vessel, is designed to provide a reasonably tight seal against leakage. Holes are purposely provided in the bottom of the refueling cavity to allow water from sprays in the upper compartment to drain to the sump in the lower compartment. Potential leakage paths exist at all the joints between the operating deck and the pump access hatches and reactor vessel enclosure slabs. The total of all deck leakage flow areas is approximately 5 square feet. The effect of this potential leakage path is small and is found to be:

$$\Delta P_{deck} = 5 \times 0.080 = 0.4 \text{ psi}$$

In the event that the Reactor Coolant System break flow is so small that it would leak through these flow paths without developing sufficient differential pressure (1 lb/ft^2) to open the ice condenser doors, steam from the break would slowly pressurize the containment. The Containment Spray System has sufficient capacity to maintain pressure well below design for this case.

The method of analysis used to obtain the maximum allowable deck leakage capacity as a function of the primary system break size is as follows:

During the blowdown transient, steam and air flow through the ice condenser doors and also through the deck bypass area into the upper compartment. For the containment, this bypass area is composed of two parts, a known leakage area of approximately 2.0 ft^2 with a geometric loss coefficient of 1.5 through the deck drainage holes location at the bottom of the refueling canal and an undefined deck leakage area with a conservatively small loss coefficient of 2.5. A resistance network similar to

that used in TMD is used to represent 6 lower compartment volumes each with a representative portion of the deck leakage, and the lower inlet door flow resistance and flow is calculated for small breaks that would only partially open these doors. The coolant blowdown rate as a function of time is used with this flow network to calculate the differential pressures on the lower inlet doors and across the operating deck.

The resultant deck leakage rate and integrated steam leakage into the upper compartment is then calculated. The lower inlet doors are initially held shut by the cold head of air behind the doors (approximately one pound per square foot). The initial blowdown from a small break opens the doors and removes the cold head on the doors. With the door differential removed, the door position is slightly open. An additional pressure differential of one pound per square foot is then sufficient to fully open the doors. The nominal door opening characteristics are based on test results.

One analysis conservatively assumed that flow through the postulated leakage paths is pure steam. During the actual blowdown transient, steam and air representative of the lower compartment mixture leak through the holes, thus less steam would enter the upper compartment. If flow were considered to be a mixture of liquid and vapor, the total leakage mass would increase, but the steam flow rate would decrease. The analysis also assumed that no condensing of the flow occurs due to structural heat sinks. The peak air compression in the upper compartment for the various break sizes is assumed with the steam mass added to this value to obtain the total containment pressure. Air compression for the various break sizes is obtained from previous full-scale section tests conducted at Waltz Mill.

The allowable leakage area for the following Reactor Coolant System (RCS) break sizes was determined: DE, 0.6 DE, 3 ft^2, 10 inch diameter, 6 inch diameter, 2 inch diameter and 0.5 inch diameter. The allowable deck leakage area for the DE break was based on the test results previously discussed. For break sizes of 3 ft^2 and 0.6 DE, a series of deck leakage sensitivity studies were made to establish the total steam leakage to the upper compartment over the blowdown transient. This steam was added to the peak compression air mass in the upper compartment to calculate a peak pressure. Air and steam were assumed to be in thermal equilibrium, with the air partial pressure increased over the air compression value to account for heating effects. For these breaks, sprays were neglected. Reduction in compression ratio by return of air to the lower compartment was conservatively neglected. The results of this analysis are shown in Table 6.2.1-12. This analysis is confirmed by Waltz Mill tests conducted with various deck leaks equivalent to over 50 ft^2 of deck leakage for the double-ended blowdown rate and is shown in Figure 6.2.1-23.

For breaks of 10 inch diameter and smaller, the effect of containment sprays was included. The method used is as follows: For each time step of the blowdown, the amount of steam leaking into the upper compartment was calculated to obtain the steam mass in the upper compartment. This steam was mixed with the air in the upper compartment, assuming thermal equilibrium with air. The air partial pressure was increased to account for air heating effects. After sprays were initiated, the pressure was calculated based on the rate of accumulation of steam in the upper compartment.

This analysis was conducted for the 10 inch, 6 inch and 2 inch break sizes, assuming one spray pump operated (4750 gpm at 100°F). As shown in Table 6.2.1-12, the 10 inch break is the limiting case for this range of break sizes.

A second, more realistic, method was used to analyze the 10 inch, 6 inch, and 2 inch breaks. This analysis assumed a 30 percent air 70 percent steam mixing flowing through the deck leakage area. This is conservative considering the amount of air in the lower compartment during this portion of the transient. Operation of the deck fan increases the air content of the lower compartment, thus increasing the allowable deck leakage area. Based on the LOTIC code analysis, a structural heat removal rate of over 6000 BTU/sec from the upper compartment is indicated [Reference 30]. Therefore, a steam condensation rate of 6 lbs/sec was used for the upper compartment. The results indicate that with one spray pump operating and a deck leakage area of 50 ft^2, the peak containment pressure is below design pressure.

The 1/2 inch diameter break is not sufficient to open the ice condenser inlet doors. For this break, the upper compartment spray is sufficient to condense the break steam flow.

In conclusion, it is apparent that there is a substantial margin between the design deck leakage area of 5 ft^2 and that which can be tolerated without exceeding containment design pressure.

6.2.1.3.6 Transient Phase Analyses

Blowdown Analysis (Short Term)

Mass and energy release rate transients generated for the TMD pressure calculation are supported by an extensive investigation of short term blowdown phenomena. The SATAN-V, WCAP 7750 (Reference 62), code was used to predict early blowdown transients. The study concerned then a verification of the conservatism of the SATAN-V calculated transients. This verification was accomplished through two approaches: a review of the validity of the SATAN-V break model, and a parametric study of significant physical assumptions.

The SATAN-V code uses a control volume approach to model the behavior of the Reactor Coolant System resulting from a large break in a main coolant pipe. Release rate transients are determined by the SATAN-V break model which includes a critical flow calculation and an implicit representation of pressure wave propagation.

The SATAN-V critical flow calculation employs appropriately defined critical flow correlations applied for fluid conditions at the break element. For the early portion of blowdown, subcooled, saturated and two phase critical flow regimes are encountered. SATAN-V uses the Moody (Reference 1) correlation for saturated and two phase fluid conditions and a slight modification of the Zaloudek (Reference 2) correlation for the subcooled blowdown regime.

Since most short term blowdown transients are characterized by a peak mass and energy release rate that occurs during a subcooled condition, the Zaloudek application is particularly significant. The Zaloudek correlation is modified to merge to Moody predicted mass velocities at saturation in the break element. This correlation appears in the critical flow routine of SATAN-V.

Comparison to Other Critical Flow Models

The Henry-Fauske critical flow correlation was considered for comparison (References 3, 4, 5). This correlation models flow nonequilibrium via an approach which includes an empirical parameter. This parameter describes the deviation from equilibrium mass transfer and depends on flow geometry.

The value is selected for a particular configuration based on the range of throat equilibrium qualities. The value for constant area ducts is used in the present analysis. This choice is based on the worst possible double ended break geometry described below.

For cold leg and hot leg breaks, the majority of the flow, about 65%, comes from the vessel side of the break. For this side, the geometry may be described as an entrance nozzle and a straight pipe of approximate 12 feet in length and with a diameter of 29 inches. This length of pipe represents the distance from the reactor vessel to the periphery of the biological shield. No double ended break can occur within the biological shield because of the restricted movement within the pipe annulus. Hence the constant area value is appropriate.

Like the SATAN-V model, the Henry-Fauske correlation yields a G_{crit} in terms of upstream conditions and like the SATAN-V model it also exhibits a steeper slope of the G vs. P line for subcooled conditions. The Henry-Fauske saturated liquid line is below the Moody saturated line (SATAN-V model) for pressure greater than about 1000 psia. For short term blowdown calculations, the significant pressure region is from 1000 psia to 1800 psia, with increased emphasis on subcooled conditions for the 1000 psia end. Subcooled mass velocity versus pressure is calculated for two fluid temperatures corresponding to P_{sat} = 1000 and P_{sat} = 1800. The slope of the Zaloudek G vs. P line is steeper in both cases. This increased sensitivity coupled with the higher value for Moody at saturation causes the SATAN-V model to predict higher mass velocities. Hence the SATAN-V model is a more conservative treatment of critical flow than the Henry-Fauske model.

In the original FLASH model (Reference 6), the Moody correlation was extended to subcooled conditions. This treatment is employed in many blowdown codes and thus it is appropriate to compare the SATAN-V model to these values. Again the Zaloudek treatment yields higher mass velocities and the SATAN-V model is more conservative.

Comparison To Experimental Data

The margin included in the modified Zaloudek prediction of subcooled critical flow rates is demonstrated by a review of experimental subcooled critical flow data (References 2,7). The review indicates that when the modified correlation is applied to Zaloudek's data, the predicted critical flow values are significantly higher than measured flow rates.

The margin associated with the SATAN-V critical flow calculation may also be demonstrated by a review of the low quality data presented by Henry (Reference 5). Exit plane quality, in terms of the Moody model, is determined as a function of upstream conditions by assuming an isentropic expansion to exit plane (i.e. critical) pressure. The lowest exit plane qualities where the Moody model is applied in the SATAN-V code occur for expansion from saturated liquid conditions. The Moody model is used in the SATAN-V code when that model gives higher exit plane quality, otherwise the Modified Zaloudek model is used.

Henry's comparison between data and model shows that for the range of exit plane quality greater than 0.02, the Moody model overpredicts the data, hence is conservative.

For the region below 0.02, it is appropriate to compare Henry's results with the Modified Zaloudek model, as used in the SATAN-V code. It can be shown that the Zaloudek model overpredicts the flow. A discharge coefficient of 0.6 would be more reasonable than the 1.0 value used in SATAN-V.

Application to Transient Conditions

The Zaloudek correlation was developed for stagnation (reservoir) pressure and quasi steady state critical flow conditions. It is extended to application in the SATAN-V break element and transient flow conditions. This extension is justified because of the following considerations.

The pressure in the break element differs from the value in a nearby large volume because of three effects:

1. Pressure drop due to friction
2. Pressure drop due to spatial acceleration (momentum flux)
3. Pressure drop due to the transient

The friction term in the reactor application is quantifiable; this term is less important than the other two. The sensitivity of the break flow rate to fluid friction was evaluated via a parametric study. For the purposes of this study, an analysis was made wherein the frictional resistance between the vessel and the break was reduced from the design values by a factor of one hundred. Over the period from 0.0 to 60 milliseconds (which includes the peak break flow), the integrated mass flow differed by less than 18 lbs from the design friction case; the total release over this period was about 5000 lbs.

Spatial acceleration is the major source of pressure drop upstream of the break between the reservoir and the pipe, causing steep pressure gradients in the approach region to critical flow. This term is not calculated explicitly in the SATAN-V code. Spatial acceleration is accounted for by the use of critical flow correlations (Zaloudek or Moody) which contain this effect. No credit is taken for pressure drop due to spatial acceleration for elements other than the break element. Hence the pressure calculated by SATAN-V may be interpreted as a stagnation pressure which is the appropriate pressure for the Zaloudek and Moody models.

Prior to the occurrence of the peak release rate, the break element and upstream reservoir pressures differ as a result of the transient described by pressure wave propagation. The applicability of the SATAN-V break model to this situation is verified by the code's ability to match recorded semi scale transients. SATAN simulations of LOFT transients support the SATAN-V transient calculation. When the LOFT pressure transient recorded near the break is compared to the SATAN-V model of the LOFT break element transient, the ability of the SATAN-V Code to track pressure waves in the broken pipe is demonstrated.

Moreover, the critical flow correlation is implemented in the present analysis by combining the correlation with the appropriate momentum equation. This provides a model for predicting break flow acceleration vis-a-vis a quasi-steady simulation. This is found to have little effect on containment pressure but is a more physical representation.

Thus the SATAN-V break model is supported by subcooled critical flow data, by comparison to other correlations, and ability to simulate short term transients.

Parametric Studies

With confirmation of the conservatism of the SATAN-V break model, a series of parametric studies were undertaken to identify the blowdown transient corresponding to the most severe TMD results. A series of basic sensitivities were first studied to set the scope of the more detailed investigations. The assumptions of break size, break type and break location were considered. The results of the analysis were evaluated using the TMD code.

Break Size, Type and Location

The influence of break location on TMD peak pressure was considered by generating blowdown transients for possible worst break locations. The results indicated that a double ended break in the pump suction leg was clearly less severe for short term blowdown release rates and that no such clear decision could be made between hot and cold leg breaks.

More detailed parametric studies were continued for the cold leg and the hot leg double ended guillotine breaks. The two locations produce intrinsically different TMD pressure responses and therefore must be dealt with in separate parametric surveys.

Hot Leg Nodal Configuration

A study of the SATAN-V nodal configuration has been applied to the hot leg double ended guillotine break. It was found that for this break the nodal configuration of the broken hot leg and the upper plenum are significant to short term transients. Spatial convergence was achieved for the upper plenum after the addition of four nodes to the Standard SATAN-V two node upper plenum model. These nodes are hemispherical shells arranged concentrically from the broken hot leg nozzles and approximate the propagation of the pressure wave in the upper plenum. They are significant in that they specify the inertial response of the upper plenum. Spatial convergence was demonstrated because doubling the number of nodes yielded less than one percent deviation in break flow at all times.

Sensitivity to nodal configuration in the broken hot leg pipe was also investigated. Models with from 4 to 16 nodes were used to generate transients.

Increasing the number of nodes was found to give a better simulation of pressure wave propagation in the pipe.

Cold Leg Studies

The cold leg break transient was also reviewed in terms of significant parameters.

The Reactor Coolant System behavior is different for cold leg breaks and the peak containment pressure occurs later for cold leg breaks. The following studies were performed.

Nodal Configuration

For the cold leg break the nodal configuration of the broken cold leg and the downcomer is significant to the transient. Spatial convergence was achieved with the addition of three nodes to the standard SATAN-V model. These are annular rings arranged concentrically from the broken cold leg nozzle and model propagation of the pressure wave in the downcomer.

As in the hot leg sensitivity, from 4 to 16 pipe node models were tried for the cold leg transient. Again, more nodes give a better simulation of pressure wave propagation in the broken pipe.

Pump Modeling

For the time period of interest, the variation in pump inlet density is small and the variation in pump speed is small. This model was found to have no effect.

Summary

From the hot leg and cold leg studies, the design basis mass and energy release rates have been finalized. The mass and energy release rate transients for all the design cases are given in Figures 6.2.1-25 through 6.2.1-34. All cases are generated from the SATAN-V break model consisting of Moody-Modified Zaloudek critical flow correlations applied at the break element. Since no mechanistic constraints have been established for full guillotine pipe rupture, instantaneous pipe severance and disconnection is assumed for all transients. Assumptions specific to the presented transients are as follows:

For the hot leg mass and energy release rate transient to loop compartments:

Figures 6.2.1-25 and 6.2.1-26

1. A double ended guillotine type break.
2. A break located just outside the biological shield.
3. A break located in the worst loop.
4. A six node upper plenum model.
5. A 16 node broken hot leg pipe model.
6. A discharge coefficient (C_D) equal to 1.0
7. A 100% power condition with T_{hot} = 634.7°F and T_{cold} = 545.1°F

For the cold leg mass and energy release rate transient to loop compartments:

Figures 6.2.1-27 and 6.2.1-28

1. A double ended guillotine type break.
2. A break located just outside the biological shield
3. A break located in the worst loop.
4. A seven node downcomer model.
5. A 16 node broken cold leg pipe model.
6. A discharge coefficient (C_D) equal to 1.0
7. A full power condition with T_{hot} = 634.7°F and T_{cold} = 545.1°F

For hot leg mass and energy release rate transients to subcompartments:

Figures 6.2.1-29 and 6.2.1-30

1. A single ended split type break.
2. A break just outside the hot leg nozzle.
3. A break in the pressurizer loop.
4. A six node upper plenum model.
5. A 16 node broken hot leg pipe model.
6. A discharge coefficient (C_D) equal to 1.0
7. A full power condition T_{hot} = 634.7°F and T_{cold} = 545.1°F

For the cold leg mass and energy release rate transient to subcompartments:

Figures 6.2.1-31 and 6.2.1-32

1. A single ended split type break.
2. A break just outside the cold leg nozzle.

3. A break in the pressurizer loop.
4. A seven node downcomer model.
5. A 16 node broken cold leg pipe model.
6. A discharge coefficient (C_D) equal to 1.0
7. A full power condition T_{hot} = 634.7°F and T_{cold} = 545.1°F

For the mass and energy release rate transient to the pressurizer enclosure a 6 inch safety valve pipe break was considered (Figures 6.2.1-33 and 6.2.1-34).

1. A guillotine type break modelled as a 0.147 ft^2 split in the cold leg at the pump discharge (area of the six inch pressurizer spray feed line) and a 0.087 ft^2 split in the top of the pressurizer (area of 4 inch spray nozzle).

2. Valves in spray line are assumed to be open

3. No pipe resistance for the feed line considered

4. A full power condition T_{hot} = 634.7°F and T_{cold} = 545.1°F

5. A discharge coefficient (C_D) equal to 1.0

LONG TERM LOCA MASS AND ENERGY RELEASE ANALYSIS

The evaluation model used for the long term LOCA mass and energy release calculations was the March 1979 model described in Reference 64. This evaluation model has been reviewed and approved by the NRC, and has been used in the analysis of other ice condenser plants.

This report section presents the long term LOCA mass and energy releases that were generated in support of the Sequoyah Nuclear Plant Units 1 and 2 ice weight optimization program. These mass and energy releases are then subsequently used in the LOTIC-1 computer code for containment integrity analysis peak pressure calculations.

LOCA Mass and Energy Release Phases

The containment system receives mass and energy releases following a postulated rupture in the RCS. These releases continue over a time period, which, for the LOCA mass and energy analysis, is typically divided into four phases:

1. Blowdown - the period of time from accident initiation (when the reactor is at steady state operation) to the time that the RCS and containment reach an equilibrium state at containment design pressure.

2. Refill - the period of time when the lower plenum is being filled by accumulator and ECCS water. At the end of blowdown, a large amount of water remains in the cold legs, downcomer, and lower plenum. To conservatively consider the refill period for the purpose of containment mass and energy releases, it is assumed that this water is instantaneously transferred to the lower plenum along with sufficient accumulator water to completely fill the lower plenum. This allows an uninterrupted release of mass and energy to containment. Thus, the refill period is conservatively neglected in the mass and energy release calculation.

3. Reflood - begins when the water from the lower plenum enters the core and ends when the core is completely quenched.

4. Post-reflood (FROTH) - describes the period following the reflood transient. For the pump suction break, a two-phase mixture exits the core, passes through the hot legs, and is superheated in the steam generators. After the broken loop steam generator cools, the break flow becomes two phase.

Computer Codes

The Reference 64 mass and energy release evaluation model is comprised of mass and energy release versions of the following codes: SATAN VI, WREFLOOD, and FROTH. These codes were used to calculate the long term LOCA mass and energy releases for the Sequoyah Nuclear Plant Units 1 and 2.

SATAN calculates blowdown, the first portion of the thermal-hydraulic transient following break initiation, including pressure, enthalpy, density, mass and energy flowrates, and energy transfer between primary and secondary systems as a function of time.

The WREFLOOD code addresses the portion of the LOCA transient where the core reflooding phase occurs after the primary coolant system has depressurized (blowdown) due to the loss of water through the break and when water supplied by the Emergency Core Cooling refills the reactor vessel and provides cooling to the core. The most important feature is the steam/water mixing model (See Reflood Mass and Energy Data section).

FROTH models the post-reflood portion of the transient. The FROTH code is used for the steam generator heat addition calculation from the broken and intact loop steam generators.

Break Size and Location

Generic studies have been performed with respect to the effect of postulated break size on the LOCA mass and energy releases. The double ended guillotine break has been found to be limiting due to larger mass flow rates during the blowdown phase of the transient. During the reflood and FROTH phases, the break size has little effect on the releases.

Three distinct locations in the reactor coolant system loop can be postulated for pipe rupture:

1. Hot leg (between vessel and steam generator)
2. Cold leg (between pump and vessel)
3. Pump suction (between steam generator and pump)

The break location analyzed for the Ice Optimization Program is the pump suction double ended rupture guillotine, DEPSG (10.46 ft^2). Break mass and energy releases have been calculated for the blowdown, reflood, and post-reflood phases of the LOCA for each case analyzed. The following information provides a discussion on each break location.

The hot leg double ended rupture has been shown in previous studies to result in the highest blowdown mass and energy release rates. Although the core flooding rate would be the highest for this break location, the amount of energy released from the steam generator secondary is minimal because the majority of the fluid which exits the core bypasses the steam generators venting directly to containment. As a result, the reflood mass and energy releases are reduced significantly as compared to either the pump suction or cold leg break locations where the core exit mixture must pass through the steam generators before venting through the break. For the hot leg break, generic studies have confirmed that there is no reflood peak (i.e., from the end of

the blowdown period, the containment pressure would continually decrease). The mass and energy releases for the hot leg break have not been included in the scope of this containment integrity analysis because for the hot leg break only the blowdown phase of the transient is of any significance. Since there are no reflood and post-reflood phases to consider, the limiting peak pressure calculated would be the compression peak pressure and not the peak pressure following ice bed meltout.

The cold leg break location has also been found in previous studies to be much less limiting in terms of the overall containment energy releases. The cold leg blowdown is faster than that of the pump suction break, and more mass is released into the containment. However, the core heat transfer is greatly reduced, and this results in a considerably lower energy release into containment. Studies have determined that the blowdown transient for the cold leg is, in general, less limiting than that for the pump suction break. During reflood, the flooding rate is greatly reduced and the energy release rate into the containment is reduced. Therefore; the cold leg break is not included in the scope of this program.

The pump suction break combines the effects of the relatively high core flooding rate, as in the hot leg break, and the addition of the stored energy in the steam generators. As a result, the pump suction break yields the highest energy flow rates during the post-blowdown period by including all of the available energy of the Reactor Coolant System in calculating the releases to containment. This break has been determined to be the limiting break for all ice condenser plants.

In summary, the analysis of the limiting break location for an ice condenser containment has been performed and is shown in this report. The double-ended pump suction guillotine break has historically been considered to be the limiting break location, by virtue of its consideration of all energy sources in the Reactor Coolant System (RCS). This break location provides mechanism for the release of the available energy in the RCS, including both the broken and intact loop steam generators.

Application of Single Failure Criteria

An analysis of the effects of the single failure criteria has been performed on the mass and energy release rates for the pump suction (DEPS) break. An inherent assumption in the generation of the mass and energy release is that offsite power is lost. This results in the actuation of the emergency diesel generators, required to power the safety injection system. This is not an issue for the blowdown period which is limited by the compression peak pressure.

The limiting minimum safety injection case has been analyzed for the effects of a single failure. In the case of minimum safeguards, the single failure postulated to occur is the loss of an emergency diesel generator. This results in the loss of one pumped safety injection train, i.e., ECCS pumps and heat exchangers.

System Characteristics and Modeling Assumptions

The mass and energy release analysis is sensitive to the assumed characteristics of various plant systems, in addition to other key modeling assumptions. Some of the most critical items are the: RCS initial conditions, core decay heat, safety injection flow, and metal and steam generator heat release modeling. Specific assumptions concerning each of these items are discussed below. Table 6.2.1-1 presents key data assumed in the analysis.

For the long term mass and energy release calculations, operating temperatures to bound the highest average coolant temperature range were used as bounding analysis conditions. The modeled core rated power of 3455 MWt adjusted for calorimetric error (+0.7 percent of power) was the basis in the analysis. The use of higher temperatures is conservative because the initial fluid energy is based on coolant temperatures which are at the maximum levels attained in steady state operation. Additionally, an allowance of +5.5 ^{0}F is reflected in the RCS temperatures in order to account for instrument error and deadband. The initial RCS pressure in this analysis is based on a nominal value of 2250 psia. Also included is an allowance of +50 psi, which accounts for the measurement uncertainty on pressurizer pressure. The selection of 2250 psia as the limiting pressure is considered to affect the blowdown phase results only, since this represents the initial pressure of the RCS. The RCS rapidly depressurizes from this value until the point at which it equilibrates with containment pressure.

The rate at which the RCS blows down is initially more severe at the higher RCS pressure. Additionally, the RCS has a higher fluid density at the higher pressure (assuming a constant temperature) and subsequently has a higher RCS mass available for releases. Thus, 2300 psia initial pressure was selected as the limiting case for the long term mass and energy release calculations. These assumptions conservatively maximize the mass and energy in the RCS.

The selection of the fuel design features for the long term mass and energy calculation is based on the need to conservatively maximize the core stored energy. The margin in core stored energy was chosen to be +15 percent. Thus, the analysis very conservatively accounts for the stored energy in the core. The fuel conditions were adjusted to provide a bounding analysis for current Sequoyah Nuclear Plant Units 1 and 2 fuel features. The following items serve as the basis to ensure conservatism in the core stored energy calculation: a conservatively high reload core loading; time of maximum fuel densification, i.e., highest BOL temperatures; and irradiated fuel assemblies are assumed to have an average burnup >15000 MWD/MTU.

Margin in RCS volume of 3% (which is composed of 1.6% allowance for thermal expansion and 1.4% for uncertainty) is modeled.

Regarding safety injection flow, the mass and energy calculation considered the historically limiting configuration of minimum safety injection flow.

The following assumptions were employed to ensure that the mass and energy releases are conservatively calculated, thereby maximizing energy release to containment:

1. Maximum expected operating temperature of the reactor coolant system (100% full power conditions.

2. An allowance in temperature for instrument error and dead band was assumed (+5.5 degrees F).

3. Margin in volume of 3% (which is composed of 1.6% allowance for thermal expansion, and 1.4% for uncertainty).

4. Core rated power of 3455 MWt.

5. Allowance for calorimetric error (+0.7 percent of power).

6. Conservative coefficient of heat transfer (i.e., steam generator primary/secondary heat transfer and reactor coolant system metal heat transfer).

7. Allowance in core store energy for effect of fuel densification.

8. A margin in core stored energy (+15 percent included to account for manufacturing tolerances).

9. An allowance for RCS initial pressure uncertainty (+50 psi).

10. A maximum containment backpressure equal to design pressure.

11. The steam generator metal mass was modeled to include only the portion of the steam generators (SG) which is in contact with the fluid on the secondary side. Portions of the SGs such as the elliptical head, upper shell and miscellaneous internals have poor heat transfer due to location. The heat stored in these areas available for release to containment will not be able to effectively transfer energy to the RCS, thus the energy will be removed at a much slower rate and time period (>10000 seconds).

12. A provision for modeling steam flow in the secondary side through steam generator turbine stop valve was conservatively addressed only at the start of the event. Turbine stop valve isolation time equal to 1.19 seconds was considered.

13. As noted in Section 2.4 of Reference 64, the option to provide more specific modeling pertaining to decay heat has been exercised to specifically reflect the Sequoyah Units 1 and 2 core heat generation, while retaining the two sigma uncertainty to assure conservatism.

14. Steam generator tube plugging leveling (0% uniform).

    - Maximizes reactor coolant volume and fluid release
    - Maximizes heat transfer area across the SG tubes
    - Reduces coolant loop resistance, which Δp upstream of break and increases break flow

Thus, based on the previously noted conditions and assumptions, a bounding analysis of Sequoyah Units 1 and 2 is made for the release of mass and energy from the RCS in the event of a LOCA to support ice weight optimization.

MASS AND ENERGY RELEASE DATA

Blowdown Mass and Energy Release Data

A version of the SATAN-VI code is used for computing the blowdown transient, which is the code used for Emergency Core Cooling System (ECCS) calculation in Reference 78.

The code utilizes the control volume (element) approach with the capability for modeling a large variety of thermal fluid system configurations. The fluid properties are considered uniform and thermodynamic equilibrium is assumed in each element. A point kinetics model is used with weighted feedback effects. The major feedback effects include moderator density, moderator

temperature and Doppler broadening. A critical flow calculation for subcooled (modified Zaloudek), two-phase (Moody), or superheated break flow is incorporated into the analysis. The methodology for the use of this model is described in Reference 64.

Table 6.2.1-13 presents the calculated mass and energy releases for the blowdown phase of the DEPSG break. For the pump suction breaks, break path 1 in the mass and energy release tables refers to the mass and energy exiting from the steam generator side of the break; break path 2 refers to the mass and energy exiting from the pump side of the break.

Reflood Mass and Energy Release Data

The WREFLOOD code used for computing the reflood transient, is a modified version of that used in the 1981 ECCS evaluation model, Reference 78.

The WREFLOOD code consists of two basic hydraulic models - one for the contents of the reactor vessel, and one for the coolant loops. The two models are coupled through the interchange of the boundary conditions applied at the vessel outlet nozzles and at the top of the downcomer. Additional transient phenomena such as pumped safety injection and accumulators, reactor coolant pump performance, and steam generator release are included as auxiliary equations which interact with the basic models as required. The WREFLOOD code permits the capability to calculate variations during the core reflooding transient of basic parameters such as core flooding rate, core and downcomer water levels, fluid thermodynamic conditions (pressure, enthalpy, density) throughout the primary system, and mass flow rates through the primary system. The code permits hydraulic modeling of the two flow paths available for discharging steam and entrained water from the core to the break; i.e., the path through the broken loop and the path through the unbroken loops. The 19 element model schematic used in this analysis is shown in Figure 6.2.1-83.

A complete thermal equilibrium mixing condition for the steam and emergency core cooling injection water during the reflood phase has been assumed for each loop receiving ECCS water. This is consistent with the usage and application of the Reference 64 mass and energy release evaluation model in recent analyses, e.g., D. C. Cook Docket (Reference 79). Even though the Reference 64 model credits steam/mixing on the intact loop and not in the broken loop, justification, applicability, and NRC approval for using the mixing model in the broken loop has been documented (Reference 79). This assumption is justified and supported by test data, and is summarized as follows:

The model assumes a complete mixing condition (i.e., thermal equilibrium) for the steam/water interaction. The complete mixing process, however, is made up of two distinct physical processes. The first is a two phase interaction with condensation of steam by cold ECCS water. The second is a single phase mixing of condensate and ECCS water. Since the steam release is the most important influence to the containment pressure transient, the steam condensation part of the mixing process is the only part that need be considered. (Any spillage directly heats only the sump.)

The most applicable steam/water mixing test data has been reviewed for validation of the containment integrity reflood steam/water mixing mode. This data is that generated in 1/3 scale tests (Reference 80), which are the largest scale data available and thus most clearly simulates the flow regimes and gravitational effects that would occur in a PWR. These tests were designed specifically to study the steam/water interaction for PWR reflood conditions.

From the entire series of 1/3 scale tests, a group corresponds almost directly to containment integrity reflood conditions. The injection flowrates for this group cover all phases and mixing conditions calculated during the reflood transient. The data for these tests were reviewed and discussed in detail in Reference 64. For all of these tests, the data clearly indicate the occurrence of very effective mixing with rapid steam condensation. The mixing model used in the containment integrity reflood calculation is therefore wholly supported by the 1/3 scale steam/water mixing data.

Additionally, the following justification is also noted. The post-blowdown limiting break for the containment integrity peak pressure analysis is the pump suction double ended rupture break. For this break, there are two flowpaths available in the RCS by which mass and energy may be released to containment. One is through the outlet of the steam generator, the other via reverse flow through the reactor coolant pump. Steam which is not condensed by ECCS injection in the intact RCS loops passes around the downcomer and through the broken loop cold leg and pump in venting to containment. This steam also encounters ECCS injection water as it passes through the broken loop cold leg, complete mixing occurs and a portion of it is condensed. It is this portion of steam which is condensed that is taken credit for in this analysis. This assumption is justified based upon the postulated break location, and the actual physical presence of the ECCS injection nozzle. A description the test and test results is contained in References 80.

Table 6.2.1-15 presents the calculated mass and energy release for the reflood phase of the pump suction double ended rupture with minimum safety injection.

The transients of the principal parameters during reflood are given in Table 6.2.1-16.

<u>Post-Reflood Mass and Energy Release Data</u>

The FROTH code [Reference 26] is used for computing the post-reflood transient.

The FROTH code calculates the heat release rates resulting from a two-phase mixture level present in the steam generator tubes. The mass and energy releases that occur during this phase are typically superheated due to the depressurization and equilibration of the broken loop and intact loop steam generators. During this phase of the transient, the RCS has equilibrated with the containment pressure, but the steam generators contain a secondary inventory at an enthalpy that is much higher than the primary side. Therefore, there is a significant amount of reverse heat transfer that occurs. Steam is produced in the core due to core decay heat. For a pump suction break, a two phase fluid exits the core, flows through the hot legs and becomes superheated as it passes through the steam generator. Once the broken loop cools, the break flow becomes two phase. The methodology for the use of this model is described in Reference 64.

After steam generator depressurization/equilibration, the mass and energy release available to containment is generated directly from core boiloff/decay heat.

Table 6.2.1-18 presents the two phase post-reflood (FROTH) mass and energy release data for the pump suction double ended case.

Decay Heat Model

On November 2, 1978, the Nuclear Power Plant Standards Committee (NUPPSCO) of the American Nuclear Society approved ANS standard 5.1 for the determination of decay heat. This standard was used in the mass and energy release model with the following input specific for the Sequoyah Nuclear Plant Units 1 and 2. The primary assumptions which make this calculation specific for the Sequoyah Nuclear Plant Units 1 and 2 are the enrichment factor, minimum/maximum new fuel per cycle, and cycle length. A conservative lower bound for enrichment of 3% was used. Table 6.2.1-8 lists the decay heat curve used in the Sequoyah Ice Weight Optimization analysis.

Significant assumptions in the generation of the decay heat curve:

1. Decay heat sources considered are fission product decay and heavy element decay of U-239 and N_P-239.

2. Decay heat power from fissioning isotopes other than U-235 is assumed to be identical to that of U-235.

3. Fission rate is constant oven the operating history of maximum power level.

4. The factor accounting for neutron capture in fission products has been taken from Equation 11, of Reference 81 up to 10,000 seconds, and Table 10, of Reference 81 beyond 10,000 seconds.

5. The fuel has been assumed to be at full power for 10^8 seconds.

6. The number of atoms of U-239 produced per second has been assumed to be equal to 70% of the fission rate.

7. The total recoverable energy associated with one fission has been assumed to be 200 MeV/fission.

8. Two sigma uncertainty (two times the standard deviation) has been applied to the fission product decay.

Steam Generator Equilibration and Depressurization

Steam generator equilibration and depressurization is the process by which secondary side energy is removed from the steam generators in stages. The FROTH computer code calculates the heat removal from the secondary mass until the secondary temperature is Tsat at the containment design pressure. After the FROTH calculations, steam generator secondary energy is removed until the steam generator reaches Tsat at the user specified intermediate equilibration pressure, when the secondary pressure is assumed to reach the actual containment pressure. The heat removal of the broken loop and intact loop steam generators are calculated separately.

During the FROTH calculations, steam generator heat removal rates are calculated using the secondary side temperature, primary side temperature and a secondary side heat transfer coefficient determined using a modified McAdam's correlation (Reference 12). Steam generator

energy is removed during the FROTH transient until the secondary side temperature reaches saturation temperature at the containment design pressure. The constant heat removal rate used is based on the final heat removal rate calculated by FROTH. The remaining SG energy available to be released is determined by calculating the difference in secondary energy available at the containment design pressure and that at the (lower) user specified equilibration pressure, assuming saturated conditions. This energy is then divided by the energy removal rate, resulting in an equilibration time.

Sources of Mass and Energy

The sources of mass considered in the LOCA mass and energy release analysis are given in Table 6.2.1-22. These sources are the reactor coolant system, accumulators, and pumped safety injection.

The energy inventories considered in the LOCA mass and energy release analysis are given in Table 6.2.1-23. The energy sources include:

1. Reactor Coolant System Water

2. Accumulator Water

3. Pumped Injection Water

4. Decay Heat

5. Core Stored Energy

6. Reactor Coolant System Metal
   - Primary Metal (includes SG tubes)

7. Steam Generator Metal
   (includes transition cone, shell, wrapper, and other internals)

8. Steam Generator Secondary Energy
   (includes fluid mass and steam mass)

9. Secondary Transfer of Energy (feedwater into and steam out of the steam generator secondary)

It should be noted that the inconsistency in the energy balance tables from the end of Reflood to the time of intact loop steam generator depressurization/equilibration, i.e., "Total Available" data versus “Total Accountable" resulted from the omission of the reactor upper head in the analysis following blowdown. It has been concluded that the results are more conservative when the upper head is neglected. This does not affect the instantaneous mass and energy releases, or the integrated values, but causes an increase in the total accountable energy within the energy balance table.

The mass and energy inventories are presented at the following times, as appropriate:

1. Time zero (initial conditions)
2. End of blowdown time
3. End of refill time
4. End of reflood time
5. Time of broken loop steam generator equilibration to pressure setpoint
6. Time of intact loop steam generator equilibration to pressure setpoint

In the mass and energy release data presented, no Zirc-water reaction heat was considered because the clad temperature did not rise high enough for the rate of the Zirc-water reaction heat to be of any significance.

The consideration of the various energy sources in the mass and energy release analysis provides assurance that all available sources of energy have been included in this analysis. Thus the review guidelines presented in Standard Review Plan Section 6.2.1.3 have been satisfied.

6.2.1.3.7 Accident Chronology

For a double-ended pump suction loss of coolant accident, the major events and their time of occurrence are shown in Table 6.2.1-21 for the minimum safeguards case.

6.2.1.3.8 Energy Balance Tables

Table 6.2.1-22 and 6.2.1-23 gives the initial energy distribution as well as the energy distribution at end of blowdown and end of reflood for the double-ended pump suction case. The release rate transients for this case are consistent with the 10 foot entrainment calculation.

6.2.1.3.9 Containment Environment, Safeguards Performance, and Energy Input Curves

The pressure curves indicate the containment total pressure as a function of time after the accident. The temperature curves show the temperature of the sump and the containment atmosphere for the first day following the accident. These curves (Figures 6.2.1-15, 6.2.1-16, and 6.2.1-17) apply to the double-ended pump suction loss of coolant case with minimum containment safeguards.

6.2.1.3.10 Containment Pressure Differentials

Consideration is given in the design of the containment internal structures to localized pressure pulses that could occur following a loss of coolant accident. If a loss-of-coolant accident were to occur due to a pipe rupture in these relatively small volumes, the pressure would build up at a rate faster than the overall containment, thus imposing a differential pressure across the walls of the structures.

These subcompartments include the steam generator enclosure, pressurizer enclosure, and upper and lower reactor cavity. Each compartment is designed for the largest blowdown flow resulting from the severance of the largest connecting pipe within the enclosure or the blowdown flow into the enclosure from a break in an adjacent region.

The following paragraphs summarize the design basis calculations:

Steam Generator Enclosure

Two break locations were investigated inside the steam generator enclosure, both considering a double-ended rupture of the steamline. Based on the investigation of the high stress points, a rupture is assumed at the second 90° bend on the steamline as it exits the steam generator. The secondary location is at the steam generator nozzle. The blowdown mass and energy releases for the Model 57AG/57AG+ replacement steam generators are given in Table 6.2.1-24. These mass and energy releases did not credit closing of the main steam isolation valves which occur by eight (8) seconds. Thus, after 8 seconds the calculations of the mass and energy release are overly conservative. The TMD computer code using the compressibility factor and the ice condenser heat transfer correlation from the 1974 Waltz Mill full scale tests and unaugmented critical flow is used to calculate the short-term pressure transient. The nodalization of the steam generator enclosure where the break occurs is shown in Figure 6.2.1-41. Node 51 is the break element which represents the case where the steamline rupture is assumed at the second 90° bend.

There is a flowpath connecting the break element 51 to the adjacent steam generator enclosure, which is a mirror image of the enclosure where the break occurs. Both enclosures are nodalized in the same manner where nodes 51 thru 60 apply to the enclosure with the break and nodes 61 through 70 apply to the adjacent enclosure. The nodal network is shown in Figure 6.2.1-42 and the TMD input data is described in Tables 6.2.1-25 and 6.2.1-26. This data has been confirmed to bound the Model 57AG/57AG+ replacement steam generator. The input data assumes that the insulation remains intact. Any additional nodalization in the enclosure is not necessary since it would introduce control volumes with fictitious boundaries. Nodalization sensitivity studies, which are applicable to this analysis, have been performed and filed on other dockets. These sensitivity studies show that the nodalization used in this analysis is conservative. The balance of plant data is similar to that presented previously in Section 6.2.1.3.4.

The pressure transients of each node in the steam generator enclosure where the break occurs are shown in Figures 6.2.1-43 through 6.2.1-52 and are based on the Model 57AG replacement steam generator design. The pressure transient in the upper compartment is shown in Figure 6.2.1-53. The maximum differential pressures across structures are listed in Table 6.2.1-27. Figures 6.2.1-54 and 6.2.1-55 illustrate the transient of the pressure differentials from nodes 51 and 60, respectively, to the upper compartment. By comparison of the pressure transients of the remaining nodes in the enclosure, it is obvious that less severe pressure differentials will result across the remainder of the structures. Significant pressure differentials will not occur across the steam generator vessel. This is shown in Figures 6.2.1-56 through 6.2.1-60, which show the differential pressure transients for nodes internal to the steam generator enclosure.

A similar analysis investigated a break postulated at the steamline exit from the steam generator. In this case, the space in the enclosure above the steam generator vessel was modelled as one node. Therefore nodes 51 and 60 were combined, as were nodes 61 and 70 in the adjacent enclosure. All of the remaining enclosure model was unchanged. The pressure transients and thus the pressure differentials across the structures, were nearly identical to the previous analysis described above.

The design of the steam generator compartments is discussed in detail in Section 3.8.3.4.8. The design differential pressure from a main steamline break was spatially varied among the nodes, but within any particular node, the pressure was applied to the structural model as a uniform constant pressure. The steam generator enclosures were originally designed for two separate pressure loadings. These loadings are (1) a 24 psi maximum internal differential pressure from a break in the main steamline and (2) a uniform internal pressure of 43 psi, which was used as part of the original design and is not required to be considered in the evaluation and/or modification of the existing structures.

The analysis for the Model 57AG/57AG+ replacement steam generator resulted in a maximum pressure differential of 19.52 psi compared to the design pressure of 24 psi. The variation in the maximum differential pressure from node to node at any given elevation in the steam generator enclosure was 0.06 psi. The variation in the maximum differential pressure from a node at one elevation to a node at another elevation was calculated to be 0.99 psi. The design differential pressure exceeds the calculated differential pressure, and the structural integrity of the steam generator enclosure is confirmed.

<u>Reactor Cavity</u>

The TMD computer code with the unaugmented homogeneous critical flow correlation was used to calculate pressure transients in the reactor cavity region.

Nodalization sensitivity studies were performed before the Sequoyah analysis was begun. The total number of nodes used varied from 6 to 61. In the 6-element model, no detail of the reactor vessel annulus was involved, and for that reason the model was discarded. Subsequent model changes primarily involved greater detail in the reactor vessel annulus. First, the annulus was divided into two vertical and eight circumferential regions. Next, some additional detail was added in the nozzle region, resulting in a 32-element model. A change to a 44 element model was affected by increasing to three vertical and eight circumferential regions. The total integrated pressure in the reactor cavity

changed only slightly because of the change from 32 to 44 elements. The next change, to 46 elements, produce the model shown, with detailed modeling around the nozzle sustaining the break. The increase to 46 elements caused virtually no change in the integrated pressure. The additional elements from 46 to 61 are external to the reactor cavity (ice condenser, inspection ports, etc.).

The nodal scheme around the reactor vessel produces a very accurate post-accident pressure profile because of its design. Element 3 is a small element inside the primary shield. It would contain internal flow losses due to turning and thus contain a pressure gradient if it were made larger. The four elements numbered 33, 34, 45 and 46 are made small to minimize internal pressure variation, and the elements farther from the break are made larger because pressure gradients are low in those regions.

Figure 6.2.1-61 shows the general configuration of the reactor vessel annulus nodalization.

Figure 6.2.1-62 shows the flow path connections for the 61-element model of the Sequoyah plant.

Figure 6.2.1-63 illustrates the positions of some of the compartments. In the model, the lower containment is divided into four loop compartments (21-24). The upper containment is represented by compartment 32. The ice condenser is modeled as five elements (48-52), neglecting any flow distribution effects. The break occurs in compartment 1, immediately around a nozzle. The rest of that pipe annulus is represented by a compartment 53. The unbroken pipe annuli are compartments 54-61. The upper reactor cavity is compartment 47, the lower reactor cavity is compartment 2, and the remainder of the elements, as shown on Figure 6.2.1-63, are in the reactor vessel annulus. Compartments 15, 42, and 16 are really adjoining compartments 17, 43, and 18 respectively. Thus, compartment 13 is on the opposite side of the vessel from the assumed break.

The break limiting restraint restricts the break size. A 100 in^2 cold leg break is the limiting case for the reactor cavity analysis. The mass and energy release rates are presented in Table 6.2.1-28.

Tables 6.2.1-29 and 6.2.1-30 provide the flow paths, lengths, diameters, flow areas, resistance factor, and volume information for the elements and their connections.

The reactor cavity nozzle covers may remain bolted down during normal operation based on "leak before break" analysis (Reference 66). All insulation is assumed in place and uncrushed during the entire transient except for the insulation between the break and the reactor vessel annulus. This insulation was conservatively assumed to crush to zero thickness.

The k values are determined by changes in flow area and by turns the flow makes in traveling from the centroid of the first node to the centroid of the second node. The k's for each path were determined from Flow of Fluids by Crane Company, pages A-26 and A-27 (Reference 35).

Representative pressure transients for the break compartment, upper and lower reactor cavities, the upper containment, and the reactor vessel annulus were plotted. (See Figures 6.2.1-63A through F for some sample plots.) These plots demonstrate that the pressure gradient is steep near the break location and is very gradual farther away from the break. This indicates that the model must be very detailed close to the break location, but less detail is required with increasing distance.

Pressurizer

The TMD computer code was used to analyze a break of the 6 inch spray line from the reactor coolant pump outlet, which feeds the pressurizer spray. The pressurizer enclosure is designed for a double-ended spray line break, assuming the valves are stuck open.

The worst break possible in the pressurizer enclosure is a double-ended rupture of the six-inch spray line. The rupture is assumed to occur at the top of the enclosure. The blowdown for this break is given in Table 6.2.1-42. The TMD computer code using the compressibility factor and assuming unaugmented critical flow is used to calculate the short-term pressure transient. The nodalization of the enclosure is shown in Figure 6.2.1-77. Node 51 is the break element. The input data is given in Table 6.2.1-43. The input assumes that the insulation remains intact. The loss coefficients were computed using Reference 35. The maximum number of nodes used was based on the geometry of the system. The pressurizer compartment is essentially symmetrical with no major obstructions to flow which would introduce asymmetric pressures on the pressurizer vessel.

The peak pressure differentials across the pressurizer enclosure walls and across the pressurizer vessel are given in Table 6.2.1-44. Figure 6.2.1-78 shows the pressure transient between the break element and the upper compartment (node 25). As Figures 6.2.1-79 through 6.2.1-81 show the significant pressure differential across the vessel are low, occur early, and are due solely to inertial effects. The pressure versus time curve for the break element is given in Figure 6.2.1-82.

6.2.1.3.11 Steamline Break Inside Containment

Differential Pressure Across Operating Deck

An analysis has been performed to determine the containment mass and energy release and differential and inertial pressure response to the spectrum of steam line ruptures for the original steam generators. The replacement steam generators are similar in design and they have comparable thermal-hydraulic parameters in comparison to the original steam generators. Therefore, the pertinent analysis results in this section are applicable to both the original and replacement steam generators. The analysis has assumed that the rupture is coincident with a single failure of either one emergency diesel generator unit, a steam line isolation valve, or a feedwater control valve. For each single failure the most limiting initial conditions have been assumed, thereby ensuring that the most severe case has been analyzed. Further, in determining the total mass and energy release for each postulated case, all potential sources of fluid mass and energy were considered. This includes those in the steam generators, steam and feedwater lines, and that added by operation of the auxiliary feedwater system.

Should a steam line rupture inside the containment, the affected or faulted steam generator will lose its fluid inventory. Further, the rapid depressurization of the steam generator will cause a sharp increase in the feedwater flow to the steam generator. This flow will be maintained until the feedwater pumps are tripped and the feed control valve is closed. If the feed control valve is postulated to fail, flow will continue to enter the steam generator until the feed isolation valve is closed. This flow may be accompanied by flashing of the fluid in the feed lines. Auxiliary feedwater flow, which is initiated on a Safety Injection signal, will also enter the faulted steam generator until action is taken by the operator to isolate the flow. Reverse steam flow from the other steam generators is prevented by isolation valves located in each steam line outside the containment. Should one of these valves be postulated to fail, the other steam generators can blow down until the respective steam line isolation valves are closed.

In lieu of analyzing a spectrum of steam line break sizes, only a break size of 1.4 ft^2, corresponding to the flow area of the main steam line flow restrictor, has been considered. However, in calculating the energy release to containment, it was assumed that only dry steam was released through the break. As outlined below, the dual assumptions of a 1.4 ft^2 break and dry steam release will overpredict the mass and energy release for both larger and smaller breaks.

For containment pressure evaluations, it is conservative to minimize the amount of water released through the break. As shown in Table 6.2.1-31, the initial break flow for a 1.4 ft^2 break is several times larger than the steady state flow. This high flow will exceed the capacity of the steam generator moisture separators to deliver dry steam, resulting in substantial amount of water being delivered to the break. As the break size is increased, the blowdown would contain still more water. Hence, assuming dry steam release for 1.4 ft^2 break will conservatively overpredict the energy release from a larger break.

As the break is reduced below 1.4 ft^2, the fraction of steam release will increase. However, the rate of depressurization in the steam generator will decrease, thereby reducing the flow into the steam generator due to feed pumping and feed flashing. Further, the release rate from the break would be slower, allowing more energy absorption by the containment heat sinks and cooling systems. Hence, assuming dry steam release from a 1.4 ft^2 break will also overpredict the mass and energy release resulting from smaller breaks.

Consequently, the following cases and specific assumptions for these cases have been considered.

<u>Case A</u>

A 1.4 ft^2 break assuming the failure of one emergency diesel generator unit, one train of Engineered Safety Features is unavailable, reducing containment energy absorption to a minimum. No other failures are assumed.

<u>Case B</u>

A 1.4 ft^2 break assuming the feedline isolation valve in the feedline going to the affected steam generator fails to close upon receiving a closure signal from an SIS actuation signal. Feedwater isolation is completed by closure of the feedwater control valve associated with the faulted steam generator. Both trains of Engineered Safety Features are assumed to be available for containment cooling.

<u>Case C</u>

A 1.4 ft^2 break assuming the feedline control valve in the feedline going to the affected steam generator fails to close upon receiving a closure signal from an SIS actuation signal. Feedwater isolation is completed by closure of the feedwater isolation valve associated with the faulted steam generator. Both trains of Engineered Safety Features are assumed available for containment cooling.

<u>Case D</u>

A 1.4 ft^2 break assuming the isolation valve on the faulted steamline fails to close. Flow from the unaffected steam generators is assumed to be isolated by closure of the steamline isolation valves associated with the unaffected steam generators.

Maximizing the steam release rate through the break was done by assuming that a high steam generator pressure is maintained. Also, the effect of subcooled feedwater flow on reducing the steam generator steam pressure was not assumed. The mass entering the steam generator is maximized by assuming a very rapid steam generator pressure decay. This is done by ignoring the heat input from the reactor coolant system and by assuming full capacity main and auxiliary feedwater flow enters the faulted steam generator at minimum enthalpy. These assumptions are essentially opposite of those used in calculating the steam release rate.

The following assumptions were made in all of the cases analyzed.

1. From the time that the steam line break occurs, all main and auxiliary feed is assumed to go to the faulted steam generator. Main feed is isolated on a feedwater isolation signal resulting from an SIS signal. Auxiliary feed is assumed to be isolated by operator action 10 minutes after the break occurs.

2. All mass released from the steamline break is assumed to be released at an enthalpy of 1200 BTU/lbm.

3. A safety injection signal, reactor trip, and steam and feedwater isolation signals were assumed to be generated at 5 seconds after the break, including instrument delays. This assumption is consistent with the actuation times for an SIS signal for the cases considered.

4. Primary feedwater isolation is provided by the main feedwater regulator valves, assumed to close in six seconds after receiving a signal to close. (See Reference 75 for a discussion justifying a stroke increase to 7.0 seconds.) Main feedwater isolation valves were assumed to close in no more than 10 seconds (see References 67 and 68 for discussion of common station service transfer additional time delay) after receiving signal to close. Full flow was assumed until a valve was completely closed.

5. After main feed isolation occurs, the entire water volume downstream of the feedwater isolation valve (or feedwater control valve if the isolation valve fails) is assumed to flash into the faulted steam generator.

6. No credit is taken for the main feedwater pump trip actuated on a feedwater isolation signal.

7. The break is assumed to occur at a no load power level. A break at no load is the worst case because of the higher steam pressure and temperature and because of the larger fluid inventory at no load (total energy available at time of break).

The mass and energy release rates for each case are presented in Table 6.2.1-31.

Since the instantaneous mass and energy release rates and the integrated values are substantially higher than the other cases considered, case D is the worst case containment steamline break for differential and inertial pressure calculations.

The peak differential pressure across the operating deck is due to the inertial peak. The TMD computer code was used to calculate the containment pressure response early in the transient until after the inertial peak was reached. The peak inertial pressure and the peak differential pressure across the operating deck was 6.2 psig and 5.9 psig, respectively.

<u>Maximum Containment Temperature</u>

<u>Introduction</u>

The LOTIC-3 computer code has been developed to analyze steamline breaks in an ice condenser plant. Details of the LOTIC-3 computer code are given in References 30 to 33. It now includes the ability to calculate superheat conditions and has the ability to begin calculations from time zero [Reference 33]. The LOTIC-3 computer code has been found to be acceptable for the analysis of steamline breaks [Reference 36] with the following restrictions.

1. Mass and energy release rates are calculated with an approved model.

2. Complete break spectra are analyzed.

3. Convective heat flux calculations as described in Reference 33 are performed for all break sizes.

Two separate condensation models are used by the LOTIC-3 computer. The 100 percent condensate reevaporization model is used for large breaks, and for small breaks the conservative 0 percent condensate reevaporization and convective heat flux models are used. As pointed out in previous LOTIC-3 submittals, this position is felt to be justified. However, it has also been shown that the small steamline break temperature transients are more severe than large break transients, even if the large break calculations assume no reevaporization of the condensate and do not take credit for convective heat flux [Reference 30].

Equipment located inside the containment needed for the safe shutdown following a MSLB is environmentally qualified. Superheating issues associated with the steam released from the affected steam generator have been addressed by TVA and reviewed and accepted by the NRC [Reference 65].

<u>Large Break Analysis</u>

These blowdowns are dry steam blowdowns representative of a 3467 Mwt plant operating at a steam pressure of 832 psia, and Model 51 steam generators. Breaks upstream and downstream of the steam line flow restrictor have been analyzed for Sequoyah. The temperature transient for these blowdowns indicates that small steam line breaks produce more severe temperature transients than the large breaks, even if the large break calculations do not assume condensate revaporization or convective heat flux.

A summary of the assumptions made in the analysis is as follows.

1. Breaks were assumed to be double-ended ruptures occurring either upstream of the flow restrictor (4.6 ft^2) or downstream of the flow restrictor (1.4 ft^2). Note: The design of the replacement steam generators includes an integral flow limiter in the main steam nozzle, which eliminates the potential for a main steam line break upstream of the flow restrictor.

2. Blowdown from the broken steam line is assumed to be saturated steam.

3. Steamline and feedwater line isolation are completed within 10 seconds (see References 67 and 68 for discussion of common station service transfer additional time delay for the feedwater isolation) after the break occurs. The isolation signal is generated by a low steam line pressure signal from the Solid State Protection System.

4. Plant power levels of 100.7 percent of nominal full load power and zero power were considered.

5. Failures of a main steam isolation valve, a diesel generator and auxiliary feedwater runout control were considered individually. A feedwater isolation valve failure was incorporated into all cases considered.

6. The auxiliary feedwater system is manually realigned by the operator after 10 minutes. Information available to the operator is given in plant emergency procedures and is available immediately upon initiation of the accident. There will be approximately three minutes from initiation of operator action to termination of auxiliary feedwater flow to the affected steam generator.

7. For the full double-ended ruptures, the main feedwater flow to the steam generator with the broken steam line was calculated based on an initial flow of 100 percent of nominal full power flow and a conservatively rapid steam generator depressurization. The peak value of this flow occurring just before isolation is 377 percent of nominal for breaks at the exit of the steam generator (i.e., upstream of the flow restrictor) and 326 percent of nominal for breaks at the flow measuring nozzle (i.e., downstream of the flow restrictor).

The auxiliary feedwater system will be actuated shortly after the occurrence of a steam line break. The mass addition to the faulted steam generator from the auxiliary feedwater system may be conservatively determined by using the following assumptions.

1. The entire auxiliary feedwater system is assumed to be actuated at the time of the break and instantaneously pumping at its maximum capacity.

2. The affected steam generator is assumed to be at atmospheric pressure.

3. The intact steam generators are assumed to be at the safety valve set pressure.

4. Flow to the affected steam generator is calculated from the auxiliary feedwater system head curves, assumptions 2 and 3 above, and the system line resistances. The effects of any flow limiting devices are considered.

5. The flow to the faulted steam generator from the auxiliary feedwater system is assumed to exist from the time of rupture until realignment of the system is completed.

6. The failure of auxiliary feedwater runout control was considered separately, as a single failure. For this case, the auxiliary feedwater flow was determined using all the assumptions listed above and in addition failure of runout control on an auxiliary feedwater pump.

The auxiliary feedwater system on Sequoyah has not been changed in any way that would effect the conclusions of the original analysis.

The analysis for Sequoyah used the following auxiliary feedwater flow rates.

1. With runout protection operational at constant auxiliary feedwater flow rate of 1400 gpm to the faulted steam generator.

2. Failure of runout protection was simulated by assuming a constant auxiliary feedwater flowrate of 2250 gpm to the faulted steam generator.

The auxiliary feedwater flow rates calculated for Sequoyah using the assumptions outlined in the response to 1 above give valves of 1530 gal/min to the faulted steam generator with runout protection operating and less than 2250 gal/min with a single failure in the runout protection system.

The analysis performed by Westinghouse for the Sequoyah BIT Removal Analysis addressed the steamline break transients and demonstrated that the limits discussed in the original report were still met for an auxiliary feedwater flowrate of 2250 gal/min to a faulted steam generator.

Several failures can be postulated which would impair the performance of various steam line break protection systems and therefore would change the net energy releases from a ruptured line. These are:

1. Failure of a main steam isolation valve increases the volume of steam piping which is not isolated from the break. When all valves operate, the piping volume capable of blowing down is located between the steam generator and the first isolation valve. If this valve fails, the volume between the break and the isolation valves in the other steam lines including safety and relief valve headers and other connecting lines will feed the break.

2. Failure of a diesel generator would result in the loss of one containment safeguards train resulting in minimum heat removal capability.

3. Failure of a feedwater regulating valve or feedwater isolation valve to close will increase the inventory of feedwater supplied to the steam generator. Upon occurrence of a main steam line break, the feedwater regulating and isolation valves will close. Although the feedwater regulating valves will close before the feedwater isolation valves, the feedwater isolation valves are located nearer the steam generators and therefore less feedwater inventory exists in the feedwater lines between the feedwater isolation valves and the steam generators. The net results during a main steam line break transient are that a greater inventory of additional feedwater will be forced into the affected steam generator if the feedwater isolation valve failed to close because of the increased line volume between the feedwater isolation valve and the feedwater regulating valve, which includes all headers and connecting lines. For this event, the most limiting case is the failure of the feedwater isolation valves to close and not the feedwater regulating valves.

4. Failure of the auxiliary feedwater runout control equipment would result in higher auxiliary feedwater flows entering the steam generator before realignment of the auxiliary feed system.

The effect of these failures is to provide additional fluid which may be released to the containment by the break or reduce the heat removal capability of the containment safeguard systems.

In the analysis, the single failures listed above have been evaluated for 4.6 ft^2 and 1.4 ft^2 breaks at 100.7% and 0% power to determine the worst steam line break cases.

Failure of the auxiliary feedwater isolation valve to close has not been considered. The maximum auxiliary feedwater flow that can be delivered to a faulted steam generator has been assumed in the analysis for 10 minutes, two cases being considered: (1) with runout protection operational, (2) with failure of runout protection. After 10 minutes, the operator takes action to isolate auxiliary feedwater to the broken steam generator. At that time, if the remote controlled auxiliary feedwater isolation valve fails to close, the operator can trip the two auxiliary feedwater pumps feeding the broken steam generator until this valve or another in the line is manually closed.

Consistent with the licensing basis for the Sequoyah Plant, operator action to realign auxiliary feedwater has been assumed only at 10 minutes.

The RWST storage basin provides storage for borated water after a postulated rupture of the tank. This basin ensures that a minimum of 20,000 gallons of borated water is maintained in the event of a simultaneous rupture of the RWST and the main steamline outside of containment. This simultaneous rupture is assumed to be caused by a tornado. This minimum volume of borated water insured by the storage basin ensures that safety injection flow is available to mitigate the most limiting steamline break event within operator action times. (Reference 90)

Since the mass and energy release rates are considerably less than the RCS double-ended breaks and their total integrated energy is not sufficient to cause ice bed meltout, the containment pressure transients generated for the RCS breaks will be more severe.

<u>Containment Transient Calculations:</u>

The following are the major input assumptions used in the LOTIC-3 steambreak analysis for Sequoyah:

1. Minimum safeguards are employed, e.g., one of two spray pumps and one of two air return fans.

2. The air return fan is effective 10 minutes after the high-high containment pressure signal is read.

3. A uniform distribution of steam flow into the ice bed is assumed.

4. The initial conditions in the containment are a temperature of 120°F in the lower volume, 100°F in the dead-ended volume, a temperature of 85°F in the upper volume, and a temperature of 15°F in the ice condenser. All volumes are at a pressure of 0.3 psig (see Table 6.2.1-33).*

5. A spray pump flow of 4750 gpm is used in the upper compartment. The spray initiation time assumed was 30 sec. after reaching the high-high setpoint..

6. Containment structural heat sinks as presented in Table 6.2.1-32 were used.

7. The air return fan empties air at a rate of 40,000 cfm from the upper to the lower compartments.

8. A series of large break cases (1.4 - 4.6 sq. ft. double-ended ruptures) were run to determine the limiting large break case (see Table 6.2.1-34). In addition, a series of small breaks were analyzed with LOTIC at the 30 percent power level (see Table 6.2.1-35).

9. The mass and energy releases for the limiting breaks are given in Tables 6.2.1-36 through 38. Since these rates are considerably less than the RCS double-ended breaks, and their total integrated energy is not sufficient to cause ice bed meltout, the containment pressure transients generated for the previously presented double-ended pump suction RCS break are considerably more severe. However, since the steamline break blowdowns are superheated, the lower compartment temperature transients calculated in this analysis will be limiting.

10. The heat transfer coefficients to the containment structures are based on the work of Tagami. An explanation of their manner of application is given in Reference 31.

11. 2.45×10^6 lbs of ice initially in the ice condenser.**

<u>Large Break</u>

The limiting case among the double-ended ruptures which yielded a calculated peak temperature of 290°F, is the 1.4 ft^2, 102 Percent Power, MSIV failure case. Figure 6.2.1-64 provides the Upper and Lower Compartment temperature transients, and Figure 6.2.1-65 illustrates the lower compartment pressure transients. Table 6.2.1-36 contains the mass and energy release rates for the above case.

<u>Small Break</u>

The most severe transient in terms of superheat temperature duration for the small break spectrum is the 0.35 ft^2, 30 Percent Power, with AFW Pump Runout Protection Failure. The temperature transient for the case is presented in Figure 6.2.1-66 and the pressure transient is provided in Figure 6.2.1-67. Table 6.2.1-37 provides the mass and energy release rates for this case.

* The temperatures listed as initial conditions are historical values. Minor increases in the analytical temperature inputs do not adversely impact the Containment temperature Analysis. (Reference 89)

** This ice mass is a historical value that was the current value when the analysis was completed. Moderate changes to the ice mass do not adversely affect the Containment Temperature Analysis as there is not enough energy on the secondary side to melt-out the ice bed and peak containment temperature resulting from a steamline break is primarily sensitive to enthalpy in the blow-down. (Reference 89)

The most limiting case in terms of peak calculated temperature is the 0.6 ft^2, 30 Percent Power, with AFW Pump Runout Protection Failure case. This case resulted in a calculated peak temperature of 325.5°F. Figure 6.2.1-68 presents the temperature transient and Figure 6.2.1-69 shows the pressure transient of the Lower Compartment. The mass and energy releases are provided in Table 6.2.1-38.

Tables 6.2.1-34 and Table 6.2.1-35 provide the overall results of the calculated peak temperatures for the Large and Small Break spectrums.

6.2.1.3.12 Maximum Reverse Differential Pressure

Following a postulated pipe break accident, the occurrence inside the ice condenser containment may be characterized by two distinct periods:

1. The initial blowdown, which occurs in approximately 10 seconds. During this period, the air initially in the lower compartment is swept into the upper compartment and the dead-ended compartment by the blowdown mass. Large mass and pressure gradients occur throughout the containment.

2. The depressurization and post-blowdown period which occurs after the end of the initial blowdown. During this period the pressure gradient within the four compartments; upper, lower, ice condenser, and dead-ended, is almost non-existent. The shape of the pressure transient resembles that of the mass and energy releases. Pressure decreases as blowdown diminishes, followed by a slow increase sometime during the reflood.

The analysis for the first period will usually require the modeling of the containment into many nodes so that the non-uniformity of pressure and mass distribution may be properly represented. This has been done in the TMD code.

On the other hand, the analysis for the second period will only require the modeling of the containment by a four compartment system. These calculations are performed by the LOTIC-code (Reference 18).

The code options and features discussed are used in calculating ECCS back-pressure and reverse pressure differentials across the operating deck.

Basic Assumptions

1. The containment is assumed to be physically divided into four compartments; upper, lower, ice condenser, and the dead-ended compartments. Each compartment is a control volume of uniform temperature, pressure and mass distribution. Steam is also assumed to be saturated in each control volume.

2. Flow between compartments is related to the pressure differential between the compartments by a flow resistance factor.

3. A two-sump model is assumed. Temperature is considered to be uniform in each sump.

Calculation of Maximum Reverse Differential Pressure

The computer model previously described was used to calculate the reverse differential pressure across the operating deck. In order to calculate a maximum reverse differential pressure the following assumptions were made:

1. The dead-ended compartment volumes adjacent to the lower compartment, fan and accumulator rooms, pipe trenches, etc., were assumed to be swept of air during the initial blowdown. This is a very conservative assumption, since this will maximize the air mass forced into the upper ice bed and upper compartment, thus raising the compression pressure. In addition, it will minimize the mass of the noncondensibles in the lower compartment. With this modeling the dead-ended volume is included with that of the lower compartment (See Figure 6.2.1-70), resulting in a 3 volume simulation of the containment.

2. The minimum containment temperatures are assumed in the various subcompartments. This will maximize the air mass forced into the upper containment. It will also increase the heat removal capability of the cold lower compartment structures.

3. A high temperature, (T = 100°F), is assumed in the RWST. This will help raise the upper containment temperature and pressure higher for a longer period of time.

4. The upper containment spray flowrates used were runout flows.

5. The containment geometry is summarized in Table 6.2.1-39.

6. The Westinghouse ECCS model (See WCAP-8339) was used for heat transfer to the structure.

7. The mass and energy releases used are given in WCAP-8479.

8. Ice condenser doors are assumed to act as check valves, allowing flow only into the ice condenser.

9. The loss coefficient (k/A^2) of the deck fans for air flow from upper to lower compartment was taken to be 0.0072 ft^{-4}. This value was based on the capabilities of the fans while running. With the fans not running the loss coefficient would be 0.0278 ft^{-4}.

With these assumptions the maximum reverse pressure differential across the operating deck was calculated to be .65 psi. The following plots have been provided:

Figure 6.2.1-71 which shows upper and lower compartment pressures.

Figure 6.2.1-72 which shows upper and lower containment temperatures.

Figure 6.2.1-73 which shows upper to lower containment flowrates.

Parametric studies have been made with this model. Various effects have been investigated to determine changes in the maximum reverse pressure differential. Table 6.2.1-40 gives some of these studies with their results. For Case 6, Figures 6.2.1-74 and 6.2.1-75 give plots similar to Figures 6.2.1-71 and 6.2.1-72. Figure 6.2.1-76 gives ice condenser drain flow as a function of time, and Table 6.2.1-41 gives additional data.

Significant margin exists between the design reverse differential pressures, 6.8 psi and 8.6 psi across the operating deck and the ice condenser lower inlet doors respectively, and those calculated pressures presented in Table 6.2.1-40.

6.2.1.4 Testing and Inspections

6.2.1.4.1 General

Primary containment leakage tests and containment isolation system valve operability tests will be performed periodically to verify that leakage from the containment is maintained within acceptable limits. The types of leakage test are as follows:

1. Test Type A

   Tests to measure the reactor primary containment overall integrated leakage rate.

2. Test Type B

   Tests to detect or measure local leaks of containment penetrations, hatches, personnel locks, electrical penetrations, fuel transfer tube covers, ice blowing lines covers, and thimble renewal cover.

3. Test Type C

   Test to detect or measure containment isolation valve leakage.

6.2.1.4.2 Testing Method and Frequency

Type A, B, and C leakage rate tests will be performed in accordance with 10 CFR 50, Appendix J, with approved exemptions. The components in these tests will be tested at approximately the peak calculated accident pressure. The total leakage rate from the type B and type C tests shall meet the limits specified in the Containment Leakage Rate Testing Program and Technical Specifications.

Test connections and pressurizing means are provided to test isolation valves or barriers for leak tightness. Either air or nitrogen is used as the pressurizing medium, depending on the physical location and service of each line. Leak testing of valves, penetrations, and the primary containment as a whole will be accomplished by one of the following methods:

1. Method 1, pressure decay

   The test volume is established by closing the appropriate isolation valves if necessary. The test volume is pressurized. The test volume pressure is recorded at intervals dependent on magnitude of test volume. The leakage rate is then computed.

2. Method 2, airflow

   The test volume is established by closing the appropriate isolation valves if necessary. This method does not require the determination of the volume to be tested. The test volume is pressurized and maintained. Pressure and airflow are recorded after stabilization of temperature, pressure and air flow.

3. Method 3, containment integrated leak test

The containment is isolated and pressurized. When test pressure is reached, containment is isolated from its pressure source and the following parameters are recorded in periodic intervals:

a. Containment absolute pressure.
b. Dry bulb temperatures.
c. Water vapor pressures.
d. Outside containment weather conditions.

During the test, ventilation inside the containment is operated as necessary to enhance an even air temperature distribution. The test data are processed at periodic intervals during the test to determine test status and leakage conditions. If it appears that the leakage is excessive, the test may be discontinued. After the identified problem is resolved, the test is restarted. After a prescribed time period and assurance of a stabilized leak rate, a leak is induced to verify the leak rate measurement. This is accomplished by precise measurement of a flow which causes a change in the weight of air in the containment that is in the same order of magnitude as the allowable leakage rate. Formulas used in computing the integrated leak rate are based on the formulas found in ANSI/ANS-56.8, 1994.

6.2.1.4.3 Inspections

Equivalent ASME Code Class MC and metallic liners of Code Class CC components shall be examined and tested in accordance with Section XI of the ASME Boiler and Pressure Vessel Code and as required by 10 CFR 50.55a(b)(2)(x), 50.55a(g)(4), and 50.55a(g)(6)(ii)(B), except where specific written relief has been granted. The in-service inspection program for Sequoyah Nuclear Plant is addressed in Section 5.2.8.

6.2.1.5 Instrument Application

Containment Pressure Monitoring

The Emergency Gas Treatment System provides two differential pressure loops to monitor the differential pressure between the annulus and the outside ambient pressure. This pressure difference is indicated and annunciated in the main control room.

Two differential pressure loops are provided to monitor the differential pressure between the annulus and the Auxiliary Building. This pressure difference is indicated and annunciated in the main control room.

The containment ventilation system provides differential pressure control loops to monitor the differential pressure between the annulus and the lower compartment of containment. Four loops are used for indication and annunciation in the main control and to provide high lower compartment pressure signals for the initiation of the safety injection, Environmental Allowance Modifier (EAM) Functions, the containment spray, and phase B containment isolation. The logic for these initiation signals is covered in Chapter 7.

Three vacuum relief paths, with isolation valves, are provided between the annulus and the upper compartment of containment. The isolation valves are normally open allowing the relief valves to vent the annulus to the containment automatically if the upper compartment pressure drops 0.1 psi below the annulus pressure. Four switches located on the relief valves provide valve position information which is indicated in the main control room. The isolation valves are closed if the containment pressure exceeds 1.5 psig. The isolation signal is generated by a two-out-of-three high-pressure switch actuation. Two isolation signals are available, one powered by train A and the other by train B.

Containment Temperature Monitoring

Temperature sensors are distributed throughout the ice bed of the ice condenser. Selected channels are displayed in the main control room and provide actuation signals for the annunciation at preset deviations from the prescribed limits of the ice bed equilibrium temperatures.

Temperature sensors are strategically located throughout the containment. A group of these sensors is monitored in the main control room to ensure that the air temperature requirements for the proper operation of equipment is maintained.

Temperature monitoring and actuation signals associated with the heat removal system are described in Subsection 6.2.2.

Sump Level Control

For a complete description of the Reactor Building sumps, see Subsection 5.2.7.

Leakage Detection Equipment

For a complete description of the leakage detection methods and equipment, see Subsection 5.2.7.

Secondary Containment

Instrumentation is provided in the main control room to give the operator information concerning the status of the active isolation valves, isolation dampers, and airlock doors in the secondary containment barrier. The isolation valves and isolation dampers are equipped with limit switches. These limit switches show the full open or full closed position by indicating light in the main control room. For all the airlocks, each side of airlock is instrumented. For airlocks between secondary containment and primary containment, the instrumentation indicates the position of each airlock door and alarms in the main control room if both sides of an airlock are open simultaneously.

6.2.1.6 Protective Coatings

Approximately 48,000 square feet of concrete surface is coated within the primary containment of each unit. These areas are coated with a catalyzed epoxy coating, which was tested in accordance with ANSI N101.2, "Protective Coatings for Light-Water Nuclear Reactor Containment Facilities," to demonstrate that the coating will remain intact on the surface to which it was applied during postulated LOCA conditions.

Major carbon steel components, such as the containment liner plates and domes, structural and miscellaneous steel, a large portion of the polar crane, etc., are protected with an inorganic zinc primer only, with no organic topcoat (approximately 79,000 square feet). In addition, approximately 46,000 square feet of inorganic zinc-primed steel is topcoated with a LOCA tested and approved catalyzed epoxy coating. These coatings were tested in accordance with ANSI N101.2.

TVA is committed to adhere to Appendix B of 10 CFR 50 and ANSI N45.2 as required to produce a quality end product. Basically, TVA believes that the Quality Assurance Program (QA) for protective coatings inside the containment should control four activities in the coating program. The four major areas to be controlled are:

1. The coating material itself, by extending requirements on the manufacturing process and qualification of coating systems through the use of applicable portions of ANSI Standards N101.2 and N5.9 or its revision N512.

2. The preparation of the surface to which coatings are to be applied.

3. The inspection process.

4. The application of the coating systems.

All four of these controlled activities must have appropriate documentation and records to meet Appendix B requirements.

TVA's protective coating program within the containment is in conformance with NRC Regulatory Guide 1.54. In addition, applicable provisions found in ANSI N101.4 have been incorporated into TVA surface preparation, coating application/inspection specifications, and coating QA procedures. In addition, all maintenance work on Coating Service Level I coatings shall use the same coating material as the existing system or a different coating that has been DBA qualified and approved for use with the existing system.

The amount of uncontrolled coatings allowed inside containment is limited to ensure that in a post-LOCA or MSLB environment, the uncontrolled coatings transported to the containment sump will not degrade the recirculation flow to the engineered safety systems via blockage of the containment sump screen or be ingested into the engineered safety systems and result in component degradation.

The original basis for qualification of coatings was the accident conditions resulting from a design basis LOCA. However, the containment temperature profile for the LOCA does not bound the temperature profile expected from an MSLB. Approximately 12,000 square feet of topcoated steel and 7,500 square feet of coated concrete inside containment, which were previously qualified, would not be qualified for the MSLB conditions.

As a result of the above information, TVA reevaluated the licensing basis for the containment sump screen blockage. While designed and constructed before the issuance of NRC Regulatory Guide 1.82, Revision 0, the original licensing basis for the containment recirculation sump included operability with an assumed 50 percent intake flow area blockage consistent with RG 1.82 recommendations. Scale model testing confirmed that the design of the original sump intake structure (i.e., a 6-inch trash curb around the base of the sump intake structure and 0.25-inch mesh intake screens sloping upward and outward from the sump opening) was sufficient to meet the 50 percent blockage criteria.

To address the potential increased failed coating debris load, an evaluation was performed using a two-dimensional physical transport model (Reference 70) to confirm the ability of the containment sump to support containment spray and emergency core cooling system pump operation. The

evaluation methodology focused on a near-sump region of influence resulting from post-accident flow fields where debris transport to the sump intake was possible. The evaluation quantified the amount of accident generated debris which could potentially be transported to the sump intake structure, established the head loss from the resulting intake screen debris blockage and confirmed that the minimum containment spray and emergency core cooling system pump suction head requirements would be met for the expected blockage. A subsequent evaluation established a maximum limit on failed coatings which could be transported to the containment recirculation sump without degrading the capabilities of the required accident mitigation systems (Reference 71). This evaluation established the revised licensing basis for containment sump intake blockage. It was summarized and submitted for NRC review in Reference 85 and was accepted in Section 3.7 of Reference 86.

To address the additional concerns contained in NRC Generic Safety Issue No. 191 (GSI-191), “Assessment of Debris Accumulation on PWR Sump Performance,” the containment sump was subsequently reanalyzed to address the susceptibility of the emergency core cooling and containment spray recirculation functions to the adverse effects of post-accident debris blockage and operation with debris laden fluids. As summarized in Reference 87, the comprehensive reanalysis used the evaluation methodology described in Reference 88. The revised analysis methodology included development of a three-dimensional computational fluid dynamics model to establish debris transport characteristics (i.e., flow directions, velocities and turbulence) in the entire sump pool during post-accident sump recirculation operation. The results of the reanalysis were used to size the flow area of the advanced design containment sump strainers which replaced the original sump intake structure. Blockage testing of the advanced containment sump strainer design with a conservative debris load (which included the assumed failure of all qualified and unqualified coatings in containment) confirmed that the containment sump will support operation of the emergency core cooling system and the containment spray system under all anticipated debris loading conditions. This includes the failure of all coatings installed inside containment.

Removal of mirror insulation due to jet impingement or pipe whip due to a LOCA (and subsequent exposure of non-qualified coatings under the mirror insulation) on the Main Reactor Coolant Piping or Steam Generator is not considered credible based on the discussions in Section 3.6.1.1. Per Section 3.6.5.1, the dynamic effects of ruptures in the primary coolant loop have been eliminated.

6.2.2 Containment Heat Removal Systems

6.2.2.1 Design Bases

Adequate containment heat removal capability for the Ice Condenser Reactor Containment is provided by the Ice Condenser (Section 6.5), the Air Return Fan System (Section 6.6), and the Containment Spray Subsystems whose components operate in the sequential modes described in Paragraph 6.2.2.2. One Containment Spray Subsystem consists of a Containment Spray train and a Residual Heat Removal Spray train (which is a portion of the Residual Heat Removal System Section 6.3).

The Containment Spray Subsystems consist of two trains of redundant equipment per reactor unit. There are four spray headers per unit. Two headers are supplied from separate Containment Spray trains; the other two are supplied by separate RHR Spray trains (see Table 6.2.1-1). Each individual train consists of a pump, a heat exchanger, appropriate control valves, required piping, and a header with nozzles located in the upper compartment of the containment with flow directed to obtain full coverage of the containment upper volume during an emergency. The systems use borated water supplied from the refueling water storage tank and/or the recirculation sump, as shown in Figure 6.2.2-1.

Minimum Engineered Safety Feature performance of the Containment Heat Removal Systems is achieved with the following:

1. Ice Condenser (Section 6.5)
2. One train of the Air Return Fan System (Section 6.6)
3. One Containment Spray Train
4. One Residual Heat Removal Spray Train (needed only after all the ice has melted)

The primary design basis for the Containment Spray Subsystems is to spray cool water into the containment atmosphere when appropriate in the event of a loss-of-coolant accident and thereby ensure that the containment pressure cannot exceed the containment shell design pressure as defined in Section 3.8.2.2. This protection is afforded for all pipe break sizes up to and including the hypothetical instantaneous circumferential rupture of the reactor coolant loop resulting in unobstructed flow from both pipe ends. The Containment Spray trains supplement the ice condenser until all the ice is melted approximately 3600 seconds after the LOCA at which time it and the Residual Heat Removal trains become the sole systems for removing energy directly from the containment. The Containment Heat Removal Systems are designed to provide a means of removing containment heat without loss of functional performance in the postaccident containment environment and to operate without benefit of maintenance for the duration of time necessary to restore and maintain acceptable containment conditions. Although the water in the core after a loss-of-coolant accident is quickly subcooled by the Emergency Core Cooling System (Section 6.3), the design of heat removal capability of each Containment Heat Removal System is based on the conservative assumption that the core residual heat is released to the containment as steam which eventually melts all ice in the ice condenser.

The heat sources and amounts of energy considered in the design of the Containment Heat Removal Systems are provided in the containment design evaluations in subsection 6.2.1.3.

The Containment Spray trains are redundant. The system is designed such that both trains are automatically started by high-high containment pressure signal. The signal actuates, as required, all controls for positioning all valves to their operating position and starts the pumps. The operator can also manually actuate the entire system from the control room. Either of the two trains is capable of delivering the design flow requirements.

The Containment Spray Subsystems are designed to withstand the design basis earthquake and the operational basis earthquake without loss of function. They are Engineered Safety Feature Systems and satisfy the TVA Class B Mechanical Requirements. The Containment Spray Subsystems will maintain their integrity and will not suffer loss of ability to perform their minimum required function due to normal operation, faults of moderate frequency, infrequent faults, and limiting faults.

Sufficient redundancy for all supporting systems necessary for minimum operational requirements of the Containment Spray Subsystems is provided and complies with the single active component failure criteria for engineered safety features. Separate divisions on essential raw cooling water supply, power equipment, heat exchangers, pumps, valves, and instrumentation are provided in order to have two completely separated trains.

The system is provided with overpressure protection from excessive pressures that could otherwise result from temperature changes, interconnection with other systems operating at higher pressures, or other means.

Those portions of the Containment Spray Subsystems located outside of the containment which are designed to circulate, during post accident conditions, radioactively contaminated water collected in the containment meet the following requirements:

1. Shielding within guidelines of 10 CFR 20 and 10 CFR 100.

2. Collection of discharges from pressure relieving devices of closed systems.

3. Remote means for isolating and draining any sections under anticipated malfunction or failure conditions.

4. Means to detect and control radioactivity leakage into the environs to limits consistent with guidelines set forth in 10 CFR 20 and 10 CFR 100.

The air cleanup aspects of the heat removal systems are discussed in Section 6.2.3.

6.2.2.2 <u>System Design</u>

Each Containment Spray train is independently capable of meeting system requirements. Each train includes a pump, heat exchanger, ring header with nozzles, isolation valves and associated piping, and instrumentation and controls. During normal operation, the pumps are idle and the associated isolation valves to containment are closed. Upon system activation during a LOCA, adequate containment cooling is provided in sequential modes. These modes are: 1) spraying a portion of the contents of the refueling water storage tank into the containment atmosphere

using the Containment Spray trains; 2) after the refueling water storage tank has been depleted, recirculation of water from the containment sump through the containment spray trains and back into containment; and 3) diversion of a portion of the recirculation flow from the Residual Heat Removal System through a RHR spray train and back into containment. The latter operation occurs in the event the containment pressure reaches a predetermined value after the ice condenser has been depleted. RHR spray will not be started earlier than 3600 seconds after the start of the event regardless of containment pressure. This limit is required to assure that the decay heat has been reduced sufficiently for the RHR flow to be diverted from the core. The diversion will be by manual operation of system components.

The spray water from the containment and RHR spray trains will be returned from the upper compartment to the lower compartment through two 14 inch drains in the bottom of the refueling canal. A small portion of this spray water is diverted to the auxiliary reactor building floor and equipment drain sump through two 3-inch drains located on the operating deck.

The flow and pump logic diagrams for this system are presented in Figures 6.2.2-1 and 6.2.2-2, respectively.

Component Description

Pumps

The Containment Spray train's flow is provided by two centrifugal type pumps driven by electric motors. The motors, which can be powered either normally or from an emergency source, are direct coupled and nonoverloading to the end of the pump curve. Design parameters for the spray pumps are included in Table 6.2.2-1. See Figure 6.2.2-3 for the containment spray pumps' characteristic curves.

Pump Motors

The containment spray train's pump motors are 700 horsepower rated for 6600 V, 3 phase, 60 Hz, with 0.50 - 13 UNC- 2A grounding terminals supplied inside the auxiliary conduit box for station grounding by TVA. The motors are WIP-I enclosure type with NEMA class B insulation or better. The motors have a 1.15 service factor. They are capable of accelerating the pump flow to full speed in 5 seconds with 90 percent of rated voltage at the motor terminals.

Power Supply

The electrical power system is designed to provide power during and after a design basis accident. It has access to both a preferred and standby power source. As a minimum it provides two redundant power trains with sufficient physical separation and electrical isolation to prevent failure of one power train from causing a loss of the other train. Each power train provides supply power to one of the two redundant Containment Spray trains. Auxiliary equipment required to operate dependent equipment is supplied from the same power train as the dependent equipment to prevent loss of power to one train from causing a loss of equipment in the redundant train.

The pump and motor design conforms as applicable to the following standards: Hydraulic Institute Section B - Centrifugal Pumps, NEMA MGI-1963 - Motors, ANSI B16.5 - Steel Pipe Flanges and Pipe Fittings, ASME Draft Code for Pumps and Valves for Nuclear Power, November 1968.

The Residual Heat Removal pumps which also provide flow to the Containment Spray Subsystems are described in Section 6.3.

Heat Exchangers

The Containment Spray heat exchangers are the vertical shell and U-tube (1B heat exchanger is a straight tube type) type with tubes welded to the tube sheet. Borated water from either the refueling water storage tank or the containment sump circulates through the tube side. Original design parameters are presented in Table 6.2.2-2. The heat exchangers conform to the following standards: Tubular Exchanger Manufacture Association (TEMA), Class R, Tube Side-ASME III, shell side-ASME Boiler and Pressure Vessel Code, Section VIII. The heat exchangers are designed using a conservative fouling resistance for water for the inside and the outside of the tubes of 0.0003 and 0.001 hr ft^{2}°F/BTU respectively, from the TEMA Standards.

The RHR heat exchangers which also provide cooling to the Containment Spray Subsystems are described in Section 6.3.

Piping

All Containment Spray Subsystem piping in contact with borated water is austenitic stainless steel. Piping joints are welded or flanged as necessary. The piping startup strainers are designed to meet the requirements of ANSI B31.1 with inspection and test requirements of ANSI B31.7 used in lieu of the applicable Nuclear Code Cases.

Spray Nozzles and Ring Headers

Each containment spray ring header contains 312 hollow cone ramp bottom nozzles. These nozzles have an approximately 3/8 inch spray orifice and will not be subject to clogging by particles less than 1/4 inch in maximum dimension. The nozzles produce a mean drop size of approximately 700 microns in diameter at rated system conditions. The spray solution is completely stable and soluble at all temperatures of interest in the containment and therefore will not precipitate or otherwise interfere with nozzle performance. Each nozzle header is independently oriented to maximize coverage of the upper containment volume inside the crane wall. This arrangement will prohibit any flow into the ice condenser.

Using conventional analytical techniques, the pumps were shown to be capable of overcoming the system flow resistance. The resistance includes elevation difference between the spray header and pump, the nozzles, the heat exchanger, piping between the pump and spray header, and water supply piping to the pump suction.

The residual heat removal spray ring headers contain 147 nozzles per header. It has the same design characteristics as the Containment Spray trains.

Refueling Water Storage Tank

During the injection phase immediately following a LOCA, the containment spray trains are supplied from the refueling water storage tank.

This tank is located in the yard. Sufficient water is provided to supply the Containment Spray trains and the ECCS trains for the injection mode at ambient temperature of 105°F maximum until switchover to the ECCS containment sump.

Material Compatibility

All parts of the Containment Spray Subsystem that are in contact with borated water are austenitic stainless steel or equivalent corrosion-resistant material.

Design of Recirculation Piping

The containment spray recirculation water supply is taken from the emergency sump inside the containment (see sections below).

NPSH

The design head of the pumps is sufficient to continue at rated capacity with a minimum level in the refueling water storage tank against a head equivalent to the sum of the design pressures of the containment, the head to the uppermost nozzles, and the line and the nozzle pressure losses. System pressure ensures compliance with the pump net positive section head (NPSH) requirements of NRC Regulatory Guide No. 1.1 for Water Cooled Nuclear Power Plants. The pumped fluid will be a subcooled liquid for all modes in system operation. Therefore, the minimum NPSH available is determined from the following equation:

NPSH = Elevation head + (Containment pressure - liquid vapor pressure) - friction losses

No credit is taken for containment overpressure (i.e., containment pressure used in calculating NPSH is one atmosphere or zero gage pressure). Adequate NPSH exists for all expected fluid temperatures without reliance on increased containment pressure. The flow characteristics of the pump are shown in Figure 6.2.2-3.

Containment Recirculation Sump

The containment recirculation sump is designed to prevent trash and debris from entering that could affect the operation of the Containment Spray trains. In addition, the sump provides for adequate NPSH for the Containment Spray pumps and Residual Heat Removal pumps to operate in the recirculation mode.

Trash and debris are eliminated by an advanced design strainer that contains perforations of 0.095 inch diameter. The strainer is designed with sufficient flow area to maintain a low fluid velocity at the entrance. Therefore, the debris that is more dense than water will settle to the containment floor rather than block the strainer. Internal baffles are provided to allow the escape of air during initial filling and to prevent the formation of vortices. 1/4-inch mesh screens are provided inside the sump pit as a final barrier to prevent debris from jeopardizing Containment Spray and Residual Heat Removal pump operation.

The sump suction piping, the guard pipes, and the isolation valves are designed to TVA Class B Mechanical Requirements. The sump, strainers, supports and associated equipment are designed to the requirements of Sequoyah Design Criteria SQN-DC-V-1.3.2 miscellaneous steel components for Class I structures. This provides the assurance that the sump will remain functional for long-term recirculation mode of ECCS and containment spray subsystems operation.

6.2.2.3 <u>Design Evaluation</u>

Performance of the Containment Spray Subsystems is evaluated through analyses of the design basis accident and various other cases described in Chapter 15. The analyses were performed using the LOTIC code and show that the Containment Spray Subsystems are capable of keeping the containment pressure below the 12.0 psig maximum internal pressure even when it is assumed that the minimum engineered safety features are operating. Also presented are a description of the analytical methods and models which were used along with verification of pertinent items from Waltz Mill tests, and curves showing the calculated performance of important variables following the design basis loss-of-coolant accident.

The design basis accident results in a required Containment Spray train flow rate of 4750 gpm using 87°F maximum average essential raw cooling water inlet temperature to the heat exchangers. Essential Raw Cooling Water flow to the Containment Spray heat exchangers is required when the Containment Spray pump suction switchover from RWST to the containment recirculation sump occurs.

The Containment Spray trains provide two full capacity heat removal loops for the containment, each of which is sized and described in Paragraph 6.2.2.1 to remove heat at the rate which will preclude an increase of the containment pressure above the 12.0 psig maximum internal pressure. All spray headers and spray nozzles are located inside the containment in the upper compartment and will withstand, without loss of function or maintenance, post accident containment environment. The remainder of the systems, with the exception of the refueling water storage tanks, which includes all active components, are located in the auxiliary building and therefore are not adversely affected by wind, tornado, or snow and ice conditions.

The design is based on the spray water being raised to the thermodynamic wet bulb temperature of the containment in falling through the steam-air mixture within the building. The minimum fall path of the droplets is approximately 100 ft from the spray ring headers to the operating deck. The actual fall path is longer due to the trajectory of the droplets sprayed out from the ring header nozzles.

The Containment Spray trains initially operate independently of other engineered safety features, with the exception of the containment spray pump suction from the refueling water storage tank. For extended operation in the recirculation mode, water can be supplied to a containment RHR spray header through the Residual Heat Removal pump and Residual Heat Removal heat exchanger.

An analysis has been made of all active components of the system to show that the failure of any single active component will not prevent fulfilling the design function. This analysis is summarized in Table 6.2.2-3. A single failure in the Residual Heat Removal System will not prevent long-term use of the spray system. The analyses of the loss-of-coolant accident presented in Chapter 15 reflect the single failure analysis. Each of the spray trains provides complete backup for the other.

The two 14-inch refueling canal drains are open to return spray water to the containment sump during all modes requiring containment spray (CS) operability. The drains are sized to accommodate the maximum RHR and CS spray flow.

The passive portions of the Containment Spray Subsystems located within the containment are designed to withstand, without loss of functional performance, a post accident containment environment and to operate without benefit of maintenance.

The spray headers which are located in the upper containment volume are separated from the reactor and primary coolant loops by the operating deck, missile shields, and inner wall of the ice bed. These spray headers are therefore protected from missiles originating in the lower compartment.

This evaluation shows that the Containment Spray Subsystems can withstand expected conditions during the 40 year life of the plant without loss of capability to perform the required safety functions. This is achieved by meeting the following NRC General Design Criteria.

1. The systems can withstand the effects of natural phenomena as required by General Design Criterion 2.

2. The systems are designed to accommodate the effects of and be compatible with the environmental conditions associated with normal operation, maintenance, testing, and postulated accidents including loss-of-coolant as required by General Design Criterion 4.

3. The systems are not shared with another nuclear power unit as required by General Design Criterion 5.

4. The systems are designed to be capable of being inspected and tested to ensure reliability throughout their life as required by General Design Criteria 39 and 40.

6.2.2.4 Testing and Inspections

Performance tests of the active components in the system were performed in the manufacturer's plant and were verified in-place by preoperational tests (Test Nos. TVA 21A and 21B).

Capability is provided to test initially and subsequently on a routine basis to the extent practical the operational startup sequence and performance capability of the Containment Spray trains including the transfer to alternate power sources. Capability to test periodically the delivery capacity of the Containment Spray trains at a position as close to the spray header as is practical and for obstruction of the spray nozzles is provided.

The containment spray trains have been hydrostatically tested to the applicable code test pressure.

All periodic tests of individual components or the complete Containment Spray trains will be controlled to ensure that plant safety is not jeopardized and that undesirable transients do not occur.

The Containment Spray trains are designed and tested to comply with ASME Section XI, Inservice Inspection of Nuclear Power Plant Components. Inservice Inspection is discussed in subsection 5.2.8.

6.2.2.5 Instrumentation Requirements

The Containment Spray trains will be actuated manually from the control room or auxiliary control station or automatically by the coincidence of two sets out of four protection set loops monitoring the lower containment pressure. The high-high containment pressure signal starts the Containment Spray pumps. The spray header valves open upon high-high containment pressure concurrent with their respective containment spray pump operating.

The operation of the Containment Spray trains is verified by instrument readout in the MCR. The Safety Related Display Instrumentation for Post Accident Monitoring is discussed in Section 7.5. Pump motor breakers energize indicating lights in the MCR to show power is being supplied to the pump motors. Containment spray pump discharge is indicated by flow meters in the MCR. Status lights in the MCR indicate valve position. The closing circuits of the normally closed motor-operated valve will be deenergized by torque switches on the operator to assure a tight seat. Containment spray heat exchanger cooling capacity is indicated by inlet and outlet temperature instrumentation available on the plant computer system in the MCR. The RHR spray discharge flow is available on the plant computer system in the MCR.

To protect the pumps from low flow conditions a minimum flow recirculation line is provided to allow pump discharge to be circulated back into the pump intake. This line is opened by a motor-operated valve when flow in the discharge line drops below that required for pump protection or, if upon starting, sufficient flow is not achieved in the spray header within a preset time interval. A flow element in each discharge line monitors the flow rate and provides the flow signal to control the minimum flow recirculation valve.

Instrumentation is provided to monitor the following parameters: containment spray pump suction and discharge pressure; heat exchanger inlet and outlet temperature; heat exchanger inlet and outlet pressure.

Thermocouples in the pump motor bearings and windings provide high temperature alarm in the control room.

In the event of a main control room evacuation, the necessary control functions are transferable to auxiliary control at the shutdown boards and motor control centers.

The system is designed for Category I seismic. The instrumentation and associated interconnected wiring and cables are physically and otherwise separated so that a single event cannot cause malfunction of the entire system.

6.2.3 Containment Air Purification and Cleanup System

Four engineered safety feature systems provide air purification and cleanup. One of these is the Containment Spray trains discussed in subsection 6.2.2. Two others are the air cleanup systems used in the two secondary containment buildings. The one serving the reactor secondary containment enclosure is the Emergency Gas Treatment System and the one serving the Auxiliary Building secondary containment enclosure is the Auxiliary Building Gas Treatment System. The fourth engineered safety feature system is the Ice Condenser System.

The Ice Condenser System is designed to serve as a Containment Air Purification and Cleanup System. The ice condenser serves primarily as a large heat sink to readily reduce the containment temperature and pressure and condense the steam. For this purpose, ice is stored

in a closed compartment between the lower and upper compartments of the containment. The containment is designed such that the only significant flow path from the lower to the upper compartment is through the ice bed. Immediately following a LOCA, a large pressure differential exists between the lower and upper compartment; thereby providing flow through the ice bed. Later in the transient, flow is provided by two containment air return fans which circulate upper containment air into the lower compartment. Since essentially all flow between the lower and upper compartments must pass through the ice bed, the ice bed also serves as a removal mechanism for fission products postulated to be dispersed in the containment atmosphere. Radioiodine in its various forms is the fission product of primary concern in the evaluation of fission product transport and removal following a LOCA. The major benefit of the ice bed is its capacity to absorb molecular iodine from the containment atmosphere. To enhance this iodine absorption capacity of the ice, the ice solution is adjusted to an alkaline pH which promotes iodine hydrolysis to non-volatile forms.

The physical characteristics of the Ice Condenser System are discussed in Section 6.5. The ice bed fission product removal capability is discussed in this section, Section 15.5, and Appendix 6A.

6.2.3.1 Design Bases

6.2.3.1.1 Containment Spray Trains

There are no formal design bases established for air cleanup by the Containment Spray trains. This was done with the knowledge that water from the Containment Spray trains will remove halogens and particulates from the containment atmosphere following a LOCA. No credit, however, was taken for this removal process in accident analyses presented in subsection 15.4.1. In such circumstances, no design bases are needed for this air purification action.

6.2.3.1.2 Emergency Gas Treatment System

The design bases for the Emergency Gas Treatment System are:

1. To keep the air pressure within each Shield Building annulus below atmospheric at all times in which the integrity of that particular containment is required.

2. To reduce the concentration of radioactive nuclides in annulus air that is released to the environs during a LOCA in either reactor unit to levels sufficiently low to keep the exclusion area boundary dose rate below the 10 CFR 100 guideline value.

6.2.3.1.3 Auxiliary Building Gas Treatment System

The design bases for the Auxiliary Building Gas Treatment System are:

1. To establish and keep an air pressure that is below atmospheric within the portion of the Auxiliary Building serving as a secondary containment enclosure during accidents.

2. To reduce the concentration of radioactive nuclides in air releases from the Auxiliary Building Secondary Containment Enclosures (ABSCE) to the environs during accidents to levels sufficiently low to keep the site boundary dose rate below the 10 CFR 100 guideline value.

3. To minimize the spreading of airborne radioactivity within the Auxiliary Building following an accidental release in the fuel handling areas.

6.2.3.1.4 Ice Condenser Design Basis (Cleanup Function)

The design basis of the ice condenser as an Iodine Removal System is to use the chemical and physical properties of ice to reduce the fission product iodine concentration in the post LOCA containment atmosphere. See Appendix 6A for a discussion of the mechanics of the iodine removal process.

6.2.3.2 System Design

6.2.3.2.1 Containment Spray Trains

See Paragraph 6.2.2.2.

6.2.3.2.2 Emergency Gas Treatment System

The Emergency Gas Treatment System is shown schematically in Figure 9.4.7-1. This system has two subsystems; the Annulus Vacuum Control Subsystem and the Air Cleanup Subsystem.

Annulus Vacuum Control Subsystem

The Annulus Vacuum Control Subsystem is a fan, duct, and control network used to establish and maintain a negative pressure within the annulus. It is utilized during normal operations in which containment integrity is required. In emergencies in which containment isolation is required, this subsystem is isolated and shutdown. This subsystem performs no safety related function and, therefore, is not classified as an engineered safety feature.

This subsystem has an independently controlled branch for each reactor unit. The air inlet for each branch is centrally located in the secondary containment annulus above the steel containment dome. The fans discharge into the fuel handling area exhaust system to the Auxiliary Building exhaust vent.

Air pressure control in each secondary containment annulus is achieved with redundant fans, differential pressure sensors, air operated dampers, and control circuitry. This equipment provides a capability to vary the volumetric flow rate drawn from the annulus to keep the pressure at a predetermined negative pressure level. This control function is accomplished with a modulating damper under control of a differential pressure sensor that adjusts the amount of relief air introduced upstream of a constant capacity fan. Two relief air intake lines with modulating dampers and controllers are provided for each unit. One serves as a backup in the event the other fails to function in the proper manner.

The fans and flow control dampers serving both reactor secondary containment annuli are installed in the EGTS room at elevation 734 adjacent to the unit 2 Shield Building.

The nominal setpoint for each annulus vacuum control equipment installation is five inches of water below reference pressure in the Auxiliary Building. The fans employed to create such a negative pressure are described in Table 6.2.1-2.

Air Cleanup Subsystem

The Air Cleanup Subsystem is a redundant shared airflow network having the capability to perform two functions for the affected reactor secondary containment during a LOCA. One of

these is to keep the secondary containment annulus air volume below atmospheric pressure. The second function is to remove airborne particulates and vapors from air drawn from the annulus that may contain radioactive nuclides.

Both of these functions are performed by processing and controlling a stream of air taken from the affected reactor unit secondary containment annulus. The air cleanup operation is conducted by drawing the air stream through a series of filters and adsorbers. Annulus air pressure control is accomplished by adjusting the fraction of the airstream that is returned to the annulus air space.

The rated capacity of each redundant air cleanup unit in the subsystem is 4000 cfm. These were designed in accordance with engineered safety feature standards.

The air flow network for the Air Cleanup Subsystem was designed to provide the redundant services needed for either reactor secondary containment annulus. The intakes and ducting in this network used to bring annulus air to the Emergency Gas Treatment System room on Elevation 734 in the Auxiliary Building are those also used by the Annulus Vacuum Control Subsystem. The intake is centrally located within each Shield Building above the steel containment dome. Within the Emergency Gas Treatment System room the network branches out to supply two air cleanup unit installations that can be aligned with flow control valves to serve either annulus air volume. After the air is processed, the Air Cleanup Subsystem air flow network directs the air to redundant damper controlled flow dividers in the affected reactor unit annulus where the flow is divided for discharge to the shield building vent and to a manifold that distributes and releases the air uniformly around the bottom of the annulus. Butterfly valves, rather than dampers, are installed in the ducts to minimize the outside air in-leakage from the shield building vent into the annulus.

Another feature incorporated into the Air Cleanup Subsystem air flow network is the capability to cool the filters and adsorbers in an inactive air cleanup unit that is loaded with radioactive material. This is accomplished with two cross-over air flow ducts that can draw air at approximately 200 cfm from the active air cleanup unit through the inactive air cleanup unit. This airflow is sufficient to keep the temperature in a fully loaded inactive air cleanup unit to less than 300° F. Two butterfly valves in series are installed in each cross-over air flow path to assure sufficient isolation to perform accurate removal efficiency tests on the HEPA filter and carbon adsorber banks.

The two air cleanup units in the Air Cleanup Subsystem are steel housings containing air treatment equipment, heaters, a drain, test fittings, and access facilities for maintenance. The air treatment equipment within the housing includes a moisture separator* relative humidity heater, prefilter bank, HEPA filter bank, two banks of carbon adsorbers in series and another HEPA filter bank. This equipment is installed in the order listed. A drain is incorporated into the housing adjacent to the moisture separator installation to allow moisture separated from the air stream to flow by gravity to a water collection tank in the Auxiliary Building. Integral to this housing are test fittings properly sized and positioned to permit orderly and efficient testing of the HEPA filter and carbon adsorber banks.

The relative humidity heater installed in the air cleanup units is an electric heater designed to heat the incoming air sufficiently to reduce the relative humidity of saturated air to 70 percent. Included in this installation is a temperature limiting controller that will shut the heater off if excessive temperatures are detected.

(*) See Table 6.2.3-1, Regulatory Guide 1.52 Section C.3.a for applicability requirements.

The HEPA filters and carbon adsorbers installed in the air cleanup units are standard items widely used in the nuclear power industry. The HEPA filters are 1000 cfm units designed to remove at least 99.97 percent of the particulates greater than 0.3 micron in diameter. These filters are water and fire resistant units fabricated in accordance with MIL-F-51068C. The carbon adsorbers are Type II unit trays, fabricated in accordance with AACC Standard CS-8. These trays contain 2-inch-thick impregnated carbon beds. These trays, rated at 333 cfm, are installed in banks in which the face velocity is less than 40 ft/min. Under such circumstances the residence time for air in the carbon bed is about 0.25 second. The total number of filters and adsorber unit trays provided in each air cleanup unit are listed in Table 6.2.1-2.

Two V-belt driven centrifugal fans are provided in the Air Cleanup Subsystem. Each of these is associated with a specific air cleanup unit. These fans were designed to function in process air flow streams at temperature up to 200°F. See Table 6.2.1-2 for additional information on these fans.

Two air flow control modules are included for each reactor unit in the Air Cleanup Subsystem. Each module consists of a differential pressure transmitter, controller, a damper actuator, two discharge modulating dampers, and two isolation dampers (exhaust and recirculation). A single actuator (mechanical linkage) adjusts the discharge modulating dampers simultaneously in opposite directions - one is closed when the other is opened.

This air flow control equipment, installed in the secondary containment annuli, provides the capability to adjust the amount of air returned to the affected reactor unit annulus. A negative 0.5 inch of water gauge controller setpoint is used to adjust the amount of air returned to the affected annulus. Annulus pressures more positive than the controller pressure setpoint (-0.5"W.G) produce a signal causing the damper actuator to begin closing the damper controlling the air flow to the annulus and simultaneously start opening the damper controlling the air flow to the reactor unit vent. Annulus pressures more negative than the controller setpoint initiate the opposite kind of damper motions.

The Unit 1 controls for the Air Cleanup Subsystem were designed for two basic control modes. One mode of control has both air cleanup units in operation simultaneously. The second mode of control has either one of the units in operation and the other in a state in which it can automatically come into operation in the event that the operating unit fails under low flow condition (a Phase A containment isolation signal must be present). If a Phase A containment isolation signal is not present, the standby unit will start on low flow signal only by manual actuation. This operating redundancy is achieved with spatially separated power and control circuitry having different independent power sources to prevent a loss of function from any single subsystem component. Power for both trains of equipment is supplied by the Emergency Power System.

The Unit 2 Air Cleanup Subsystem has four isolation valves (two valves per train) installed in the secondary containment annulus which provide isolation of the pressure control dampers. Each train has a handswitch in the control room positioned so that both trains of isolation valves are in A Auto. A containment isolation Phase A signal causes the valves to open. The open isolation valves provide a flow path for both trains of pressure control dampers which modulate to control annulus pressure.

Operation of the Air Cleanup Subsystem during accidents is initiated by the Phase A Containment Isolation Signal. Both the A and the B trains will be started by this signal coming from either reactor unit. A capability is also provided to start both trains with hand switches in the main control room. Damper alignment and shield building vent isolation valve positioning is also initiated by the same signal, however, just those associated with the affected reactor unit will be activated. On Unit 1, another adjustment of a hand switch in the main control room will change the operating mode to the single train operation with the redundant train in a standby status.

6.2.3.2.3 Auxiliary Building Gas Treatment System

The Auxiliary Building Gas Treatment System is a fully redundant air cleanup network provided to reduce radioactive nuclide releases from the ABSCE during accidents. This system draws air from various parts of the Auxiliary Building to establish a negative pressure in the Auxiliary Building with respect to outside atmosphere. The air is directed to air cleanup equipment before being discharged through the Shield Building Vent.

The rated capacity of each redundant air cleanup unit in this gas treatment system is 9000 cfm. These were designed in accordance with engineered safety feature standards.

The Auxiliary Building Gas Treatment System flow diagram is shown on Figure 9.4.2-5. The airflow network for this system consists of two parallel duct installations originating from exhaust ducting that normally serves various areas in the Auxiliary Building. Each of these ducts lead directly to an air cleanup unit, to the fan associated with the air cleanup unit and then directly to the Shield Building Vent.

The air flow network that is not unique to this system consists of most of the normal ventilation ducting installed in the ABSCE. When the Secondary Containment enclosure is isolated this duct network provides a flow path for reducing the air pressure level in all parts of this enclosure.

Two air cleanup units are utilized in the Auxiliary Buildings Gas Treatment System. Heaters located just upstream of the air cleanup units are designed to reduce the relative humidity of incoming saturated air to 70 percent. The air cleanup units are galvanized steel housings equipped with a prefilter bank, HEPA filter bank and a carbon adsorber bank. This equipment is installed in the order listed.

Integral to this housing are test fittings properly sized and positioned to allow HEPA filter and carbon adsorber bank leakage tests to be conducted in an orderly and efficient manner.

Air is drawn through each of these air cleanup units by a belt driven centrifugal fan. The drive for the fan is an electric motor rated at 20 horsepower. Additional information on these fans is given in Table 6.2.1-2.

Two air flow control modules, each assigned to a particular air cleanup unit, are utilized in the Auxiliary Building Gas Treatment System. These contain a differential pressure sensor and transmitter, control circuitry and an air operated modulating damper.

These two air flow control modules provide the capability for keeping the pressure within the ABSCE at or more negative than 1/4 inch of water below atmospheric. The modulating damper is controlled by the differential pressure transmitter to adjust the amount of outside air introduced into the duct network just upstream of the constant capacity fan described above. Such action will bring in sufficient outside air to keep the fan at its rated flow and to establish and keep the desired negative pressure level.

The controls for the Auxiliary Building Gas Treatment System were designed to provide two basic control modes. One control mode has both air cleanup units in operation simultaneously. The second control mode has either one of the air cleanup units in operation and the other in a state in which it can automatically come into operation in the event the operating unit fails under low flow condition (an auto-start signal must be present). If an auto-start signal is not present,

the standby unit will start on low flow signal only by manual actuation. This operational redundancy is achieved with spatially separated power and control circuitry having different independent power sources to prevent a loss of function from any single system component failure. Power for both equipment trains is supplied by the Emergency Power System.

Operation of the Auxiliary Building Gas Treatment System begins automatically upon receipt of a:

1. Phase A containment isolation signal from either reactor unit, or a

2. High radiation signal from the fuel handling area radiation monitors, or a

3. High radiation signal from the Auxiliary Building exhaust vent monitor, or a

4. High temperature signal from the Auxiliary Building air intakes.

A capability is also provided to start both trains with hand switches in the main control room. Another adjustment capability provided in the hand switches in the main control room will change the operating mode to the single train operation with the redundant train in a standby status. The standby fan will restart on a low-flow signal from the operating fan if an auto-start signal is present.

Employment of this operating mode is expected after the first 30 minutes of operation. In this instance the main control room operator has the capability to select either unit to remain in operation.

6.2.3.2.4 Ice Condenser System

The function of post-LOCA iodine removal is served by the Ice Condenser through chemically controlling the alkaline ice to a pH range of 9.0 to 9.5. This is accomplished by adding sodium tetraborate to the Grade A feedwater in the solution of $Na_2 B_4 O_7 \cdot 10H_2O$ with 2000 $\pm$ 100 ppm of Boron prior to ice basket loading. During the accident, the melting ice provides a medium for removal of iodine from the containment atmosphere and fixation in solution. The component description of the Ice Condenser System is given in subsection 6.5. The operation of the Ice Condenser System is described in subsection 6.5.15.

6.2.3.3 Design Evaluation

6.2.3.3.1 Containment Spray Trains

See subsection 6.2.2.2.

6.2.3.3.2 Emergency Gas Treatment System

The Emergency Gas Treatment System has the capabilities needed to preserve safety in accidents as severe as the design basis LOCA. This was determined from functional analyses of the system to verify that the proper features are provided, reviews of Regulatory Guide 1.52 sections to assure licensing requirement conformance, and from performance analyses conducted to verify that the system has the desired accident mitigation capabilities. The system is shown in Figure 9.4.7-1.

The functional analysis conducted on the Emergency Gas Treatment System have shown that:

1. Adequate isolation of the Annulus Vacuum Control Subsystem during accidents is provided. The two low leakage dampers in series up- stream of the Annulus Vacuum Control Subsystem fans used to isolate the two subsystems--one operated by each subsystem train--give assurance that the Annulus Vacuum Control Subsystem will be isolated during accidents. These dampers fail closed.

2. The air flow control valves in the Air Cleanup Subsystem will align to service the affected reactor units. The network was designed to have all of the air flow control valves needed to service a particular reactor unit responsive to only the containment isolation signal from that particular reactor unit.

3. The system intake and recirculation air outlets within the Shield Building annulus are ideally positioned to promote mixing and dilution of primary containment leakage. Positioning the recirculated air manifold and the air outlets almost completely around the base of the annulus below the level of the containment penetrations assures a clean air flow past most of the penetrations. This air, warmed somewhat by the relative humidity heater, will flow upward past these likely sources of leakage at about 2 ft/min. In doing so, the many flow impediments (i.e., penetrations, and structures within the annulus) will tend to redirect this air flow to some degree to induce mixing and dilution. Substantial amounts of mixing and dilution appear likely in the vertical rise of over 168 feet to the system air intake above the steel containment dome.

4. System startup reliability is very high. The practice of starting up both full capacity trains in the system simultaneously gives greater assurance that one train of equipment will function promptly upon receipt of an accident signal.

5. The use of a single actuator in each equipment train to adjust dampers controlling the air flow recirculated and vented improves train reliability and minimizes the possibility of annulus pressure instability. Train reliability is enhanced by minimizing the number of components utilized to perform this operation. Simultaneous adjustment that closes one damper and opens the other eliminates the hunting problems that could arise from non-simultaneous operation of separately actuated dampers.

6. The Train A and Train B air cleanup units are adequately protected from each other to eliminate the possibility of a single failure destroying the capability to process annulus air during emergencies. The 13.5 feet high and 27-inch-thick concrete wall built between the two units protects each from missiles originating in the other unit. The review of the EGTS conducted to determine its conformance with Regulatory Guide 1.52 has shown that this system, designed prior to issuance of the guide, is in good general agreement with its requirements. Details on this compliance with Regulatory Guide 1.52 are given in Table 6.2.3-1.

The performance analyses conducted to verify that the Emergency Gas Treatment System had the required accident mitigation capabilities was conducted in three basic parts. One of these was concerned with the capability for keeping the Shield Building annulus below atmospheric pressure at all times during a LOCA. The second part was an analysis of the cooling capabilities provided to keep temperatures at safe levels within filters and adsorbers which are fully loaded

with radioactive nuclides. The third part was concerned with the exclusion area boundary and LPZ dosage contribution from radioactive nuclides present in annulus air releases during the design basis LOCA.

Annulus Negative Pressure Control Capability

The capability of the Emergency Gas Treatment System to keep the Shield Building annulus below atmospheric pressure during a design basis LOCA was established with a time iteration analysis performed by a computer. Energy and mass balances were accomplished successively in accordance with mass and volume changes calculated to take place during each time increment. Such a methodology allowed sufficient freedom to account for:

1. Steel containment vessel growth from internal pressure,

2. Steel containment vessel growth from thermal expansion,

3. Outside air in-leakage into the Shield Building annulus, and

4. Heat transfer from the steel containment structure to the annulus air mass.

To assure that this analysis was valid and conservative:

1. The steel containment vessel expansion due to internal pressure was based upon the average strain in the vessel wall. This pressure induced growth was assumed to occur instantaneously at the start of the LOCA.

2. The steel containment vessel growth due to thermal expansion was based upon wall temperatures in three different parts of the containment vessel. One of these is the vessel wall around the lower compartment, the second is the vessel wall around the ice condenser compartment, and the third is the vessel wall around the containment upper compartment. In calculating these vessel wall temperatures, consideration was given to the heat transferred from the containment upper compartment, the heat transferred from the containment atmosphere to the vessel wall, the heat capacity of the vessel wall and the heat transferred to the annulus air mass and the enclosing Shield Building structure. Constant heat transfer coefficients higher than the peak transient coefficients were used for this analysis.

3. Outside air leaking into the Shield Building annulus was assumed to be at a rate of 500 cfm when the pressure differential was 0.5 inches of water. This air was assumed to have a density of air at 0°F. The thermal effect of this outside air in-leakage was neglected.

4. The air temperature in the annulus was assumed to be a thermally mixed average.

5. Only one train of the Emergency Gas Treatment System was assumed to operate during the accident. This train was assumed to operate at 3600 CFM (4000 CFM less 10%). It was also assumed that the EGTS fans can be operational and that the exhaust flow dampers can be in position 9.5 seconds after the annulus pressure increases to -0.5 inches of water (approximately 46 seconds after the LOCA).

The initial steady state conditions used in this analysis were as follows:

	Pressure	Temperature	Relative Humidity
Containment Upper Compartment	Atm.	110°F	0%
Ice Condenser Compartment	Atm.	15°F	0%
Containment Lower Compartment	Atm.	120°F	0%
Shield Building Annulus	-5 in. w.g.	50°F	0%
Outside	Atm.	0°F	0%

The results of annulus pressure versus time and the exhaust flow versus time obtained from this analysis are shown in Figure 6.2.3-1. The maximum annulus pressure occurs at 50.0 seconds and is roughly -1/5 inches of water. The pressure exceeds -1/4 inches of water for approximately 8 seconds; however, the offsite dose limits specified in 10 CFR 100 are not exceeded. Such results indicate that:

1. The negative pressure level of 5 inches of water below atmospheric in the Shield Building annulus maintained by the Annulus Vacuum Control Subsystem before an accident is adequate to assure that the offsite dose will not exceed 10 CFR 100 guidelines.

2. The rated flow rate of 4000 cfm for each train of the Air Cleanup Subsystem is adequate for keeping the annulus pressure below atmospheric throughout the remaining period of the LOCA.

The Sequoyah purge valves, whether used for purging or venting, are administratively controlled by technical specifications, and have position indication and automatic closure capability. Based on the purge valve design features and technical specification controls, these openings when venting can be considered intermittent and the purge lines themselves can be considered normally closed, therefore, no specific secondary containment enclosure analysis is required.

Inactive Air Cleanup Unit Cooling Capabilities

The second performance analysis (Reference 82) conducted to show that the Emergency Gas Treatment System can cope with circumstances that may occur in a LOCA examined the adequacy of the heat removal capabilities provided by the air flow in the inactive air cleanup unit (train) for the HEPA filters and adsorbers loaded with radioactive material. The analysis conducted assumed accident releases in accordance with Regulatory Guide 1.4 plus 1 percent particulates, containment leakages of 0.25 percent/day for the first day and 0.125 percent/day after the first day with all the activity being collected in a single air cleanup unit. An additional assumption made was that half the gamma and all of the beta energy releases were transformed into heat within the filters and adsorbers.

This analysis determined that in the inactive air cleanup unit, the temperature of the HEPA and charcoal adsorbers are less than the 250°F and 300°F, respectively, and that the air temperature at the fan is less than 200°F. These results demonstrate that the 200 cfm air flow rate through a fully loaded inactive air cleanup unit is sufficient to maintain all temperatures below the design temperatures for these major components of the EGTS ACUs. The analysis showed that an air flow rate of 200 cfm through the fully loaded inactive air cleanup unit is sufficient to maintain the exiting air temperature below 200°F, which provides additional assurance that the 620°F carbon ignition temperature is not approached.

Exclusion Area Boundary and LPZ Dosage Contributions

The third performance analysis conducted to show that the Emergency Gas Treatment System has the capability to perform in the required manner to preserve safety during a LOCA was concerned with the exclusion area boundary and LPZ dosage contributions arising from annulus air releases to the environs. This analysis is described and evaluated in Section 15.5 and Appendix 15A.

6.2.3.3.3 Auxiliary Building Gas Treatment System

The Auxiliary Building Gas Treatment system has the capabilities needed to preserve safety in accidents as severe as a LOCA. This was determined by conducting a functional analysis of the system to verify that the system has the proper features for accident mitigation, by reviewing Regulatory Guide 1.52 sections to assure licensing requirement conformance, and from a performance analysis conducted to verify that the system has the desired accident mitigation capabilities.

The functional analysis conducted on the Auxiliary Building Gas Treatment System has shown that:

1. The air intakes for the system are properly located to minimize accident effects. The use of the air intakes provided in the fuel handling and waste disposal areas will tend to minimize the spread of airborne contamination that may be accidentally released at these positions in which the probability of an accidental release is more likely. This localization effect is provided without reducing the effectiveness of the system to cope with multiple activity releases throughout the ABSCE that may occur during a LOCA. Such coverage is accomplished by utilizing the normal ventilation ducting to draw outside air in-leakage from any point along the secondary containment enclosure to the fuel handling and waste disposal areas.

2. Sufficient accident indication signals are utilized to bring the Auxiliary Building Gas Treatment System into operation to assure that the system will function when needed to mitigate accident effects. All accidents in which this system is needed to preserve safety will generate at least one of the four signals that result in system startup.

3. System startup reliability is very high. The practice of starting up both full capacity trains in the system simultaneously gives greater assurance that one train of equipment will function promptly upon receipt of an accident signal.

4. The method adopted to establish and keep the negative pressure level within this secondary containment enclosure minimizes the time needed to reach the desired pressure level. Initially, the full capacity of the Auxiliary Building Gas Treatment System fans will be utilized for this purpose. After reaching the desired operating level, the system control module allows outside air to enter the air flow network just upstream of the filters at a rate to keep the fans operating at full capacity with the enclosed volume at the desired negative pressure level. In this situation, the amount of air withdrawn from the enclosed volume will be equal to the amount of outside air in-leakage through the ABSCE.

5. The negative pressure level selected for the ABSCE is appropriate. A negative pressure of 1/4 inch of water is sufficient to reduce the amount of unprocessed air escaping from this secondary containment enclosure to the atmosphere to insignificant quantities. This negative pressure level is also sufficient to assure that any air leakage between the Auxiliary Building and the Shield Building is from the Auxiliary Building into the Shield Building.

6. The Train A and Train B air cleanup units are sufficiently separated from each other and from other engineered safety feature equipment to eliminate the possibility of a single failure destroying the capability to process Auxiliary Building air prior to its release to the atmosphere. Two concrete walls and a distance of more than 80 feet separate the two trains. Each of these are the only engineered safety feature equipment installed in their respective rooms. The use of separate trains of the Emergency Power System to drive the air cleanup trains is further assurance of proper equipment separation.

The review conducted of the Auxiliary Building Gas Treatment System to determine its conformance with Regulatory Guide 1.52 has shown that this system, designed prior to issuance of the guide, is in good general agreement with these requirements. Details on this compliance with Regulatory Guide 1.52 are given in Table 6.2.3-2.

A performance analysis to determine the capability of the Auxiliary Building Gas Treatment System to establish and maintain a negative pressure in the ABSCE was based on the following assumptions:

1. Infiltration into the ABSCE is equal to 7000 cfm at a negative pressure differential of 1/4-inch water gauge relative to the atmosphere.

2. Only one air cleanup unit of the Auxiliary Building Gas Treatment System operates, and it operates at its rated capacity of 9000 cfm.

3. The air cleanup unit fan begins to operate 30 seconds after initiation of the LOCA.

4. The initial static pressure inside the ABSCE is assumed to be equal to atmospheric pressure. This is a conservative assumption since the ABSCE typically is under a negative pressure during normal operation.

5. The wind pressure head equals 1/8-inch water gauge.

6. The initial ABSCE air temperature equals 104°F.

7. Atmospheric temperature and pressure are 97°F and 14.4 lb/in^2a, respectively.

The performance analysis conducted to verify that the Auxiliary Building Gas Treatment System has the required accident mitigation capabilities has shown that:

1. The system flow rate was sized properly to handle all expected outside air in-leakage at a 1/4 inch of water negative pressure differential. This indicated that the flow rate of 9000 cfm is sufficient to assure an adequate margin above the expected ABSCE in-leakage.

2. The system has the necessary capability to establish and maintain a negative pressure of 1/4-inch water gauge inside the ABSCE within 5 minutes of the occurrence of a LOCA. This is based on an assumed initial delay of 4 minutes to establish the ABSCE and 1 minute to draw down the ABSCE to a negative 1/4-inch water gauge. Actual testing has confirmed that a negative pressure of 1/4-inch water gauge can be obtained in less than one minute. Additionally, the normal Auxiliary Building ventilation lineup maintains approximately 1/4-inch water gauge negative pressure in the Auxiliary Building.

3. The system contains sufficient air cleanup facilities to keep the contributions to the exclusion area boundary and LPZ dosage arising from Auxiliary Building air releases to small fractions of the 10 CFR 100 guideline values. This part of the analysis is presented and evaluated in Section 15.5 and Appendix 15A.

6.2.3.3.4 Ice Condenser System

As a result of experimental and analytical efforts by Westinghouse, the Ice Condenser System has been proven to be an effective passive system for removing elemental iodine from the containment atmosphere and thereby reducing the offsite doses following a LOCA. This is discussed in detail in Appendix 6A and Section 15.5.

6.2.3.4 Testing and Inspections

6.2.3.4.1 Containment Spray Trains

See subsection 6.2.2.4.

6.2.3.4.2 Emergency Gas Treatment System

Preoperational testing of the Emergency Gas Treatment System was conducted and verified the capabilities needed during startup and operating requirements and demonstrated the capability to function properly after failure of any system component. Included in this test scope were functional tests on all system instrumentation, alarms, and data displays. Periodic testing is conducted to verify that the Emergency Gas Treatment System can respond properly and perform its intended functions. These are described in the SQN Technical Specifications.

6.2.3.4.3 Auxiliary Building Gas Treatment System

Preoperational testing of the Auxiliary Building Gas Treatment System was conducted and verified the capabilities of the system to function during accidents. Included in the test scope were functional tests on all system instrumentation, controls, and alarms. In particular, the tests:

1. Verified the startup and control capabilities of the system, considering a single operating component failure.

2. Verified the capability of the air flow control modules to create and maintain a negative 1/4-inch water pressure within the ABSCE.

3. Verified each air cleanup unit's leaktightness, HEPA filter bank efficiency, carbon adsorber bank leakage efficiency, and heater performances.

Periodic testing is conducted in accordance with Technical Specifications.

6.2.3.4.4 Ice Condenser System

During the initial ice loading, periodic tests were conducted to verify that the boron concentration and pH of the ice was within acceptable limits. This was accomplished by measuring the pH and boron concentration of samples of the solution prior to freezing. At routine intervals during plant operation, samples of the ice are measured for pH and boron concentration to verify that these values are still within acceptable limits. The initial

concentration of boron can only increase due to dissipation of some H_2O by sublimation. Ice condenser is serviced in each refueling cycle. Prior to adding new ice, a sample is taken from every new bin of ice made to verify that the boron concentration and the pH are acceptable.

6.2.3.5 Instrumentation Requirements

6.2.3.5.1 Containment Spray Trains

See subsection 6.2.2.5

6.2.3.5.2 Emergency Gas Treatment System

The air flow control instrumentation requirements for the EGTS are described in subsection 6.2.3.2.2. The emergency mode of the EGTS is actuated by a Phase A containment isolation signal. Process and effluent radiological monitoring of the EGTS is described in Section 11.4.

Permanently installed pressure differential gauges across the prefilter, HEPA filter, and both carbon adsorbers allow periodic surveillance of dust loadings and pressure drops on individual components in the filter trains.

Temperature instrumentation indicates air temperatures both upstream and downstream of the relative humidity heaters. The relative humidity heaters are equipped with high temperature cutoffs.

6.2.3.5.3 Auxiliary Building Gas Treatment System

Instrumentation required for the air flow control modules and air cleanup units are discussed in subsection 6.2.3.2.3. The logics, controls, and instrumentations of this Engineered Safety Feature System are such that a single failure of any component will not result in the loss of functional capability for the system.

The filtration systems are equipped with differential pressure gauges for dust loading surveillance on individual filtration components. The relative humidity heaters are equipped with high temperature cutoffs. Instrumentation is also provided for low flow detection in the air cleanup units.

Process and effluent radiological monitoring of the ABGTS is described in Section 11.4.

6.2.3.5.4 Ice Condenser System (Cleanup Function)

The ice condenser is a passive system which requires no control instrumentation to fulfill its design function during an accident.

6.2.3.6 Materials

6.2.3.6.1 Containment Spray Subsystems

See subsection 6.2.2.2.

6.2.3.6.2 Emergency Gas Treatment System

HEPA filters and carbon adsorbers in the Emergency Gas Treatment System are designed for stability and dependability in accident environments discussed above. The HEPA filters have a fire-retardant glass fiber filter, aluminum separators, and carbon steel frame. This type of filter is capable of functioning at rated conditions at temperatures up to 250°F and gamma doses of up to 10^8 rads. The carbon adsorbers will be individually encased, flat-bed, tray-type units. Each tray will contain new, commercially pure, activated carbon treated with iodine or iodine compound to facilitate removal of organic and inorganic iodine compounds. The carbon ignition temperature after impregnation will be greater than 620°F. Adsorber material and gaskets will withstand gamma doses of 1×10^8 rads accumulated in a 1 month period.

6.2.3.6.3 Auxiliary Building Gas Treatment System

Same as subsection 6.2.3.6.2 above.

6.2.4 Containment Isolation Systems

The purpose of containment isolation is to provide positive closure methods in lines penetrating primary reactor containment in the event of a loss of coolant accident within containment or another event that creates one of the containment isolation signals. Primary reactor containment is the third of the three principle fission product barriers (fuel clad, RCPB, reactor containment) necessary for the protection of the public health and safety. The objective of containment isolation is to allow the normal or emergency passage of the following while preserving the integrity of the containment boundary:

1. Engineered Safety Feature system fluids, or
2. Fluid of systems which are not required to function following a LOCA but, if available, can be used to accomplish a function similar to an engineered safety feature system.

Other fluid systems shall be isolated upon the appropriate isolation signal. Penetrations through the containment boundary shall be leak rate tested as necessary. An integrated test is used to pressurize the entire containment and prove performance of all penetrations. Penetrations are also individually tested unless specific requirements are met as detailed herein (e.g. closed systems).

The bases for containment isolation and containment integrity ensures that the release of radioactive materials from the containment atmosphere will be restricted to those leakage paths and associated leak rates assumed in the accident analysis and within the limits of 10CFR100. The limitation on containment leakage ensures that the total containment leakage volume will not exceed the value assumed in the accident analysis at the peak accident pressure.

The limitations on closure and leak rate for the containment airlocks are required to satisfy CONTAINMENT INTEGRITY. Surveillance testing of the airlock seals provide assurance that the overall airlock leakage will not become excessive during the intervals between overall airlock leakage tests. The structural integrity of the containment steel vessel will be maintained comparable to the original design standards for the life of the facility. Structural integrity is required to ensure the vessel will withstand the maximum pressure of 12 psig in the event of a LOCA. The visual inspection in conjunction with the Type A integrated test demonstrates this integrity. Containment isolation valves that must isolate on various signals are identified in Reference 73. The operability of these valves ensures that the containment atmosphere will be

isolated from the outside environment in the event of an accident that requires containment isolation. Containment isolation valve closure within the time limits specified ensures that the release of radioactive materials to the environment will be consistent with the assumptions used in the accident analysis. Additional valves have been identified as barrier valves which are a part of the accident monitoring instrumentation in Tech Spec 3/4.3.3.7 and as designated as Category 1 in accordance with Reg Guide 1.97 R2. Containment Isolation valve position indication requirements are specified by Tech Spec 3/4.3.3.7.

A visual inspection which verifies that no loose debris (rags, trash, clothing, etc.) is present in the containment which could be transported to the containment sump and cause restriction of the pump suctions during LOCA conditions. This visual inspection shall be performed:
1. For all accessible areas of the containment prior to establishing CONTAINMENT INTEGRITY, and
2. Of the areas affected within containment at the action of each containment entry when "CONTAINMENT INTEGRITY" is established.

DEFINITIONS

BYPASS LEAKAGE PATH is a potential path for leakage to escape from both the primary containment and annulus pressure boundary. Only one type of BYPASS LEAKAGE PATH is recognized:

a. BYPASS LEAKAGE PATHS TO THE AUXILIARY BUILDING are those paths that would potentially allow leakage from the primary containment to circumvent the annulus secondary containment enclosure and escape directly to the Auxiliary Building secondary containment enclosure.

CLOSED SYSTEM: A piping system that penetrates containment and is a closed loop either inside or outside the containment. Under normal operating conditions or LOCA conditions for closed systems inside containment, the fluid in the system does not communicate directly with either primary coolant or the containment atmosphere.

CONTAINMENT INTEGRITY shall exist when:
a. All penetrations required to be closed during accident conditions are either:
    1) Capable of being closed by an OPERABLE containment automatic isolation valve system, or
    2) Closed by manual valves, blind flanges, or deactivated automatic valves secured in their closed positions, except as provided by Technical Specification 3.6.3.
b. All equipment hatches are closed and sealed, and
c. Each air lock is in compliance with the requirements of Technical Specification 3.6.1.3, and
d. The containment leakage rates are within the limits of Technical Specification 4.6.1.1.c, and
e. The sealing mechanism associated with each penetration (e.g., welds, bellows, or O-rings) is OPERABLE, and
f. Secondary Containment Bypass Leakage Rates are within the limits of Technical Specification SR 4.6.3.8 and TS 6.8.4.h.

CONTAINMENT ISOLATION SIGNAL: A signal that automatically initiates the accident isolation function and establishes isolation barrier(s) in containment penetrations to mitigate the potential consequences of an accident. SQN has the following signals that will isolate valves in lines penetrating containment: Phase A, Phase B, Containment Ventilation Isolation, and Containment Pressure. Auxiliary Feedwater initiation, safety injection, main steam isolation, and feedwater isolation are other ESF actuation signals that are credited for isolating valves in lines penetrating containment.

ENGINEERED SAFETY FEATURE(S): Systems which are required to prevent, arrest, or mitigate the consequences of an accident.

L_a: Allowable leakage from containment (0.25% of the containment free air volume per day at accident pressure of 12 psig). The overall integrated leak rate is limited to 0.75 $L_{a.}$ The combined leakage from all penetrations and valves subject to Type B and C tests is limited to 0.60 L_a. The combined bypass leakage paths to the Auxiliary Building from penetrations and valves subject to Type B and C tests is limited to 0.25L_a.

PRIMARY CONTAINMENT: For SQN, the freestanding steel vessel that encloses the reactor vessel and other components of the RCPB and which provides an essentially leaktight barrier against the uncontrolled release of fission products to the environment.

REACTOR COOLANT PRESSURE BOUNDARY (RCPB): All those pressure retaining components such as pressure vessels, piping, pumps, and valves that are:

a) part of the reactor coolant system,
b) connected to the reactor coolant system up to and including any or all of the following:

1. the outermost containment isolation valve in system piping that penetrates the primary containment,
2. the second of two valves normally closed during normal reactor operation in system piping that does not penetrate primary containment, or
3. the reactor coolant system safety and relief valves.

TEST TYPE A: Tests to measure the reactor primary containment overall integrated leakage rate. The containment leak rate test will be conducted in accordance with Appendix J of 10 CFR 50, with approved exemptions.

TEST TYPE B: Tests to detect or measure local leaks of containment penetrations, hatches, personnel locks, electrical penetrations, fuel transfer tube covers, ice blowing lines covers, and thimble renewal cover.

TEST TYPE C: Tests to detect or measure containment isolation valve leakage.

VALVE CLOSURE TIME: Time it takes for a power operated valve to be in the fully closed position after the actuation power has reached the operator assembly; this does not include the delay time for instruments and controls.

6.2.4.1 Design Bases

General Design Criteria (GDC) 54 through 57 of Appendix A to 10CFR50 contain NRC design requirements for isolation of piping systems penetrating containment. GDC 54 contains general provisions for leak detection, redundancy, and reliability. GDC 55 requires each line that is part of the RCPB and that penetrates containment to have isolation valves as listed below, unless it can be demonstrated that the provisions for a specific class of lines are acceptable on some other defined basis.

1. one locked closed valve inside and one locked closed valve outside
2. one automatic valve inside and one locked closed valve outside
3. one locked closed valve inside and one automatic valve outside
4. one automatic valve inside and one automatic valve outside

A simple check valve may not be used as the automatic valve outside containment. GDC 56 contains similar provisions for lines that connect directly to the containment atmosphere and that penetrate containment. GDC 57 addresses systems that penetrate containment but that do not communicate directly with either the RCPB or the containment atmosphere and requires at least one valve (not a simple check valve).

10 CFR 50 Appendix J contains NRC requirements for leak rate testing of containment and containment penetrations. Piping systems penetrating the containment have been provided with test vents and test connections or have other provisions to allow periodic leak testing when required. Those automatic isolation valves with air or motor operators that do not restrict normal plant operation are periodically tested to ensure operability. The CI System complies with the requirements and intent of NRC GDC 54-57 and Appendix J through the system design, approved exemptions, and other defined basis.

The criteria for containment penetrations ensure that all fluid lines penetrating the containment have at least one isolation valve near the point of penetration. Most fluid lines that communicate directly with the containment atmosphere have, as a minimum, two isolation valves in series. These lines and isolation valves are designed to SSE requirements and are missile protected. Where possible, lines communicating with the containment atmosphere are designed to meet NRC General Design Criterion 56, Primary Containment Isolation. An exception to this criterion is the containment pressure-sensing lines which are required to function following a DBE.

All closed systems penetrating the containment are designed to meet NRC General Design Criterion 57, Closed System Isolation Valves, with the exemptions identified.

All containment isolation valves and piping shall be seismic Category I (or equivalent) and Safety Class 2 (or equivalent).

Electrical penetrations shall meet the requirements of IEEE 317-1971(canister types) and IEEE 317-1976 or 1983 (modular types). Electrical penetrations are further discussed in Section 7.1.

The regulations allow demonstration of acceptability on "some other defined basis" (for example, where isolation would be detrimental to overall safety in essential lines such as ECCS). TVA had traditionally relied upon the closed system outside containment instead of designating an outboard remote manual valve as a containment isolation valve. This isolation design was considered acceptable and the SQN license SER (ref 40.g) concluded that the containment isolation system was acceptable but did not specifically address the "other defined basis." During the 1985-1988 restart effort, the NRC staff position communicated to TVA (ref 40.h) was that a closed system outside containment is not generally acceptable as an isolation barrier for lines covered by GDC 55 or 56. Leak rate testing per Appendix J was also reevaluated. Following numerous correspondence, specific exemptions were submitted by TVA and approved by the NRC. Refer to Reference 73 for a discussion of each penetration subject to an exemption.

CONTAINMENT ISOLATION SYSTEMS

The Containment Isolation (CI) Systems provide the means of isolating fluid systems that pass through containment penetrations so as to confine to the containment any radioactivity that may be released in the containment following a DBE. The CI Systems are required to function following a DBE to isolate applicable fluid systems penetrating the containment. Isolation design is achieved by applying common criteria to penetrations in many different fluid systems and by using ESF signals to actuate appropriate valves. The following design criteria applies to the containment isolation system.

DESIGN CRITERIA

1. The design pressure of all piping and connected equipment comprising the isolated boundary is equal to or greater than the design pressure of the containment.

2. All valves and equipment which are considered to be isolation barriers are designed in accordance with seismic Category I criteria and are protected against missiles and jets, both inside and outside the containment.

3. A system is closed outside the containment if it meets all of the following:

   a. It does not communicate with the atmosphere outside the containment.
   b. Its safety class is the same as for engineered safety systems.
   c. Its internal design pressure and temperature are greater than or equal to containment design pressure and temperature.
   d. It is missile and jet protected.
   e. Withstand LOCA transients and environment.

4. A system is closed inside the containment if it meets all of the following:

   a. It does not communicate with either the Reactor Coolant System or the reactor containment atmosphere.
   b. Its safety class is the same as for engineered safety systems.
   c. It will withstand external pressure and temperature equal to containment design pressure and temperature.
   d. It will withstand accident temperature, pressure, and fluid velocity transients, and the resulting environment, including internal thermal expansion.
   e. It is missile and jet protected.

Note: Any systems not completely meeting the requirements of criteria 3. or 4. are considered open systems.

5. A check valve inside the containment on the incoming line is considered an automatic isolation valve.

6. A pressure-relief valve that relieves toward the inside of the containment is considered an automatic isolation valve.

7. A locked closed valve may be used for isolating containment, and does not require any additional operator action.

8. To qualify as an automatic isolation valve, a power-operated valve must fail in the position to provide the greatest safety control on loss of air, power, etc.

9. All valves used for containment isolation will be capable of tight shutoff against gas leakage from containment design pressure down to approximately 12-lb/in^{2}g.

10. Remote-manual valves may be used for isolation provisions associated with engineered safety features (such as the ECCS) instead of automatic isolation valves.

The design bases for the CI Systems include provision for the following:

1. A double barrier at the containment penetration in those fluid systems that are not required to function following a DBE.

2. Automatic, fast, efficient closure of those valves required to close for containment integrity following a DBE to minimize release of any radioactive material.

3. A means of leak-testing barriers in fluid systems that serve as containment isolation unless leak testing is specifically exempt based on Appendix J or an approved exemption.

4. The capability to periodically test the operability of containment isolation valves.

CONTAINMENT INTEGRITY

The main function of the CI System is to provide containment integrity when needed. Containment integrity is defined in Technical Specifications.

CONTAINMENT ISOLATION SIGNALS

Containment isolation primarily consists of 3 phased signals: Phase A, Phase B and Containment Ventilation Isolation. There is also a high containment pressure signal specifically for the containment vacuum relief isolation valves. Other ESF signals are also credited for isolating valves in containment penetrations (e.g., SIS, AFW initiation, MSI, and MFWI).

Phase A signal is generated by either of the following:

1. Manual - Either of two momentary controls.

2. Safety injection signal generated by one or more of the following:

    a. Low steam line pressure loops.
    b. Low pressurizer pressure.
    c. Two out of three high containment pressure signals.
    d. Manual - Either of two momentary controls.

Phase B signal is generated by either of the following:

1. Manual - Two sets (two switches per set) - actuation of both switches necessary in either set for spray initiation.

2. Two out of four high-high containment pressure signals.

Containment Ventilation Isolation is generated by any of the following:

1. Manual Phase A

2. Manual Phase B

3. Safety Injection Signal (see above)

4. High Radiation in containment purge exhaust.

Containment isolation Phase A should exist if containment isolation Phase B exists, when the Phase B signal is initiated by automatic instrumentation. Phase A containment isolation does not occur when the Phase B signal is initiated manually. Phase B containment isolation does not occur when the Phase A signal is initiated manually. Containment isolation logic is shown in Figure 6.2.4-1.

A containment isolation signal initiates closing of automatic isolation valves in those lines which must be isolated immediately following a DBE. There is no sequence of timing for isolation valve closure. However, on loss of alternating current power, the diesel will have to be started prior to closure. The containment isolation signal is discussed in section 7.3.

Containment high-pressure set point is established low enough to ensure that containment isolation will occur prior to reaching blowdown peak pressure following a double-ended LOCA. The set pressure is high enough to ensure that normal operation transients of the ventilation systems or temperature changes from cold to hot will not approach the high-pressure set point.

CONTAINMENT ISOLATION VALVES

The criteria for the number and location of containment isolation valves in each fluid system depend on its function and whether it is open or closed to the containment atmosphere or Reactor Coolant System. Four isolation classes of fluid system penetrations are defined as follows:

1. Isolation Class I - Fluid lines which are open to the atmosphere outside the containment and are connected to the RCS or are open to the containment atmosphere. Each isolation Class I System has a minimum of two isolation valves in series. Where system design permits, one valve is located inside and one valve is located outside containment.

2. Isolation Class II - Fluid lines which are connected to a closed system outside the containment and are connected to the RCS, or are open to the containment atmosphere. Also included in isolation Class II are fluid lines which are open to the atmosphere outside the containment and are separated from the RCS and the containment atmosphere by a closed system inside the containment. Each isolation Class II System has, as a minimum, one isolation valve.

3. Isolation Class III - Fluid lines which are connected to a closed system, both inside and outside the containment. Isolation Class III Systems have, as a minimum, one isolation valve.

4. Isolation Class IV - Fluid lines which must remain in service subsequent to a DBE, such as lines serving ESF Systems. Isolation valves on these lines are not automatically closed by the containment isolation signal. Each isolation Class IV System has, as a minimum, one isolation valve (remote-manual operation preferred).

Fluid instrument lines penetrating the containment are designed to meet the General Design Criteria except where specific exemptions or other defined basis exists as described in References 73, 39, and 40.

The CI Systems automatic isolation valves will be required to function upon receiving an actuating signal following a DBE. The 2-barrier scheme used where possible for the Sequoyah Nuclear Plant ensures that in the event of failure of any component to function, a backup means exists to isolate the containment.

Motor-operated, solenoid operated, and air-operated valves are used in containment isolation. Most air-operated and solenoid operated valves fail to the closed position in the event the power supply is lost or fails. All motor-operated valves receive power during normal conditions from the normal power source. Under loss of normal power conditions, power is supplied from the standby power source.

Valves, in non-safety-related systems where function permits, are normally positioned closed to minimize any release following a DBE. Those valves that are required to change position following a DBE are equipped with fast-acting valve operators to immediately close the valve.

Containment isolation valves and operators are designed to withstand the maximum integrated radiation dose occurring during the 40-year life of the plant and the exposure that would occur following a DBE.

Containment isolation valves that are located inside the containment are designed to function under the pressure-temperature conditions of both normal operation and that during the DBE. The pressure-temperature conditions used in normal operation design or conditions for a DBA are stated in the environmental design criteria (section 3.11). Missile protection of the containment and containment isolation valves is discussed in Section 3.5.

Containment isolation valves are designed to seismic Category I requirements. The valves are capable of operation during and after seismic loadings. Valves with operators or similar features of extended proportions are designed to withstand an inertial SSE load, in addition to normal operating loads. Electrical switches or other actuating mechanisms are designed to withstand the inertial load without changing position and causing change of position of the valve disc.

Check valves are used under conditions where differential pressure will close the valves to maintain containment integrity. Lines, which for safety reasons must remain in service subsequent to a DBE, are provided with at least one isolation valve.

Automatic isolation valves that receive a containment isolation signal to close, where closure of the valve will not limit or restrict normal plant operation, are periodically functionally tested by the on-line testing capability described in Section 7.3. All other valves are periodically tested for CIS circuit electrical continuity. All containment isolation valves are tested to the requirements of ASME Section XI, (see section 6.8).

A barrier is defined as a valve, a gasket and a blind flange, or a closed piping system. Piping that forms part of the containment isolation boundary is ANS N18.2 Safety Class 2a, TVA Class B. All automatic valves that are activated by a containment isolation signal also have hand switches in the control room or locally for manual actuation to close in the event the valve fails to go to the closed position.

6.2.4.2 <u>System Design</u>

The penetrations are classified in different types as discussed below. The penetrations are tabulated and schematically illustrated in Reference 73.

<u>Penetration Types I and II Main Steam and Feedwater</u>

The main steam and feedwater line penetrations, shown on drawing 47W331-1, are the "hot" type in which the penetrations must accommodate thermal movement. Each "hot" process line, where it passes through the containment penetration, is enclosed in a guard pipe that is attached

to the process line through a multiple-flued fitting. The guard pipe protects the bellows should the process line fail within the annulus between the containment vessel and the Shield Building. Released fluids from such a failure are directed by the guard pipe into the containment vessel, thereby precluding the discharge of fluids into the annulus. The inner end of the guard pipe is fitted with an impingement ring which protects the bellows from jets originating from pipe breaks inside containment. In addition, the guard pipe for this type of penetration extends through and is supported by the crane wall. This avoids transmitting loads to the containment vessel. Also, it discharges fluid in the event of a pipe rupture into the reactor compartment rather than smaller rooms outside the crane wall, thus preventing over pressurization of these smaller rooms.

For each of these penetrations, the penetration sleeve is welded to the containment vessel. The process line which passes through the penetration is allowed to move both axially and laterally. A 2-ply bellows expansion joint is provided to accommodate any movement between the process line and the containment vessel, and relative movement between the containment vessel and the Shield Building under any conditions. The bellows will be designed to withstand containment design pressure. When an embedded anchor is not utilized, a low-pressure flexible closure will seal the process line to the sleeve in the Shield Building, which will not impose significant stress on the penetration.

This flexible closure is located in the steam valve vaults and serves to contain any leakage from the flued head so that the leakage is routed back to the annulus and to seal the annulus from the outside environment.

Guides and anchors limit movement of pipes such that design limits on the containment penetration and bellows are not exceeded during all conditions of plant operation, test, or postulated accidents.

<u>Penetration Type III RHR Pump Supply and Return</u>

The RHR pump supply and return penetrations, shown on drawing 47W331-1, are also the "hot" type. For these penetrations, the guard pipe does not penetrate the crane wall. This type penetration will be anchored at the Shield Building wall in addition to being supported from the internal concrete structure to minimize loads transmitted to the steel containment vessel.

The Shield Building sleeves have embedded anchors, and the flued heads are in the Auxiliary Building. There is no need for low-pressure flexible closures as used in penetration types I and II since any leakage from the flued head will be processed by the Auxiliary Building Gas Treatment System.

<u>Penetration Types IV and V</u>

Types IV and V penetrations are also thermally "hot" with insulation and bellows, as shown on drawing 47W331-1. Any leakage through the flued heads or through the bellows will be into the annulus and thereby processed by the Emergency Gas Treatment System. The two types differ by only the weld ends.

<u>Penetration Types VI, VII, and VIII</u>

Penetration types VI through X, and XII through XVIII, and XXI are the "cold" penetrations.

For "cold" piping penetrations, a low-pressure flexible closure will seal the cold pipe to the sleeve penetrating the Shield Building. The piping configuration and supports on either side of the penetration will be designed to preclude over stressing the containment vessel at the penetration under any conditions, including postulated accidents.

Relatively small thermal movement or stress is expected for the "cold" penetrations. The clearance space provided for the pipe going through the Shield Building wall is computed by the summation of the relative movements of the pipe and the Shield Building for all design conditions. Ample clearance space will be provided so that the pipe will not be in contact with the Shield Building sleeve under any condition.

Penetration types VI and VII have provisions for dissimilar metal weld. The two types differ in their weld ends only. Penetration types VI and VII are on drawing 47W331-2. The flued heads of both types are located in the annulus.

Penetration type VIII is similar to that of penetration types VI and VII except that there is no dissimilar metal weld. Penetration type VIII is illustrated on drawing 47W331-2.

Penetration Type IX Containment Spray and RHR Spray Headers

There is no difference in penetration types VIII and IX except that penetration type IX is located at the dome. Type IX penetration is illustrated on drawing 47W331-2. The flued heads are located in the annulus.

Penetration Type X Multiple-Line and Single-Line Sleeves

Type X penetrations are primarily for instrumentation lines, such as sampling and monitor lines, and nitrogen supply lines. Typical multiple- line and single-line sleeves are shown on drawing 47W331-2.

Penetration Types XI and XII Emergency Sump

During long-term post accident conditions, containment sump water is recirculated through the RHR System and the Containment Spray Subsystems. The water collects in the floor of the containment and flows to the emergency sump. The water flows out of the containment through type XII penetrations (two per unit) shown on drawing 47W331-2. Each line contains an isolation valve. The valves are enclosed in a valve compartment (two per plant unit). The penetration between the valve compartments and the Auxiliary Building is a type XI penetration (two per plant unit) illustrated on drawing 47W331-1.

The type XII penetration has a flued head located in the containment sump. The outer sleeve (guard pipe) of the flued head is welded directly to the containment liner, which is completely embedded in the concrete.

The type XI penetration has the flued head located in the Auxiliary Building. The penetration is insulated because of the hot sump water which would pass through it in the event of a DBE.

Penetration Type XIII Ventilation

Heating and ventilation ducts utilize penetration type XIII, as shown on drawing 48N406. Process lines are welded directly to these penetrations.

Additional information on ventilation duct penetrations is given in the section on possible leakage paths.

Penetration Type XIV Equipment Hatch

An equipment hatch, fabricated from welded steel and furnished with a double-gasketed flange and bolted dished door, is provided. A test connection to the space between the gaskets is provided to pressurize the space for leak rate testing, as shown on drawings 48N406 and 44N250.

Penetration Type XV Personnel Access

Two personnel locks are provided. Each personnel lock, as shown on drawings 48N406 and 44N240, is a double door, welded steel assembly. Quick-acting type equalizing valves are provided to equalize pressure in the airlock when entering or leaving the containment vessel. The doors are sealed with double gaskets. A test connection to the space between the gaskets is provided to pressurize the space for leak rate testing. The emergency air supply connection to the space between the double doors serves as a test connection to pressurize this space for leak rate testing. A special holddown device is provided to secure the inner door in a sealed position during leak rate testing of the space between the doors.

The two doors in each personnel lock are interlocked to prevent both being opened simultaneously and to ensure that one door and its equalizing valve are completely closed before the opposite door can be opened. Remote indicating lights and annunciators, located in the control room, indicate the door is in operational status. Provision is made to permit bypassing the door interlocking system with a special tool to allow doors to be left open during plant cold shutdown. Each lock door hinge is designed to be capable of adjustment to assure proper seating.

Penetration Type XVI Fuel Transfer Tube

A 20 inch outside diameter transfer tube penetration is provided for fuel movement between the refueling canal in the containment and spent fuel pit. The penetration consists of 20 inch stainless steel pipe installed inside a 24 inch carbon steel pipe, as shown on drawing 47W455-1. The inner pipe acts as the transfer tube and is fitted with a double-gasketed blind flange in the refueling canal and a standard gate valve in the spent fuel pit. The inner pipe is welded to the containment penetration sleeve. Expansion bellows are provided on the pipes to compensate for any differential movement between the two pipes or other structures.

Penetration Type XVII Thimble Renewal

Incore instrumentation thimble renewal requires penetrations in both the steel containment and the Shield Building at the same elevation and azimuth. These are separate penetrations and are not connected in the annulus. The containment penetration is illustrated on drawing 48N406, a similar seal is used on the Shield Building (47W470-3). Double O-ring ring gaskets and leak rate test connectors are provided on both sides of the steel containment penetration as shown on drawing 48N406.

Penetration Type XVIII Ice Blowing

The ice-blowing line penetrations have a blind flange with a double 0-ring gasket inside and outside the containment, as shown on drawings 48N406 and 47W462-7 . Sealing between the Auxiliary Building and the annulus is provided by a blind flange, fitted with a gasket (47W462-7).

Penetration Type XIX Containment Vacuum Relief

The penetrations for the Containment Vacuum Relief System, are shown on drawings 48N406 (sleeve) and 69-5545-77 (assembly). There are no bellows and no flued heads.

Penetration Type XX Electrical

The electrical penetration assemblies will provide a means for the continuity of power, control, and signal circuits through the primary containment structure. The electrical penetration assemblies are designed to maintain containment integrity. Additional discussion of electrical penetrations is provided in Section 7.1.3.

Penetration Type XXI Cold Water Penetrations

The penetration for cold water lines such as ERCW is shown on drawing 48N406. There are no bellows or flued heads.

Penetration Type XXII Maintenance Type

The penetration for X-108 and X-109 are shown on drawings 48N406 (sleeve), 47W331-1 (flued head type XIV), 47W331-3 (test flange). This flued head is similar to the flued heads in penetration Types IV and V but with the difference that the Type XXII penetration does not use insulation.

LEAKAGE PATHS

The possible leakage paths from primary containment are discussed below.

These leakage paths are defined on the basis that the annulus pressure is always less than outdoor ambient, the Auxiliary Building, and the containment pressures. Therefore, whenever containment is required, leakage is into the annulus. The possible leakage paths considered do not include containment leakage through the steel plates or through the full penetration welds in the containment vessels. Neither do the possible leakage paths include Shield Building embedments. This is acceptable, as any leakage through any of these paths will be into the annulus and the leakage will be processed by the Emergency Gas Treatment System.

The more probable sources of containment and Shield Building leakage, such as elastomer seals, bellows, and through line, are considered as possible leak path types. Each penetration that contains elastomer seals or a bellows has at least one leakage path defined in the PENETRATION TABLES. All penetrations not open to the annulus are considered as possible paths for through-line containment and have one or more isolation valves. Thus, every pipe penetration has at least one type of leak path listed. The five different types of possible leakage paths are discussed separately below.

Type A Leakage Path

Leakage type A is leakage from the Auxiliary Building into the annulus.

Type B Leakage Path

Type B leakage paths are from the containment to the annulus.

Type C Leakage Path

Type C leakage is leakage from the outside environment into the annulus.

Type D Leakage Path

Type D leakage path covers the through-line leakage from the containment to the Auxiliary Building.

The motor-operated containment isolation gate valves in each containment spray line are not required to be leak tested provided there is sufficient inventory in the riser between the valves and the ring headers to maintain a water cover on the gate valves at 1.1 Pa for 30 days. This water cover assures there will be no leakage of containment atmosphere to the Auxiliary Building through the containment spray line. The water cover is ensured by verifying water level between elevation 801 and 804 feet at least once each refueling outage prior to re-establishing containment integrity. The Containment Spray System and RHR System are closed loops outside containment and designed to remain water-filled pre-and post-accident. In addition, the Primary Coolant Sources Outside Containment Program (TS 5.5.2) will identify and correct any pressure boundary leakage of these systems.

Type E Leakage Paths

Type E leakage paths are paths from the containment that may potentially bypass the annulus and Auxiliary Building and leak directly past the air cleanup systems.

Through-line leakage from the main steam line, the feedwater lines, and the steam generator blowdown lines constitute one of the two possible paths for type E leakage. The flexible bellows outside the Shield Building for the main steam and feedwater serve to route any leakage from the flued heads back into the annulus. The main steam, feedwater, and blowdown lines are all connected to the secondary side of the steam generator, and thus are not open to containment. In addition, the secondary side of the steam generator is kept at a higher pressure than the primary side soon after the LOCA occurs. Any leakage between the primary and secondary sides of the steam generator is thus directed inward to the containment.

The second possible type E leak path is through the Essential Raw Cooling Water (ERCW) System. Essential raw cooling water is used for normal containment cooling. Under LOCA conditions, the system is isolated by both inboard and outboard containment isolation valves. Any leakage between the containment and the ERCW would normally be to the containment since the ERCW System pressure would be above the maximum containment pressure. If ERCW pressure was less than containment pressure then a possible leakage path exists, via the isolated containment valves, then past radiation monitors, and thence out-of-doors. The layout of the ERCW piping from the intake station to the containment provides a loop seal. The difference in pressure between the large break LOCA post-accident containment environment, considering the elevation head of the highest ERCW user (Upper Compartment Coolers), and the ERCW intake, will prohibit containment out leakage via the ERCW lines. The ERCW valves are tested in accordance with 10 CFR 50, Appendix J, and the results are provided in types B and C test reports.

Another possible Type E leakage path is through the hydrogen analyzer calibration and reagent gas lines for the B-Train analyzer. These lines, however, are sealed by a gas from the calibration or reagent gas bottles on the outboard side of the reagent or calibration gas line flow solenoid containment isolation valves. These valves are located immediately outside the ABSCE boundary, and the reagent and calibration gas lines are welded between the ABSCE boundary and the valves. Thus, any leakage past these valves will be into the auxiliary area, and thus not directly to the environment.

The shutdown maintenance access penetrations (X-108 & X-109) on Unit 1 also are a possible Type E leakage path since the Unit 1 ABSCE boundary has been removed from the Unit 1 additional equipment building. These penetrations are a blind flange, double O-ring design with a zero leakage criteria and are not open during power operation.

6.2.4.3 Design Evaluation

The CI Systems are designed to present a double barrier to any flow path from the inside to the outside of the containment using the double barrier approach to meet the single-failure criterion and satisfy the general design criteria except with approved exemptions.

When permitted by fluid system design, diverse modes of actuation were used for automatic isolation valves. In addition to diverse modes of operation, channel separation was also maintained. This also ensures that the single-failure criterion is met.

The CI System complies with the intent of the NRC Criteria 54, 55, 56, and 57, issued after the establishment of the design basis for Sequoyah, with approved exemptions.

Adequate protection is provided for piping, valves, and vessels against dynamic effects and missiles which might result from plant equipment failures, including a LOCA. Isolation valves inside the containment are located between the crane wall and the inside containment wall where possible. The crane wall serves as the main missile barrier. Other missile barriers are discussed in the FSAR Section 3.5.

The requirements and intent of NRC General Design Criteria 54, 55, 56, and 57, Appendix J and Regulatory Guide 1.11, have been met with specific exemptions and other defined basis as allowed by the regulations. These exemptions and other defined basis are described in detail in References 73, 39, and 40 for the below penetrations:

a. RVLIS. Penetrations X-25C, X-26C, X-27D, X-86A, X-86B, X-86C.
b. Containment Pressure Sensors. Penetrations X-25B, X-26A, X-27A, X-27B, X-85B, X-97.
c. Vacuum Relief Lines. Penetrations X-111, X-112, X-113.
d. RHR Sump Lines. Penetrations X-19A, X-19B.
e. ECCS Injection. Penetrations X-20A, X-20B, X-21, X-22, X-32, X-33.
f. RCP Seal Injection. Penetrations X-43A, X-43B, X-43C, X-43D.
g. RHR Hot Leg Injection. Penetration X-17.
h. CVCS Charging. Penetration X-16.
i. Relief Valve Discharge. Penetration X-24.
j. CCS Supply/Return to Excess Letdown Heat Exchanger. Penetrations X-35, X-53.
k. CVCS Letdown. Penetration X-15
l. RHR Suction From Hot Leg 4. Penetration X-107.
m. CS and RHR Spray. Penetrations X-48A, X-48B, X-49A, X-49B.
n. Main Steam Lines. Penetrations X-13A, X-13B, X-13C, X-13D.
o. Hydrogen Analyzers. Penetrations X-92A, X-92B, X-99, X-100.
p. Blind Flanges. Penetrations X-1, X-3, X-40D, X-54, X-79A, X-79B, X-88, X-108, X-109, X-117, X-118.
q. Personnel Airlocks. Penetrations X-2A, X-2B.
r. Spare Penetrations are listed in the Sequoyah Containment Isolation System Description, Number N2-88-400.
s. Electrical Penetrations X-120E through X-170E (except the spares listed above).
t. Valve Position Indication for seal water filter outlet valves. X-43A, 43B, 43C, & 43D.

6.2.4.4 Tests and Inspections

All components of the CI Systems were designed, fabricated, and tested under quality assurance requirements in accordance with 10 CFR 50, Appendix B, as further described in Chapter 17.

Nondestructive examination was performed on the components of the system in accordance with the applicable codes described in Chapter 3. Subsequent to initial plant operation, CI Systems were periodically tested under conditions of normal operation. Automatic isolation valves that receive a containment isolation signal to close, where closure of the valve will not limit or restrict normal plant operation, are periodically functionally tested by the online testing capability described in Section 7.3. All other valves are periodically tested for CIS circuit electrical continuity. Primary containment leakage tests and containment isolation system valve operability tests will be performed periodically to verify that leakage from the containment is maintained within acceptable limits (see Section 6.2.1.4). Valves shall also be tested in accordance with ASME Section XI (see section 6.8).

6.2.4.5 Materials

The materials for penetrations, including the personnel access airlocks, the equipment access hatch, the piping and duct penetration sleeves, and the electrical penetration sleeves, will conform with the requirements of the ASME Boiler and Pressure Vessel Code, Section III, Class MC. The penetration materials shall meet the NDT impact values as required by this Code. The materials used for various systems are described in the appropriate sections for those systems. The radiolytic or pyrolytic decomposition products, if any, of each material will not interfere with safe operation of the engineered safety feature systems. Protection is provided against the consequence of the failure of penetrations due to brittle fracture by impact testing of the materials and the use of impact tested welding procedures to applicable code requirements.

6.2.5 Hydrogen Sampling In Containment

Following a beyond design basis degraded core event, hydrogen may accumulate within the containment as a result of:

1. Zirconium-water reaction involving the fuel cladding and the reactor coolant.

2. Radiolytic decomposition of water in the core.

3. Radiolytic decomposition of water in the containment sump.

4. Corrosion of materials within the containment.

6.2.5.1 Design Bases

A redundant hydrogen sampling system is designed to detect and give MCR indication of the presence and concentration of hydrogen in the primary containment atmosphere.

6.2.5.2 System Design

The Hydrogen Sampling System is designed to continuously monitor hydrogen concentration inside containment during an accident. Portions of the hydrogen analyzers are located in the auxiliary building and the reactor building annulus and monitor the containment through stainless steel tubing coming from one point in the upper compartment and one point in the lower compartment.

These lines are equipped with normally closed, fail-closed solenoid operated and remote manual isolation valves. The return line is stainless steel and is equipped with isolation valves identical to those on the incoming lines. Because portions of the analyzers are in the annulus, those portions of the analyzers are designed to operate in the annulus following an accident. The analyzer internals are designed to process containment atmosphere at conditions up to 56 psig, 300°F, and 100 percent relative humidity. Hand switches, indicators, and alarms are located in the main control room. The analyzer electronics, as well as calibration and reagent gas lines and bottles, are located in the auxiliary building. The system is seismically qualified.

When the system is actuated, containment atmosphere is continuously drawn through a series of sample conditioners before entering the analyzer including a trap, and moisture separator. The atmosphere from the upper and lower compartments is mixed before entering the analyzer. As a result of the analyzer capability and the mixing afforded by the hydrogen collection system which draws from compartments within the containment and the containment dome, a true indication will be given of the hydrogen concentration within containment.

The analyzers are calibrated to measure hydrogen concentrations between 0 and 10 percent with an indicated accuracy in the main control room of plus or minus 1.5 percent hydrogen. This range is sufficient to measure hydrogen releases from metal-water reactions of up to 40 percent of the zirconium fuel cladding.

6.2.5.3 Design Evaluation

The Hydrogen Sampling System's primary safety function during a DBA is containment isolation and ABSCE integrity where portions of the closed instrument boundary are located outside the ABSCE.

6.2.5.4 Testing and Inspections

The Hydrogen Analyzers are routinely tested. They are calibrated using gases containing 1 volume percent hydrogen with the balance nitrogen and 4 volume percent hydrogen with the balance nitrogen.

6.2.5A Hydrogen Mitigation System

6.2.5A.1 Design Basis

The Hydrogen Mitigation System (HMS) is designed to increase the containment capability to accommodate hydrogen that could be released during a degraded core accident. The system, which is based on the concept of controlled ignition using thermal igniters to induce periodic burns to moderate energy addition rates, has been designed to be redundant, capable of functioning in a postaccident environment, seismically supported, and capable of actuation from the main control room. In addition, the system is designed to have an ample number of igniters distributed throughout the containment to mitigate the effects of hydrogen releases in the Sequoyah containment.

6.2.5A.2 System Description

To assure that any hydrogen released would be ignited at any containment location as soon as the concentration exceeded the lower flammability limit, durable thermal igniters capable of maintaining an adequate surface temperature are used. The igniter has been shown by experiment to be capable of maintaining surface temperatures in excess of the required minimum for extended periods, initiating combustion, and continuing to operate in various combustion environments.

The igniters in the HMS are equally divided into two redundant groups, each with independent and separate controls, power supplies, and locations, to ensure adequate coverage even in the event of a single failure. Manual control of each group of igniters is provided in the main control room and the status (on-off) of each group will be indicated there. A separate train of Class 1E 480 V ac auxiliary power is provided for each group of igniters and is backed by automatic loading onto the diesel generators upon loss of offsite power. Each individual circuit powers two igniters.

To assure adequate spatial coverage, a total of 68 igniters are distributed throughout the various regions of the containment in which hydrogen could be released or to which it could flow in significant quantities (see Figures 6.2.5A-1 through 6.2.5A-5). There are at least two igniters, controlled and powered redundantly, located in each of these regions. Following a degraded core accident, any hydrogen which is produced would be released into the lower compartment inside the crane wall. To cover this region, 22 igniters (equally divided between trains) are provided. Eight of these are distributed on the reactor cavity wall exterior and crane wall interior at an intermediate elevation to ensure the partial burning that accompanies upward flame propagation. Two igniters are located at the lower edge of each of the five enclosures for the four steam generators and the pressurizer, two in the top of the pressurizer enclosure, and another pair above the reactor vessel in the cavity. These 22 lower compartment igniters prevent flammable mixtures from entering the ice condenser. Any hydrogen not burned in the lower compartment is carried up through the ice condenser and into

its upper plenum. Since steam is removed from the mixture as it is passed through the ice bed, mixtures that were nonflammable in the lower compartment tend to be flammable in the ice condenser upper plenum. This phenomenon is supported by the CLASIX containment analysis code which predicts more sequential burns to occur in the upper plenum of the ice condenser than in any other region. Therefore, the system is designed to take advantage of the favorable combustion characteristics of the upper plenum by the provision of 16 igniters having two igniters in each of its eight regions. Fourteen igniters shall be located in the upper compartment: four igniters are located around the upper compartment dome, four at intermediate elevations on the outside of the steam generator enclosures, four more around the top inside of the crane wall, and one above each of the two air return fans. The air return fans provide recirculation flow from the upper compartment through several dead-ended compartments (see section 6.2.1.3.3) back into the main part of the lower compartment. To cover this region, there are pairs of igniters in each of the 8 rooms (a total of 16 igniters) through which the recirculation flow passes. The location of the HMS igniters is shown in Figures 6.2.5A-1 through 6.2.5A-5.

The components of the HMS inside containment are seismically supported and will maintain functional capability under postaccident conditions.

6.2.5A.3 Operation

The HMS will be energized manually from the main control room in accordance with emergency procedures following any accident which indicates inadequate core cooling.

6.2.5A.4 Safety Evaluation

The HMS, due to its igniter type and locations, redundancy, capability of functioning in a postaccident environment, seismic support, main control room actuation, and remote surveillance will perform its intended function in a manner that provides adequate safety margins. Extensive areas research and analysis has verified the functionability and durability of the igniters [Reference 76]. The containment structures will survive the effects of credible degraded core accidents when hydrogen hazards are mitigated by the HMS.

6.2.5A.5 Testing

Surveillance testing for the HMS consists of energizing the system from the main control room and taking voltage and current readings from each circuit at the distribution panels located in the auxiliary building. These readings are then compared to baseline data to determine whether or not both igniters on each circuit are operational. The operability of at least 33 of the 34 igniters per train would conservatively guarantee an effective coverage throughout the containment. Test intervals and restoration to operable status are provided in the technical specifications.

Igniter temperatures are checked in accordance with the applicable surveillance instructions based on the intervals as specified by the Technical Specification. Technical Specification also identifies the acceptance criteria for the igniters' temperature.

6.2.5B HYDROGEN RECOMBINERS

Two electric hydrogen recombiner units are located in the upper containment compartment, and separate control panels and power supplies for each recombiner unit are located outside containment. The power panel for each recombiner unit contains an isolation transformer plus a controller to regulate power input to the recombiner. Figure 6.2.5B-1 is a sketch of the recombiner unit.

The recombiners are no longer required to control hydrogen following a design basis accident.

6.2.6 Vacuum Relief System

6.2.6.1 Performance Objectives

The primary containment vessel is fitted with a vacuum relief (VR) system. The purpose of the VR system is to protect the vessel from an excessive external force. The VR system does not serve accident mitigating functions or serve to limit the spread of radioactivity. It is a self-activited system that limits external pressure on the vessel in the event of maloperation or inadvertent operation of systems that result in additional external forces on the containment vessel.

The containment vessel vacuum relief system assures that the external pressure differential on the containment vessel does not exceed the design external pressure of 0.5 psid. When the external pressure exceeds the valve set pressure, air flows from the annulus space through the VR valves into the containment vessel. The operation of the VR system results in a pressure reduction in the annulus space between the containment vessel and the shield building. The shield building is designed to withstand this pressure reduction in the annulus.

6.2.6.2 Design Basis

The VR system is not required to mitigate accidents such as a loss of coolant accident (LOCA). Rather, it is a system designed to protect the containment vessel in the event of excessive cooling and the subsequent external pressure on the containment vessel. The system is designed to mitigate the following abnormal occurrences:

1. Inadvertent containment spray actuation.
2. Inadvertent containment air return (CAR) system operation.
3. Simultaneous occurrence of both.

Other abnormal occurrences such as heating and ventilation equipment malfunction may result in external pressures on the containment vessel. However, the effect is always less than for those occurrences listed above.

Provisions are made in the plant design to prevent inadvertent spray operation. The causes for inadvertent spray operation are not postulated. In the event that the containment spray is inadvertently operated, the spray will quickly vaporize and saturate the upper compartment air. The temperature of the sprayed volume approaches the unsprayed wet bulb temperature in the containment upper compartment. A net external pressure on the steel containment results. The maximum external pressure on the containment vessel is the sum of (1) the maximum depressurization due to vaporization and resultant temperature decrease, and (2) the initial pressure

differential, if any. The magnitude of the maximum depressurization depends on the initial upper compartment relative humidity and on the spray water temperature. The set point of the vacuum relief system is used as the initial pressure differential. During the initial vaporization period, the CAR system is conservatively assumed to be inoperative. However, because of the large areas, small moments of inertia, and the fast responses of the ice condenser doors, pressure equalization between the ice condenser and the upper compartment and subsequently between the ice condenser and the lower compartment is taken into consideration. It is conservatively assumed that no heat is generated inside the containment during an inadvertent containment spray operation and/or a CAR system operation.

After the initial vaporization process and pressure transient due to an inadvertent spray operation, the upper containment vessel atmosphere is at 100 percent relative humidity and vaporization of spray ceases. As long as the spray is in operation, the upper and lower compartment temperatures will continue to drop until they reach the spray water temperature. During this period, the CAR system may also be in operation, thus transferring air and water vapor from the upper compartment to the lower compartment and from the lower compartment to the ice condenser. The CAR system brings cold, dry air from the ice condenser into the upper compartment, further dropping the upper compartment temperature and pressure.

When the upper compartment pressure drops to the containment vessel vacuum relief set pressure, the vacuum relief valves respond. As a result of the containment vessel VR system operation, there is a pressure reduction in the annulus. This pressure reduction is a principle design feature of the VR system, for it effectively reduces the external pressure differential across the containment vessel, thereby reducing the required vacuum relief capacity.

The design basis, parameters, and resultant design for the VR system are summarized in Table 6.2.6-1.

6.2.6.3 System Design

The VR system is designed in accordance with the containment system general design criteria of Section 3.1. The system is designed to withstand a SSE without failure.

The containment vessel VR system has three identical units, all located on the dome, at the same elevation, and 120° apart. One of the three units is redundant. In essence, each unit contains a vacuum relief valve in series with a containment isolation valve, the vacuum relief valve being outside of the isolation valve, as shown in Figure 9.4.7-1. The units are installed such that there is sufficient space between the VR system and the Shield Building to prevent contact during seismic or pressure transient motion and to allow for an adequate airflow path.

Each containment vessel vacuum relief valve is a 24 inch, self-actuated, horizontally installed, swing-disc valve, with an elastomer seat. The seat material will withstand post-LOCA temperature, pressure, and radiation conditions. Each unit has a design airflow rate of 28 pounds per second at a pressure differential of 0.5 psid across the entire unit. Each normally closed vacuum relief valve is equipped with limit switches so that open and closed positions of the valve are indicated in the Main Control Room (MCR). The opening of any of these valves is indicated in the MCR. The valves begin opening at a containment external pressure differential of 0.1 psid and will be fully open in 2.2 seconds for a vacuum relief system design basis event.

Each containment vessel vacuum relief isolation valve is a pneumatically operated butterfly valve with an elastomer seat. The valve, including seat material, will withstand a post-LOCA temperature, pressure, and radiation conditions. Two separate trains of control air supplies are available to the two independent solenoid valves which power the isolation valve. The isolation valve, which is normally open, fails open, and will close when containment high pressure reaches the set pressure of 1.5 psid. The high pressure signal is developed from either of two independent sets of three pressure sensors and is completely independent of other containment isolation signals for other systems. Each isolation valve is equipped with a limit switch so that open and closed positions are indicated in the MCR.

6.2.6.4 Design Evaluation

The containment vessel vacuum relief units are located in the annulus and thus are not affected by flood, wind, ice, snow, or tornado. The units are located such that they are also free from the danger of missile damage.

The relief capacities and set pressure of the VR system are based on conservative combinations of parameters. Extra margin is allowed for deviations in the actual vacuum relief flow rate. Based on the assumptions, analyses, and on the specified design limits, it was found that for all events requiring mitigation by the vacuum relief system, the integrity of the primary containment is assured.

Figure 6.2.6-1 shows the upper compartment pressure transient during the initial vaporization stage as a function of time after inadvertent spray initiation. The CAR system is conservatively assumed to be operating during this period. The design case is for an initial upper compartment relative humidity of 4 percent. A principle aspect considered in the design of the vacuum relief system is that the initial containment vessel pressure is not necessarily the same as that in the annulus space. Thus, the pressure transient due to inadvertent spray operation must be considered as an addition to the initial pressure differential across the containment vessel. This consideration is, to a large extent, responsible for the low set pressure of 0.1 psid for the containment vessel vacuum relief valves. The annulus is assumed to have a negative pressure of 5 inches water gauge initial to the inadvertent spray saturation transient and the containment vessel is 0.1 psi below the annulus pressure (i.e., at the setpoint of the vacuum relief system). The analyses show that the design limit of 0.5 psid for the external pressure differential on the steel containment is not exceeded during the short term initial vaporization stage of an inadvertent spray operation. For the initial vaporization stage, the minimum upper compartment pressure occurs at about 12 seconds after the spray is initiated. After that time, the rise in water vapor pressure and the effects of the vacuum relief system are greater than the drop in pressure due to cooling. The upper compartment atmosphere becomes 100 percent saturated at about 24 seconds as indicated in Figure 6.2.6-3.

As indicated in Reference 92, the vacuum relief system is assumed to operate 2.2 seconds after the transient begins. One vacuum relief valve is assumed to fail to open in keeping with single failure criteria. The remaining two vacuum relief valves are assumed to be fully open at 2.2 seconds after the initiation of the inadvertent spray. Since the transient begins with the containment at the setpoint of the VR system, the vacuum relief units would begin to open at the initiation of the containment spray. However, no credit is taken for flow through the VR valves that would occur while they are opening.

Figure 6.2.6-1 thru 6.2.6-3 show the short and long term transients for containment differential pressure, temperature, and relative humidity for inadvertent spray and air return fan operation. The compartment relative humidity is initially at 4 percent. A conservatively low containment VR system capacity of 28 pounds per second at 0.5 psid is used, assuming that the

redundant unit is not operative. As indicated in Reference 92, an initial negative pressure of 5 inches water gauge is assumed for the annulus and the containment vessel initial pressure is again 0.1 psi below the annulus pressure. Figure 6.2.6-1 shows that for initial containment relative humidity at 4 percent, the worst pressure transient occurs during the initial saturation stage.

In the event of an inadvertent air return fan operation without operation of the containment spray, the containment atmosphere would eventually approach ice bed temperatures. However, even with both fans running, the pressure transient is much slower than that shown in Figure 6.2.6-1 because of the lower cooling rate. The containment external pressure (i.e., annulus pressure) is essentially equal to that of the vacuum relief unit set pressure. The annulus pressure, if unrelieved, would drive the shield building external pressure to approach the design value. However, the containment annulus vacuum control subsystem provides a flow path for air from the auxiliary building to go into the annulus, if necessary, so that the shield building external design pressure of 2 psid is never reached.

In setting the design flow rates and pressure setting for the VR system, considerable design effort and safety margins were made in providing proper annulus pressure reduction so that the integrities of both the containment vessel and the shield building are assured. Assurance of integrity is achieved by making certain that at a particular driving head both the maximum and minimum flow rates are within design limits, considering the operation and non-operation of the redundant units and considering all design basis accidents within the containment.

6.2.6.5 Testing and Inspection

All components of the VR system are readily accessible for inspection, maintenance, and testing. The VR system is designed in accordance with the criteria set forth in section 3.1. A test connection between the vacuum relief valve and the isolation valve is provided in each unit for periodic pressure and leak testing, in conformance with Appendix J of 10 CFR 50, with approved exemptions. The system is designed and tested in accordance with applicable ASME Codes. Tests made during fabrication include hydrostatic pressure test, leak test across seals, and flow capacity test on VR system components. In-place tests include periodic tests on the actuator for its ability to move the disc and to operate the position indicating lights in the MCR.

6.2.6.6 Materials

The VR system is not a safety feature system, although the valves will act as containment isolation valves on containment high pressure. The materials used meet the Class 2 requirements of the draft ASME Code for Pumps and Valves for Nuclear Power, 1968 Edition. The radiolytic or pyrolytic decomposition product, if any, of each material will not interfere with the safe operation of any Engineered Safety Feature System.

92. SQN Calculation, SQN APS2037 "Analysis of Inadvertent Containment Spray."

93. SQN Drawing Series, 46W501 "Architectural ABSCE Boundary"

TABLE 6.2.1-1 (Sheet 1)

GENERAL INFORMATION RELATED TO CONTAINMENT

I.	General Information	
A.	Design pressure, psig	12
B.	Design temperature, °F	327
C.	Free volume, ft^3	1,186,920
D.	Design and maximum allowable leak rates, %/day	0.25
II.	Initial Conditions	
A.	Reactor Coolant System (at design overpower of 100.7% and at normal liquid levels)	
	1. Reactor power level, mwt	3,479.2
	2. Average coolant temperature, °F	578.2
	3. Mass of Reactor Coolant System liquid, lbm	538,640
	4. Mass of Reactor Coolant System liquid, lbm	4660
	5. Liquid plus steam energy, BTU (relative to 32°F)	334.6×10^6
B.	Containment	
	1. Normal pressure, psig	0
	2. Normal inside temperature, °F	
	- upper compartment	85
	- lower compartment	100
	- ice condenser	15
	3. Outside temperature, °F	Not applicable
	4. Average relative humidity, %	30
	5. Maximum essential raw water temperature, °F	87
	6. Maximum refueling water temperature (if applicable), °F	105
	7. Initial ice mass (min.), lb	1.916×10^6
C.	Stored Water (as applicable)	
	1. Refueling water storage tank, gal	375,000
	2. Quench spray tank, ft^3	Not applicable
	3. Four safety injection accumulators, ft^3)	4,372 maximum 4,253 minimum per unit
	4. Condensate storage tanks, ft^3	106,337 total of two tanks for both units
III.	The Design Basis Accident	
	See Figures 6.2.1-15, 6.2.1-16, 6.2.1-17, 6.2.1-18, and 6.2.1-19	
IV.	Mass and Energy Addition Tables	
	See Tables 6.2.1-13, 6.2.1-15, and 6.2.1-18	

TABLE 6.2.1-1 (Sheet 2)

GENERAL INFORMATION RELATED TO CONTAINMENT

V. Passive Heat Sinks - Upper Compartment

Structure	Heat Transfer Area (ft^2)	Thickness and Material (As Noted)	Thermal Conductivity (BTU/ft hr F)	Volume Heat Capacity (BTU/ft^3 F)

GENERAL INFORMATION RELATED TO CONTAINMENT

VI. Engineered Safety Systems Information	Full Capacity	Value Used for Containment Analysis
A. Passive Safety Injection Systems		
1. Low-pressure Accumulators		
a. Number of accumulators	4	4
b. Volume of water injected, ft^3 each minimum	1,103	1,103
c. Minimum pressure, psig	624	600
B. Active Safety Injection Systems		
1. High-pressure Safety Injection		
a. Number of injection lines	4	4
b. Number of pumps (centrifugal charging)	2	1
c. Flow rate, gpm each	150	600.7
2. Intermediate Pressure Safety Injection		
a. Number of injection lines	4	4
b. Number of pumps (safety injection)	2	1
c. Flow rate, gpm each	425	597
3. Low-pressure Safety Injection (RHR)		
a. Number of injection lines	4	4
b. Number of pumps	2	1
c. Flow rate, gpm each	4,500	Varies
C. Containment Spray Subsystems		
1. Containment Spray		
a. Number of lines	2	1
b. Number of pumps	2	1
c. Number of headers	2	1
d. Flow rate, gpm each header	4,750	4,750

TABLE 6.2.1-1 (Sheet 6)

GENERAL INFORMATION RELATED TO CONTAINMENT

			Full Capacity	Value Used for Containment Analysis

VI. Engineered Safety Systems Information	Full Capacity	Value Used for Containment Analysis
h. Source of cooling water	ERCW	ERCW
i. Flow begins, seconds	226 (maximum)	250
3. Component Cooling Water		
a. Type	Plate	Shell & Tube* (Split flow)
b. Number (per train)	2	1
c. Heat exchanger surface area, ft^2 per train	6,135	16,163
d. Tube plugging, % each	0	15
e. Heat transfer capacity, 10^6 BTU/hr per train	89.7	32.55
f. Heat transfer coefficient (UA) 10^6 BTU/hr-°F each, shell and tube heat exchangers modeled with 5% tube plugging, maximum fouling factor, and a split flow correction factor of 0.72		
Plate heat exchanger (per pair)	4.05	2.793 (Modeled as counterflow type heat exchanger)
g. Flow rates		
1. Tubeside (ERCW), gpm each	10,000	4,000
2. Shellside, (CCS) gpm each	8,000	5,000
h. Source of Cooling Water	ERCW	ERCW

NOTES: 1. Full capacity refers to rated condition.

* Values used for containment analysis are based on shell and tube heat exchangers. These have been replaced by plate heat exchangers whose values bound the shell and tube heat exchangers.

TABLE 6.2.1-2

SECONDARY CONTAINMENT CHARACTERISTICS

I. Shield Building

A. Annulus air volume: 375,000 Ft^3

B. Allowable inleakage rate at 0.5 in. wg.: 500 cfm

C. Recirculation EGTS fans*

1. Number: 2
2. Type: Centrifugal
3. Air flow rate: 4000 cfm each at 11 in. wg
4. Filters in EGTS air cleanup system:

Type	Banks/Train	Number/Bank	Number/Train	Total Number
Prefilter	1	2	2	4
HEPA	2	4	8	16
Carbon	2	12	24	48

D. Annulus Vacuum Exhaust fans**

1. Number: 4 (2 for each reactor unit)
2. Type: Centrifugal
3. Air flow rate: 1000 cfm each at 6.5 in. wg

II. Auxiliary Building

A. Free volume: 3,480,000 Ft^3

B. Exhaust fans (Auxiliary Building Gas Treatment System)

1. Number: 2
2. Type: Centrifugal
3. Air flow rate: 9000 cfm at 8 in. Wg
4. Filters

Type	Banks/Train	Number/Train	Total Number
Prefilter	1	9	18
HEPA	1	9	18
Carbon	1	27	54

*The fans described are the air cleanup subsystem fans in the Emergency Gas Treatment System that operate only in the postaccident period.

**The fans described are the annulus vacuum control fans in the Emergency Gas Treatment System that operate only during nonaccident operations.

Key Assumptions

-18 month fuel cycle
-Standard and V5H fuel
-End of Cycle Core Average Burnup of 52,687 Mwd/MTU
-Low bound for enrichment: 3.0%

* Total decay heat found by multiplying the fractions from above by the reactor power.

TABLE 6.2.1-9

ENERGY ACCOUNTING

	Approx† End of Blowdown (t = 10.0 Seconds)	Approx†† End of Reflood (t = 216.0 Seconds)
		(In Millions of Btus)
Ice Heat Removal	195.86	244.4
Structural Heat Sinks*	18.05	61.74
RHR Heat Exchanger Heat Removal*	0.00	0.00
Spray Heat Exchanger Heat Removal*	0.00	0.00
Energy Content of Sump	183.7	235.6
Ice Melted (Pounds)(10^6)	0.632	0.8266

*Integrated Energies

† End of Blowdown is redefined in LOTIC-1 to occur at 10 seconds, per results from the Waltz Mil Ice condenser test.

†† The approximate time is the time closest to the event that is captured in the LOTIC-1 code major print out. Table 6.2.1-21 provides the actual sequence of events

TABLE 6.2.1-10

ENERGY ACCOUNTING

	Approximate† Time of Ice Melt Out (t=3363 Seconds)	Approximate† Time of Peak Pressure (t=6983 Seconds)
	(In Millions of Btus)	
Ice Heat Removal	516.45	516.45
Structural Heat Sinks*	79.795	121.440
RHR Heat Exchanger Heat Removal*	16.085	45.919
Spray Heat Exchanger Heat Removal*	4.165	69.33
Energy Content of Sump	623.99	651.71
Ice Melted (Pounds)(10^6)	1.916	1.916

*Integrated Energies

† - The approximate time is the time closest to the event that is captured in the LOTIC-1 code major printout. Table 6.2.1-21 provides the actual sequence of events.

TABLE 6.2.1-12

ALLOWABLE LEAKAGE AREA FOR VARIOUS REACTOR COOLANT SYSTEM BREAK SIZES

Break Size	5 ft^2 Deck Leak Air Compression Peak (psig)	Deck Leakage Area (ft^2)	Resultant Peak Containment Pressure (psig)
Double-ended	7.8	54	12.0
0.6 Double-ended	6.6	40	12.0
3 ft^2	6.25	46	12.0
10 inch diameter	5.75	38	12.0
10 inch diameter*	5.75	50	10.7*
6 inch diameter	5.5	41	12.0
6 inch diameter*	5.5	50	10.0*
2 inch diameter	5.0	50	5.0
2 inch diameter*	4.0	50	4.2*
1/2 inch diameter	3.0	>50	3.0

* This case assumes upper compartment structural heat sink steam condensation of 6 lb/sec and 30 percent of deck leakage is air.

Note: One spray at 4750 gpm at 100°F was assumed for all breaks smaller than the 3 ft^2 break.

TABLE 6.2.1-33

SEQUOYAH ICE CONDENSER DESIGN PARAMETERS
REACTOR CONTAINMENT VALUE (NET FREE VOLUME)
USED FOR CONTAINMENT TEMPERATURE ANALYSIS

Upper Compartment, ft^3	651,000
Ice Condenser, ft^3	
Lower Plenum	24,200
Ice Bed	86,300
Upper Plenum	47,000
Lower Compartment (active), ft^3	289,000
Total Active Volume, ft^3	1,097,590
Lower Compartment (dead ended), ft^3	94,000
Total Containment Volume, ft^3	1,191,500
Ice Condenser Parameters	
Weight of Ice in Condenser, lb.	$2.45\ 10^6$ *

* This ice mass is a historical value that was the current value when the analysis of record was completed. Moderate changes to the ice mass do not adversely affect the Containment Temperature Analysis as there is not enough energy on the secondary side to melt-out the ice bed and peak containment temperature resulting from a steamline break is primarily sensitive to enthalpy in the blow-down. (Reference 89)

TABLE 6.2.1-39 (Sheet 1)

CONTAINMENT DATA
MINIMUM CONTAINMENT BACKPRESSURE ANALYSIS

I. Conservatively High Estimate of Containment Net Free Volume

CONTAINMENT VOLUME IN FT^3

Upper Compartment	651,000
Lower Compartment	271,000
Ice Condenser	181,000
Dead End Compartments (Include all accumulator rooms, both fan compartments, instrument room, pipe tunnel)	130,000
	1,233,000

II. Initial conditions

A.	Containment Pressure	15.0 psia
B.	Lowest Operational Containment Temperature for the Upper, Lower and Dead Ended Compartments	85°F 100°F
C.	High Refueling Water Storage Tank Temperature	100°F
D.	Lowest Temperature Outside Containment	5°F
E.	High Initial Spray Temperature	100°F
F.	Lowest Annulus Temperature	40°F

III. Structural Heat Sinks**

A. For Each Surface

1. Description of Surface
2. Conservatively High Estimate of Area Exposed to Containment Atmosphere — See Table 6.2.1-1
3. Location in Containment by Compartment

TABLE 6.2.1-39 (Sheet 2)

CONTAINMENT DATA
MINIMUM CONTAINMENT BACKPRESSURE ANALYSIS

B.	For Each Separate Layer of Each Surface	
	1. Material	
	2. Conservatively Large Estimate of Layer Thickness	See Table 6.2.1-1
	3. Conservatively High Value of Material Conductivity	See Table 6.2.1-1
	4. Conservatively High Value of Volumetric Heat Capacity	See Table 6.2.1-1
IV.	Spray System	
A.	Runout Flow for a Spray Pump*** (Containment Spray)	7700 gpm
B.	Number of Spray Pumps Operating with No Diesel Failure	2/Unit
C.	Number of Spray Pumps Operating with One Diesel Failure	1/Unit
D.	Assumed Post Accident Initiation of Spray System	25 secs.
V.	Deck Fans	
A.	Fastest Post Accident Initiation of Deck Fans	10 mins.
B.	Conservatively High Flow Rate per Fan	42,000 cfm
VI.	Conservatively Low Hydrogen Skimmer System Flow Rate	100/ea cfm

** Structural Heat Sinks should also account for any surfaces neglected in Containment Integrity Analysis.

*** Runout flow is for a break immediately downstream of the pump. In that event, the spray water will not enter the containment.

TABLE 6.2.1-40

MAXIMUM REVERSE DIFFERENTIAL PRESSURE SENSITIVITY ANALYSIS
BASE CASE

Westinghouse ECCS Structural Heat Transfer Model

Hot Sprays at Runout Flow

Minimum Containment Temperature

Dead Ended Volume is swept

Max Reverse Differential Pressure = 0.65 psi

Case	Variable	Change in Max ΔP (psi)
1.	Ice condenser flow through the drains acts as 50 percent thermal efficient spray when flow stops into ice condenser	+0.2
2.	Same as Case 1, except 100 percent thermal efficiency	+0.4
3.	Maximum containment temperature	-0.2
4.	Heat transfer coefficient to sump equals 5 times H_{MAX}	Less than 0.1
5.	Same as Case 2, except drain flowrate times 1.5	+0.6
6.	Combination of Cases 2 and 4	+0.4
7.	1 bay of ice condenser doors remains open	-0.65
8.	Same as Case 6 except Equation (3) written as $H = H_{stag} + [H_{max} - H_{stag}]\, e^{-.025[t-tp]}$	+.55
9.	Same as Case 6 except 5 times upper to lower resistance	+2.0

TABLE 6.2.2-1

CONTAINMENT SPRAY PUMP DESIGN PARAMETERS

Characteristic	Data
Quantity Per Unit	2
Design Pressure, psig	300
Design Temperature Degree, °F	250
Design Flow Rate, gpm	4,750
Design Head, ft	374

Note: The pump motors are direct coupled and nonoverloading to the end of the pump curve.

TABLE 6.2.2-2

CONTAINMENT SPRAY HEAT EXCHANGER DESIGN PARAMETERS

Characteristic	Data
Quantity Per Unit	2
Type	Shell and Tube (Counterflow)
Heat Transfer Per Unit, BTU Per Hour	95×10^6
Flow Shell Side, gpm	6,028
Flow Tube Side, gpm	4,750
Tube Side Inlet Temperature, °F	146
Shell Side Inlet Temperature, °F	83
Tube Side Outlet Temperature, °F	106
Shell Side Outlet Temperature, °F	115
Design Pressure Shell Tube, psig	150/300
Design Temperature Shell Tube, °F	200/300

TABLE 6.2.2-3

REDUNDANCY AND INDEPENDENCE

Component	Malfunction	Comments and Consequences
Spray Nozzles	Clogged	The large number of nozzles makes the clogging of a significant number of nozzles incredible.
Spray Pump	Stops running or fails to start	Two 100 percent capacity pumps provide redundancy.
Heat Exchangers	Tube leak	Two 100 percent capacity heat exchangers provide redundancy.
Valve	Fails to open	Two 100 percent flow paths

C.3.h	Yes	---			

Notes:

1. The Emergency Gas Treatment System is designed to withstand conditions resulting from the design basis LOCA.

2. The design is consistent with assumptions found in Regulatory Guide 1.4; Regulatory Guides 1.3 and 1.25 are not applicable.

3. No significant pressure surges to this system are envisioned resulting from the design basis LOCA. Thus, the system needs no special protection features to offset pressure surges.

TABLE 6.2.3-1 (Sheet 2)
(Continued)

REGULATORY GUIDE 1.52 (REV 2) SECTION APPLICABILITY
FOR THE EMERGENCY GAS TREATMENT SYSTEM

4. Compliance with this section is not required since the system was designed and fabricated well before publication of the regulatory guide.

5. There are no outdoor air intakes associated with the Emergency Gas Treatment System.

6. No enhancement in safety is foreseen by utilizing low leakage ducting in this system. Any leakage which occurs inside the Shield Building would eventually re-enter the Emergency Gas Treatment System and be processed. No leakage is foreseen to the Auxiliary Building from the ducting between the Shield Building and the filter housing since air inside the duct will be at a lower pressure than the surroundings. If any leakage did occur to the Auxiliary Building, it would be processed by the Auxiliary Building Gas Treatment System before release to the atmosphere. Leakage from ducting on the downstream side of the filter housing would cause no problem since it would have been cleaned by the Emergency Gas Treatment System filters and absorbers.

7. Compliance with this section is not required since the system was designed and fabricated before the present revision of 1.52 (Rev. 2).

8. Water sprays are provided, also the capability is provided to cool an inactive unit which is loaded with radioactive material and to limit the temperature rise from radioactivity induced heat and thus prevent auto ignition of the charcoal.

9. Compliance with ANSI N510 is not required since the system was designed and fabricated well before publication of the ANSI document. However, the system (i.e., filter banks) will be tested using the procedures outlined in ANSI N510.

10. Compliance with ANSI N509 is not required since the system was designed and fabricated well before publication of the ANSI document. The system met this section of Reg. Guide 1.52 at the time of design and fabrication. However, whenever possible parts or components which are replaced, the replacement parts and components will comply fully with the latest issue of ANSI N509.

11. Compliance with this section is not required since charcoal filter testing is performed in accordance with ASTM D3803-1989, “Standard Test Method for Nuclear-Grade Activated Carbon,” in order to provide assurance for complying with the current licensing basis, per NRC Generic letter 99-02, “Laboratory Testing of Nuclear-Grade Activated Charcoal.”

12, Compliance with this section is not required based on the calculated low relative humidity (<70%) inlet air entering the EGTS filter housing air cleanup units during accident conditions. Reference EDC E21761A and EN DES calculation TI-ECS-98, Rev. 1 (B45 860324 236).

13. The position is met except that demister pads are not provided. See Note 12 for demisters requirements.

14. Compliance with this section is not required due to changes made by the Improved Technical Specifications (ITS) license amendment request (LAR) and acknowledged in the associated NRC safety evaluation report. The system met this section of RG 1.52 at the time of design and fabrication. However, the ITS LAR revised the required run time from 10 hours to fifteen minutes. The NRC endorsed licensee control of the monthly frequency requirement through approval of the use of the Surveillance Frequency Control Program.

Notes:

1. The postulated DBA for the Auxiliary Building Gas Treatment System is the design basis LOCA.

2. The design is consistent with assumptions found in Regulatory Guide 1.4.

TABLE 6.2.3-2 (Sheet 2)
(Continued)

REGULATORY GUIDE 1.52 (REV 2) SECTION APPLICABILITY
FOR THE AUXILIARY BUILDING GAS TREATMENT SYSTEM

3. Compliance with this system is not required since the system was designed and fabricated well before publication of the regulatory guide.

4. The position is met except that demisters are not provided and there are not HEPA filters downstream of the carbon absorbers.

5. No significant pressure surges to this system are envisioned resulting from the design basis LOCA. Thus the system needs no special protection features to mitigate pressure surges.

6. It would be possible to remove the unit intact but not practical. The need to do so is considered to be negligible.

7. Low leakage would not enhance the safety of the system since any leakage that occurs will eventually be routed back to the ABGTS and be processed before being released to the atmosphere. Leakage from the ABSCE to the atmosphere will be negligible since it is maintained at a negative pressure with respect to the atmosphere.

8. Compliance with ANSI N509 is not required since the system was designed and fabricated well before publication of the ANSI document. However, the system will be tested, whenever possible, using the procedures outlined in ANSI N509.

9. Demisters are not provided in the system.

10. Compliance with this section is not a licensing requirement.

11. Compliance with ANSI N510 is not required since the system was designed and fabricated well before publication of ANSI document. However, the system will be tested using the procedures outlined in ANSI N510.

12. Compliance with this section is not required since charcoal filter testing is performed in accordance with ASTM D3803-1989, “Standard Test Method for Nuclear-Grade Activated Carbon,” in order to provide assurance for complying with the current licensing basis, per NRC Generic letter 99-02, “Laboratory Testing of Nuclear-Grade Activated Charcoal.”

13. Compliance with this section is not required due to changes made by the Improved Technical Specifications (ITS) license amendment request (LAR) and acknowledged in the associated NRC Safety evaluation report. The system met this section of RG 1.52 at the time of design and fabrication. However, the ITS LAR revised the required run time from 10 hours to fifteen minutes. The NRC endorsed licensee control of the monthly frequency requirement through approval of the use of the Surveillance Frequency Control Program.

TABLE 6.2.6-1

DATA TABLE FOR THE VACUUM RELIEF SYSTEM

Design Basis:	
Maximum containment external pressure differential	0.5 psid
Maximum shield building external pressure differential	2.0 psid
Design Parameters:	
Upper compartment free volume	651,000 ft^3
Lower compartment free volume	253,114 ft^3
Ice condenser free volume	110,521 ft^3
Dead end compartment free volume	129,900 ft^3
Upper ice plenum free volume	54,940 ft^3
Annulus space free volume	375,000 ft^3
Number of containment spray headers	2
Flow rate for each containment spray header	4,750 gpm
Distance between spray headers and upper deck	152 feet
Number of air return fans	2
Flow rate for each air return fan	40,000 cfm
Maximum initial upper compartment dry bulb temperature	110 °F
Maximum initial lower compartment dry bulb temperature	120 °F
Minimum initial upper compartment relative humidity	4 percent
Minimum containment spray water temperature	60 °F
Ice condenser temperature (dry air)	15 °F
Set pressure of ice condenser doors connected to the upper and lower compartment	1 psf
Resultant Design:	
Number of steel containment vacuum relief units	3 (1 redundant)
Maximum initial external pressure differential on the containment (containment vacuum relief system set pressure)	0.1 psid
Design flow rate of each containment vacuum relief unit at 0.5 psid	28 lb_m/sec
Maximum response time for any unit to be fully open for a design basis event	2.2 sec

6.3 EMERGENCY CORE COOLING SYSTEM

The Emergency Core Cooling System (ECCS) is discussed in detail in this section. For additional information on the ECCS see the following sections:

1. Compliance with the Interim Acceptance Criteria is discussed in Subsection 15.4.1.
2. Components which are necessary following a postulated Loss-of-Coolant Accident (LOCA) over the entire range of break sizes are discussed in Sections 15.3 and 15.4.
3. External forces and their effect on the operation of the ECCS are treated in Sections 3.7 and 3.9.
4. Pre-operational system testing is discussed in Chapter 14.
5. The actuation of the ECCS following a LOCA is discussed in detail in Section 7.3.
6. Instrumentation available to the operator to monitor conditions after a LOCA is found in Section 7.5.
7. Testing intervals are discussed in the SQN Technical Specifications.

6.3.1 Design Bases

6.3.1.1 Range of Coolant Ruptures and Leaks

The Emergency Core Cooling System is designed to cool the reactor core as well as to provide additional shutdown capability following initiation of the following accident conditions:

1. A pipe break or spurious valve lifting in the Reactor Coolant System (RCS) which cause a discharge larger than that which can be made up by the normal makeup system, up to and including the instantaneous circumferential rupture of the largest pipe in the RCS.
2. Rupture of a control rod drive mechanism causing a rod cluster control assembly ejection accident.
3. A pipe break or spurious valve lifting in the secondary system, up to and including the instantaneous circumferential rupture of the largest pipe in the secondary system.
4. A steam generator tube rupture.

The analysis and acceptance criteria for the consequence of each of these accidents is described in Chapter 15 in the respective accident analyses sections.

6.3.1.2 Fission Product Decay Heat

The primary function of the Emergency Core Cooling System following a loss of coolant accident is to remove the stored and fission product decay heat from the reactor core such that fuel rod damage, to the extent that it would impair effective cooling of the core, is prevented.

6.3.1.3 Reactivity Required for Cold Shutdown

The Emergency Core Cooling System provides shutdown capability for the accidents listed above by means of chemical poison (boron) injection. The most critical accident for shutdown capability is the steam line break.

6.3.1.4 Capability to Meet Functional Requirements

In order to ensure that the Emergency Core Cooling System will perform its desired function during the accidents listed above, it is designed to tolerate a single active failure during the short term immediately following an accident, or to tolerate a single active or passive failure during the long term following an accident. This subject is detailed in Section 3.1.

The Emergency Core Cooling System is designed to meet its minimum required level of functional performance with onsite emergency diesel power system operation (assuming offsite power is not available) or with offsite electrical power system operation (assuming onsite power is not available) for any of the above abnormal occurrences assuming a single failure as defined above. During shutdown conditions, full ECCS capability may not be available. Operator action is utilized to initiate ECCS as required.

The Emergency Core Cooling System is designed to perform its function of ensuring core cooling shutdown capability following an accident under simultaneous safe shutdown earthquake loading. The seismic requirements are defined in Chapter 3.

6.3.2 System Design

6.3.2.1 Schematic Piping and Instrumentation Diagrams

A flow diagram of the Emergency Core Cooling System is shown in Figure 6.3.2-1. The SIP logic is provided in Figure 6.3.2-2. The CCP logic is on Figure 9.3 4-5.The RHR pump logic is on Figure 5.5.7-2. The safety injection signals and their logic is presented in Figure 7.2.1-1 (sheet 8).

6.3.2.2 Equipment and Component Design

Pertinent design and operating parameters for the components of the ECCS are given in Table 6.3.2-1. The codes and standards to which the individual components of the Emergency Core Cooling System are designed, are listed in Table 3.2.1-2.

The component design and operating conditions are specified as the most severe conditions to which each respective component is exposed during either normal plant operation, or during operation of the Emergency Core Cooling System. For each component, these conditions are considered in relation to the code to which it is designed. By designing the components in accordance with applicable codes, and with due consideration for the design and operating conditions, the fundamental assurance of structural integrity of the ECCS components is maintained. Components of the ECCS are designed to withstand the appropriate seismic loadings in accordance with their class as given in Table 3.2.1-2.

Cold Leg Injection Accumulators

These accumulators are pressure vessels filled with borated water and pressurized with nitrogen gas. During normal operation each accumulator is isolated from the RCS by two check valves in series. Should the RCS pressure fall below the accumulator pressure, the check valves open and borated water is forced into the RCS. One accumulator is attached to each of the cold legs of the RCS. Mechanical operation of the swing-disc check valves is the only action required to open the injection path from the accumulators to the core via the cold leg.

Connections are provided for remotely adjusting the level and boron concentration of the borated water in each accumulator during normal plant operation as required. Accumulator water level may be adjusted either by draining to the reactor coolant drain tank or by pumping borated water from the refueling water storage tank to the accumulator using the safety injection pump.

Accumulator pressure is provided by supplying a blanket of nitrogen gas in the accumulator tank, and can be adjusted as required during normal plant operation; however, the accumulators are normally isolated from the source of this nitrogen supply. Gas relief valves on the accumulators protect them from pressures in excess of design pressure.

The accumulators are located within the containment but outside of the secondary shield wall which protects them from missiles. Since the accumulators are located within the containment, a release of the nitrogen gas in the accumulators would cause an increase in normal containment pressure. Containment pressure increase following release of the gas from all accumulators has been calculated and is well below the containment pressure setpoint for ECCS actuation.

Release of accumulator gas would be detected by the accumulator pressure indicators and alarms. Thus the operator could take action promptly as required to maintain plant operation within the requirements of the SQN Technical Specification covering accumulator operability.

Injection Tank

The injection tank contains normal RCS water and is connected to the discharge of the centrifugal charging pumps. Upon actuation of the safety injection signal, the charging pumps provide flow through the tank into the RCS when the isolation valves open.

The injection tank incorporates a sparger type inlet which distributes the incoming boric acid in a 360 degree fan as it enters the tank. Any leakage into the tank will be detected by a pressure indicator.

Pumps

Residual Heat Removal Pumps

Residual heat removal pumps are provided to deliver water from the refueling water storage tank or the containment sump to the RCS should the RCS pressure fall below their shutoff head. Each residual heat removal pump is a single stage, vertical position, centrifugal pump. It has an integral motor-pump shaft, driven by an induction motor. The unit has an external mechanical seal cooling system. Component cooling water is the mechanical seal heat exchange medium. A minimum flow bypass line is provided for the pumps to recirculate through the residual heat exchangers and return the cooled fluid to the pump suction should these pumps be started with their normal flow paths blocked. Once sufficient flow is established to the RCS, the bypass line is automatically closed. This line prevents deadheading the pumps and permits pump testing during normal operation.

The residual heat removal pumps are also discussed in Subsection 5.5.7.

Centrifugal Charging Pumps

These pumps deliver water from the refueling water storage tank through the injection tank to the RCS at the prevailing RCS pressure. Each centrifugal charging pump is a multistage, diffuser design, barrel type casing with vertical suction and discharge nozzles. The pump is driven through a speed increaser connected to an induction motor. The unit has a self contained lubrication system, and mechanical seal cooling system. Component cooling water is the normal heat exchange medium for the mechanical seals and ERCW cools the lube oil heat exchanger. The centrifugal charging pump seals are designed with a secondary safety bushing that limits leakage from the pumps in the event of a loss of CCS seal failure. This allows the pumps to continue operation without CCS and after pump seal failure. Credit for centrifugal charging pump operation in this condition is assumed in the Sequoyah Probability Risk Assessment for reactor coolant pump seal integrity. This condition is applicable only to John Crane mechanical seals (Type 1B-RS).

A minimum flow bypass line is provided on each pump discharge to recirculate flow to the pump suction after cooling in the seal water heat exchanger, if required, to protect the pumps at the shutoff head. The minimum flow bypass line contains two isolation valves in series. These

valves have been de-energized and are open. The charging pumps may be tested during normal operation through the use of the minimum flow bypass line. The centrifugal charging pumps are also discussed in Subsection 9.3.4.

Safety Injection Pumps

The safety injection pumps deliver water from the refueling water storage tank after the RCS pressure is reduced below their shutoff head. Each safety injection pump is a multistage, centrifugal pump. The pump is driven directly by an induction motor. The unit has a self contained lubrication system, and mechanical seal cooling system. ERCW cools the lube oil heat exchanger and CCS cools the mechanical seals.

A minimum flow bypass line is provided on each pump discharge to recirculate flow to the refueling water storage tank in the event the pumps are started with the normal flow paths blocked. This line also permits pump testing during normal operation. Two motor operated valves in series are provided in this line. These valves are closed by operator action during the recirculation mode.

Residual Heat Exchangers

The residual heat exchangers are conventional shell and U-tube type units. During normal operation of the Residual Heat Removal System, reactor coolant flows through the tube side while component cooling water flows through the shell side. During emergency core cooling recirculation operation, water from the containment sump flows through the tube side. The tubes are seal welded to the tubesheet.

A further discussion of the residual heat exchangers is found in Subsection 5.5.7.

Valves

Design features employed to minimize valve leakage include:

1. Where possible, packless valves are used.
2. Globe valves are installed with recirculation fluid pressure under the seat to prevent leakage of recirculated (radioactive) water when the valves are closed.
3. Relief valves have totally enclosed bonnets. Relief valve discharges are piped to a collection system except for the accumulator relief valves (in the N_2 space of each accumulator) which discharge to the containment atmosphere.
4. Control and motor-operated valves, 2 inches and above, exposed to recirculate flow may have double packed stuffing boxes and stem leakoff connections piped where possible to the Waste Processing System. Some valves may have their leakoff line connections plugged after packing has been upgraded with graphite packing rings. These new configurations and materials provide improved sealing abilities to reduce the possibilities of stem leakage.

Motor Operated Gate Valves

The seating design of all motor operated gate valves is of the parallel disc design or the flexible wedge design. These designs aid in releasing the mechanical holding force during the first increment of travel so that the motor operator is assisted in opening. The discs are guided throughout the full disc travel to prevent chattering and to provide ease of gate movement. The seating surfaces are hard faced to prevent galling and to reduce wear.

Where a gasket is employed for the body to bonnet joint, it is a fully trapped, controlled compression, spiral wound gasket with provisions for seal welding. Valve stuffing boxes' original design is a lantern ring leakoff connection with a minimum of a full set of packing below

the lantern ring and a minimum of a one-half set of packing above the lantern ring. A full set of packing is defined as a depth of packing equal to 1-1/2 times the stem diameter. Some valves may have their leakoff line connections plugged after packing has been upgraded with graphite packing rings. These new configurations and materials provide improved sealing abilities to reduce the possibilities of stem leakage.

The motor operator incorporates a "hammer blow" feature that allows the motor to attain its operational speed prior to being subjected to operational loads.

Manual Globes, Gates, and Check Valves

Gate valves are either wedge design or parallel disc and are straight through. The wedge is either split or solid. All gate valves have backseat and outside screw and yoke.

Globe valves, "T" and "Y" style are full ported with outside screw and yoke construction.

Check valves are spring loaded lift piston types for sizes 2 inches and smaller, and swing type for size 3 inches and larger. Stainless steel check valves have no penetration welds other than the inlet, outlet and bonnet. The check hinge is serviced through the bonnet.

The stem packing and gasket of the stainless steel manual globe and gate valves are similar to those described above for motor operated valves. Carbon steel manual valves are employed to pass non-radioactive fluids only and therefore do not contain the double packing and seal weld provision.

Diaphragm Valves

The diaphragm valves use the diaphragm member for shutoff with even weir bodies. These valves are used throughout the ECCS where pressures and temperatures permit.

Accumulator Check Valves

The low pressure accumulator check valves are designed with a low pressure drop configuration with all operating parts contained within the body.

Design considerations and analyses which assure that leakage across all the check valves located in each accumulator injection line will not impair accumulator availability are as follows:

1. During normal operation the differential pressure is approximately 1635 psid for the check valves in the cold leg lines. Since the valves remain in this position except when tested or when called upon to function, they are not subject to the abuses of flow operation or impact loads caused by sudden flow reversal and seating. They do not experience significant wear of the moving parts and hence are expected to function with minimal leakage.

2. When the RCS is being pressurized during the normal plant heatup operation, the check valves are tested for leakage in accordance with Technical Specifications. This test confirms the seating of the disc.

3. The experience derived from the check valves employed in the emergency injection systems indicate that the system is reliable and workable. This is substantiated by the satisfactory experience from operation of the Ginna and subsequent plants where the usage of check valves is identical to this application.

Relief Valves

The accumulator relief valves are sized to pass nitrogen gas at a rate in excess of the accumulator gas fill line delivery rate. The relief valves will also pass water in excess of the

expected accumulator in leakage rate, but this is not considered to be necessary, because the time required to fill the gas space gives the operator ample opportunity to correct the situation. Other relief valves are installed in various sections of the ECCS to protect lines which have a lower design pressure than the RCS. Some relief valves discharge to the pressurizer relief tank. The valve stem and spring adjustment assembly are isolated from the system fluids by a bellows seal between the valve disc and spindle.

Butterfly Valves

Each main residual heat removal line has an air-operated butterfly valve which is normally open and is designed to fail in the open position. These valves are left in the full open position during normal operation to maximize flow from this system to the RCS during the injection mode of the ECCS operation.

Throttle Valves

The correct position of each mechanical stop shall be verified within 4 hours following action of each valve stroking operation or maintenance on the valve when the ECCS subsystems are required to be operable for the following ECCS throttle valves: Charging Pump Injection Throttle Valves (63-582,63-583, 63-584, and 63-585) Safety Injection Cold Leg Throttle Valves (63-550, 63-552, 63-554, and 63-556) and Safety Injection Hot Leg Throttle Valves (63-542, 63-544, 63-546, and 63-548)

Piping

All piping joints are welded except for pump connections, butterfly valves, relief valves, orifice plate flange connections, and flanged connections for maintenance.

Weld connections for pipes sized 2-1/2 inches and larger are butt welded. Reducing tees are used where the branch size exceeds one-half of the header size. Branch connections of sizes that are equal to or less than one-half of the header size conform to the ANSI B31.1.0-1967 Edition Code. Branch connections 1/2 through 2 inches are attached to the header by means of full penetration welds, using pre-engineered integrally reinforced branch connections.

Minimum piping and fitting wall thickness as determined by ANSI B31.1.0-1967 Edition formula are increased to account for the manufacturer's permissible tolerance of minus 12-1/2 percent on the nominal wall and an appropriate allowance for wall thinning on the external radius during any pipe bending operations in the shop fabrication of the subassemblies.

To assure that air pockets, which may cause disruptive water hammer and/or pump binding, are eliminated from the ECCS, vent valves have been located at high points throughout the system. The use of these valves when filling will ensure a solid system from the suction valves at the containment sump to the inlet valve to the containment spray header. The piping from the containment sump to the suction valve is normally maintained dry and have been designed to be self venting. The RHR spray header is maintained with a 30 day water seal for 10CFR50 Appendix J. The spray header is also self venting.

Once the system is filled, a positive static pressure provided by the RWST precludes the leaking of air into the system.

Leak detection is discussed in Sections 5.2.7 and 6.3.2.11.

System Operation

The operation of the ECCS following a Loss of Coolant Accident, can be divided into two distinct modes:

1. The injection mode in which any reactivity increase following the postulated accidents is terminated, initial cooling of the core is accomplished, and coolant lost from the primary system in the case of a LOCA is replenished, and

2. The recirculation mode in which long term core cooling is provided during the accident recovery period.

A discussion of these modes follows.

Break Spectrum Coverage

The principal mechanical components of the ECCS which provide core cooling immediately following a loss of coolant accident are the accumulators, the safety injection pumps, the centrifugal charging pumps, the residual heat removal pumps, refueling water storage tank, injection tank, and the associated valves, and piping.

For large pipe ruptures, the RCS would be depressurized and voided of coolant rapidly, and a high flow rate of emergency coolant is required to quickly cover the exposed fuel rods and limit possible core damage. This high flow is provided by the passive cold leg accumulators, the charging pumps, safety injection pumps, and the residual heat removal pumps discharging into the cold legs of the RCS. The residual heat removal and safety injection pumps deliver into the accumulator injection lines, between the two check valves, during the injection mode. The charging pumps deliver through the injection tank directly into the cold legs during the injection mode.

Emergency cooling is provided for small ruptures primarily by the high head injection pumps. Small ruptures are those, with an equivalent diameter of 6 inches or less, which do not immediately depressurize the RCS below the accumulator discharge pressure. The centrifugal charging pumps deliver borated water at the prevailing RCS pressure to the cold legs of the RCS. During the injection mode, the charging pumps take suction from the refueling water storage tank.

The safety injection pumps also take suction from the refueling water storage tank and deliver borated water to the four cold legs of the RCS. The safety injection pumps begin to deliver water to the Reactor Coolant System after the pressure has fallen below the pump shutoff head.

The residual heat removal pumps take suction from the refueling water storage tank and deliver borated water to the four RCS cold legs. These pumps begin to deliver water to the RCS only after the pressure has fallen below the pump shutoff head. The RHR system is designed such that there are four injection legs for ECCS operation. As such, a minimum of one RHR pump must provide flow to all four RCS cold legs during the injection mode (when RCS pressure has decreased).

Core protection is afforded with the minimum engineered safety feature equipment. The minimum engineered safety feature equipment is defined by consideration of the single failure criteria as discussed in Section 3.1. The minimum design case will ensure the entire break spectrum is accounted for and core cooling is met.

For large RCS ruptures, the accumulators and the active high head and low head pumping components serve to complete the core refill. If the break is small (6 inch equivalent diameter or less), the accumulators with one charging pump and one safety injection pump ensure adequate cooling during the injection mode. Long term recirculation requires one residual heat removal pump and components of the auxiliary heat removal systems which are required to transfer heat from the ECCS (e.g., Component Cooling System and Essential Raw Cooling Water System).

Certain deviations (i.e., reduced component availability) to the normal operating status as given in Table 6.3.2-3 of the ECCS are permissible without impairing the ability of the ECCS System to provide adequate core cooling capability. Accordingly, Technical Specifications have been established to cover these limiting conditions for operation.

The Technical Specifications permit one train of an ECCS subsystem to be inoperable during power operation for a specified time period, provided that the opposite train is operable or both trains inoperable provided 100% of the ECCS flow equivalent to a single operable ECCS train is available. Out of service action times and specific actions are described in Technical Specifications.

Accumulator injection occurs immediately when the RCS is depressurized below accumulator operating pressure. The cold leg injection accumulators can be isolated from the RCS by closure of their motor operated isolation valves, or the accumulators can be vented to containment to prevent the injection of nitrogen into the RCS during subsequent RCS depressurization.

Injection Mode After Loss of Primary Coolant

The injection mode of emergency core cooling is initiated by the safety injection signal ("S" signal). This signal is actuated by any of the following:

1. Low pressurizer pressure
2. High containment pressure
3. Low steam line pressure
4. Manual

Operation of the ECCS during the injection mode is completely automatic. Refer to Figure 7.2.1-1 (Sheet 8) for complete safety injection logic and control diagrams. The safety injection signal, in addition to activating various ESF equipment, automatically initiates the following actions:

1. Starts the diesel generators, provides backup reactor trip signal, control room isolation, Containment Ventilation Isolation containment phase A isolation and main feedwater isolation.

2. Starts the centrifugal charging pumps, the safety injection pumps, and the residual heat removal pumps.

3. Aligns the charging pumps for injection by:
   a. Closing the valves in the charging pump discharge line to the normal charging line.
   b. Opening the valves in the charging pumps suction line from the refueling water storage tank.
   c. Closing the valves in the charging pump normal suction line from the volume control tank.
   d. Opening the injection tank inlet and discharge line isolation valves.

4. Provides a backup signal to the SIS accumulator valves and RHR HTX discharge butterfly valves to auto-open these normally open valves should they not be fully open

Remotely operated valves for the injection mode which are under manual control (i.e., valves which normally are in their ready position and do not require a safety injection signal) have their position indicated on a common portion of the control board. If a component is out of its proper position, its monitor light will indicate this on the control panel. At any time during operation when one of these valves is not in the ready position for injection, this condition is shown visually on the board, and an audible alarm is sounded in the main control room.

Shutdown LOCA (SDLOCA)

Full ECCS capability is not available during shutdown conditions. A SDLOCA relies on the effectiveness of Operator action to manually establish ECCS flow (see 6.3.2.17). For SDLOCA events in Mode 4 during the injection phase, one train of ECCS provides sufficient flow for core cooling to meet the analysis requirements for a credible Mode 4 Loss of Coolant Accident (LOCA). For the SDLOCA case, the required flow is met by the centrifugal charging subsystem supplying each of the four cold legs. While not necessary, RHR injection into at least two of the four cold legs is acceptable with respect to fulfilling the accident function of the RHR subsystem for a Mode 4 LOCA.

Recirculation Mode

The injection mode continues until the RHR pumps have been realigned to the recirculation mode. During the injection mode all pumps take suction from the refueling water storage tank (RWST) until a low level signal from the RWST in conjunction with the "S" signal and a high sump level signal aligns the residual heat removal pumps to take suction from the containment sump. The RHR pump suction valves (FCV-74-3 and FCV-74-21) are automatically closed coincident with

the opening of the sump isolation valves (FCV-63-72 and FCV-63-73). The automatic positioning of these valves is initiated only in the event that actuation signals are generated by the safeguards protection logic ("S" signal), two of four RWST low level protection logic signals, and two out of four sump high level signals. The RHR pumps continue to receive adequate suction flow during this automatic change over; thus there is no possibility of pump damage due to loss of suction. Alarms on RWST low level and level indications from both the sump and RWST are used by the operator to appraise the accident situation and complete the remainder of switchover sequence. Table 6.3.2-4 describes the sequence of changeover operation from injection to recirculation for the RHR system.

The switchover initiation point and minimum assured final volume in the RWST before completion of switchover are selected on the basis of maximizing the allowable operator action time for accompanying manual operations and total water injected to the RCS while avoiding the potential problems due to low levels in either the active sump inside containment (area A, Figure 6.3.2-3) or in the RWST. Crane wall penetrations inside containment are sealed as necessary between elevations 679.78 and 693 to retain more water in the active sump, thereby maximizing the active sump water level at the onset of the recirculation switchover. Area C, Figure 6.3.2-3 cannot flood until area A is filled to elevation 693 feet.

An analysis of the double ended cold leg break documents that the ECCS sump water inventory present during the switch over from injection to recirculation mode, at the time suction is first taken from the sump, will conservatively meet all ECCS flow requirements, including ensuring adequate pump NPSH and precluding unacceptable vortexing. This inventory will be present even if it is postulated that the volume below the reactor vessel (area B, Figure 6.3.2-3 floods before any water enters the active sump (for example, if the break is at the reactor vessel nozzle). Assumptions used in this analysis include: technical specification minimum volumes in the RWST and the SIS accumulators; technical specification minimum ice mass; switchover sequence as described in Table 6.3.2-4; ice melt as shown in Figure 6.2.1-19; maximum expected holdup of containment spray water in the upper compartment (area D, Figure 6.3.2-3); and subcooled sump fluid temperature of 160°F. Reactor coolant inventory was not considered on this analysis except for breaks which may flood the volume below the reactor vessel.

Curbs are added to the peripheries of the operating deck (elevation 733.63) to ensure containment spray runoff on elevation 733.63 is directed to the refueling canal. To avoid containment spray water loss outside the crane wall to accumulator rooms #3 and #4 via the containment air return fans, curbs and drain lines are provided to collect water in these rooms and transfer it to the sump inside the crane wall (See Figure 9.3.3-1).

The sequence (as delineated in Table 6.3.2-4) is followed regardless of which power supply is available (offsite or emergency onsite).

The time required to complete the sequence is essentially the time required for operator to perform the accompanying manual operations. Controls for ECCS components are grouped together on the main control board. The component position lights verify when the function of a given switch has been completed.

After the injection phase of core cooling, water collected in the containment sump is cooled and returned to the RCS by the low head/high head recirculation flow path. The RCS can be supplied simultaneously from the residual heat removal pumps, and from a portion of this discharge taken after the residual heat exchangers which is then directed to the charging pumps and safety injection pumps. The charging and safety injection pumps return the water to the RCS. The latter mode of operation assures flow in the event of a small rupture where the depressurization proceeds more slowly such that the RCS pressure is still in excess of the shutoff head of the residual heat removal pumps at the onset of recirculation.

Hot leg recirculation will be initiated to assure against an excessive buildup of boric acid concentration in the core approximately 5.5 hours after event initiation.

The containment sump isolation valve is interlocked with its respective low head, RHR pump suction/refueling water storage tank isolation valve. This interlock prevents remote manual opening the sump isolation valve when the refueling water storage tank isolation valves are open and thus prevents dumping the refueling water storage tank contents into the containment sump. However, when an accident signal is present this interlock is bypassed to allow the automatic switchover as described in Table 6.3.2-4.

The refueling water storage tank is protected from back flow of reactor coolant from the RCS. All connections to the refueling water storage tank are provided with check valves to prevent back flow. When the RCS is hot and pressurized there is no direct connection between the refueling water storage tank and the RCS. When the RCS is being cooled and the Residual Heat Removal System is cut in, the Residual Heat Removal System is isolated from the refueling water storage tank by a motor operated valve (FCV-63-1) in addition to a check valve.

Redundancy in the external recirculation loop is provided for by the inclusion of duplicate charging, safety injection, and residual heat removal pumps and residual heat exchangers. In addition, the safety injection pump discharges into all four hot legs as shown in Figure 6.3.2-1.

The low head pumps take suction through redundant lines from the containment sump and discharge through separate paths to the RCS. This design provides sufficient flow area and adequate NPSH for the residual heat removal pumps to operate in the recirculation mode.

The containment sump is protected at entry by the advanced design strainers. Each strainer contains perforations with a diameter of 0.095 inch. The dynamic effects of double-ended postulated pipe ruptures in the reactor coolant loops have been eliminated from the design basis of the Sequoyah Nuclear Plant by the application of leak-before-break technology. Therefore, there are no RCS blowdown forces which impact the strainers. Water flowing into the sump passes through the strainers and through a 1/4 inch mesh screen inside the sump, and enters the twin recirculation pipes connecting the sump to the RHR and containment spray pumps. Containment sump with vortex modifications suppression is shown in Figure 6.3.2-4. For further discussion of sump design and performance refer to subsection 6.2.2.2.

Each recirculation line from the sump is routed outside the containment to a sump isolation valve. This valve is surrounded with a steel enclosure and the section of piping joining it to the sump is run within a guard pipe welded to the enclosure. Any leakage from the sump piping or valve body will be contained and cannot leak into the atmosphere or cause a loss of recirculation fluid. Any excessive leakage or passive failure downstream of the sump valves can be controlled and isolated by closure of the sump valve in the affected train.

External Recirculation Loop

The ECCS recirculation loop piping and components external to containment is surrounded by shielding. This shielding is designed to permit access for maintenance to a component such as a pump while the redundant component is recirculating sump fluid.

Pressure relieving devices, from portions of the ECCS located outside containment which might contain radioactivity, discharge to the pressurizer relief tank.

An analysis has been performed to evaluate the radiological effects of recirculation loop leakage. The leakage loop is assumed to include a high head injection pump, a residual heat removal pump, a residual heat exchanger and the associated piping even though the loop can be isolated with a redundant flow path providing adequate core cooling. In the analysis, a maximum leakage was assumed as given in Table 6.3.2-5. The analyses given in Chapter 15, demonstrate that the offsite does resulting from such leakage and other sources described in the analysis is less than the guidelines of 10 CFR 100.

During recirculation, significant margin exists between the design and operating conditions (in terms of pressure and temperature) of the ECCS components.

Since redundant flow paths are provided during recirculation, a leaking component in one of the flow paths may be isolated. This action curtails any further leakage and renders the component available for corrective maintenance.

6.3.2.3 Applicable Codes and Classifications

The codes and standards to which the individual components of the ECCS are designed are listed in Table 3.2.1-2.

6.3.2.4 Materials Specifications and Compatibility

Materials employed for components of the ECCS are given in Table 6.3.2-6. Materials are selected to meet the applicable material requirements of the codes in Table 3.2.1-2 and the following additional requirements:

1. All parts of components in contact with sump solution during recirculation are fabricated of austenitic stainless steel or equivalent corrosion resistant material.

2. All parts of all components in contact with borated water are fabricated of, or clad with, austenitic stainless steel or equivalent corrosion resistant material, with the exception of pump seals and valve packing.

3. Valve seating surfaces are hard-faced with Stellite No. 6 or equivalent to prevent galling and reduce wear.

4. Valve stem materials are selected for their corrosion resistance, high tensile properties, and resistance to surface scoring by the packing.

The elevated temperature of the sump solution is well within the design temperature of all the ECCS components. In addition, consideration has been given to the potential for corrosion of various types of metals exposed to the fluid conditions prevalent immediately after the accident or during the long term recirculation operations.

Environmental testing of the ECCS equipment inside the containment, which is required to operate following a LOCA, is discussed in Reference (1). The chemistry used in the test program was obtained by using a spray solution of 1.5 w/o boric acid solution and adjusting the pH to a value of approximately 9.25 with sodium hydroxide. This solution is similar to that of a post accident environment resulting from the release of sodium-tetraborate following the ice-melt. The ice-melt is discussed in greater detail in Section 6.2. The results of the test program indicate that the safety features will operate satisfactorily during and following exposure to the combined containment post-accident environments of temperature, pressure, chemistry, and radiation.

6.3.2.5 Design Pressures and Temperatures

The component design pressure and temperatures are given in Table 6.3.2-1. These pressure and temperature conditions are specified as the most severe conditions to which each respective component is exposed during either normal plant operation or during operation of the ECCS.

For each component, these conditions are considered in relation to the code to which it is designed. By designing the components in accordance with applicable codes (see Section 3.2) and with due consideration for the design and operating conditions, the fundamental assurance of structural integrity of the Emergency Core Cooling System components is maintained.

6.3.2.6 Coolant Quantity

The minimum storage volume for the accumulators and the refueling water storage tank is given in Table 6.3.2-3. The minimum storage volume in the RWST and the accumulators is sufficient to ensure that, after a RCS break, sufficient water is injected and is available within the containment to permit recirculation cooling flow to the core, and to meet the net positive suction head requirements of the residual heat removal pumps. A further discussion of coolant requirements is contained in Sections 15.3 and 15.4.

6.3.2.7 Pump Characteristics

Performance curves for the residual heat removal pumps are given in Figure 6.3.2-5. Performance curves for the safety injection pumps are given in Figure 6.3.2-6. Performance curves for the centrifugal charging pumps are given in Figure 6.3.2-7. Power requirements for the pumps are given in Section 8.3.

6.3.2.8 Heat Exchanger Characteristics

Residual Heat Exchanger Characteristics are found in Subsection 5.5.7 (see Table 5.5.7-2).

6.3.2.9 ECCS Flow Diagrams

The SIS flow diagram is given as Figure 6.3.2-1.

6.3.2.10 Relief Valves

The ECCS relief valves, their capacities and settings are given in Table 6.3.2-2.

6.3.2.11 System Reliability

Definition of Terms

Definitions of terms used in this section are located in Subsection 3.1.1.

Active Failure Criteria

The ECCS is designed to accept any single failure at any time following the incident without loss of its protective function. The system design will tolerate the failure of any single active component in the ECCS itself or in the necessary associated service systems at any time during the period of required system operations following the incident.

A single active failure analysis is presented in Table 6.3.2-7, and demonstrates that the ECCS can sustain the failure of any single active component in either the short or long term or any passive component failure in the long term (see Table 6.3.2-8) and still meet the level of performance for core cooling.

Since the operation of the active components of the ECCS following a steam line rupture is identical to that following a loss of coolant accident, the same analysis is applicable and the ECCS can sustain the failure of any single active component and still meet the level of performance for the addition of shutdown reactivity. Passive failure is not considered for the short term.

Passive Failure Criteria

The following philosophy provides for necessary redundancy in component and system arrangement to meet the intent of the NRC General Design Criteria on single failure as it specifically applies to failure of passive components, in the ECCS. Thus, for the long term, the system design is based on accepting either a passive or an active failure.

Redundancy of Flow Paths and Components for Long-Term Emergency Core Cooling

In design of the Emergency Core Cooling System, Westinghouse utilized the following criteria.

1. During the long-term cooling period following a LOCA, the emergency core cooling flow paths are separable into two sub-systems, either of which can provide minimum core cooling functions and return spilled water from the floor of the containment back to the RCS.

2. Either of the two sub-systems can be isolated and removed from service in the event of a leak outside the containment.

3. Adequate redundancy of check valves is provided to tolerate failure of a check valve during the long-term as a passive component.

4. Should one of these two sub-systems be isolated in this long-term period, the other sub-system remains operable.

5. Provisions are also made in the design to detect leakage from components outside the containment, collect this leakage and to provide for maintenance of the affected equipment.

Thus, for the long-term emergency core cooling function, adequate core cooling capacity exists with one flow path removed from service whether isolated due to a leak, because of blocking of one flow path, or because failure in the containment results in a spill of the delivery of one injection flow path. It should be noted that closure of the A-Train Safety Injection Pump Suction Isolation Valve (FCV-63-47) during power operation will prevent B-Train Residual Heat Removal from supplying either Centrifugal Charging Pump in the cold leg recirculation mode. This results in the inoperability of both trains of ECCS because at least one complete independent train cannot be established in all ECCS modes; however, entry into LCO 3.0.3 is not required provided that at least 100 percent of the ECCS flow equivalent to a single operable ECCS train is available. The design intent of the ECCS piping layout is to maximize the number of options available to the control room operator for response to a passive failure. This is consistent with the defense in depth approach for ECCS design.

Subsequent Leakage from Components in Safeguards Systems

With respect to piping and mechanical equipment outside the containment, considering the provisions for visual inspection and leak detection, leaks will be detected before they propagate to major proportions. A Westinghouse review of the equipment in the system indicates that the largest sudden leak potential would result from the sudden failure of an RHR or CS pump shaft seal. Evaluation of seal leakage assuming only the presence of a seal retention ring around the pump shaft showed flows less than 50 gpm would result. Piping leaks, valve packing leaks, or flange gasket leaks have been of a nature to build up slowly with time and are considered less severe than the pump seal failure.

1. The piping is classified in accordance with ANS Safety Class 2 and receives the ASME Class 2 quality assurance program associated with this safety class.

2. The piping, equipment and supports are designed to insure no loss of function for the Safe Shutdown Earthquake.

3. The system piping is located within a controlled area on the plant site.

4. The piping system receives periodic tests and is accessible for periodic visual inspection.

5. The piping is austenitic stainless steel which, due to its ductility, can withstand severe distortion without failure.

Based on this review, design of the Auxiliary Building and related equipment is based upon handling of ECCS leaks up to a maximum of 50 gpm. To assure adequate core cooling, design features are provided to prevent this limiting passive failure from causing any loss of function in the other train of the ECCS equipment due to flooding of redundant components or loss of NPSH to the ECCS pumps. Independent means are available to provide information to the operator for use in identifying ECCS leakage into certain locations in the Auxiliary Building. These means include the Auxiliary Building flood detection system, the instrumentation and alarms associated with the drainage and waste processing systems which normally handle drainage into these areas.

A flood detection system utilizing conductivity type water level detector devices is used to monitor and actuate alarms for ECCS and other leakage at specific locations in the Auxiliary Building. Individual detectors are located in each ECCS pump compartment, in the ECCS heat exchanger rooms, in the pipe gallery for each unit, and in the pipe chase. A common alarm in the main control room will alert the operator when any of these flood detectors are tripped. A flood detector indicator panel, located immediately outside the control room, then identifies the exact location of the tripped detector. The detector panel is provided with a test switch which can be used to verify the availability of power to each individual detector. These flood detectors are to be tested to verify initial operability and will be periodically tested as a part of the plant instrument surveillance and maintenance program.

Since each ECCS pump and heat exchanger room is monitored by a level detection device, the operator may immediately identify leakage into one of these rooms and determine which subsystem must be shut down and secured to terminate the leak. The operator can readily accomplish this action from the main control room by stopping the appropriate subsystem pump and by closing the corresponding sump isolation valves and individual pump discharge valves. The time necessary for the operator to detect leakage into one of these rooms is dependent on the leakage rate. A limiting 50 gpm leak in the largest ECCS pump room can be detected within 30 minutes. Slower leaks will require proportionally longer detection times.

Leakage into the SIS or CVCS pump rooms, the pipe chase, or the pipe gallery (all at elevation 669) is piped through the floor drain header to the floor drain collector tank at elevation 653. ECCS leakage into the RHR or CS pump rooms or the pipe chase (all at elevation 653) is piped to the Auxiliary Building floor and equipment drain sump. The floor drain in each of these areas is provided with a standpipe which assures that the setpoint for the water level detector is reached prior to draining the leakage from the room. However, the standpipes each have drilled holes to allow minor normal leakage to drain from the room.

The Auxiliary Building floor and equipment drain sump is provided with redundant 50 gpm pumps which automatically start on high level. Pump flow can be directed to either the floor drain collector tank or to the tritiated drain collector tank. Operation of these pumps is indicated in the

main control room. The Auxiliary Building floor and equipment drain sump has a high level alarm which indicates in the main control room. If the waste disposal system is available, the operator can manually initiate processing of the contents of the tritiated drain collector tank or floor drain collector tank through the waste disposal system. If the waste disposal system is not available, both the tritiated drain and floor drain collector tanks can fill and discharge through overflow piping to the Auxiliary Building floor and equipment drain sump.

If the waste disposal system cannot keep up with the leak rate, when the Auxiliary Building floor and equipment drain sump (ABFEDS) fills up, the cross-tie valve (0-VLV-77-916) between the ABFEDS and the passive sump can be opened making available the volume of the passive sump to help contain the excessive flow.

Leakage into an ECCS pump or heat exchanger room can be detected by the flood detection system as described above. Leakage into areas other than these rooms can be detected by the flood detectors, by indication of sump pump operation, or by a high level alarm from the sump or the floor drain collector tank. However, the exact location of the leak, if from other than an ECCS pump or heat exchanger room, may not be immediately identified. Since ECCS leaks other than a pump seal failure are of a nature to develop very slowly and are less severe than a seal failure, the operator has an extended time period to detect and isolate the leak. Isolation of these minor leaks can be accomplished by arbitrarily selecting and isolating an ECCS subsystem and evaluating the response of the flood detector system. A factor which minimizes the probability of leakage into these areas is that the piping and valves in the RHR and CVCS systems are normally operated at temperatures and pressures which are greater than the post-accident conditions. Additionally the entire ECCS is periodically inspected as a part of the inservice inspection program.

The flood detection system described above is not designed to meet the requirements of IEEE 279-1971. The detectors, indicator panel, and control room alarm are single train and are powered from nondivisional boards. However, the system is designed such that a loss of power to any individual detector will be indicated on the indicator panel and will actuate the control room common alarm. Additionally, the nondivisional boards which supply the flood detection system are powered from a class IE power board which is automatically loaded on the diesel generators. This insures continued operability of the flood detection system following an accident.

In addition to the flood detection and normal drainage processing systems described above, water level sensor is provided in the Auxiliary Building passive sump (elevation 643). This sensor is designed to alarm in the main control room.

A determination of the time available for corrective operator action before functioning of the redundant train of ECCS equipment would be impaired was made based on the assumed continuous leakage rate of 50 gpm. An evaluation was made of the minimum time required to fill the passive sump (volume = 209,000 gallons) due to overflow of the tritiated drain collector tank. The calculated time of 2.6 days is conservative because no credit was taken for processing of leakage through the waste disposal system. An additional evaluation was made of the time available before the required NPSH for the redundant ECCS pumps would be lost due to decreasing water level in the reactor building sump. The calculated time of 5.3 days is conservative because no credit was taken for the volume of water which will be available due to melting of the ice condenser system ice. These time periods are much longer than the time necessary for the operator to detect and isolate the limiting 50 gpm leakage into an ECCS pump compartment.

With these design ground rules, continued function of the ECCS will meet minimum core cooling requirements. A single passive failure analysis is presented in Table 6.3.2-8. It demonstrates that the ECCS can sustain a single passive failure during the long term phase and still retain an

intact flow path to the core to supply sufficient flow to maintain the core covered and affect the removal of decay heat. The procedure followed to establish the alternate flow path also isolates the component which failed.

ECCS Intersystem Leakage

This subject is discussed in detail in subsection 5.2.7.8.

Leakage into the Cold Leg Accumulator Lines is detected by the two level sensors which are on each accumulator.

Leakage into the Safety Injection System is detected by the pressure sensors located in the two Safety Injection System pump discharge lines. If the pressure in these lines reaches 1750 psig the three pressure relief valves in the line will discharge to the pressurizer relief tank. The level sensor in the tank will indicate an increase. There is also a temperature sensor in the pressurizer relief tank which will show an increase.

There is no leakage problems into the Chemical and Volume Control System from the Reactor Coolant System due to the higher pressure at which the Chemical and Volume Control System is generally maintained.

Leakage into the Residual Heat Removal System may be detected by the pressure sensors in the Residual Heat Removal System pump discharge lines or instrumentation on the PRT. If pressure in these lines reaches 600 psig the relief valves will discharge to the pressurizer relief tank as described for Safety Injection System leakage.

Reactor Coolant System out leakage is also detected by monitoring of the Reactor Coolant System inventory and the inventory control operations.

6.3.2.12 Protection Provisions

The provisions taken to protect the system from damage that might result from dynamic effects are discussed in Section 3.6. The provisions taken to protect the system from missiles are discussed in Section 3.5. The provisions to protect the system from seismic damage are discussed in Sections 3.7, 3.9, and 3.10. Thermal stresses on the RCS are discussed in Section 5.2.

Emergency Core Cooling System Piping Failure

The rupture of the portion of an injection line from the last check valve to the connection of the line to the RCS can cause not only a loss of coolant but impair the injection as well. To reduce the probability of an emergency core cooling line rupture causing a loss of coolant accident, the check valves which isolate the ECCS from the RCS are installed immediately adjacent to the reactor coolant piping.

For a small break, the reactor pressure maintains a relatively uniform back pressure in all injection lines so that a significant flow imbalance does not occur. A rupture in the cold leg accumulator injection line is accounted for in the analyses by assuming that for cold leg breaks the entire contents of the associated accumulator is discharged from the break.

6.3.2.13 Provisions for Performance Testing

The provisions incorporated to facilitate performance testing of components are discussed in Subsection 6.3.4.

6.3.2.14 Net Positive Suction Head

The ECCS is designed so that adequate net positive suction head is provided to system pumps. Adequate net positive suction head is shown to be available for all pumps as follows:

1. Residual Heat Removal Pumps

The net positive suction head of the residual heat removal pumps is evaluated for normal plant shutdown operation, and for both the injection and recirculation modes of operation for the design basis accident. Recirculation operation gives the limiting net positive suction head requirement, and the net positive suction head available is determined from the containment pressure, vapor pressure of liquid in the sump, containment sump level relative to the pump elevation and the pressure drop in the suction piping from the sump to the pumps. The net positive suction head evaluation is based on all pumps operating at the maximum design flow rates. The residual heat removal pump head-capacity and net positive suction head curves are given in Figure 6.3.2-5.

2. Safety Injection and Centrifugal Charging Pumps

The net positive suction head for the safety injection pumps and the centrifugal charging pumps is evaluated for both the injection and recirculation modes of operation for the design basis accident. The end of the injection mode of operation gives the limiting net positive suction head available. The net positive suction head available is determined from the elevation head and vapor pressure of the water in the refueling water storage tank, which is at atmospheric pressure, and the pressure drop in the suction piping from the tank to the pumps. At the end of the injection mode when suction from the refueling water storage tank is terminated (low refueling water storage tank level), adequate net positive suction head is supplied from the containment sump by the booster action of the RHR pumps. The net positive suction head evaluation is based on all pumps operating at the maximum design flow rates. The head-capacity, and net positive suction head curves for the safety injection pumps are given in Figure 6.3.2-6. The head-capacity and net positive suction head curves for the charging pumps are given in Figure 6.3.2-7.

6.3.2.15 Control of Motor-Operated Isolation Valves

The design of the control circuit for the motor operated isolation valves in the lines connecting a cold leg accumulator to the RCS provides protection against inadvertent closure. The cold leg accumulator isolation valves are FCV-63-118, accumulator 1 (train A), FCV-63-98, accumulator 2 (train B), FCV-63-80, accumulator 3 (train A), and FCV-63-67, accumulator 4 (train B). During heatup and pressurization of the RCS, these valves are manually opened in accordance with technical specification requirements. After the valves are opened, electrical power is removed to prevent inadvertent valve closure. During cooldown, electrical power is restored so that the valves can be manually closed from the main control room when allowed by technical specifications. Control power and therefore position indication is retained when motor power is removed to provide for main control room indication of valve position. Although the valves are normally open during operation, they receive a safety injection signal to open. These valves are also automatically opened when the system pressure exceeds the P-11 permissive level (1970 psig).

6.3.2.16 Motor Operated Valves and Controls

Remotely operated valves for the injection mode which are under manual control (i.e., valves normally in the ready position not requiring an SIS signal) have their positions indicated on a common portion of the control board. If a component is out of its proper position, its status monitor light will indicate this on the status monitor control panel. At any time during operation

when one of the valves is not in the ready position for injection, this condition is shown visually on the board, and an audible alarm is sounded in the main control room. The motor-operated isolation valves located between the high pressure RCS and the relatively low pressure RHRS are discussed in Subsections 5.5.7 and 7.6.2.

6.3.2.17 Manual Actions

No manual actions are required during the injection phase except for the Shutdown LOCA (SDLOCA) where the operator must manually establish sufficient ECCS flow. Actions required by the operator for proper ECCS operation following injection are those required to realign the system for cold leg recirculation and hot leg recirculation mode of operation.

During a Shutdown LOCA initiated after the RHR is aligned for shutdown cooling, the RHR pump suction piping might have to be cooled prior to starting the RHR pumps using either the RWST or the Containment Sump as the suction source. The cooling might be necessary in order to ensure that the RHR pumps have adequate NPSH and to ensure that potential steam voids in the RHR system piping cannot cause a waterhammer event or damage to the RHR pump. The cooling might also be necessary to ensure that the Containment Spray pumps have adequate NPSH when being realigned to the containment Sump.

6.3.2.18 Process Instrumentation

Process instrumentation available to the operator in the control room to assist in assessing post loss of coolant accident conditions are tabulated in Section 7.5.

6.3.2.19 Materials

Materials employed for components of the ECCS are given in Table 6.3.2-6. These materials are chosen based upon their ability to resist radiolytic and pyrolitic decomposition. (See Subsection 6.3.2.4) Coatings specified for use on the ECCS components (mainly, the cold leg accumulators) are designated to meet the requirements of ANSI 101.2-1972; "Protective Coatings (Paints) For Light Water Nuclear Reactor Containment Facilities," as a minimum.

6.3.3 Performance Evaluation

6.3.3.1 Evaluation Model

The following analyses are performed to ensure that the limits on core behavior following a RCS pipe rupture are met by the ECCS operating with minimum design equipment:

1. Large pipe break analysis
2. Small line break analysis
3. Main steam system line rupture
4. Recirculation cooling

The flow delivered to the RCS by the ECCS as a function of reactor coolant pressure with the operation of minimum design equipment is analyzed in Section 15.4.

The design basis performance characteristic is derived from the specified performance characteristic for each pump with a conservative estimate of system piping resistance, based upon piping layout for the flow diagram illustrated in Figure 6.3.2-1.

The performance characteristic utilized in the accident analyses includes a 5 percent decrease in the design head for margin. When the initiating incident is assumed to be the severance of an injection line the injection curve utilized in the analysis accounts for the loss of injection water through the broken line.

6.3.3.2 ECCS Performance

The large pipe break analysis is used to evaluate the initial core thermal transient for a spectrum of pipe ruptures from a break size of 0.5 ft^2 up to the double ended rupture of the largest pipe in the Reactor Coolant System.

The injection flow from active components is required to control the cladding temperature subsequent to accumulator injection, complete reactor vessel refill, and eventually return the core to a subcooled state. The results indicate that the maximum cladding temperature attained at any point in the core is such that the limits on core behavior as specified in Section 15.4 are met.

A flow balance test shall be performed during shutdown following action of modifications to the ECCS subsystem that alter the subsystem flow characteristics and verifying the following flow rates:

1. For safety injection pump lines with a single pump running:

   a. The sum of the injection line flow rates, excluding the highest flow rate is greater than or equal to 443 gpm, and

   b. The total pump flow rate is less than or equal to 675 gpm.

2. For centrifugal charging pump lines with a single pump running:

   a. The sum of the injection line flow rates, excluding the highest flow rate is greater than or equal to 309 gpm, and

   b. The total pump flow rate is less than or equal to 555 gpm.

3. For all four cold leg injection lines with a single RHR pump running a flow rate greater than or equal to 3931 gpm.

6.3.3.3 Alternate Analysis Methods

The small pipe break analysis is used to evaluate the initial core thermal transient for a spectrum of pipe rupture from 3/8 inch up to and including the rupture of a six inch diameter pipe. For breaks 3/8 inch or smaller (except those in the PRZ vapor space), the charging system can maintain the pressurizer level and the Reactor Coolant System operating pressure and the Emergency Core Cooling System would not be actuated.

The results of the small pipe break analysis indicate that the limits on core behavior are adequately met, as shown in Section 15.3.

Main Steam System Single Active Failure

Analyses of reactor behavior following any single active failure in the main steam system which results in an uncontrolled release of steam are included in Section 15.2. The analyses assume that a single valve (largest of the safety, relief, or bypass valves) opens and fails to close, which results in an uncontrolled cooldown of the Reactor Coolant System.

Results indicate that if the incident is initiated at the hot shutdown condition, which results in the highest reactivity worth, the DNB criteria is satisfied. Thus, the Emergency Core Cooling System provides adequate protection for this incident.

Steam Line Rupture

Following a steam line rupture the Emergency Core Cooling System is automatically actuated to deliver borated water from the RWST to the Reactor Coolant System. The response of the Emergency Core Cooling System following a steam line break is identical to its response during the injection mode of operation following a loss of coolant accident.

This accident is discussed in detail in Section 15.4 the limiting steam line rupture is a complete line severance.

In the case of a steam line rupture when offsite power is not assumed lost, credit is taken for the uninterrupted availability of power for the Emergency Core Cooling System components.

The results of the analysis in Section 15.4 indicate that the design basis criteria are met. Thus, the Emergency Core Cooling System adequately fulfills its shutdown reactivity addition function.

A technical specification is established to ensure the availability of the RWST which provides the shutdown reactivity.

The safety injection actuation signal initiates identical actions as described for the injection mode of the loss of coolant accident, even though not all of these actions are required following a steam line rupture, e.g., the residual heat removal pumps are not required since the Reactor Coolant System pressure will remain above their shutoff head.

The delivery of borated water from the RWST results in a negative reactivity change to counteract the increase in reactivity caused by the system cooldown. The charging pumps continue to deliver borated water from the refueling water storage tank, until enough water has been added to the Reactor Coolant System to make up for the shrinkage due to cooldown. The safety injection pumps also deliver borated water from the refueling water storage tank for the interval when the Reactor Coolant System pressure is less than the shutoff head of the safety injection pumps. After pressurizer water level has been restored, the injection is manually terminated. A high pressurizer water level alarm in the control room would warn the operator to terminate injection flow if this were not done previously.

The sequence of events following a postulated steam line break is described in Section 15.4.

6.3.3.4 Fuel Rod Perforations

Discussions of peak clad temperature and metal-water reactions appear in Subsections 15.3.1 and 15.4.1. Analyses of the radiological consequences of RCS pipe ruptures also are presented in Subsection 15.5.

6.3.3.5 Evaluation Model Does not apply to this plant (BWRs only).

6.3.3.6 Fuel Clad Effects Does not apply to this plant (BWRs only).

6.3.3.7 ECCS Performance Does not apply to this plant (BWRs only).

6.3.3.8 Peak Factors Does not apply to this plant (BWRs only).

6.3.3.9 Fuel Rod Perforations Does not apply to this plant (BWRs only).

6.3.3.10 Conformance With Interim Acceptance Criteria Does not apply to this plant (BWRs only).

6.3.3.11 Effects of ECCS Operation on the Core

The effects of the ECCS operation on the reactor core are discussed in Sections 15.3 and 15.4.

6.3.3.12 Use of Dual Function Components

The Emergency Core Cooling System contains components which have no other operating function as well as components which are shared with other systems and perform normal operating functions. Components in each category are as follows:

1. Components of the Emergency Core Cooling System which perform no other function are:

a. One accumulator for each loop which discharges borated water into its respective cold leg of the reactor coolant loop piping.

b. Two safety injection pumps which supply borated water for core cooling to the Reactor Coolant System. These pumps are also used for filling the accumulators.

c. Associated piping, valves and instrumentation.

2. Components which also have a normal operating function are as follows:

   a. The residual heat removal pumps and the residual heat exchangers:
   These components are normally used during the latter stages of normal reactor cooldown and when the reactor is held at cold shutdown or refueling for core decay heat removal. However, during all other plant operating periods, they are aligned to perform the low head injection function.

   b. The centrifugal charging pumps: These pumps are normally aligned for RCP seal injection and charging service as part of the Chemical and Volume Control System. The normal operation of these pumps is discussed in Section 9.3.4.

   c. The refueling water storage tank: This tank is used to fill the refueling canal for refueling operations. It is normally aligned to the suction of the safety injection pumps and the residual heat removal pumps for the ECCS function and to the suction of containment spray pumps. It is normally isolated from the RHR pump suction when the RHR pumps are aligned to the RCS for shutdown cooling. The RWST may be aligned to the RCS during RCS drain and fill operations. The charging pumps are aligned to the suction of the refueling water storage tank upon receipt of the safety signal.

An evaluation of all components required for operation of the Emergency Core Cooling System demonstrates that either:

1. The component is not shared with other systems, or

2. If the component is shared with other systems, it is aligned during normal plant operation to perform its accident function; or if not aligned to its accident function, two valves in parallel are provided to align the system for injection, and two valves in series are provided to isolate portions of the system not utilized for injection. These valves are automatically actuated by the safety injection signal.

Table 6.3.3-1 indicates the alignment of major components during normal operation, and the realignment required to perform the accident function.

<u>Dependence on Other Systems</u>

Other principal systems which operate in conjunction with the Emergency Core Cooling System are as follows:

1. The Component Cooling System cools the residual heat exchangers during the recirculation mode of operation. It also supplies cooling water to the mechanical seal coolers for the centrifugal charging pumps and the safety injection pumps, and the seal water heat exchangers for the residual heat removal pumps.

2. The Essential Raw Cooling Water System provides cooling water to the component cooling heat exchangers, various coolers for the centrifugal charging pumps and the safety injection pumps, and the ESF equipment room coolers.

3. The electrical systems provide normal and emergency power sources for the Emergency Core Cooling System.

4. The Engineered Safety Features Actuation System generates the initiation signal for emergency core cooling.

5. The Auxiliary Feedwater System supplies feedwater to the steam generators.

Limiting Conditions for Operation

The design philosophy with respect to active components in the high head/low head injection system is to provide backup equipment so that maintenance is possible during operation, in accordance with Technical Specification Action limitations, without impairment of the safety function of the system.

6.3.3.13 Lag Times

The minimum active components will be capable of delivering full rated flow within a specified time interval after process parameters reach the setpoints for the safety injection signal. Response of the system is automatic, with appropriate allowances for delays in actuation of circuitry and active components. The active portions of the system are actuated by the safety injection signal. In analyses of system performance, delays in reaching the programmed trip points and in actuation of components are established on the basis that only emergency onsite power is available. A further discussion of the starting sequence is given in Subsection 8.3.1.

In the loss of coolant accident analysis presented in Sections 15.3 and 15.4, no credit is assumed for partial flow prior to the establishment of full flow. In addition, for the small break analysis in Section 15.3, no credit is assumed for the availability of offsite power sources.

For smaller loss of coolant accidents, there are some additional delays before the process variables reach their respective programmed trip setpoints since this is a function of the severity imposed by the accident. Allowances are made for this in the analyses of the spectrum of reactor coolant pipe breaks.

6.3.3.14 Thermal Shock Considerations

Thermal shock considerations are discussed in Section 5.2.

6.3.3.15 Limits on System Parameters

A comprehensive testing program has been undertaken to demonstrate that the Emergency Core Cooling System components and associated instrumentation and electrical equipment which are located inside the containment will operate for the time period required in the combined post loss of coolant accident conditions of temperature, pressure, humidity, radiation, and chemistry (Reference 1). Components such as remote motor operated valves and flow and pressure transmitters have been shown capable of operating for the required post-accident periods, when exposed to post loss of coolant environmental conditions.

The specification of individual parameters as given in Table 6.3.2-1 includes due consideration of allowances for margins over and above the required performance value (e.g., pump flow and net positive suction head), and the most severe conditions to which the component could be subjected (e.g., pressure, temperature, and flow).

This consideration ensures that the Emergency Core Cooling System is capable of meeting its minimum required level of functional performance.

6.3.4 Tests and Inspections

Performance tests of the components are performed in the manufacturer's shop. An initial pre-operational system flow test is performed to demonstrate the proper functioning of all of the components. In order to demonstrate the readiness and operability of the Emergency Core Cooling System, components are subjected to periodic tests and inspections in accordance with the ASME Section XI programs and the 10CFR50 Appendix J program as required. The Emergency Core Cooling System components are designed and fabricated to permit inspection and in-service tests in accordance with ASME Code Section XI.

Quality Control

Tests and inspections are carried out during fabrication of each of the Emergency Core Cooling System components. These tests are conducted and documented in accordance with the Quality Assurance program discussed in Chapter 17.

Pre-Operational Tests

These tests are intended to evaluate the hydraulic and mechanical performance of the passive and active components involved in the injection mode by demonstrating that they have been installed and adjusted so they will operate in accordance with the design intent. These tests are divided into three individual sections that may be performed as plant conditions allow without compromising the integrity of the tests.

One of these individual sections consists of system actuation tests to verify: The operability of all Emergency Core Cooling System valves initiated by the safety injection "S" signal, the phase A containment isolation "T" signal; the operability of all safeguard pump circuitry down through the pump breaker control circuits; and the proper operation of all valve interlocks.

Another of the individual sections is the accumulator injection test. The objective of this section is to check the accumulator injection line to verify that the lines are free from obstructions and that the accumulator check valves operate correctly. The test objectives will be met by a low pressure blowdown of each accumulator. The cold leg accumulator test was performed with the reactor head and internals removed.

The last of the individual sections consists of operational tests of all of the major pumps - i.e., the charging pumps, the residual heat removal pumps, and the safety injection pumps. The purpose of these tests is to evaluate the hydraulic and mechanical performance of the pumps delivering through the flow paths required for emergency core cooling. These tests will be divided into two parts: pump operation under mini flow conditions and pump operation at full flow conditions. The predicted system resistance will be verified by measuring the flow in each piping branch, as each pump delivers from the refueling water storage tank to the open reactor vessel, and adjustment made where necessary to assure that no one branch has an unacceptably low or high resistance. During this flow test, the system will also be checked to assure there is sufficient total line resistance to prevent excessive run out of the pump. At the completion of the flow test, the total pump flow and relative flow between the branch lines will be compared with the minimum acceptable flows as determined for the safety analysis.

The systems are accepted only after demonstration of proper actuation of all components and after demonstration of flow delivery of all components within design requirements.

Periodic Component Testing

Routine periodic testing of the Emergency Core Cooling System components and necessary support systems is performed in accordance with plant Technical Specifications. Components not covered by Technical Specifications may also be periodically tested at power in accordance with approved plant maintenance program procedures.

Pumps and valves are periodically tested in accordance with Technical Specifications and ASME Section XI. If such testing indicates a need for corrective maintenance, the redundancy of equipment in these systems permits such maintenance to be performed without shutting down or reducing load under certain conditions as permitted by Technical Specifications.

Containment drainage paths from accumulator rooms 3 and 4 to the containment sump are verified unblocked each refueling outage. This verification is in accordance with plant procedure. This test is in compliance with the response to NRC Bulletin 2003-01.

Test lines are provided for periodic measurement of the leakage of reactor coolant back through the accumulator discharge line check valves and to ascertain that these valves seat whenever the Reactor Coolant System pressure is raised. These tests are routinely performed in accordance with Technical Specifications and ASME Section XI when the reactor is being returned to power after an outage and

the reactor pressure is raised above the accumulator pressure. To implement the periodic component testing requirements, the SQN Technical Specifications have been established. During periodic system testing, a visual inspection of assessable pump seals, valve packings, flanged connections, and relief valves can be made to detect leakage. Inservice inspection provides further confirmation that no significant deterioration is occurring in the Emergency Core Cooling System fluid boundary.

Design measures have been taken to assure that the following testing can be performed:

1. Active components may be tested periodically for operability (e.g., pumps on mini flow, certain valves, etc.).

2. An integrated system actuation test can be performed when the plant is cooled down and the Residual Heat Removal System is in operation. The Emergency Core Cooling System can be arranged so that no flow will be introduced into the Reactor Coolant System for this test. Details of the testing of the sensors and logic circuits associated with the generation of a safety injection signal together with the application of this signal to the operation of each active component are given in Section 7.2.

3. An initial flow test of the full operational sequence can be performed.

The design features which assure this test capability are specifically:

1. Power sources are provided to permit individual actuation of each active component of the Emergency Core Cooling System.

2. The safety injection pumps can be tested periodically during plant operation using the minimum flow recirculation lines provided.

3. The residual heat removal pumps are used every time the Residual Heat Removal System is put into operation. They can also be tested periodically using the miniflow recirculation lines.

4. The centrifugal charging pumps are either normally in use for charging service or can be tested periodically on miniflow or charging flow.

5. Remote operated valves can be exercised.

6. Level and pressure instrumentation are provided for each accumulator tank, for continuous monitoring of these parameters during plant operation.

7. Flow from each accumulator tank can be directed through a test line to determine check valve leakage.

8. A flow indicator is provided in the safety injection pump header, and in the residual heat removal pump headers. Pressure instrumentation is also provided in these lines.

9. An integrated system test can be performed during shutdown to demonstrate the operation of the valves, pump circuit breakers, and automatic loading of Emergency Core Cooling System components on the diesels (by simultaneously simulating a loss of offsite power to the vital electrical buses).

6.3.5 Instrumentation Application

6.3.5.1 Temperature Indication

Residual Heat Exchanger Inlet and Outlet Temperature

The fluid temperature at the inlet and outlet of each residual heat exchanger is recorded in the main control room.

the reactor pressure is raised above the accumulator pressure. To implement the periodic component testing requirements, the SQN Technical Specifications have been established. During periodic system testing, a visual inspection of assessable pump seals, valve packings, flanged connections, and relief valves can be made to detect leakage. Inservice inspection provides further confirmation that no significant deterioration is occurring in the Emergency Core Cooling System fluid boundary.

Design measures have been taken to assure that the following testing can be performed:

1. Active components may be tested periodically for operability (e.g., pumps on mini flow, certain valves, etc.).

2. An integrated system actuation test can be performed when the plant is cooled down and the Residual Heat Removal System is in operation. The Emergency Core Cooling System can be arranged so that no flow will be introduced into the Reactor Coolant System for this test. Details of the testing of the sensors and logic circuits associated with the generation of a safety injection signal together with the application of this signal to the operation of each active component are given in Section 7.2.

3. An initial flow test of the full operational sequence can be performed.

The design features which assure this test capability are specifically:

1. Power sources are provided to permit individual actuation of each active component of the Emergency Core Cooling System.

2. The safety injection pumps can be tested periodically during plant operation using the minimum flow recirculation lines provided.

3. The residual heat removal pumps are used every time the Residual Heat Removal System is put into operation. They can also be tested periodically using the miniflow recirculation lines.

4. The centrifugal charging pumps are either normally in use for charging service or can be tested periodically on miniflow or charging flow.

5. Remote operated valves can be exercised.

6. Level and pressure instrumentation are provided for each accumulator tank, for continuous monitoring of these parameters during plant operation.

7. Flow from each accumulator tank can be directed through a test line to determine check valve leakage.

8. A flow indicator is provided in the safety injection pump header, and in the residual heat removal pump headers. Pressure instrumentation is also provided in these lines.

9. An integrated system test can be performed during shutdown to demonstrate the operation of the valves, pump circuit breakers, and automatic loading of Emergency Core Cooling System components on the diesels (by simultaneously simulating a loss of offsite power to the vital electrical buses).

6.3.5 Instrumentation Application

6.3.5.1 Temperature Indication

Residual Heat Exchanger Inlet and Outlet Temperature

The fluid temperature at the inlet and outlet of each residual heat exchanger is recorded in the main control room.

Refueling Water Storage Tank (RWST) Temperature

Two temperature channels are provided to monitor the RWST temperature. Both are indicated in the main control room. A high/low temperature alarm is provided in the main control room.

6.3.5.2 Pressure Indication

CCP Injection Tank Pressure

CCP injection tank outlet pressure is indicated in the main control room. A high pressure alarm is provided.

Safety Injection Header Pressure

Safety injection pump discharge header pressure is indicated in the main control room.

Cold Leg Accumulator Pressure

Duplicate pressure channels are installed on each cold leg accumulator. Pressure indication in the control room and high and low pressure alarms are provided by each channel.

Residual Heat Removal Pump Discharge Pressure

Residual heat removal discharge pressure for each pump is indicated in the main control room. A high pressure alarm is actuated by each channel.

6.3.5.3 Flow Indication

Charging Pump Injection Header Flow

The total centrifugal charging pump injection flow, which discharges to the cold leg injection header, is indicated in the main control room.

Residual Heat Removal Pump Injection Flow

Flow through each residual heat removal injection and recirculation header leading to the reactor cold or hot legs is indicated in the main control room.

Test Line Flow

“Bucket testing” or an alternate flow measurement device can be used to determine test line flow to verify proper seating of the accumulator check valves between the injection lines and the reactor coolant system.

Residual Heat Removal Pump Minimum Flow

Installed in each residual heat removal pump discharge header is a local flow meter and flow switches for miniflow valve control.

6.3.5.4 Level Indication

Refueling Water Storage Tank Level

Six water level indicator channels, which indicate in the main control room, are provided for the refueling water storage tank. Four wide range channels alarm on low and low-low water levels,

and are indicated on the main control board. Two narrow range channels are also provided with low and high-level alarms indicated on the main control board.

Accumulator Water Level

Duplicate water level channels are provided for each accumulator. The channels monitoring the level in the cold leg accumulators do so directly. Both channels provide indication, for each accumulator, in the main control room and actuate high and low water level alarms.

Containment Sump Water Level

Four containment sump water level indicator channels provide the main control room with water level indication.

6.3.5.5 Valve Position Indication

Valve positions are indicated on the control board such that a valve not in its proper position will cause a white monitor light to illuminate and thereby give a highly visible indication to the operator.

Valve position is also indicated by a second system employing a "red-green" light system on the control board. Thus should any bulb fail in service, the true position of the valve can still be determined.

Accumulator Isolation Valve Position Indication

The accumulator isolation valves are provided with red (open) and green (closed) position indication lights located at the control switch for each valve. These lights are powered by valve control power and actuated by valve motor operator limit switches.

A monitor light that is on when the valve is not fully open is provided in an array of monitor lights that are all off when their respective valves are in proper position enabling safeguards operation. This light is energized from a separate monitor light supply and actuated by a valve motor operated limit switch.

An alarm annunciator point is activated by both a valve motor operator limit switch and by a valve position limit switch activated by stem travel whenever an accumulator valve is not fully open for any reason with the system at pressure (the pressure at which the safety injection block is unblocked). A separate annunciator point is used for each accumulator valve. This alarm will be recycled at approximately one hour intervals to remind the operator of the improper valve lineup.

Refueling Water Storage Tank Isolation Valve

The control and indications provided for these valves are identical to those provided for the cold leg accumulator isolation valves, with the exception that a safety injection signal is not applied to the valves between the safety injection pumps, and residual heat removal pumps, and the refueling water storage tank.

SEQUENCE OF CHANGEOVER OPERATION

SEQUENCE OF CHANGEOVER OPERATION FROM
INJECTION TO RECIRCULATION FOR THE RHR SYSTEM

NOTE: Sequence of the first three actions in the following list may be changed to optimize procedure step sequence.

1. Check RHR System by verifying the RHR pumps are running.

2. Establish CCS to RHR Heat Exchangers, Panel M-27b, by opening the component cooling water isolation valve to each RHR heat exchanger (FCV-70-153, 156).

3. Verify automatic switchover when RWST level is low (130 inches) and containment sump level is high (30 inches above elevation 680') by verifying the containment sump valves FCV-63-72, 73 start to open at the same time RWST-RHR suction valves FCV-74-3 and 21 are starting to close.

4. Close SI pump miniflow valves (FCV-63-3, 4, 175).

5. Close the two valves in the crossover line downstream of the RHR heat exchangers (FCV-74-33, 35).

6. Open the 2 parallel valves in the common suction line between the charging pump suction and the safety injection pump suction (FCV-63-6, 7).

7. Open the valve in the line from the train A RHR pump discharge to the charging pump and train A SI pump suction (FCV-63-8) and the valve in the line from the train B RHR pump discharge to the train B safety injection pump suction (FCV-63-11).

8. Reset the SIS signal at the system level.

9. Close the two parallel valves in the line from the RWST to the charging pump suction (FCV-62-135, 136).

10. Close RHR suction from RWST by restoring power to FCV-63-1 (Rx MOV Bd A1-1) then closing it.

11. Close the valve in the line from the RWST to the Safety injection pump suction (FCV 63-5).

TABLE 6.3.2-4 (Sheet 2)

SEQUENCE OF CHANGEOVER OPERATION

SEQUENCE OF CHANGEOVER OPERATION FROM
INJECTION TO RECIRCULATION FOR CONTAINMENT SPRAY SYSTEM

1. Stop both containment spray pumps ("pull to lock in stop" to preclude the possibility of pump restart while realigning suction valves).

2. Open the essential raw cooling water isolation valves to each containment spray heat exchanger (FCV-67-125, 126, 123, 124). This action may be initiated early (prior to stopping containment spray pumps).

   NOTE: Individual trains may be realigned and restarted in series to minimize the time with no spray flow.

3. Close the spray pump/RWST isolation valve at the suction of each containment spray pump (FCV-72-22 and 21).

4. Open the sump isolation valve at the suction of each containment spray pump (FCV-72-23, 20).

5. Verify containment spray suction valves are open (Train A FCV-63-72, FCV-72-23; Train B FCV-63-73, FCV-72-20).

6. Start containment spray pumps and verify containment spray flow (FI-72-34, 13).

TABLE 6.3.2-4 (Sheet 3)

SEQUENCE OF CHANGEOVER OPERATION

REALIGNMENT OF ECCS FROM COLD LEG RECIRCULATION MODE
TO THE HOT LEG RECIRCULATION MODE

1. Aligning RHR Train A for Hot Leg Recirculation (Train B similar)

    a. CLOSE RHR Train A cold leg isolation FCV-63-93

    b. Verify RHR Train B discharge crosstie valve CLOSED FCV-74-35

    c. OPEN RHR Train A discharge crosstie valve FCV-74-33

    d. OPEN RHR hot leg injection FCV-63-172

    e. Verify RHR hot leg flow on FI-63-173

    f. Close RHR Train B cold leg isolation valve FCV-63-94

2. Aligning SI Pumps For Hot Leg Recirculation

    a. STOP SI Pump A-A

    b. CLOSE Train A crosstie FCV-63-152

    c. Verify FCV-63-152 CLOSED, then OPEN Train A hot leg injection FCV-63-156

    d. START SI Pump A-A and verify Train A hot leg flow on FI-63-151

    e. STOP SI Pump B-B

    f. CLOSE Train B crosstie FCV-63-153

    g. Verify FCV-63-153 CLOSED, then OPEN Train B hot leg injection FCV-63-157

    h. START SI pump B-B and verify Train B hot leg flow on FI-63-20

    i. Check power available and CLOSE SI pump cold leg injection FCV-63-22

6.4 HABITABILITY SYSTEMS

6.4.1 Habitability Systems Functional Design

6.4.1.1 Design Bases

One segment of the Main Control Room Habitability System design bases is a composite set of circumstances that describe the most adverse conditions that could take place. These were found to occur during a loss of coolant accident (LOCA) on a calm, hot day with the essential raw cooling water (ERCW) heat sink at its highest temperature. Such conditions were assumed to be concurrent, with the hot summer conditions lasting for the full duration of the emergency.

Another segment of the Main Control Room Habitability System design bases is a composite set of circumstances that describe the worst set of conditions envisioned during the winter months. These would occur during a LOCA on a calm, cold day with the ERCW heat sink at its lowest temperature. These conditions were also considered to be concurrent, with the weather conditions holding for the full duration of the emergency.

The last segment of the Main Control Room Habitability System design bases is a set of performance requirements. These are associated with the capability to maintain an environment within the main control room habitability system area that is in accordance with the requirements specified in Criterion 19 (10 CFR 50, Appendix A). The environment is maintained for the duration of the emergency even after suffering any single component or subsystem active failure.

Details associated with the above design bases are presented in other parts of this document. Information on wind conditions, sources, and amount of radioactivity that surround and enter the main control room is given in subsection 15.5.3. Peak outside environmental conditions and peak conditions within the main control room are described in subsection 3.11. A description of the cold weather limits adopted and information on normal operating conditions are described in subsection 9.4.1.

6.4.1.2 System Design

The Main Control Room Habitability System is designed to provide a safe, comfortable and appropriately equipped location for personnel controlling plant operations during normal operation and during accidents. Features incorporated into this Habitability System to assure these aspects include:

1. Adequate shielding from all potential radiation sources,

2. A Heating, Ventilating, Air Conditioning, and Air Cleanup (HVACAC) System designed to keep the main control room pressurized to at least a positive 1/8-inch w.g. relative to outside atmosphere and a slightly positive pressure relative to its surroundings and also, to maintain a slightly positive pressure in other rooms in the habitability zone relative to adjoining spaces during control room emergency operation mode at temperatures, humidities, and air purity levels adequate for conducting safe, efficient plant control operations (See section 9.4.1).

3. A low leakage enclosure for the main control room and its adjoining rooms to provide the capability for keeping a positive air pressure level within the enclosure,

4. Airborne hazards monitors that detect high temperature (e.g. steam) and unsafe radioactive gas levels annunciate the presence of the hazard and transfer the HVACAC system to its accident mode of operation. Operator action is credited for detection and actuation of the accident mode of operation for the HVACAC system for smoke,

5. Office and living accommodations appropriate for long term occupancy,

6. An amply stocked inventory of emergency equipment and supplies.

The Main Control Room Habitability System analyses is presented in Subsection 12.1.1. Factors considered in these design analyses were the LOCA induced activity releases and gamma shine from adjacent structures that could contain radioactivity are provided in Subsection 12.1.2.

This HVACAC System contains several aspects that are significant to the Main Control Room Habitability System. One of these is that this system has full capacity redundancy to assure a capability for controlling the environment after any single component or subsystem failure. Another important aspect is the capability to keep the main control room at least a 1/8-inch w.g. positive pressure relative to the outside atmosphere and a slightly positive pressure relative to its surroundings and also, to maintain a slightly positive pressure in other rooms in the habitability zone relative to adjoining spaces during control room isolation emergency operating mode, except during a tornado isolation mode. A third important aspect is the capability for selecting emergency pressurizing air, during accidents, from intakes on opposite ends of the building. This permits the operator to select the cleaner air source during such periods. A fourth aspect of interest to the Habitability System is the air cleanup units that purify both make-up and recirculated air flows during emergencies.

Each air cleanup unit in the HVACAC System contains a bank of HEPA filters and a bank of carbon adsorbers. The HEPA filter bank contains four filter units and the carbon adsorber bank contains twelve adsorber modules (see subsection 9.4.1 for further details). Type II unit trays, fabricated in accordance with AACC Standard CS-8, containing impregnated charcoal are used in the carbon adsorber bank. In this installation the face velocity across the bank of unit trays is less than 40 feet per minute and the residence time is in excess of 0.25 seconds to assure a high removal efficiency.

A third important feature in the Main Control Room Habitability System is its low leakage enclosure. This enclosure is formed by:

1. Monolithic reinforced concrete floor, walls, and roof described in subsection 3.8.4.4,

2. Metal pressure barrier beneath each control room console,

3. Low leakage seals for all electrical lines penetrating the enclosure,

4. Low leakage doors and door seals, and

5. Low leakage ventilation system isolation dampers.

The operational modes are the normal operations mode, and the emergency mode. The normal operations mode will be the mode utilized during all normal plant operations. The emergency operations mode will be initiated automatically by the receipt of a safety injection signal from either reactor unit, upon the detection of high temperature or radioactivity in the control building air intake duct, or manually by the operator (e.g., smoke).

In the normal operations mode, all access doors into the main control room habitability system area will be normally closed and will be used just for necessary ingress and egress.

In the emergency operations mode, ingress into and egress from the main control room habitability system area will be administratively restricted to essential movement. During this period, up to 1000 cfm of outside air will be brought in and mixed with recirculated air, filtered through an air cleanup unit, and processed for proper temperature level. In this mode, air leakage resistance from the main control room habitability system area will assure the maintenance of at least a 1/8-inch w.g. positive pressure in the main control room relative to outside atmosphere and a slightly positive pressure relative to its surroundings and also, maintenance of a slight positive pressure in other rooms in the main control room habitability system area relative to adjoining spaces. Such a capability was demonstrated during a preoperational test and periodically thereafter in accordance with Technical Specifications.

Little contamination is expected to enter the main control room habitability system area during ingress or egress activities during the emergency operating mode. The basis for this position is that during this brief period when the door is open the air flow will be from inside the main control room habitability system area to the outside. Since the pressure will never be below atmospheric in the main control room habitability system area during this interval, little contamination is expected to leak into the area. In such circumstances the makeup air input of up to 1000 cfm to the main control room habitability system area is considered sufficient to prevent significant infiltration.

Offices including the technical support center, living accommodations, and emergency equipment and supplies are also important features in the Main Control Room Habitability System. The scope of the office and living accommodations provided is shown in Figure 1.2.3-3. This shows that sanitary facilities provided include a toilet, shower, and locker room. Also provided is a kitchen that is equipped with a microwave, refrigerator, cabinet space, and a sink. Cabinets located within a main control room contain emergency supplies, first aid equipment, full coverage goggles, contamination clothing for whole body protection from beta radiation, face masks, self-contained breathing apparatus, and emergency radiation monitoring equipment to support possible emergency operations. The self-contained breathing apparatus is effective against smoke, airborne radioactive contamination, and an oxygen deficient atmosphere.

Fire protection for the main control room is described in the Fire Protection Report (see Section 7.4 and 9.5.1).

Face masks and self-contained breathing apparatus are provided to permit emergency operation.

Safe shutdown can be achieved and maintained from the backup control center (i.e., alternate shutdown) even with main control building completely destroyed. Alternate shutdown is described in the Fire Protection Report (see 9.5.1).

Environmental parameters for equipment in the Main Control Room are described in subsection 3.11. Details on the noncombustible control panels and consoles and on the fire resistant wiring installed in the Main Control Room are given in subsection 7.4.1.1.

The hazard to the control room from potential smoke generated by outside facilities is minimal due to the distance of separation between the sites and the control building air intake. The capabilities described above in Subsection 6.4.1.2, System Design, provide for the mitigation of consequences from smoke intrusion into the control room from any source. See subsection 2.2.3.5 for additional details on toxic gases.

6.4.1.3 Design Evaluation

The Main Control Room Habitability System has several features that collectively provide the capability needed to satisfy Criterion 19 (10 CFR 50, appendix A). An evaluation of this system, therefore, must take into consideration the contribution provided by the:

1. Shielding enclosing the main control room. Analyses presented in subsection 12.1.2 show that this shielding reduces the control room personnel dose from external sources created during a LOCA to a fraction of that permitted.

2. Low leakage enclosure for the main control room. The enclosure provides the capability for keeping a positive pressure within the main control room during control room isolation emergency operating mode.

3. Positive pressure level maintained in the main control room during control room isolation emergency operating modes. This capability assures that in-leakage of contaminated air is minimized.

4. Widely separated intakes for emergency pressurizing air. The two fresh air intakes for the control room are located at elevation 752, one at the north end of the building and the other near the south end. The intake at the north end may be used during both normal and emergency operations. During a radiological emergency, air is automatically supplied from both intakes until the operator manually shuts off the supply from one intake. Details concerning the radiation monitoring of the emergency pressurizing air and the selection of the air intake source are discussed in subsection 11.4.2.2.5. The option given the main control room operator to benefit from a wind-generated cleaner air mass may reduce contamination concentrations within the main control room significantly.

5. Sufficiently sized emergency pressuring air flow rate. The pressurizing air intake of up to 1000 cfm is sufficient for main control room pressurization and small enough to limit the amount of contamination drawn into the Main Control Room.

6. Filters and adsorbers incorporated into the HVACAC System. These air cleanup units help provide the capability for reducing the iodine inhalation dose to less than 30 rem and the whole body dose from gammas to well below the 5 rem limit. In these determinations, continuous 30 day occupancy was assumed and no credit was taken for utilizing the cleaner pressurizing air source capability described in item 4 above.

7. Airborne hazards monitor and control subsystem. Fully redundant monitors and controls allow automatic detection of high temperature (steam) and radiation levels and the capability to annunciate and to switch the HVACAC System to the accident mode of operation to help maintain an acceptable air purity level in the Main Control room. Operator action is credited for detection and actuation of the accident mode of operation due to smoke.

8. Accessibility of the HVACAC System dampers. This feature provides a capability for adjusting flow control or isolation dampers in the event one of these does not fail in the intended fail-safe position during an emergency.

9. Use of full coverage goggles and protection clothing provided in the control room emergency equipment stores kit to keep eye and whole body beta doses below the 5 rem whole body dose limit or its equivalent to any part of the body. Credit for occupancy was taken in this determination. Guidelines for occupancy were:

   100 percent occupancy during the first 24 hours, 60 percent occupancy beginning with the second day and ending after the fourth day, 40 percent occupancy beginning with the fifth day and ending after the thirtieth day.

   No credit, however, was taken for using cleaner pressurizing air available from one of the separated air intakes cited in item 4 above.

10. Office and living accommodations provided adjacent to the Main Control Room. These facilities provide a capability for long-term occupancy by control room personnel needed for accident control operations.

11. A backup control center located in the Auxiliary Building. This backup control center serviced by an Auxiliary Building Ventilation System gives a capability to conduct an emergency plant shutdown in the event that the Main Control Room becomes unavailable.

6.4.1.4 Testing and Inspection

Tests and inspections conducted on the Main Control Room Habitability System are mainly concerned with the HVACAC System, the capability to keep a positive pressure within the main control room, and the operation of the airborne hazards monitors. The scope includes preoperational and periodic tests. The preoperational tests objectives were to demonstrate that the HVACAC System, the main control room enclosure, and the airborne hazards monitors are capable of detecting hazards and are capable of establishing and maintaining acceptable conditions for safe, long-term occupancy. In this testing, the capability for performing all

necessary functions was verified. The periodic tests are scheduled to be performed during the plant lifetime in accordance with the Technical Specifications. Additional details are given in subsection 9.4.1.4.

6.4.1.5 Instrumentation Requirement

Several kinds of instrumentation are utilized in the Main Control Room Habitability System. Beta radiation sensors are installed in the makeup air intake duct. Static differential pressure indicators are installed in the Elevation 732 Mechanical Equipment room that indicate the pressure differential between the Main Control Room and the atmosphere external to the Control Building. Thermostats are positioned in the Main Control Room to control HVACAC System operations. Static pressure differential sensors are installed in the air cleanup units to measure the pressure change across each air purification element bank. Flow sensors are installed downstream from each Main Control Room air handling unit to sense the presence of substandard air flows and initiate startup of the standby redundant HVACAC train.

Design details of this instrumentation and associated control networks are given in Chapter 7.

6.5 ICE CONDENSER SYSTEM

See Figure 6.5.1-1 for Isometric of Ice Condenser.

6.5.1 Floor Structure and Cooling System

6.5.1.1 Design Bases

The ice condenser floor is a concrete structure containing embedded refrigeration system piping.

Figure 6.5.1-2A shows the general layout of the original floor structure. For Unit 1 only, Bays 13, 14, and 15, the wear slab is “modified.” The “modified” wear slab eliminated the ¼” steel plate and foam concrete section, as shown in Figure 6.5.1-2.B and replaced them with concrete. The “modified” wear slab is a monolithic reinforced concrete section with embedded cooling pipes. The “modified” wear slab is approximately 20 inches thick and acts as a filler/insulator material. The functional requirements for both normal and accident conditions can be separated into five groups: Wear slab, floor cooling, insulation section, subfloor and the floor drain. Each group is now described in detail.

Wear Slab and Floor Cooling System

Due to water intrusion and freezing under the slabs, the wear slabs in some bays have moved. This movement has impacted the slope of the wear slabs. The change in slope has not adversely affected the flow parameters. The embedded glycol piping and flex hose for the floor cooling system is acceptable for the movement in the wear slab.

Enhancement to the wear slabs to restrict the intrusion of moisture under the slabs include insulating between the 12" diameter drains and the 16" diameter sleeve, adding an insert with a gasket to seal the gap between the floor drain and the grate, and selectively applying sealant to the slab joints/cracks.

1. Functional Requirements

   The wear slab is a concrete structure whose function is to provide a cooled surface as well as to provide personnel access support for maintenance and/or inspection. The wear slab also serves to contain the floor cooling piping.

   The floor cooling system intercepts approximately 90% of the heat flowing toward the ice condenser compartments from the lower crane wall and equipment room during normal operation. The floor cooling system is designed with defrost capability. During periods of wall panel defrosting it may be necessary to heat the floor above 32°F. Selected bays have been modified to provide vertical drainage paths (well points) for removal of accumulated water from the foam concrete to reduce slab movement.

Design Criteria and Codes

Refer to the General Design Criteria, Subsection 3.8.3. The following codes are also used in the design:

American Welding Society Structural Welding Code - 1972, AWS Publication D1.1-72.

ANSI Standard Code for Pressure Piping Refrigeration Piping ANSI B31.5-66 including Addenda B31.5a 1968.

2. Design Conditions

a. Thermal Conditions

i. Initial cooldown -	top of Wear Slab	70°F	(except Unit 1 Bays 13, 14, & 15)
	bottom of Wear Slab	12°F	
ii. Defrost Cycle –	top of Wear Slab	33°F	
	bottom of Wear Slab	70°F	

b. Seismic Loading

i. 1/2 Safe Shutdown Earthquake (1/2 SSE) Loads	
Vertical 1/2 SSE	0.35g.
Horizontal 1/2 SSE	0.24g. radial; 0.36g. tangential
ii. Safe Shutdown Earthquake (SSE) Loads	
Vertical SSE	0.55g.
Horizontal SSE	0.37g. radial; 0.56g. tangential

c. Design Basis Accident (DBA) Loads

i. Pressure load on floor	19.3 psi
ii. Floor momentum load (due to deflectors)	78 kips

d. Ice Loading - assume 6 in solid ice on floor	4300 lbs/bay
e. Live Loading	250 lb/ft^2
f. Dead Loads	
1/4" plate	1410 lbs/per bay (except Unit 1, Bays 13, 14, & 15)
1/2" pipe	164 lbs/per bay
Concrete Wear Slab	9700 lbs/per bay (except Unit 1, Bays 13, 14, & 15)
“Modified” Concrete Wear Slab	22575 lbs/per bay (Unit 1, Bays 13,14, & 15)

g. Wall Panel - 121 lbs/in over back 8 in. of slab

h. Volume of cavity in floor structure — 5.3 yds^3/bay
"Foam" concrete density — 35 lbs/ft^3 (except Unit 1, Bays 13, 14, & 15)

During seismic and/or accident conditions the insulation is designed to support loads transferred by the wear slab. See Section 6.5.1.3 titled, "Original Wear Slab Insulation Section," for an evaluation of the effects of water intrusion and freezing within the foam concrete.

Structural Subfloor

The design of the structural subfloor is presented in Subsection 3.8.3.

Floor Drain

1. Functional Requirements

The floor drain is a passive structural component during normal operation as its only function is to minimize heat/air inflow to the lower plenum.

The section of floor drain pipe inserted vertically below the wear slab is designed to provide a high thermal resistance to minimize heat gain to the ice condenser. Under accident conditions the floor drains must not fail in a mode which prevents outflow of water.

Design Criteria and Codes

The floor drains and associated piping shall meet the requirements of TVA Class G piping, with the following provisions:

1. Seismic Category (pressure boundary)

2. Shall not crimp such that the cross-sectional area is reduced by more than 25 percent.

Welding of structural components shall comply with American Welding Society Structural Welding Code, AWS D1.1-1972.

Welding of piping components shall be in accordance with the requirements of ANSI B31.1 (1967).

The need for tack welds, originally specified between the sleeve and the floor drain grate, has been eliminated by incorporation of a flexible boot assembly into the floor drain to accommodate slab movement caused by intrusion of ice under the wear slab.

Design Conditions

Normal Operation
Design temperature, maximum - 120°F
Nominal DP across valve - less than 1 psf

Accident Conditions
ΔP across check valve - 14 psi (max.)
Temperature pipe and valve - 250°F

6.5.1.2 System Design

Original Wear Slab and Floor Cooling System

The original wear slab is a 4 inch thick layer of concrete (4000 psi) having an exposed top surface area of 139 sq-ft/bay. See Figure 6.5.1-3 for top surface typical geometry. The concrete has a density of 150 lbs/ft^3 and is prepared with air entrainment admixtures to minimize spalling from freeze/thaw cycles. Steel reinforcing is used in the wear slab to assure adequate and uniform strength. A protective coating is applied to the top of the wear slab which provides an additional water barrier for the wear slab. The floor cooling system consists of 1/2 inch schedule 80 carbon-steel ASTM A-333 Grade 6 piping which is embedded in the wear slab of each bay in a serpentine fashion (See Figure 6.5.1-3) thereby providing ample cooling of the wear slab surface. The cooling pipes contained in each wear slab rest on a steel plate which extends across the full width of the floor for maximum effectiveness in intercepting heat passing up through the floor. Expansion joints are located at each bay and expansion material is located at the slab perimeter. The floor cooling system design pressure is 150 psi. The floor coolant flow rate per bay is adjusted by means of needle valves and is monitored by a temperature sensing element located at the downstream end of each of the bay floor piping. Should a leak develop each individual bay piping loop can be isolated by closing two valves. The coolant contained in the piping is a corrosion inhibited glycol/water solution.

For defrosting purposes, electric heating of the glycol is provided. Components requiring periodic maintenance such as pumps, heaters and control valves are located outside of the ice condenser.

The insulation cavity is filled with a low density, closed cell, foam concrete. The nominal density of the foam concrete is 35 lbs/ft^3, the compressive strength is 110 psi. The thermal conductivity per inch thickness is normally 1.0 BTU/hr-°F-ft^2. The insulation cavity for the foam concrete is sealed by a vapor barrier to provide additional assurance that the insulation section will resist infusion of water vapor and thus retain a high thermal resistance. The top surface of the foam concrete is covered with a course of grouting which provides seating surface for the floor plate and cooling coil assemblies.

The foam concrete, however, has been exposed to water and over time became saturated which has resulted in degradation due to freeze-thaw action. The foam concrete is no longer considered capable of fully supporting the design loads experienced by the wear slab. This freeze-thaw action has also contributed toward upward heaving of the wear slab. The water source for the freeze-thaw action has been postulated to be leakage through the existing joint seals. During outage periods, water from ice condenser maintenance and cleaning has leaked through the joint seals and assimilated underneath the wear slab. The heaving action has resulted in the formation of cracks in the wear slab plus voids and fissures in the foam concrete.

Selected bays are “dewatered” by melting and removing ice from the foam concrete during outages as appropriate to reduce slab movement during plant operation. Foam concrete in selected bays has also been injected with a glycol based antifreeze agent to reduce freezing and thus further limit slab uplift caused by ice formation. A temporary floor movement monitoring system is installed to provide floor movement information during plant operation.

The inability of the foam concrete to function as a total support for the wear slab has been evaluated and found to be acceptable (see Reference 25). No adverse secondary effects were

identified that would prevent the ice condenser from performing its intended function. To help control the upward heaving of the wear slabs, well points may be installed in designated ice condenser bays. Following installation of the well points, the floor may be defrosted causing water in the foam concrete to migrate and collect in the wells where it can be removed. A sealant system has also been applied as necessary to seal the cracking formed by the heaving action. This sealant system is designed to retard the future intrusion of water.

Modified Wear Slab and Floor Cooling System

For Unit 1 only, Bays 13, 14, and 15, the "modified" wear slab is a 20.25 inch thick layer of concrete (4000 psi) having an exposed top surface area of approximately 139 sq-ft/bay. The concrete has a density of 118 lb/ft^3 and a nominal thermal conductivity of 6.0 BTU-in/hr-ft^2-°F. Steel reinforcement is used to control temperature and shrinkage stresses. The floor cooling system consists of ½ inch schedule 40 carbon steel ASTM A-333 Grade 6 piping which is embedded in the wear slab of each bay (13, 14, and 15) is a serpentine fashion thereby providing ample cooling of the "modified" wear slab surface. The cooling pipes contained in each wear slab rests on a steel framework, with cooling pipes extending across the full width of the floor for maximum effectiveness in intercepting heat passing up through the floor. Expansion joints are located between each bay and expansion material is located along the slab perimeter. The floor cooling system design pressure is 150 psi. The floor coolant flow rate per bay is adjusted by means of a needle valve and temperature is monitored by a temperature sensing element located on the downstream end of the coil piping for each bay. Should a leak develop, each individual bay piping loop can be isolated by closing two valves. The coolant contained in the piping is a corrosion inhibited ethylene glycol/water solution.

Floor Drain

Special consideration has been given in the design to prevent freezing of the floor drains and to minimize check valve leakage.

The floor drains employ a low thermal conductivity (transite) section of pipe 12 inch in diameter, inserted vertically in the wear slab to minimize heat gain to the ice bed. The top of the drain pipe is covered with a grating which is fastened to the floor. See Figure 6.5.1-2 for piping details. The drain check valve is a 12-inch diameter horizontal valve fabricated from 304 or 316 SS. The valve is designed to remain closed against the cold air head in the ice condenser to minimize any heat inleakage and air outleakage during normal operation. The valve is designed to tolerate a 15 psi back pressure when closed. The check valve is in a warm environment and no freezing will occur.

6.5.1.3 Design Evaluation

Wear Slab

The original wear slab is a structural element and during normal operating conditions is subject only to its dead weight consisting of concrete, steel reinforcing, steel plates, and piping. Below this is a foamed concrete fill for insulation purposes. These layers sit upon a structural slab and are both analyzed as sitting upon the structural slab. The original wear slab and fill dead weight is equivalent to 1.26 psi. Some bays have been modified. The "modified" condition has no independent wear slab. The volume where the original wear slab and fill was located is replaced by a concrete fill of light weight insulating concrete that contains the piping and is not considered a structural element. The modified configuration results in a light weight concrete fill dead weight equivalent to 1.41 psi. Six inches of 100% density ice is assumed to be uniformly distributed over the entire floor. The live load for maintenance purposes is assumed to be 250 lbs/ft^2. The vertical seismic input is 0.35 g for 1/2 SSE and 0.55 g for SSE. The dead load plus seismic loads are insignificant because the highest load on the floor is contributed by blowdown pressure during design accident conditions. The blowdown pressure is 9 psi, and added to this value, for design purposes, is a 40 percent design margin, and a dynamic load factor of 1.53. This results in a minimum value for design of 19.28 psi.

The most severe loading condition is the combination of the dead load, the SSE seismic acceleration of 0.55g, the 19.28 psi pressure load and 8.1 psi locally near the deflectors due to flow inpulse loadings. The wear slab is designed to accommodate the heatup and cooldown cycles and 1/2 SSE without overstressing the concrete and coolant piping (see section below titled, “Original Wear Slab Insulation Section,” for discussion of the effects of ice in the foam concrete).

Floor Cooling System

The embedded piping for floor cooling of the wear slab is 1/2 inch schedule 80 pipe and ½ inch schedule 40 pipe is used for the “modified” wear slab. The floor cooling system design pressure is 150 psi and the piping is tested to 200 psi. The pipe is sized to allow for at least 38 mils of corrosion. Nevertheless, the glycol coolant contains corrosion inhibitors and as a result pipe corrosion will be negligible. For the unmodified wear slab, the 1/4 inch floor plate is integrated with the concrete through 1/2 inch diameter anchors welded to the plate on 12 inch centers. These anchors prevent thermal loads from concentrating in the piping.

Original Wear Slab Insulation Section

The original insulation section supported wear slab loads. For a conservative analysis the wear slab dead weight + seismic + DBA loads were assumed to be transferred to the foam concrete section. The original compressive strength of the foam concrete was sufficient to accept these floor loads.

The insulation section consists of foam concrete. As the result of freeze-thaw action experienced, the foam concrete in Units 1 and 2 is no longer considered to support wear slab loads as originally designed. This condition has been evaluated and is acceptable (see reference 25).

Floor Drain

Drains are provided at the bottom of the ice condenser compartment to allow the melt/condensate water to flow out of the compartment during a loss-of-coolant accident. These drains are provided with check valves that are designed to seal the ice condenser during normal plant operation to prevent loss of cold air from the ice condenser. These check valves remain closed against the cold air head (1 psf) of the ice condenser and open before the water head reaches a value of 18 inches of water. The check valves also disburse the drain flow to obtain the spray pattern used to establish the ice condenser drain lower compartment heat removal mechanism described in References 27 and 28.

For a small pipe break, the water inventory in the ice condenser produced in proportion to the energy added from the accident. The water collecting on the floor of the condenser compartment then flows out through the drains. For intermediate and large pipe breaks the ice condenser doors are open and water drains through both the doors and the drains.

For a large pipe break, a short time of the order of seconds is required for the water to fall from the ice condenser to the floor of the compartment. Results of full scale section tests performed at Waltz Mill showed that, for the design blowdown accident, a major fraction of the water drained from the ice condenser and no increase in containment pressure was indicated even for the severe case with no drains.

A number of tests were performed with the reference flow proportional type door installed at the inlet to the ice condenser and a representative hinged door installed at the top of the condenser. Tests were conducted with and without the reference water drain area, equivalent to 15 ft^2 for the plant, at the bottom of the condenser compartment.

These tests were performed with the maximum reference blowdown rate, with an initial low blowdown rate followed by the reference rate, and with a low blowdown rate followed by the simulated core residual heat rate.

The results of all of these tests showed satisfactory condenser performance with the reference type doors, vent, and drain for a wide range of blowdown rates. Also, these tests demonstrate the insensitivity of the final peak pressure to the water drain area. In particular, the results of these full scale section tests indicated that, even for the reference blowdown rate, and with no drain area provided, the drain water did not exert a significant back pressure on the ice condenser lower doors. This showed that a major fraction of the water had drained from the ice condenser compartment by the end of the initial blowdown. The effect of this test result is that containment final peak pressure is not affected by drain performance.

Although drains are not necessary for the large break performance, 15 ft^2 of drain area was provided for small breaks.

For small breaks, water flows through the drains at the same rate that is produced in the ice condenser. Therefore, the water on the floor of the compartment reaches a steady height which is dependent only on the energy input rate.

To determine that the 15 ft^2 drain area met these requirements, the water height was calculated for various small break sizes up to a 30,000 gpm break. Above 30,000 gpm the ice condenser doors would be open to provide additional drainage. The maximum height of water required was calculated to be 2.2 ft above the drain check valve. Since this height resulted in a water level which was more than 1 ft below the bottom elevation of the inlet doors, it was concluded that water does not accumulate in the ice condenser for this condition and that a 15 ft^2 drain gives satisfactory performance.

During normal plant operation, the sole function of the valve is to remain in a closed position, minimizing air leakage across the seat. To avoid unnecessary unseating of the valve, a 1-1/2 inch drain line leading to a 2 inch drain header is connected to the 12 inch line immediately ahead of the valve. Any spillage or defrost water drains off without causing the valve to be opened.

Special consideration has been given in the design to prevent freezing of the check valves and to minimize check valve leakage.

To minimize the potential for valve freezing, a low conductivity (transite) section of pipe is inserted vertically below the seal slab, while the horizontal run of pipe (steel) is imbedded in a warm concrete wall before it reaches the valve. The valve itself is in the upper region of the lower compartment, where ambient temperature is above the freezing temperature.

The valve is held in a closed position by virtue of its design as an almost vertical flapper with a hinge at the top. The flap is held closed by gravity.

In order to reduce valve leakage to an acceptable value a sealant is applied to the seating surface after installation of the valves. Tests show that this reduces leakage to practically zero. Maximum allowable leakage rate would be approached as a limit only if all the sealant were to disappear completely from all the valves, which is unlikely. Sealant will be replaced as necessary. Water soluble paper is usually placed beneath the floor drain grating to serve as an additional vapor barrier against heat influx.

Conclusion

On the basis of the original analysis performed on the floor structure, it was concluded that the floor structure is adequate for all anticipated loading conditions. Water intrusion and subsequent uplift of the floor slab due to freezing have necessitated enhancement of the floor system. Joints in the slab have been sealed to prevent further water intrusion and the movement of the slab is now monitored to ensure that the free movement of the lower inlet door is not restricted. Three bays in Unit 1 have been replaced with new concrete.

On the basis of the latest structural analysis and engineering evaluation performed on the floor system (see Reference 25), it is concluded that the effect of freeze-thaw action on the foam concrete will not prevent the Ice Condenser from functioning as designed.

6.5.1.4 Testing and Inspection

Inservice inspection of the floor drain valves is described in SQN Technical Specification 3.6.15.

6.5.2 Wall Panels

6.5.2.1 Design Basis

Function

The wall panels are designed under normal operating conditions, to thermally insulate the ice bed from the heat conducted through the crane wall, the containment wall and the end walls. In addition, they are designed to provide a circulation path for cold air and a heat transfer surface next to the ice bed so that the ice is maintained at its design temperature range.

The supporting structure of the wall panel also provides for transfer of radial and tangential loads from the lattice frame columns to the crane wall anchor embedments.

Criteria and Codes

The structural parts of the wall panels are designed to meet the requirements given in Subsection 3.8.3.

Design Conditions

The service temperature range is 10 to 20°F. The Design Basis Accident temperature is 250°F.

The design loads are presented in Table 6.5.2-1. The loading combinations considered in the design are those given in Subsection 3.8.3. For the SSE plus DBA combination, ten (10) loading cases are considered.

6.5.2.2 System Design

The wall panel design incorporates provisions for installation on the crane wall, containment wall, and end walls of the ice bed annulus. Containment and end wall panels are similar except for the omission of the lattice frame column attachments. The design of a crane wall panel is shown in Figures 6.5.2-1 and 6.5.2-2.

The crane wall panel design incorporates transverse beam sections which are fabricated from a standard structural section and to which the lattice frame column mounting lugs are attached. These sections are attached to the rear mounting angle assemblies through two stainless steel side plates of bolted construction.

Wall panels are attached to the crane and end walls by studs welded to the anchor embedments and to the containment by studs welded to the shell. Details of the design of the crane wall anchor embedments are covered in Subsection 3.8.3. The crane wall panels extend from the bottom of the upper plenum to the lower support structure where they are supported on the inner circumferential beams of the horizontal platform. The containment wall panels extend from the bottom of the upper plenum to the top of the floor wear slab.

Cooling ducts are incorporated in the design to provide flow from the air handlers in the duct adjacent to the ice bed and return flow in the outer duct of the panel. This provides an even distribution of duct face temperature. Each bottom duct assembly provides a flow path between the inner and outer duct to allow return flow through the outer duct.

The ducts are fabricated as sandwich panels utilizing corrugated sheet sections enclosed in sheet metal enclosures. This type of sandwich construction provides resistance to differential pressure loads and results in minimal overall weight and flow restrictions.

The back cover sheet of the panel is mechanically fastened to prevent leakage, facilitate installation of insulation and to provide a vapor barrier. Attachment of lap strips between adjacent wall panels is made to the side plates of the panels. Joining of wall panel members is accomplished using fillet welds and mechanical fasteners on load carrying members. Lighter sections are joined by spot welding where structural rigidity and/or positive sealing are not required. Flow sections of wall panels are seal welded to prevent air leakage.

Materials of construction of the wall panels conform to requirements stated in Subsection 3.8.3.

Areas between air ducts and walls are insulated and areas between adjacent air ducts are insulated and covered with a lap strip to provide a seal between wall surface and ice bed. Elastomers and sealants will be insignificantly affected by exposure to a 5 r/hr gamma radiation field over a period of forty years.

The insulation between the containment wall and the air duct is polyurethane foam insulation. The auto ignition temperature of this material is about 1000°F. Ignition temperature is 400 to 500°F. Decomposition starts at 300°F. The major decomposition products are $C0_2$, CO, and NO_2.

6.5.2.3 <u>Design Evaluation</u>

The wall panels have been analyzed for seismic and Design Basis Accident loading conditions as well as service loads.

<u>Analysis for DBA Pressure Load</u>

The wall panels as shown in Figure 6.5.2-2, are bolted to transverse beam sections with a maximum span of about 24 inches. In the analysis, the wall panels were taken as a 24 in. x 36 in. sandwich plate simply supported on all four sides.

The stress analysis was based on the general theory for sandwich plates presented in References 7 through 9. Elastic constants were determined by the method given in Reference 10.

A local stress analysis was also performed assuming an elastic foundation and the stability of the leg of the corrugated core was investigated, Reference 11 (see Figure 6.5.2-3). The results of these analyses are summarized in Table 6.5.2-2.

It is noted that a DBA pressure of 18.7 psig was used in these analyses. The duct internal pressure was neglected in the analyses because it is negligible in relation to the 18.7 psig (internal design pressure 0.5 psig).

Analysis for Seismic and DBA Transverse Beam Loads

A transverse beam section was investigated for its ability to transmit the imposed Seismic and DBA loads from the lattice frame column attachment to the crane wall. A two dimensional beam analysis utilizing the "STASYS" program was employed. Various loading modes were used with values as shown in Table 6.5.2-1 B, C, D & E. Results are summarized in Tables 6.5.2-2 and 6.5.2-3.

Overall Conclusion

Based on the analyses described in the foregoing, it is concluded that the wall panel assembly meets the design requirements given in Subsection 3.8.3.

6.5.3 Lattice Frames and Support Columns

6.5.3.1 Design Basis

Function

The lattice frames and support columns assembly provide the following functions:

1. Positions the ice baskets in the ice bed and establishes the hydraulic diameter (free flow area between the ice baskets).

2. Provides lateral support for the ice baskets under normal, seismic and accident loads.

3. Allows passage of steam and air through the space around ice baskets.

4. Allows for basket installation and removal requirements.

Structural Requirements

Refer to Subsection 3.8.3.

Design Criteria

1. The lattice frames shall be designed to be compatible with the periodic weighing procedure for the ice baskets.

2. The structure shall be designed to position the ice columns in the required array to maintain the performance of the ice condenser. In particular, the flow area around each ice column shall be maintained within the limits established by the general design criteria.

3. The lattice frame shall allow loading of the ice baskets in position, and shall permit lifting of complete basket columns for removal in sections.

Materials Requirements

1. Refer to the listing of acceptable materials in Subsection 3.8.3.

General Thermal and Hydraulic Performance

1. The lattice frames shall space the ice basket columns so that the hydraulic diameter around each ice column is maintained for all modes of operation.

2. Differential thermal expansion between crane wall and lattice frame structure, together with other applicable loads, shall not stress the lattice frames or its associated supporting structure beyond the design limits, or adversely affect the spacing between lattice frames.

3. Forces across the lattice frames in the horizontal and vertical direction due to seismic and blowdown loads together with other applicable loads shall not overstress the lattice frame and supporting structure beyond the design limits.

Interface Requirements

1. Lattice frame to Ice basket Columns The lattice frame locates and aligns the ice basket array. Sufficient clearance shall be provided to assure ease of ice basket installation but shall limit radial basket motion to a nominal amount. The lattice frame structure must also be capable of withstanding design and operating seismic and accidental loading.

2. Lattice frame to Lattice Frame Column The lattice frame shall be attached to the lattice frame columns. The column bases shall be adjustable so that matching of columns to lower support structure can accommodate the range of manufacturing and installation tolerances.

3. Lattice Frame Columns to Crane Wall Air Duct Panels The lattice frame columns shall be bolted to the wall panel cradles. Lateral seismic loading from ice baskets and lattice frame shall be transmitted to the crane wall through the lattice frame columns and the wall panels. The studs at the crane wall shall be capable of meeting the structural design criteria.

4. Lattice Frame Columns to Lower Support Structure Lattice frame columns interface with the lower support structures. The columns shall be designed to allow for accumulation of dimensional tolerances at interfaces.

5. Lattice Frame Columns to Intermediate Deck The top end of the lattice frame columns at each bay shall support the intermediate deck and related supports.

6. Allowance shall be made for mounting the ice condenser temperature sensing system onto the lattice frames.

Design Load

The lattice frames and support columns are designed to withstand dead loads, live loads, seismic loads including impact and accident loads and remain within the allowable limits established in Subsection 3.8.3. Differential thermal expansion loads due to normal and accident conditions are also considered. Structural loads are not transmitted through the lattice frames and columns to the containment structure.

Figures 6.5.3-1 and 6.5.3-2 shows the lattice frame loading orientation and distribution.

The lattice frame and column design loads are listed below.

1. Dead Loads

Lattice Frame Weight, lbs each	1200
Column Weight Crane Side, lbs each (2-1/4 inch x 4 inch bar at 30.6 lbs/ft)	1500
Column Weight Containment Side, lbs each (3 inch x 5 inch x 1/2 inch x 48 ft @ 20.88 lbs/ft)	1000
Column Connector Bracket Weight, lbs/pair	50
Load on Columns from Intermediate Deck Doors, Framing and Grating, lbs per column	490

2. Seismic Loads

1/2 Safe Shutdown Earthquake (1/2 SSE)

Horizontal:
(See Table 6.5.3-1 for 1/2 SSE at 6 ft. increments in elevation from 15 to 57 ft. above floor. Table 6.5.3-2 presents local load on lattice frame due to single ice basket)

Vertical:
1/2 SSE to be applied to Dead Loads in Vertical Direction, g 0.35.

Safe Shutdown Earthquake (SSE)

Horizontal - Radial and Tangential:
(See Table 6.5.3-3 for all safe shutdown earthquake loads for each of the eight levels of lattice frames).

Vertical:
SSE to be applied to Dead Loads in Vertical Direction, g 0.55.

3. Design Basis Accident (DBA) Loads

Horizontal - Radial and Tangential
(See Table 6.5.3-3 for all lattice frame DBA loads for each of the eight levels of lattice frames).

Vertical - Lattice Frames:
A design margin of 40 percent and a dynamic load factor of 1.1 should be used with the values in Table 6.5.3-4.

Vertical DBA Loads from Intermediate Deck on Lattice Frame (DLF) Columns:

Col. Position	DBA+.4 Margin	1.2 DLF	Drag Load at Max. Hinge Load DBA+.4 Margin
1. Crane Wall-Primary	18,800 lbs	22,600 lbs	1135 lbs
2. Crane Wall-Intermediate	9,400	11,300	567
3. Crane Wall-Intermediate	9,400	11,300	567
4. Crane Wall-Primary	18,800	22,600	1135
5. Containment-Primary	20,500	24,600	1135
6. Containment-Intermediate	10,250	12,300	567
7. Containment-Intermediate	10,250	12,300	567
8. Containment-Primary	20,500	24,600	1135

Column loads are sequential and reflect adjacent bay loads. Primary columns are located at the bay ends and intermediates are between the primary.

4. Combined DBA & SSE Loads

Forces are transmitted to lattice frame and columns by the ice basket when blowdown and vertical SSE occur simultaneously. Blowdown forces the baskets laterally against the lattice frame structural members while vertical SSE transmits the friction load vertically to lattice frames and columns.

Table 6.5.3-3 lists the horizontal tangential and radial DBA and SSE force for each of the eight lattice frame levels. Using a friction coefficient of 0.50, the load for individual frames and columns are calculated. These friction forces are summarized in Table 6.5.3-5.

Specific Plant Parameters are as follows:

1. Minimum Service Temperature Inside Ice Condenser, °F	10
2. Maximum Service Temperature Outside Ice Condenser, °F	120
3. Operating Pressure, psig	0.3-0.5
4. Accident (DBA) Pressure (maximum), psig	9 + 4.0% = 12.6
5. Accident temperature, °F	250

6.5.3.2 System Design

The lattice frames are structural steel grid work structures located in the ice condenser annulus and fitted between the lattice frame support columns and clearing the wall panel air ducts.

The lattice frames are mounted radially across the ice condenser annulus for the full 300 degrees of annulus circumference at each of eight levels between the lower support structure and the intermediate deck. The first level is located 15 ft above the wear slab or ice condenser floor and the next seven levels are vertically spaced at 6 ft intervals. A total of 576 lattice frames are required for the ice condenser assembly. Three lattice frames are required per level in each of the 24 bays and this configuration is repeated for the eight levels.

The lattice frames are mounted to rectangular steel columns which are placed at the crane wall side and at the containment side of the condenser annulus. The column bases are attached to the lower support structures. Columns at the crane wall are attached along the length to the wall panel cradles and the lower support structure, while those at the containment side are free-standing i.e., the bases are fastened to the lower support structure but there are no connections with the wall panels or the containment vessel wall. This arrangement prevents transmission of loads from ice baskets, lattice frames and columns to the containment vessel. The vertical columns and crane wall support maintain the lattice frame geometry during normal and accident loading conditions.

The lattice frames are welded steel structures consisting of radial struts supported by welded cross bracing as shown in Figure 6.5.3-3. Basically the lattice frame is about 125 in. long, 48 in. at its widest point and 7-1/2 in. deep. The entire welded structure weighs about 1200 lbs. Individual free path penetrations are provided for each of twenty-seven ice baskets. The lattice frame struts that form the ice basket restraints are all double fillet welded to the stringers. This assures a consistent weld design and ensure the integrity of the entire structure in operation.

Flexible radial members on the lattice frame are located at the containment side to accommodate differential thermal expansion in the tangential direction, and to allow for minor column misalignment at installation. The flexible radial members are attached to the vertical support columns.

The lattice frame attachment at the crane wall consists of horizontal ear-like tabs that accommodates the bolting. One tab is slotted in the tangential direction to allow for differential thermal expansion between the concrete crane wall and the steel structures. Lattice frame tabs are fastened to brackets on the vertical support columns. The wall panel cradles are fastened to the crane wall studs and transmit the lattice frame and ice basket horizontal loads to the crane wall, while the vertical loads are transmitted to the lower support structure.

The cross bracings and radial struts are arranged so that the ice baskets are positioned in the free path penetrations. The free path diameter controls the radial clearance between ice baskets and the lattice frames. The penetrations are spaced to assure the proper hydraulic diameter around each ice basket and to allow free passage of air and steam through the surrounding passages. Small pads on the radial struts control the tangential ice basket clearance.

All of the welding and inspection will be done in accordance with the American Welding Standard Procedure, D1.1-72. The welds are inspected visually and then by magnetic particle examination. The magnetic particle examination is applied to selectively located welds throughout the structure.

6.5.3.3 Design Evaluation

The lattice frames were analyzed using The ICES-STRUDL II system of computer programs for frame analysis. STRUDL is a general program operating as a subsystem of the Integrated Civil

Engineering (ICES) program. The lattice frames were treated as three dimensional structures composed of joints, support joints, and structural members connecting the joints. Figure 6.5.3-4 illustrates the analytical model generated for the lattice frames. Each structural joint is assigned a circled number, and each structural member an uncircled number.

The lattice frame is treated as a cantilevered structure in the horizontal plane and restrained vertically at the four column connections in the vertical direction. The model in Figure 6.5.3-4 shows flexible connections at the crane wall and no connection at the containment wall. Variations in flexibility of the crane wall connections were considered in the analysis to simulate the behavior of the slotted tab connection and the connections to lattice frame columns and air duct wall panels.

The analysis of the loads for the individual maximums of D + 1/2 SSE, D + SSE and D + DBA was determined. A survey was also conducted for the loading combinations of D + SSE + DBA for each lattice frame level at reference seismic orientation, 45 degrees, and 90 degrees from reference (Refer to Figure 6.5.3-1) to determine the maximum loading condition on the lattice frame. The survey showed that the highest loads occur on the lattice frame at the 15 ft. level, and that the combination of D + SSE + DBA, horizontally and vertically produces the maximum stresses.

Maximum stresses are calculated at each structural member at the end of the fillet weld for all loading conditions. These maximum stresses are summarized in Table 6.5.3-6.

Fatigue stresses due to 1/2 SSE loading were calculated and are within the allowable limits defined in Subsection 3.8.3. Table 6.5.3-7 summarizes the fatigue analysis.

The vertical support columns and brackets which support the lattice frames have been structurally analyzed to determine structural integrity. The worst load combinations of D + 1/2 SSE, D + SSE, D + SSE + DBA were considered in the analysis. The resulting stress analysis indicates that the stresses in the supporting structure are within the allowable stress criteria limits defined in Subsection 3.8.3.

The vertical support members were also analyzed to determine buckling characteristics. Analysis using classical buckling methods indicates that this phenomena is not a concern.

6.5.3.4 Testing and Inspection

For inservice inspection, see Technical Specification 3.6.12.

6.5.4 Ice Baskets

6.5.4.1 Design Basis

Function

The function of the ice baskets is to contain borated ice in 12 inch diameter columns 48 feet high. The ice absorbs the thermal energy resulting from LOCA or steam line break in the containment structure. The baskets are arranged to promote heat transfer from the steam to ice

during and following these accidents. The function of the ice baskets is also to provide adequate structural support for the ice and maintain the geometry for heat transfer during or following the worst loading combinations.

Loading Modes

The following loading conditions are considered in the design of the ice baskets; dead weight, seismic loads, blowdown loads, and impact loads between the basket, ice and lattice frames. The baskets withstand these loads and remain within the allowable limits established in Subsection 3.8.3.

Design Consideration

1. The structural stability and deformation requirements are determined to ensure no loss of function under accident and safe shutdown earthquake loads.

2. The ice baskets are designed to facilitate maintenance and for a lifetime consistent with that of the plant.

3. The structure is designed to maintain the ice in the required array to maintain the integrity of performance of the ice condenser. In particular, the hydraulic diameter and heat transfer area are maintained within the limits established by test to be consistent with the containment design pressure.

4. Any section of the ice basket is capable of supporting the total weight of the ice above that section.

General Thermal and Hydraulic Performance Requirements

The ice baskets are fabricated from perforated sheet metal which has open area to provide sufficient ice heat transfer surface. The adequacy of the design and the performance were confirmed by test.

Interface Requirements

1. Lattice Frame The lattice frames at every 6 ft. act as horizontal restraints along the length. The design provides a nominal 1/4 in. radial clearance between the ice baskets and the lattice frames. Lattice frame and basket coupling elevations coincide to prevent damage to the basket during impact.

2. Lower Support Structure Ice basket bottoms are designed to be supported by and held down by attachments to the lower support structure. The basket supports are designed for structural adequacy under accident and safe shutdown earthquake loads and permit weighing of selected ice baskets.

3. Basket Alignment The ice condenser crane aligns with baskets to facilitate basket weighing and/or removal. The baskets are capable of accepting basket lifting and handling tools.

4. Basket Loading The ice baskets are capable of being loaded by a pneumatic ice distribution system. The baskets shall contain the minimum ice weight as specified in Technical Specifications.

5. External Basket Design The baskets are designed to minimize any external protrusions which would interfere with lifting, weighing removal and insertion.

6. Basket Coupling Baskets are capable of being coupled together in 48 ft. columns.

7. Basket Couplings and Stiffening Rings Couplings or rings are located at 6 ft. intervals along the basket and have internal flanges to support the ice from falling down to the bottom of the ice column during and after a DBA and/or SSE. The first 6 ft. interval from the top of each basket does not require a support.

Design and Test Loads

The minimum test and basic design loads are given in Table 6.5.4-1 and 6.5.4-2.

6.5.4.2 System Design

The ice condenser is an insulated cold storage room in which ice is maintained in an array of vertical cylindrical columns. The columns are formed by perforated metal baskets with the space between columns forming the flow channels for steam and air. The ice condenser is contained in the annulus formed by the containment vessel wall and the crane wall circumferentially over a 300° arc.

The ice columns are composed of four baskets approximately 12 feet long each, filled with flake ice. The baskets are formed from a 14 gauge (.075) perforated sheet metal, as shown in Figure 6.5.4-1. The perforations are a 1.0 in x 1.0 in holes, spaced on a 1.25 inch center. The radius at the junction of the perforation is 1/16 inch. The ice basket material is made from ASTM-A569 which is a commercial quality low carbon steel. The basket component parts are corrosion protected by a hot dip galvanized process. The perforated basket assembly has an open area of approximately 64 percent to provide the necessary surface area for heat transfer between the steam/air mixture and the ice to limit the containment pressure within design limits. The basket heat transfer performance was confirmed by the autoclave test.

Interconnection couplings and stiffening rings are located at the bottom and 6 ft. levels respectively of each basket section. The bottom coupling and stiffening ring are cylindrical in shape approximately 3 inches high with a rolled internal lip. The lip provides stiffening to the basket and a stop for the cruciforms at 6 ft. intervals. These cruciforms prevent the ice in the basket from displacing axially in the event of loss of ice caused by sublimation or partial melt down due to accident conditions. Testing performed by TVA and Westinghouse has confirmed that a cruciform insert is not required for the first 6 ft. interval from the top of each basket. (See Reference 26). These couplings are attached to the ice basket by locking sheet metal and screw and basket detents.

The baskets are assembled into the lattice frames to form a continuous column of ice 48 ft. high. The bottom wire mesh is designed to allow water to flow out of the basket and has attachments for mechanical connection to the lower support structure to prevent uplift of the baskets during SSE and DBA. The lattice frames provide only lateral ice basket support at intervals corresponding to the stiffened ice basket sections. The vertical loads of the ice and ice basket is

transmitted by the basket to the lower support structure. The attachment between the ice basket and the lower support structure is disengaged to permit weighing of the baskets. The columns of ice can be lifted and removed in sections, and provision is made for lifting and weighing the whole length of selected columns for surveillance purposes.

Fabrication

1. The sheet metal is purchased in the hot-rolled and pickled condition.

2. The perforator oils and perforates the material and ships to the basket fabricator.

3. The basket fabricator rolls the perforated metal into a cylindrical shape 12 inches in diameter by 143 inches long and material is degreased.

4. The sides of the rolled cylinder are continuously welded using the gas metal arc process.

5. Following the welding the cylinder is pickled, washed, fluxed, hot dip galvanized, and dipped in a sodium dichromate bath.

6. The couplings and stiffening ring blanks are cut from sheets or coils of hot rolled, pickled and oiled material. These are formed by a rolling process and are 3 inches high with a roll-formed internal lip and are of a diameter to fit inside the perforated basket.

7. The cruciforms are die-formed from steel strip.

8. Following the forming operations, the stiffeners and couplings with cruciforms in place are pickled, washed, fluxed, hot dip galvanized, and dipped in a sodium dichromate bath.

9. The column bottom is fabricated by a procedure similar to item (6) above. The proper appurtenances are welded in place and the piece is galvanized per item 8 above.

10. The remaining appurtenances are cut to size, machined, welded, and plated where required.

11. The completed couplings, bottoms, appurtenances, stiffening rings and cylinders are next assembled. The stiffening rings are inserted inside the cylinder until the side is adjacent to the 2.5 inch unperforated area in the center of the cylinder and attached by a self drilling, self tapping, locking machine metal screw and four basket detents.

12. For the column bottom, two U-bolts and nuts and washers fasten the mounting bracket assembly to the plate of the basket end.

13. The bottom is inserted into the cylinder until the cylinder rests against the step of the bottom and is attached mechanically by twelve self drilling, self tapping locking machine screws.

14. For the upper baskets, the couplings are inserted in the cylinders approximately 1-1/2 inches and attached with twelve screws as above.

15. All welding and inspection are performed in accordance with AWS publication D.1.1-72, including latest revisions.

Installation

The completed baskets are placed in the lattice frames from the top deck by first lowering a bottom basket into the lattice frames and locking in place, extending approximately 2 inches above the top lattice frame. The second upper basket is lifted with the crane and gripper fixture and placed on top of the bottom basket inserting the coupling into the top of the bottom basket and attaching with, self drilling, self tapping screws.

Next the locking or holding fixture is released and the two baskets lowered until the top is approximately 2 inches above the lattice frames as above. The third and fourth baskets are installed in the same manner as the second.

When the full column is assembled and ready to set on the lower support structure, the bolts and mounting bracket are loosened and the column lowered to facilitate alignment of the yoke with hole in the support structure. After alignment and insertion of the clevis pin, the four bolts are tightened. A hitch pin cotter is inserted to retain the clevis pin.

Materials

The listing of acceptable materials for the ice basket are presented in Subsection 3.8.3.

6.5.4.3 Design Evaluation

Basket Evaluation

The perforated metal baskets of A-569 low carbon of 14 gauge sheet and 1.0 in. by 1.0 in. holes on 1.25 in. centers have been evaluated by analyses and tests and found to be within the allowable limits defined in Subsection 3.8.3. Three different methods were used in determining the baskets adequacy. The first method employed classical strength of materials techniques, the second used limit analysis and the third confirmed the basket integrity by tests.

Stress Analysis

This method considers the ice basket as being composed of a number of line (vertical basket element) and stay (circumferential basket element) elements and the collapse of the ice basket may be precipitated by the local yielding and/or buckling of the individual line elements.

When the basket is loaded both axially and laterally as a beam, the line elements are subjected to an axial compression, a lateral shear and a bending load. This combined stress state can possibly lead to local yielding, plastic collapse, line element buckling and ultimately to structural failure. All these modes of possible failures were analyzed and the results were found to be well within the allowable criteria. Analysis indicates that the critical line element buckling load is about 303,000 lbs. The maximum vertical load, D + SSE is 2782 lbs. Therefore the possibility of elastic buckling is remote. For a case with only lateral load, the analysis indicates that a factor of safety of 3.15 exists between the allowable basket load and the maximum lateral load that exists. A summary of stresses are tabulated in Table 6.5.4-3. For the various design cases considered, it is seen that the design stress is always below the allowable stress.

The effect of unequal ice sublimation or non-uniform ice density causing torsional loads on the ice basket, has been investigated. From Table 6.5.4-3 the horizontal load of 1017 lbs. occurring under (D + SSE + DBA) conditions at the 12 ft. elevation is considered. This is equivalent to a shear stress at the neutral axis of the line element of 3403 psi. The effect of non-uniform ice distribution was represented by considering the ice mass center-of-gravity offset at an eccentricity of one inch, and neglecting the loss of ice weight, this gave an additional shear stress of 302 psi, for a total combined shear stress of 3705 psi. This is well below the allowable shear stress.

Analysis was also made of the same where the ice melts out so that it occupies only one half side of the basket. The eccentricity would be 3 inches but the ice mass would be halved giving a shear stress of 450 psi, for a combined maximum shear stress of 3850 psi, again well below the allowable.

Limit Analysis

Limit analysis was performed on the ice basket in order to determine by analysis the lower bound collapse load when the basket is simultaneously loaded in the axial and lateral directions. The following mode of failures were considered as follows:

1. Plastic collapse of the compression side
2. Plastic yield of the compression side
3. Shear yield of the neutral plane
4. Plastic yield of the neutral surface of line elements.

A summary of the combinations of concentric axial load and distributed load that will cause basket failure is presented in Figure 6.5.4-2. Also superimposed in this figure is the design and test load envelope. It can be seen that this envelope is well below the governing failure mechanism of plastic yielding of the neutral surface of the line elements.

Ice Basket Appurtenances Evaluation

The ice basket connections are analyzed to ensure structural integrity during all design load combinations of dead weight, 1/2 Safe Shutdown Earthquake, Safe Shutdown Earthquake and Design Bases Accident. The primary area of concern is the ice basket to lower support structure connection. This area is shown in Figure 6.5.4-1. The item, material and minimum yield stress are presented in Table 6.5.4-4. The allowable stress limits for D + 1/2 SSE, D + SSE or D + DBA, and D + SSE + DBA are tabulated in Tables 6.5.4-5, 6.5.4-6 and 6.5.4-7 respectively. The loads used in analysis of these parts envelope minimum design loads plus load factors necessary for the TVA analysis.

Clevis Pin

The clevis pin transmits the ice basket loads to the lower support structure through a 1x2 inch bar welded to the top of the structure. Sufficient clearance is provided both vertically and horizontally to provide a pinned connection, thereby eliminating the transfer of any moment to the structure resulting from basket deflection because of horizontal loads.

The stresses on the 1/2 inch diameter pin are tabulated in Table 6.5.4-8.

Column Bottom Mounting

The mounting bracket is attached to the basket bottom as shown in Figure 6.5.4-1. The design loads are transmitted through the mountings and clevis pin from the ice basket bottom.

The stresses in the mounting bracket assembly, plate, and U-bolt are tabulated in Tables 6.5.4-9, -10 and -11 respectively.

Column Bottom

The column bottom is shown in Figure 6.5.4-1. The loads that are transmitted through the clevis pin assembly are distributed to the ice basket through the rigid plate and the cylindrical ice basket end section. Wire mesh is used to contain the ice and to provide drainage for water. The stress summary for the ice basket end is shown in Table 6.5.4-12.

The intermediate ice baskets' couplings were also analyzed and the results of the analysis, given in Tables 6.5.4-13, -14, -15 and -16, indicate that the intermediate couplings are structurally adequate for maximum loading conditions defined in Subsection 3.8.3.

6.5.4.4 Testing and Inspection

Inservice inspection of the ice baskets is described in SQN Technical Specification 3.6.12.

6.5.4.5 Modifications

Modifications have been implemented on some damaged baskets which cause the basket/basket support configuration to differ slightly from the original configuration. The modifications ensure that the modified basket configuration meets or exceeds the equipment performance requirements of the original basket configuration evaluated in the previous paragraphs of FSAR Section 6.5.4.

6.5.5 Crane and Rail Assembly

6.5.5.1 Design Basis

Function

The crane and rail assembly is designed to carry components and tools into, out of, and within the ice condenser area during erection, maintenance, and inspection periods.

Criteria and Codes

The crane is designed in accordance with the requirements of the Electric Overhead Crane Institute Specification 61. It is designed so that under all loadings it will not be derailed.

The rail is designed according to the General Design Criteria of Subsection 3.8.3. These criteria provide assurance that the rail will maintain its structural integrity.

Design Conditions

The service temperature range is 15 to 100°F.

During plant erection, two cranes can be used in the ice condenser region, each carrying up to 6000 pounds. A separation of at least two bays is maintained between their centers. Prior to installation of air handling units, one crane is removed. The heaviest load actually expected after

this time is less than 2,500 pounds. The crane will remain normally parked (without load) outside the ice condenser while the reactor is at power. The crane and supporting structure are designed to withstand dynamic loading during operating modes specified above.

The design loads for the crane are presented in Table 6.5.5-1.

6.5.5.2 System Design

The bridge, boom and hoist of the crane are all motor operated. The bridge speeds are approximately 38 and 110 feet per minute. The boom member is capable of rotating 360° in either direction at a speed of approximately 2 revolutions per minute. The electric hoist is mounted on the boom member with 2 stainless steel cables reeved over 2 sheaves mounted on the boom and around 2 sheaves on the block assembly. The hoist provides approximately 71 feet of lift at speeds of 7 and 20 feet per minute. It is equipped with an upper and lower limit switch to insure that the cables will not completely unwind from the hoist drum.

The hoist will automatically switch to low speed approximately 2 feet below the highest point of travel.

The total crane weight is approximately 7200 pounds.

The predominant material of construction is A36 steel. The main structural members are painted to prevent corrosion.

The crane travels on two circular rails that run through the ice condenser area. The circular diameters of the rails are 95 and 109 feet. The top flange plate and rail section are continuously welded to the web plate under controlled conditions. The top flange and web plates are A36 steel and the lower rail section is special analysis steel with a hard non-peening rolling surface.

6.5.5.3 Design Evaluation

The crane rails and supporting structures were analyzed as a part of the top deck structure (see Subsection 6.5.11). It was found that all stresses were maintained within limits prescribed in Subsection 3.8.3 for all design conditions defined in 6.5.5.1.

6.5.6 Refrigeration System

6.5.6.1 Design Basis

Functional Requirements

The refrigeration system serves to cool down the ice condenser from ambient conditions of the reactor containment and to maintain the desired equilibrium temperature in the ice compartment. It also provides the coolant supply for the ice machines during ice loading. The refrigeration system additionally includes a defrost capability for critical surfaces within the ice compartment.

During a postulated loss of coolant accident the refrigeration system is not required to provide any heat removal function. However, the refrigeration system components which are physically located within the containment must be structurally secured (not become missiles) and the component materials must be compatible with the POST-LOCA environment.

Design Conditions

Operating Conditions

See individual component sections:

1. Floor cooling Subsection 6.5.1
2. Air handling unit Subsection 6.5.7
3. Isolation valves Subsection 6.5.7

Performance Requirements

1. The mandatory design parameters that relate to refrigeration performance are:

a.	Maximum initial total weight of ice in columns	3,162,289 lbs
b.	Minimum total weight of ice in columns	2,082,024 lbs
c.	Normal overall average operating temperature range of ice bed	10° - 20 °F

2. The design must also provide a sufficiently well insulated ice condenser annulus such that with a complete loss of all refrigeration capacity, sufficient time exists for an orderly reactor shutdown prior to ice melting. A design objective is that the insulation of the cavity is adequate to prevent ice melting for at least 7 days in the unlikely event of a complete loss of refrigeration capability.

3. The non-directly safety related design objective parameters are:

   a. Ice sublimation: Ice sublimation and mass transfer shall be reduced to the lowest possible limits by maintaining essentially isothermal conditions within the ice bed and by minimizing local temperature gradients. A design objective is to limit the sublimation of the ice bed to less than 2 percent per year by weight. The normal steady state sublimation appearing on the wall panels as frost is calculated to be significantly less than the total design objective.

   b. An appropriate combination of refrigeration capacity and insulation capability shall be achieved to permit the following;

      i. Maintain the average ice bed temperature in the range of 10 to 20°F under the most adverse non-accident conditions.

      ii. Cool the ice condenser down to 15°F in 14 days (initial cooldown prior to ice loading).

The ice condenser is structurally designed to withstand the various extreme loading parameters including DBA + SSE. The ice condenser design and the reactor containment supporting walls were analyzed for heat transfer through the boundaries of the ice condenser. The configuration and sizing of the cooling components were then determined to achieve the various design requirements.

One of the most important design criteria for the ice condenser is that the insulation shall maintain the ice condenser chamber below 30°F for a significant period of time given that a malfunction or failure of any refrigeration component has occurred. Most system anomalies can be remedied during this period. For any repair which would require more time, a scheduled reactor shutdown can be completed in a safe and orderly fashion. Eliminating the "emergency factor" from the operation of the refrigeration system places the performance of the refrigeration components in an operational category without mandatory safety related design requirements.

6.5.6.2 System Design

The refrigeration system serves as a central heat sink for sensible heat and heat of fusion picked up, respectively, in the ice condensers and in the ice machines. A circulating system of ethylene glycol solution carries the heat from the various heat transfer surfaces to the glycol chillers. Cooling of the ice condenser is achieved by a three stage system:

1st stage - refrigerant loop
2nd stage - glycol loop
3rd stage - air cooling loop

First stage - Refrigerant loop

Six original 25 ton* glycol chillers and four replacement 25 ton** glycol chillers are installed in the plant. Each glycol chiller is self contained and operates independently. The glycol chillers are common equipment shared by Units 1 & 2. Each chiller unit is a closed refrigeration system consisting of a compressor, a condenser, expansion valves, and evaporator. The original six 25 ton* units utilize analog controls; the replacement four 25 ton** units utilize digital controls. Ethylene glycol solution is cooled during its passage through the evaporator, and heat is removed from the chiller unit by cooling water flowing through the condenser. The condenser cooling water is provided from the raw cooling water system.

Refer to Table 6.5.6-1 for chilling machine parameters.

Second Stage - Glycol Loop

The second cycle, Figure 6.5.6-1, carries the heat removed from the ice condenser air handling units, the floor cooling system and the ice machines (when operating) to the refrigerant cycle evaporator/cooler units. The liquid circulating through this cycle is a corrosion inhibited 50% ethylene glycol solution. It is compatible with most common piping materials and standard gasket and packing materials. Piping and valve materials used in this loop are predominantly carbon steel with stainless or alloy trim. Diaphragm valves are provided with ethylene propylene diaphragms. Piping and equipment carrying chilled ethylene glycol solution are covered with low temperature thermal insulation.

Six glycol circulating pumps have been provided to convey cooled glycol from the ten refrigeration units to the air handling units (30 per containment) and to the ice compartment floor cooling system of each containment. The design includes provisions for interconnecting the chiller units and pumps, as follows: the A through H chillers can be aligned to either Unit's Ice Condenser or to the Ice Machines, the I and J chillers can be aligned to the Unit 2 Ice Condenser or to the Ice Machines, but not to the Unit 1 Ice Condenser. The heated glycol is then returned to the refrigeration units thereby completing the glycol loop. The heat is extracted from the air in its passage through the air handlers and from the floor cooling system. Two rows of air handlers located along inner and outer walls are served by respective glycol supply and return headers. The

*Nominal refrigeration rating of original chillers based on 85°F RCW Condenser inlet temperature
**Nominal refrigeration rating of replacement chillers based on 88°F RCW Condenser inlet temperature

return headers are connected to a vented expansion tank located above the upper deck in each unit. Inboard and outboard containment isolation valves are installed on both supply and return lines. Closure of these valves in response to a Phase A containment isolation will isolate the ethylene glycol piping inside the containment vessel from the external refrigeration system. In the event of a LOCA, the glycol heats up from approximately 0°F to the containment accident temperature and expands harmlessly into the expansion tank. The liquid trapped between a pair of isolation valves is relieved around the inner isolation valve through a bypass line via a small check valve. The bypass line also contains test connections for periodic leak testing of the isolation valves and the check valve.

The ice condenser floor is kept cold by chilled glycol solution circulating through pipe coils embedded in the concrete wear slab. (See Subsection 6.5.1 for floor cooling diagrams). During normal operation, one floor cooling pump feeds a circular header, which distributes the coolant to individual coils located in each bay. A second circular header returns the flow to pump suction.

The floor glycol solution is maintained at the proper temperature by continuously bleeding solution out of the system and feeding cold solution into it at the same rate. The cold solution may be taken from the glycol stream returning from the air handling units to the external refrigeration system. The bleed flow is sent back into the same line downstream of the feed connection. Feed and bleed flow is maintained by the same pump that drives solution through the coils. Bleed flow rate is regulated by a temperature control valve. A second pump is available for use while pump no. 1 is being serviced. A manual throttling valve bypassing the temperature control valve can perform the latters' function.

Floor temperature will generally be maintained between the temperatures of the ice bed and the wall panels. There should, therefore, be essentially no frosting on the floor surface. It is sometimes necessary, however, to heat the floor above 32°F when any time the wall panels are being defrosted in order to keep the water melting off the wall panels from freezing to the floor. At this time, the floor will be heated with warm glycol. After defrosting is completed, the system is restored to its normal cooling status. The defrost cycle is relatively brief and its effect on the ice bed will be negligible.

Components requiring periodic maintenance (pumps, heater, control valve) are located outside of the containment. The cooling coils in the concrete wear slab intercept heat passing up through the floor. The coils are made of heavy steel pipe to minimize chances of developing a leak by gradual corrosion of pipe material. Should a leak develop, any individual loop can be isolated by closing two valves inside the lower region of the ice condenser.

Table 6.5.6-1 has additional detailed parameters for the glycol cycle components.

The structural summary of the glycol cycle components are discussed in the following sections:

1. Floor Cooling System Subsection 6.5.1
2. Isolation Valves Subsection 6.5.7

<u>Third Stage - Air Cooling Loop</u>

The ice condenser compartment is designed to be kept below the freezing point throughout the life of the plant. It is cooled to 15°F prior to ice loading and kept near that temperature

indefinitely, barring occurrence of a loss-of-coolant accident, extensive failure of the refrigeration system, or permissible excursion during ice loading. Ice bed temperature is maintained at the specified level by means of chilled air circulating through the boundary planes of the compartment. Starting in the upper plenum, which constitutes the top boundary, air enters one of 30 air handling packages located in the plenum. The air handler cools the air and blows it down through a series of insulated duct panels lining the inner, outer and end walls of the ice condenser. When the air reaches the lower support structure at the inner wall or end walls or the floor level at the outer wall, it turns back up to the plenum through a parallel path in the wall panels.

The air handling units are designed for automatic self-defrost operation. The self defrost cycle is initiated by a preset timer. The timer programs defrost time and duration for each individual AHU coil. Both the time and duration of the defrost can be adjusted by resetting the timer. When the defrost time reaches the time setting for defrosting, the timer contact will close. This action will energize the coil defrost, drain pan, and condensate drain heaters; stop operation of the AHU fan motor; and shut off the solenoid operated glycol valve stopping glycol flow. The air handling unit will remain in defrost until the timer completes the defrost timing period. At that time, the above noted actions will be reversed, returning the AHU to normal operation. During the defrost period, the defrost termination (DT) switch may reach the 100°F cutout point before the time completes the defrost cycle. In this case, the DT switch will open and de-energize the heaters. However, the fan motor and glycol valve will not return to their normal operation modes until the timed defrost period ends. Optimum defrost cycles will be determined by experience gained during plant operation.

The coil defrost heaters, drain pan heater, and condensate drain heater have a high limit thermostat that will terminate the defrost heat if the defrost termination thermostat should fail.

Provisions also exist for defrosting the wall panels by circulating heated air through the wall panels. The structural function and capabilities of the air cooling cycle components are discussed in the following sections:

1. AHU Subsection 6.5.7
2. Wall panels Subsection 6.5.2
3. Air distribution ducts Paragraph 6.5.13

Table 6.5.6-1 has additional parameters for the air handling units.

6.5.6.3 <u>Design Evaluation</u>

The refrigeration system is sized to maintain the required ice inventory even under worst case operating conditions. The total capacity of the 10 glycol chillers is sufficient to maintain both ice condensers.

The design conditions for the hot boundaries of the ice condenser are:

1.	Lower containment, air temperature	125°F
2.	Upper containment, air temperature	105°F
3.	Equipment room air temperature	120°F
4.	Outer containment wall	110°F

Items 1 through 3 are specified in the general design criteria. Item 4 is the design dry-bulb temperature in the region of Tennessee where the Sequoyah Nuclear Plant units are located for a 50 year hot summer, plus an additional margin of 7°F. The 1% factor is defined such that only 1% of the time the dry-bulb temperature during the summer months will be above the specified temperature for a 50 year hot summer. Data was obtained from ASHRAE climatic guide for cooling and heating design conditions. For an average summer, the 1% design dry-bulb temperature for Chattanooga is 98°F and for a 50 year hot summer, is 103°F.

The major thermal boundaries of the ice condenser including the floor, cooled walls with ducts, lower inlet doors, and top deck support beams are analyzed using a Westinghouse developed computerized technique, TAP-A, (or TAP-B) - Computing Transient or Steady-State Temperature Distributions, WANL-TME-1872, Dec. 1969. Subcontract NP-1.

The TAP-A program is applicable to both "transient and steady-state heat transfer in multi-dimensional systems having arbitrary geometric configurations, boundary conditions, initial conditions, and physical properties. The program can be utilized to consider internal conduction and radiation, free and forced convection, radiation at external surfaces, specified time dependent surface temperatures, and specified time dependent surface heat fluxes."

The solution of the general heat conduction equation is determined with finite difference techniques. The program will solve the equation as determined for the particular finite element or nodal model set up, either explicitly or implicitly. All case studies for the ice condenser are solved implicitly.

The TAP-B program is a variation of TAP-A but includes fluid coupling to the finite element model. The TAP-B variation was used to analyze the cooled wall panels. Since the duct air temperature distribution is included in the model it is possible to evaluate the temperature distribution of the surface of the wall panel facing the ice condenser over the complete length of the duct.

The wall panel heat load comprises about 70% of the total heat load, through the thermal boundaries with the inner surface area of the wall panels covering just under 30,000 ft^2.

The wall panel model for the crane wall is 48 ft. long with 8 axial stations each 6 ft. in length. The width of the model covers the region from the center line of the duct region to the centerline of the lap strip region.

At each axial station there are typically three nodes distributed over the duct region, four nodes over the lap strip region and one node for the lattice frame support column. There are 41 interior surface nodes representing the two ducts at each axial station. The total number of internal material modes is 640 and the total number of surface nodes is 472 for the 48 ft. length of the model.

Roughly 70% of the thermal load through the wall panels flows through the mounting brackets (or about 50% of the total thermal load of the ice condenser). The cold boundary temperature of the model was assumed to be 12°F in the ice bed with a 10°F duct entrance temperature.

The original floor model utilized TAP-B. The results of the basic model justified the design concept. Hand calculations were used to estimate heat loads for design variations. The total

floor model is comprised of approximately 1200 nodes in 5 layers and covers one quarter of a typical floor bay, of which there are 24 bays. The air temperature over the floor was assumed to be 14°F. The temperature of the glycol boundary was calculated for each fluid node. Over 90% of the heat entering the floor region is found to be removed by the floor cooling system. Use is made of the transient capabilities of the program to determine the defrost or warm-up time required when the glycol is heated. The heat transfer through the top surface of the floor is in two directions, both into and out of the wear slab. The net flow from the top surface to the ice condenser chamber is about 1000 BTU/hr. About 78,000 BTU/hr total is absorbed by the floor glycol coolant.

The “modified” wear slab was analyzed using the ANSYS code to evaluate the heat transfer characteristics of the modified floor structure. The use of this evaluation resulted in a modified cooling coil design which would conservatively intercept the nominal heat load through the modified floor structure.

The lower inlet door region while not contributing significantly to the overall thermal load on the refrigeration system is extremely important when considering sublimation. Various models of portions of the door were postulated to determine effective means of limiting the heat flux through the lower inlet doors.

The total heat load through doors with appropriate insulation is maintained at less than 11,000 BTU/hr to the ice bed. The door assembly was analyzed in two segments, there are 24 complete 2 door assemblies in the ice condenser. The first door model covered the region from the centerline of one door panel to the central seal region. Hand calculations were used to determine the nature of the convection between the two door panels in the central seal region, and in the outer hinge region. The information on the type of convection present was necessary to locate insulation and to determine any advantage to be gained from positioning flaps or boots around the door center because the convection was determined to be laminar with air conduction dominating. The central door model contained about 150 internal nodes including insulation. The second region covered by a model was the hinge region. The hinge model was 15 inches deep (about 1/6 of) the door length and included effects of the reinforcement channels along the full width of the door. The extremities further away from the hinge region were only grossly modeled. There were a total of 168 internal nodes in the "hinge" model including a protective boot around the hinge. The hinge model also included effects of the pillar in the crane wall upon which the door is mounted. The hinge region is of major importance in contributing to the internal thermal load with most of the heat input coming from the massive concrete pillar. It is necessary to protect the hinges with boots to limit the convective heat transfer which is quite effective in reducing the heat flow.

The top deck support beams are similarly modeled using TAP-A. The beams are a major source of thermal load in the plenum and are thermal boundaries, but only a small fraction of the total thermal load on the air handlers (not including air handler motor heat).

The modeling required for analysis of the components is extensive and detailed. The admittance of each node and connection; involving the determination of the length, volume, and area of each element was conservatively estimated where simplification of the model was required. The models are realistic since sufficient detail was considered and all significant modes of heat transfer were considered. Hand calculations back-up all major assumptions used to arrive at a model.

The summation of the thermal analysis gives a total nominal thermal load of 60.6 tons or 727,600 BTU/hr, based on the original foam concrete floor structure design. The “modified” wear slab and embedded cooling coil was designed such that the nominal thermal load through the floor was similar to the original design. As such, the overall heat gain in the ice condenser is approximately the same.

The breakdown is listed below. The values given are considered to be maximum expected loads. Design changes required as a result of seismic load changes or other design re-evaluations would of course change the final summation. The final thermal load will still be maintained at the same level consistent with stated required refrigeration requirements.

	x 10^4 BTU/hr
Wall panels	29.33
Plenum and Top Deck	9.32
Leakage (50 cfm) (see Note 1)	1.31
Lower inlet doors	1.10
Floor (including floor pump heat)	12.00
End walls	.91
Total thermal load	53.97

Note 1. Plant testing has verified a nominal leakage of 250 cfm. Sufficient margin was provided in system design to ensure that minimum total ice weight not be reached between refueling outages, as demonstrated by past operating experience.

The calculated heat loads show that a heat gain of 465,300 BTU/hr per containment may be expected from thermal boundaries of the ice condenser. Additionally the air handling unit fan motors generate 75,800 BTU/hr of motor heat. The floor cooling system including pump heat has a heat gain of 120,000 BTU/hr.

The circulating pumps (2 operating) add a total of 100,200 BTU/hr. The piping is estimated to pickup 7,000 BTU/hr. Therefore, a chiller capacity of 790,000 BTU/hr per containment (base load) is required. The glycol chillers are common equipment serving both Units and the total chiller package capacity was chosen to be 3.8 times the total two unit base load which is approximately 3,000,000 BTU/hr. Since eight glycol chillers are rated nominally at 300,000 BTU/hr* and two glycol chillers are rated at 300,000 BTU/hr**, depending on cooling water temperatures, the total installed capacity is, therefore, 3,000,000 BTU/hr (nominal rating).

The six circulating pumps (4 operating, 2 standby) are conservatively sized to deliver the required cooling to each plant. Two standby pumps are included in the design to assure adequate cooling solution flow even in the event of a pump failure. Similarly the air handling units are conservatively sized to handle the worst case cooling load. Thirty air handling units are installed based on a 10/7 ratio of (per the original system design basis) installed capacity to base load.

*Nominal refrigeration rating of original chillers based on 85°F RCW Condenser inlet temperature
**Nominal refrigeration rating of replacement chillers based on 88°F RCW Condenser inlet temperature

Therefore at least nine (9) air handling units are available to take care of unit failures or units temporarily out of service due to normal air handling unit defrosting.

It is significant that the ice bed is sufficiently subcooled and insulated so that even a complete breakdown of the refrigeration system or of all air handlers will not initiate the melting of any ice for a period of one week. Anomalous conditions in the ice condenser will be indicated by alarm annunciation from expansion tank level switches, the temperature monitoring system, or the door position monitoring system.

Consideration has been given to the effect on refrigeration performance of component failure. The basic consideration to keep in mind is that if the refrigeration system were to fail completely it would take a period of more than 1 week for the ice bed to reach an average temperature of 30°F under maximum environmental conditions.

It is obvious from the manner in which the number of air handlers were sized that there is adequate air handler capacity to compensate for multiple air handling unit failures. If one bay using the original foam concrete structure in the floor is not cooled because the glycol flow has to be isolated from that bay the heat nominal load from that bay is under 3,000 BTU/hr. The effective nominal sublimation rate for that bay would be approximately .25% per year per bay. It would be expected that one bay would not be permitted to go uncooled for more than 1 year. Once an operational sublimation rate is established it would not be unreasonable to assume that possibly 3 isolated - uncooled floor bays could be permitted to be uncooled for about 1 year. If the floor cooling system is shut off completely it should be put back in operation in 3 to 6 months. An annual sublimation rate of about 4 to 5% per year will result with no cooling in the floor.

For the “modified” wear slab bays, a loss of cooing would result in a slightly higher heat transfer through the monolithic concrete relative to the foam concrete. However, the slight increase in heat transfer considering an isolated cooling coil would not be expected to increase nominal sublimation rates previously determined.

6.5.7 Refrigeration System - Components

The following discusses Refrigeration System components which require structural integrity.

6.5.7.1 Design Basis

1. Air Handling Units (AHU)

   During normal operation the air handling units serve to cool the air and to circulate the cooled air through the ice condenser walls panels to keep the ice subcooled in the ice beds. Normal structural loads expected are dead weight seismic 1/2 SSE and thermal loads. During an accident the AHUs are designed to resist the normal structural loads plus SSE + DBA induced loads. Welding, welder qualification and weld procedures are in accordance with ANSI B31.5 Refrigeration Piping and the ASME Boiler and Pressure Vessel Code, Section IX "Welding Qualification."

2. Isolation Valves

   During normal operation the containment isolation valves are open, thereby permitting glycol coolant flow to the containment as well as coolant return from the containment to

the glycol chillers. During a LOCA, the automatic diaphragm valves are commanded to shut which terminates the glycol coolant flow and isolates the part of the system inside containment. The valves constitute part of reactor containment. The valve operation satisfies the requirements of 10 CFR 50 Appendix A, GDC 57 "Closed System Isolation." In addition a small check valve is included within containment which provides a passage for expanding liquid trapped between the automatic diaphragm valves thereby avoiding a destructive pressure buildup. At the same time the check valve prevents reverse flow (out of containment) and therefore also satisfies the requirements of GDC 57.

The valves are required to function under SSE and/or DBA conditions and must seal against the circulating pump head.

3. AHU Support Structure

Functional Requirements

The AHU support structure supports the Air Handling Unit package under various design conditions which are detailed below:

Design Criteria and Codes

Refer to the Design Criteria Subsection 3.8.3.

Design Conditions

Normal Operation

Deadweight loads due to AHU, structure, transformer	2500 lbs
Design temperature, min.	15°F

Accident conditions

Post-Accident Temperature (no uplift)	190°F

6.5.7.2 System Design

1. Air Handling Units

Each AHU is supported from its support structure, transmitting its major loads to top deck cross beams. See the AHU Support Structure Design Criteria for additional details.

The air is drawn by each AHU from the upper plenum, is cooled in the AHU and is discharged into the air distribution header. The design gross cooling capacity of each AHU package is 30,000 BTU/hr with the plenum air entering at 19°F maximum and cooled by the AHU to 10°F nominal. Each package has a nominal 2400 CFM air delivery capacity. The entering glycol mixture is at -5°F nominal temperature and the discharge glycol temperature is 0°F nominal. These glycol temperatures may vary as needed to maintain the desired ice condenser temperature. The optimum normal operating temperature of the ice condenser has been demonstrated to be 19°F in order to minimize concrete expansion, floor heaving, and frost buildup. Electrical power is provided for fan motor and defrost heaters as well as for temperature control circuits.

In order to support seismically induced loads the AHU and supports are designed to have a natural frequency in excess of 20 Hz. All materials used in the AHU's are compatible with both normal and post LOCA environments.

2. Isolation Valves

The valves are made of carbon steel to ASTM A216, Grade WCB, normalized with a diaphragm and soft disc or seat material of ethylene propylene rubber. The valve bodies can tolerate a maximum internal pressure of 200 psig. The diaphragm valves are subjected to a normal flow rate of 360 gpm and can operate over a temperature range of -10 to 190°F. Materials and paints are corrosion resistant and present no material compatibility problems during either normal or accident conditions. Provisions exist for periodic leak testing of the isolation valves in place. Electric power exists for valve operation and valve position instrumentation is employed. The valves and associated piping are supported so as to limit the stresses due to earthquake and thermal loads.

3. AHU Support Structure

The support structure supports the air handling unit vertically and tangentially from the cross beam of the top deck structure and is radially hinged from channels attached to the crane or containment wall. All parts are coated with a paint suitable for use inside containment. Figure 6.5.7-1 shows the design of the structure.

6.5.7.3 Design Evaluation

Configuration

The uniformity of temperature in the ice bed is important to reduce the amount of sublimation.

The flow pattern of the duct work is planned to minimize temperature variation on the inner "ice bed side" surface. The cold air exhausting from the air handler units enters the ducts which are divided into two sections. The inlet section covers the entire front surface of the duct except for the insulated lap strip region. The cold air flows down the length of the ice condenser wall to the door top, or floor, then returns flowing up the backside facing the hot boundary. The ducts are isolated with thin insulation. The regenerative effect is very small since the 2 film coefficients on either side of the insulation provide a resistance that in combination with the low transverse gradient result in a relatively nominal or small heat flow from the hotter to the colder inside duct. In fact this flow helps to slightly mitigate the vertical gradient. The change in the temperature on the ice bed side surface of the duct is less than 2°F over all. The insulation between the containment wall or crane wall and the duct provides the primary resistance to reduce the heat flow into the ice bed.

Detail analysis of the panel surface also shows a very small temperature difference between the lap strip region and the duct surface. This uniformity (less than 1°F ΔT) results from tying the lattice frame support columns into the upflow or return duct by means of a heavy bracket and support pad attached to the back of the duct, then to the wall, rather than directly to the hot wall.

The wall panels act also to effectively reduce the heat flow into the ice bed in the unlikely event of a complete refrigeration failure.

The air handlers exhaust the supply of cold air into a common manifold with takeoffs to each of the 150 wall panel assemblies. The exhaust from the ducts enters a common plenum above the ice bed where mixing and balancing of the flows occurs. The exhaust of each duct need not be controlled by dampers, etc., since the system is relatively well balanced and insensitive to 10% variations in flow. It is unlikely that adjacent air handler units will be other than temporarily out of service and since excess performance capability is installed together with an equalizing inlet manifold occasional defrost etc. will not cause a problem.

Temperature variations along the containment wall will not cause temperature variations along the ice bed side for the reason that there is very little regenerative effect between the downflow and return ducts.

The outer containment wall is sealed against vapor migration by the containment shell, the inner crane wall is sealed and painted, however, no credit is taken for the effectiveness of the paint in preventing vapor migration. A calculation was made to check the permeability of the crane wall to moisture. It was determined that if the gap between the crane wall panel and the crane wall communicated with the dry upper plenum that vapor would migrate to the cold plenum rather than to the relatively warm back of the wall panel. It is required however that an effective vapor barrier be provided for the duct insulation which is accomplished by the sealed metal back facing of the wall panel.

The expected operating temperature difference between the upper plenum and the top of the ice bed is small. The plenum is isolated from the ice bed by the intermediate deck doors. The gradient across the deck is on the order of 1°F. This gradient is one of the most difficult of all parameters to predict with accuracy coincident with size of the gradient. However, since the gradient is small the intermediate deck heat load will not be significant.

Vents in the intermediate and top deck are installed to provide replacement air which will compensate for leakage flow through the lower inlet doors. These vents complete the circuit of flow and ensure that the flow through the lower inlet doors is always from the ice bed to the lower containment without depleting the cold head in the lower ice bed. Diffusion against the design flow was checked and found to be small or negligible, especially with flapper valves in the vents. (See Section 6.5.6.3.)

<u>Sizing Calculations</u>

The pressure drop through the ducts and manifolds was estimated by using loss coefficients determined by using a standard Reference 12 as a guide. The pressure drop through the air handlers was determined by test. The overall system flow rate was established by superimposing the system flow versus ΔP curve over the fan flow versus ΔP curve.

With the flow rate established the capacity of the air handlers was determined. First the air handler capacity was theoretically determined for a set of design conditions approximating operating conditions. Next the air handler units were tested by the manufacturer to the set of specified design conditions. It was determined that the theoretical relationships adequately predicted air handler performance and these techniques were then used to adjust the test values

to those of actual operation. The gross operating capacity of one air handler is just under 30,000 BTU/hr by manufacturer's test and calculation. Gross operating capacity has been found to be lower than 30,000 BTU/hr, however, the ice bed temperature has been successfully maintained at or below the Technical Specification limit.

The air handling unit heat load is adjusted by a factor of 10/7 per the original design basis to insure adequate capacity under operating conditions for fouling, defrosting or isolated instances of one or several unit failures. Maintenance and inspection will greatly increase or insure reliable mechanical operation and cooling performance.

An estimate of the number of air handlers required was made to initiate the calculation, the flow pressure and rates drops were then calculated and the fan motor heat and heat transfer rates of the air handler unit predicted. The predicted performance was compared with the required capability and the calculation was reiterated varying the number of AH units until the predicted performance just exceeded the required capability.

The final number of required air handlers was determined to be 30.

The capacity of the chiller packages was determined by commercial design practices. The expected thermal load was summed for the air handler units, pumps, floor system etc. and multiplied by a factor of 3 to size the chiller units. The expected loads were used rather than the design loads utilizing the 10/7 factor since it is not necessary or desirable to double up on fouling or excess capacity factors. The six original glycol chillers are rated for a capacity of 300,000 BTU/hr* per unit, and the four replacement glycol chillers are rated for a capacity of 300,000 BTU/hr** per unit with specifications as follows:

	original	new	
glycol outlet:	- 5°F	- 5.2°F	(as confirmed by test)
glycol inlet:	+ 2.3°F	+ 2.3°F	(as confirmed by test)
cooling water temperature:	85°F	88°F	

It should be noted that the chiller outlet is specified as approximately -5°F (nominal) and that the air handler inlet is also specified as -5°F (nominal). A check calculation of the line heat gains for 200 ft of 2 inch std pipe indicates a ΔT rise of .02°F for a nominal insulation thickness of 3 inch of foam glass.

Sublimation Calculations

The heat gain contributing to sublimation was determined to be under 16,000 BTU/hr as a result of the calculations discussed in Subsection 6.5.6. An enthalpy flow balance was employed to determine the fraction of heat entering the ice bed which results in sublimation. The fraction is about 30% of the heat transferred by convection.

Since the door and lower ice condenser volume is the major source of heat contributing to sublimation a simplified but conservative model was established for that situation. The door surface temperature was conservatively calculated to be 20°F with the ice bed temperature at 13°F for the descending cold air. The heat load to the ice bed was calculated to be less than

*Nominal refrigeration rating of original chillers based on 85°F RCW Condenser inlet temperature
**Nominal refrigeration rating of replacement chillers based on 88°F RCW Condenser inlet temperature

10,000 BTU/hr from the door with the insulation in place. Radiation and convection were taken into consideration in the calculations, both with respect to the heat input and removal. A typical deposition of frost was assumed to be on the wall panels with a nominal conductivity of 0.07 BTU/hr-ft^2-°F.

The area of deposition of frost varies with the air flow but the quantity remains constant (with constant heat input). Several techniques were utilized to bracket the air flow and corresponding sublimation calculations completed for each case.

The overall sublimation rate was calculated to be 0.2 to 0.5% per year when radiation was included as a mode of heat transfer. Previous calculations considering only convection ranged from 1 to 2% per year. It is obvious that the inclusion of radiant heat transfer effects significantly reduces the overall sublimation rate.

The model for sublimation considered only the lower ice bed volume door; the effects of heat loads from other sources intermediate deck etc., are not as significant and therefore included only in the final calculation to determine the quantity of ice deposited on the walls. Also not included was ice removal due to leakage of dry air.

A modal frequency analysis was performed for the air handling unit housings and support structure. The results indicate that the design frequency is approximately 20 Hz, so that the fundamental mode is well out of the frequency range of peak amplification on the response spectra. In the process of designing the structure on the basis of stiffness, strength of members subjected to various combinations exceeds specified limits by generous margins.

6.5.8 Embedments

See Sections 3.7 and 3.8.

6.5.9 Lower Inlet Doors

6.5.9.1 Design Basis

Function

The ice condenser inlet doors form the barrier to air flow through the inlet ports of the ice condenser for normal plant operation. They also provide the continuation of thermal insulation around the lower section of the crane wall to minimize heat input that would promote sublimation and mass transfer of ice in the ice condenser compartment. In the event of a loss of coolant accident, LOCA, causing a pressure increase in the lower compartment, the doors open, venting air and steam relatively evenly into all sections of the ice condenser.

The door panels are provided with tension spring mechanisms that produce a small closing torque on the door panels as they open. The magnitude of the closing torque is equivalent to providing approximately a one pound per square foot pressure drop through the inlet ports with the door panels open to a position equivalent to the full port flow area. The zero load position of the spring mechanisms is set such that, with zero differential pressure across the door panels, the gasket holds the door slightly open. This setting provides assurance that all doors will be open slightly, upon removal of cold air head, therefore eliminating significant inlet maldistribution for very small incidents.

For larger incidents, the doors open fully and flow distribution is controlled by the flow area and pressure drops of inlet ports. The doors are provided with shock absorber assemblies to dissipate the large door kinetic energies generated during large break incidents.

Criteria

Radiation Exposure

Maximum radiation at inlet door is 5 r/hr gamma during normal operations. No secondary radiation due to neutron exposure.

Structural Requirements

Refer to Subsection 3.8.3.

Loading Modes

1. The door hinges and crane wall embedments must support the dead weight of the door assembly during all conditions of operation. Door hinges shall be designed and fabricated to preclude galling and self welding.

2. Seismic loads will tend to open the door.

3. During normal operations the outer surface of the door will operate at a temperature approaching that of the lower compartment while the inner surface will approach that of the ice bed. During loss of coolant accidents, the outer surface will be subjected to higher temperatures on a transient basis. Resultant thermal stresses are considered in the door design.

4. During large break accidents, the doors will be accelerated by pressure gradients then stopped by the shock absorber system. During small break accidents, doors will open in proportion to the applied pressure with restoring force provided by springs. Upon removal of pressure, door closure will result as a result of spring action.

Design Criteria - Accident Conditions

1. All doors shall open to allow venting of energy to the ice condenser for any leak rate which results in a divider deck differential pressure in excess of the ice condenser cold head.

   The force required to open the doors of the ice condenser shall be sufficiently low such that the energy from any leakage of steam through the divider barrier can be readily absorbed by the containment spray system without exceeding containment design pressure.

2. Doors and door ports shall limit maldistribution to 150 percent maximum, peak to average mass input for the accident transient, for any reactor coolant system release of sufficient magnitude to cause the doors to open.

3. The basic performance requirement for lower inlet doors for design basis accident conditions is to open rapidly and fully, to insure proper venting or released energy into the

ice condenser. The opening rate of the inlet doors is important to insure minimizing the pressure buildup in the lower compartment due to the rapid release of energy to that compartment. The rate of pressure rise and the magnitude of the peak pressure in any lower compartment region is related to the confinement of that compartment. The time period to reach peak lower compartment pressure due to the design basis accident is approximately 0.05 seconds.

4. Doors shall be of simple mechanical design to minimize the possibility of malfunction.

5. The inertia of the doors shall be low, consistent with producing a minimal effect on initial pressure.

<u>Design Criteria - Normal Operation</u>

1. The doors shall restrict the leakage of air into and out of the ice condenser to the minimum practicable limit. (See Section 6.5.6.3.)

2. The doors shall restrict local heat input in the ice condenser to the minimum practicable limit. Heat leakage through the doors to the ice bed should be a total of 20,000 BTU/hr or less (for 24 pairs of doors).

3. The doors shall be instrumented to provide indication of their closed position. Testing of prototype doors has established that their normal position under zero differential pressure conditions is 3/8” ± 1/8” open.

4. Provision shall be made for adequate means of inspecting the doors during reactor shutdown.

5. The doors shall be designed to withstand earthquake loadings without damage so as not to affect subsequent ice condenser operation for normal and accident conditions. These loads are derived from the seismic analysis of the containment.

6. The door system shall provide a flow proportioning capability for small break conditions in accordance with Figure 6.5.9-1.

<u>Interface Requirements</u>

1. Crane wall attachment of the door frames is via studs with a compressible seal. Attachment to the crane wall is critical for the safety function of the doors.

2. Sufficient clearance is required for doors to open into the ice condenser. Items to be considered in this interface are floor clearance, lower support structure clearance and floor drain operation.

   Original ice basket qualification testing (Topical Report WCAP-8110, Supplement 9-A Reference 21), has shown freshly loaded ice is considered fused after 5 weeks. In the event of an earthquake (OBE or greater) which occurs within 5 weeks following the completion of ice basket replenishment, plant procedures require a visual inspection of applicable areas of the ice condenser within 24 hours to confirm that opening of the ice condenser lower inlet doors is not impeded by any ice fallout resulting from the seismic disturbance. The 24 hour time frame for inspection is applicable during modes where the lower inlet doors are required to be operable, otherwise perform this inspection prior to startup. This alternative method of compliance with the requirements of GDC 2 is credible based upon the reasonable assurance that the ice condenser doors will open following a seismic event during the 5 week period and the low probability of a seismic event occurring coincident with or subsequently followed by a Design Basis Accident.

3. Door opening and stopping forces will be transmitted to the crane wall and lower support structure, respectively.

Design Loads

Pressure loading during LOCA was provided by the Transient Mass Distribution (TMD) code from an analysis of a double-ended hot leg break in the corner formed by the refueling canal, with 100 percent entrainment of water in the flow. For conservatism, TMD results were increased by 40 percent in performing the design analysis for the lower inlet doors.

The lower inlet door design parameters and loads are presented in Table 6.5.9-1.

6.5.9.2 System Design

Twenty-four pairs of inlet doors are located on the ice condenser side of ports in the crane wall at an elevation immediately above the ice condenser floor. General location and details of these doors are shown in Figures 6.5.9-2 through 6.5.9-6. Each door panel is 92.5 in. high, 42 in. wide and 7.5 in. thick. Each pair is hinged vertically on a common frame.

Each door consists of a 0.5 in. thick Fiber Reinforced Polyester (FRP) plate stiffened by six steel ribs, bolted to the plate. The FRP plate is designed to take vertical bending moments resulting from pressures generated from a LOCA and from subsequent stopping forces on the door. The ribs are designed to take horizontal bending moments and reactions, as well as tensile loads resulting from the door angular velocity, and transmit them to the crane wall via the hinges and door frame.

Seven inches of urethane foam are bonded to the back of the FRP plate to provide thermal insulation. The front and back surfaces of the door are protected with 26 gauge stainless steel covers which provide a complete vapor barrier around the insulation. The urethane foam and stainless steel covers do not carry overall door moments and shearing forces.

Three hinge assemblies are provided for each door panel; each assembly is connected to two of the door ribs. Loads from each of the two ribs are transmitted to a single 1.572 inch diameter hinge shaft through brass bushings.

These bushings have a spherical outer surface which prevents binding which might otherwise be caused by door rib and hinge bar flexure during accident loading conditions. The hinge shaft is supported by two self-aligning, spherical roller bearings in a cast steel housing. Vertical positioning of the door panel and shaft with respect to the bearing housing are provided by steel caps bolted to the ends of the shaft and brass spacer rings between the door ribs and bearings. Shims are provided between the shaft and caps to obtain final alignment. Each bearing housing is bolted to the door frame by four bolts, threaded into tapped holes in the housing. Again, shims are provided between the housings and door frame to maintain hinge alignment. Hinges are designed and fabricated to prevent galling and self welding.

The door frame is fabricated mainly from steel angle sections; 6 in. x 6 in. on the sides and 6 in. x 4 in. on the top and bottom. A 4 in. central I beam divides the frame into sections of each door. At each hinge bracket, extensions and gusset plates, fabricated from steel plate, are welded to the frame to carry loads to the crane wall.

The door panel is sealed to the frame by compliant bulb-type rubber seals which fit into channels welded to the door frame. During normal plant operations these seals are compressed by the cold air head of the ice bed acting on the door panels. As the seals operate at a much warmer temperature than the ice bed, frosting of the seal region is extremely unlikely. The inservice inspection program, described in Paragraph 6.5.9.4, will verify this fact on a periodic basis.

Each door is provided with four flow proportioning springs. One end of each spring is attached to the door panel and the other to a spring housing mounted on the door frame. These springs provide a door return torque proportional to the door opening angle and thus satisfy the requirement for flow proportioning. In addition, they assure that the doors will close in the event they are inadvertently opened during normal plant operations. The springs are adjusted during assembly such that, with no load on the doors, the doors are slightly open. For small door openings, the required 3/8 inch effective door opening is controlled by a 3/8 inch gap between panels and is, thus, independent of the door position as measured in degrees.

In order to dissipate the large kinetic energies resulting from pressures acting on the doors during a LOCA, each door is provided with a shock absorber assembly as shown in Figure 6.5.9-6. The shock absorbing element is a wedge shaped phenolic foam pad 89 in. high, 32 in. wide, and 28 in. thick at its maximum section. The pad is bonded to a base plate which is bolted to the ice condenser lower support structure. The pad is covered with a flexible, reinforced plastic sheet to prevent water ingress during operation and to retain foam particles following a LOCA. The plastic cover is in turn protected on the front, top, and bottom by a thin, stainless steel cover and on the remaining sides by a stainless steel mesh.

In operation, the door panel first contacts the shock absorber pad at an opening angle of 55° and crushes to approximately 30% of its original thickness. Stopping forces are distributed evenly over the outer two-thirds of the door panel, centered about the door center of percussion. The foam material is selected to provide an essentially constant crushing force over its crushing distance with minimum elastic recovery. Thus forces and bending moments on the door are minimized and, once opened, there is a negligible tendency for the door to "bounce" closed again.

Material

Door materials are consistent with the listing of acceptable materials as presented in Subsection 3.8.3. All exposed surfaces are made of stainless steel or coated with paint suitable for use inside the containment. All insulation material is compatible with containment chemistry requirements for normal and accident conditions.

6.5.9.3 Design Evaluation

The lower inlet doors were dynamically analyzed to determine the loads and structural integrity of the door for the design basis load conditions.

Using TMD results as input, the door dynamic analysis was performed using the "DOOR" Program. This computer program has been developed to predict door dynamic behavior under accident conditions. This program takes the door geometry and the pressures and calculates flow conditions in the door port. From the flow are derived the forces on the door due to static pressure, dynamic pressure and momentum. These forces, plus a door movement generated force, i.e., air friction, are used to find the moment on the door and from this are derived the hinge loads. Output from the program includes door opening angle, velocity and acceleration as functions of time as well as both radial and tangential hinge reactions.

Analysis Due to LOCA

The net load distributions on the door for both opening and stopping were determined by considering the applied pressures acting on the door and then solving the rigid body equations of motion such that the net forces and moments at the hinge point are zero. In the process, this produced expressions for the inertial forces in the door and the hinge reaction as functions of the applied pressure.

The expressions for net load distribution were integrated to determine door shear and moment as functions of distance from the hinge point. The resultant load, shear and moment distribution curves and the total hinge loads, calculated by the "DOOR" Program, provided the inputs for subsequent stress analysis.

Using this input, the door assembly was analyzed as a stiffened plate structure with vertical bending being taken by the FRP outer plate and horizontal bending plus radial tensile loads being resisted by the steel ribs. As inertial forces are directly accounted for in the analysis, no dynamic load factor was applied.

Hinge pin, hinge bracket, and frame stresses were analyzed under hinge reactions considering the effects of tension, shear bending, and torsion as appropriate. For these components, a dynamic load factor of 1.2 was calculated and applied.

Stresses in the flow proportioning springs were calculated considering dynamic effects as well as static ones. Welded and bolted connections were analyzed as part of the overall door, frame and hinge analysis.

All portions of the door and frame showed factors of safety greater than one. The general acceptance criterion was that stresses be within the allowable limits of the AISC-69 Structural Code. This provides an additional margin of conservatism over the general ice condenser design criteria for D+DBA which permit stresses up to 1.33 times the AISC limits. For materials and components not covered by the Code, i.e., bearings, non-metallic materials, etc., conservative acceptance criteria were established on the basis of manufacturer's recommendations and/or engineering evaluations.

Flow proportioning characteristics of the door were evaluated by determining the door opening as a function of applied pressure. Assuming a triangular pressure distribution across the door, the flow area vs pressure at full door opening, was determined to be consistent, within 10% of the curve shown on Figure 6.5.9-7. In addition the effects of door closure were evaluated assuming the pressure was suddenly released from a fully opened door and the door allowed to shut under the effect of the door proportioning springs. Stress levels in the door, gasket, and frame were found to be acceptable for this condition. In addition to the above analysis, full scale simulated blowdown tests have been performed on prototype door and shock absorber assemblies. These tests confirm the adequacy of these components at test levels up to 140% of maximum loading conditions predicted by the TMD Code.

Analysis of Seismic Loading

Seismic analysis of the doors indicates that stresses are insignificant in comparison with those occurring during a LOCA. Under a SSE, the doors could open several inches (actually, the crane

wall will move away from the doors). At the termination of the earthquake, the doors will immediately close and reseal under the effects of proportioning spring tension and the ice bed cold air head. Thus, any loss of cold air during a 1/2 SSE or SSE will be small and limited to a short period of time.

6.5.9.4 Testing and Inspection

Inservice inspection of the lower inlet doors is described in SQN Technical Specification 3.6.13.

6.5.10 Lower Support Structure

6.5.10.1 Design Basis

Function

The lower support structure is designed to support and hold down the ice baskets in the required array, to provide an adequate flow area into the ice bed for the air and steam mixture in the event of a Design Basis Accident, to direct and distribute the flow of air and steam through the ice bed, and to protect the containment structure opposite the ice condenser inlet doors from direct jet impingement forces.

The last two functions are accomplished by turning vanes that are designed to turn the flow of the air and steam mixture up through the ice bed in the event of a Design Basis Accident. For such an event, the vanes would serve to reduce the drag forces on the lower support structural members, reduce the impingement forces on the containment across from the lower inlet doors and to distribute the flow more uniformly over the ice bed. In addition to the turning vanes, the lower support structure has slotted plates, which are continuous around the outer circumference of the lower support structure and are designed to reduce the jet impingement forces on the containment structure across from the lower inlet doors in the event of a Design Basis Accident.

Criteria and Codes

The loading combinations, stress limits and material specifications used in the design of the lower support structure are given in Subsection 3.8.3.

Design Conditions

The normal operating temperature range is 10 to 20°F. The normal operational temperature change, including maintenance operations is 10°F to 70°F. The maximum temperature during a Design Basis Accident is 250°F.

The loads used for the design of the lower support structure are given in Table 6.5.10-1. The loads consist of dead weight (gravity), forces as a result of DBA, 1/2 SSE and SSE seismic loads and loads as a result of thermal changes.

The dead loads include the weight of the crane wall insulated duct panels, the weight of the intermediate deck doors and frames, the weight of the lattice frames and columns, and the

weight of the turning vanes. The weight of the ice baskets filled with ice, the slotted jet impingement plate assemblies and the door shock absorber, also act on the lower support structure.

Forces and loadings that occur during LOCA were provided by the Transient Mass Distribution (TMD) Code from analysis of double-ended breaks in an end compartment near the refueling canal, with 100 percent entrainment of water in the flow. For conservatism, all forces and loads that are a result of TMD were increased by 40% in performing the detail design and analysis for the lower support structure. However, the loads as shown on Table 6.5.10-1 are the basic forces and have not been increased by the 40% factor.

The lower support structure seismic design loads were developed using dynamic seismic analysis and the defined seismic response curves for the Sequoyah Nuclear Power Plant.

Thermal loading conditions, which result from two thermal excursions were specified for the lower support structure. One thermal excursion from 10°F to 70°F, is defined as a normal operating service load, and the other, defined as 70°F to 250°F, is the thermal excursion seen by the lower support structure following a LOCA.

The loading combinations considered in the design are given in Subsection 3.8.3.

6.5.10.2 System Design

The lower support structure is shown on Figure 6.5.10-1. The lower support structure is contained in a 300-degree circular arc of the containment. The three-pier lower support structure consists of 24 horizontal platform assemblies, 24 upper turning vane assemblies, 24 floor turning vane assemblies and 24 slotted impingement plate assemblies. The aforementioned assemblies are supported by 25 radial portal frame assemblies with columns at radii of 45'6 inch, 49'11-3/4 inch, and 55'8-1/2 inch. The 25 portal frame assemblies are spaced at approximately 12-1/2 degrees between adjacent portal frames. The total height of the structure is 9'7-3/8 inch, measured from the top surface of the floor wear slab. The design is such that the flow area at the ice basket interface for all 24 bays is at least 1088 square feet.

The horizontal platform consists of an inner and outer platform assembly for each bay. As assembled, the platform includes inner, middle and outer straight circumferential beams which span each portal frame. Nine radial beams formed by boxed-channel sections are welded to the inner, middle and outer circumferential beam. There is horizontal cross bracing between the inner and middle circumferential beams and the outer and middle circumferential beams.

The outer horizontal platform assembly consists of nine radial beams welded to the outer circumferential beam and welded to a channel-shaped plate girder which forms one half of the middle circumferential beam. The inner horizontal assembly is similar to the outer platform assembly. The channel-shaped plate girders of the inner and outer horizontal platform assemblies are field bolted to form a continuous middle circumferential beam.

For each bay, the platform inner and middle circumferential beams are connected to the portal frames with a shear connection, i.e., no moment is transmitted to the columns. The outer circumferential beam is shear connected to the portal column, but the connection is designed to transmit moment about a vertical axis. Every alternate horizontal platform (per bay) is connected

to the columns at one side by bolted connections, which are slotted along the axis of the circumferential beams to accommodate circumferential thermal expansion. The adjacent bay is not slotted in the circumferential direction and supplies the tangential shear resistance for the slotted bay.

There are nine radial beams in each portal bay and each radial beam supports nine ice basket columns. Provision is made for attaching, by bolting, each ice basket column to the radial beams.

The inner and outer circumferential beams of the platform assembly have the lattice frame column supports bolted to them. The insulated duct panels on the containment wall interface the floor and the insulated duct panels on the crane wall are supported by the inner circumferential beams of the lower support structure. The inner, middle, and outer circumferential beams are straight beams.

Each radial portal frame is comprised of three columns. The primary radial shear resistance is provided by a 1 in. thick plate box section that welds to the inner and middle columns (columns at radii 45'6 inch and 49'11-3/4 inch, respectively), thus forming a steel shear wall. The outer column (radius 55'8-1/2 inch) is attached to the middle column assembly by a 1 in. thick plate as shown on Figure 6.5.10-1. The 1 in. thick plate is pin-connected to the outer column by bars pinned at both ends and welded to the middle column. The column base plates are pin-connected to the ice condenser support floor. To accommodate thermal expansion, the middle pier column pin connections are designed to allow radial expansion, and every other outer column base plate pin connection is designed to allow circumferential expansion. The inner pier columns (near the crane wall) are designed to transmit all three force components. The base plate pin arrangement is shown on Figure 6.5.10-2. The lower inlet door shock absorbers are mounted to the 1 in. thick plates that are welded to the inner and middle columns of the portal frames of the lower support structure.

Tangential or circumferential rigidity of the lower support structure is provided by a cross bracing system between the outer columns. The cross bracing system is provided in alternate bays, which coincide with the bays in which the circumferential platform beams are not slotted in their axial direction at the column attachment points.

To turn, direct and distribute the flow through the lower inlet doors during a LOCA, each portal bay has five turning vanes that span between the adjacent radial portal frames. The vanes are as indicated on Figure 6.5.10-1. The vanes are slotted on one side in each bay to allow circumferential thermal growth. The vanes are also slotted at the other end to facilitate positioning of vanes to provide clearance of the vanes above the wear slab.

In addition to the turning vanes, a beam gridwork spans between adjacent outer columns (Figure 6.5.10-1) and acts as a jet impingement shield for the fluid flow not turned by the vanes. The beam gridwork assembly is provided in each bay of the lower support structure and is attached to the outer columns with a bolted connection. Similar to the turning vanes, the beam gridwork assembly is bolted on one side with slotted holes to allow for circumferential thermal growth.

The materials for the lower support structure are ASTM-A588 steel. Bolting materials are ASTM-A320 Grade L7 and nut material is ASTM-194 Grade 7. These materials conform to the

requirements stated in Subsection 3.8.3. All welding meets the requirements of the American Welding Society Structural Welding Code-1972-AWS Publication D1.1-72.

The material used for the pins in the lower support structure is ASTM-A434 steel, E4340, Class BD. The material is normalized, then quenched and tempered. Chemical properties, physical test data and Charpy-V Notch test values at minus 20°F are required.

Bolting materials are ASTM-A320 Grade L7 and nut material is ASTM-194 Grade 7. These materials conform to the Design Criteria, Subsection 3.8.3. All welding meets the requirements of the American Welding Society Structural Welding Code-1972-AWS Publication D1.1-72.

The minimum yield stress as defined in AISC-69 Code, was reduced by 10 percent for design purposes. This is more conservative than the requirements of Subsection 3.8.3 - Design Criteria.

6.5.10.3 Design Evaluation

1. General

The lower support structure was analyzed using a finite element model. The ANSYS structural analysis program was used in the analysis. The seismic responses, in terms of equivalent acceleration and interface forces, in two horizontal directions (radial and tangential) and the vertical direction (z) were developed from a dynamic seismic response analysis performed for a combined lattice frame/ice basket/lower support structure model. The seismic loads, as well as loads due to dead weight, thermal and the forces due to DBA, were applied to the lower support structure as static forces.

Figures 6.5.10-3 through 6.5.10-8 show the finite element model used to represent the three pier lower support structure. The model is comprised of three dimensional beam elements having six degrees of freedom per node; flat triangular shell elements, each having six degrees of freedom per node such that both membrane and bending action of the plates is considered; and general six degrees-of- freedom lumped masses having a 6 x 6 diagonal mass matrix with three values, M_x, M_y, M_z and three moments of inertia, I_x, I_y, and I_z. No horizontal ice mass was considered since this effect on the seismic response was accounted for in the results of the dynamic analysis of the combined lattice frames/ice baskets/lower support structure model. Rotary inertia terms were not used for the lumped masses.

2. Structural Representation

Figure 6.5.10-5 shows an overall view of the one bay finite element model of the structural members. Each of the line members represents three dimensional beam elements as follows:

Columns	- WF12 x 120 lb/ft.
Inner Circumferential Beam	- Built Up Plate Beams
Middle Circumferential Beam	- Built Up Plate Beams
Outer Circumferential Beam	- Built Up Plate Beams
Platform Bracing	- 3 in. Diameter Bars

Radial Beams	- Channels, 10 inch x 25 lbs/ft. with Web Plates and Nose Angles
Circumferential Brace	- Built Up Section From Angles
Door Shock Absorber Box Section	- 1 in. Flange Plates and 1 in. Web Stiffeners
Slotted Impingement Plate	- 3/4 in. Plate with Tee Stiffeners

The beam gridwork which spans the chord between the two outer columns was modeled using equivalent beam elements. The beam properties were developed considering the composite action of the beam gridwork assembly. In the computations, the minimum cross section through the beam gridwork was used to determine the equivalent bending properties. Figure 6.5.10-5 shows the beam representations of the beam gridwork.

Two one inch plates are used to distribute the loads from the lower inlet door shock absorber to the portal frame. The one inch plates form a box section assembly composed of flange plates with internal rib stiffeners. The box assembly welds to the inner and middle columns in each portal frame.

An equivalent modulus and thickness were calculated for the uniform flat triangular shell elements used to model the portal frame box section assembly. Figure 6.5.10-8 shows the element pattern of the triangular elements used.

At beam connections where the beam centroidal axes do not intersect, either rigid links or specified offsets, which can be automatically accommodated for ANSYS beam elements, were used to preserve geometric compatibility between the elements. The connections of the horizontal platform to the portal frame were considered to be pin connections except at the outer column line where it is assumed that a moment around a vertical axis can be transmitted.

The beam gridwork assembly is attached to the outer columns assuming no moment can be transmitted from the assembly to the columns.

Similarly, the upper and floor turning vanes are idealized as beam elements which are pin connected to the portal assemblies. The remaining structural connections were considered to be moment connections.

Mass Distribution

Structural Mass: The structural mass of the lower support structure is represented automatically in the ANSYS program through the use of consistent mass matrices associated with each of the structural finite elements. Thus, only the material density is input to account for the structural mass. For the plate model of the impact plate box section, a density was calculated to preserve the correct structural weight considering the composite plate to be comprised of two one-inch plates.

Ice Mass: The mass of the ice baskets is represented as lumped masses at node points along each radial beam as shown on Figure 6.5.10-6. The mass was distributed as shown on Figure 6.5.10-6 and is based on the geometric placement of the ice baskets on the radial beams. Only mass in the vertical, Z direction, was assigned to the lumped masses representing the ice baskets, since the horizontal seismic effect of the ice basket mass was incorporated as loads on the radial beams. The horizontal seismic loads were determined from a dynamic analysis of a combined lattice frame/ice basket/lower support structure model.

Displacement Boundary Conditions

Displacement boundary conditions were not specified for the tops of the columns nor for other nodes contained in the column radial plane. However, forces are applied to the columns which account for the adjacent bay loading.

To accommodate the thermally induced loads in the structural members, the base plates of the two middle columns are free to expand in a radial direction. Likewise, to accommodate the circumferential thermal expansion, every other outer column base plate connection is free to expand circumferentially.

Referring to Figure 6.5.10-3 which shows a schematic of the ice condenser floor and the column lines, the above boundary conditions imply that the outer column bases at odd numbered column lines are restrained against motion in the vertical, radial and circumferential directions, while the other column bases at even numbered column lines are free to displace circumferentially.

The middle columns are free to move in the radial direction at all column lines and the inside columns (near the crane wall) are restrained for all three translations at all column lines. These boundary conditions minimize the thermally induced stresses and the floor loads.

Seismic Loads

a. General

Analysis indicates that the frequency of the lower support structure is sufficiently high relative to the peaks of the response spectra and is one mode dominant in the vertical direction, so that a seismic modal response analysis is not required. Instead, an equivalent static analysis was performed for vertical accelerations based on the assumption of one mode dominance. For horizontal seismic loads, the largest forces in the radial and tangent directions as determined from a dynamic analysis of a combined ice basket/lattice frame/lower support structure model were applied as static concentrated forces to the lower support structure.

b. Vertical Excitation

For vertical seismic excitation of the lower support structure, a value of 0.55 g was used for the Safe Shutdown Earthquake (SSE) and 0.35 g for the 1/2 Safe Shutdown Earthquake (1/2 SSE). The floor reaction forces and internal structural forces and moments corresponding to both SSE and 1/2 SSE loading were obtained by scaling the results for the gravity loading case by ± 0.55 and + 0.35, respectively.

c. Horizontal Radial Excitation

To account for the seismic loads transmitted from the ice baskets, lattice frames, and lattice columns, a dynamic analysis of the lattice frame and ice basket structures coupled to the lower support structure by means of flexibility coefficients which represent the lower support structure was performed. The loads transmitted to the lower support structure at the interface between the lower support structure and the ice baskets were applied as static concentrated forces. To account for the seismic loads transmitted from adjacent bays, radial forces were applied to the model at the required nodes. The earthquake loads are tabulated in Table 6.5.10-1.

d. Horizontal Tangential Excitation

The tangential loads transmitted from the lattice frames and ice baskets were determined in the same manner as the radial forces from the dynamic analysis performed.

The total tangential loads applied to the radial beams by the ice baskets were distributed in the same manner as the mass as shown on Figure 6.5.10-6. Since the ice baskets are attached to the top surface of the radial beams, concentrated torques were applied at each of the nodes of the radial beams to account for the distance of approximately six inches from the top of the radial beam. The seismic loads from adjacent bays were considered by applying concentrated circumferential forces to the appropriate nodes. The loads considered are tabulated in Table 6.5.10-1.

Blowdown Loads

a. General

The blowdown forces applied to the lower support structure have been divided into four classifications:

i. Vertical Forces
ii. Horizontal Radial Forces
iii. Lower Inlet Door Impact Forces
iv. Horizontal Tangential Forces

The following sections discuss the loads for each of the classifications and the application of the loads to the finite element model of the three pier lower support structure.

b. Vertical Blowdown Loads

i. General

The vertical uplift loads acting on the lower support structure arise from the following phenomena:

a) Uplift on the ice baskets
b) Uplift on the radial beams
c) Uplift on the horizontal platform bracing
d) Uplift pressure across the intermediate deck
e) Uplift on lattice frames and lattice columns

The forces are transient in nature. However, only the basic static values with Dynamic Load Factors applied to account for the transient nature of the loading have been applied to the structural model.

ii. Uplift on Ice Baskets

The force per ice basket is as shown in Table 6.5.10-1. These loads were applied as concentrated vertical forces acting at the nodes of each radial beam, as shown on Figure 6.5.10-6. The node positions approximate the actual ice basket attachment points.

To account for the force on ice baskets in the adjacent bays, concentrated forces are applied at nodes 14, 314, 34, 334, 54 and 354 and are distributed in accordance with the adjacent bay mass shown on Figure 6.5.10-6.

iii. Uplift on the Radial Beams

The distributed uplift force on each radial beam of the inner platform and each radial beam of the outer platform are shown in Table 6.5.10-1. The loads were applied to the finite element model as a uniformly distributed load acting on each of the beam elements comprising a radial beam, for each of the nine radial beams.

For the force on the radial beams of adjacent bays, concentrated vertical forces were applied to nodes 14, 314, 34, 334, 54, and 354 and were distributed to account for the differences in spans between the inner and outer platforms.

iv. Uplift on the Horizontal Platform Bracing

The total uplift force acting on the cross bracing in the inner and outer segment of the platform (between the inner and middle circumferential beams and between the middle and outer circumferential beams, respectively) are shown on Table 6.5.10-1.

One-half the total load for each platform segment was applied at the intersection of the two cross brace elements, or node 1199 for the inner platform and 1200 for the outer platform. The remaining one-half of the total load was distributed equally to the four end points of the cross bracing in each segment of platform.

Analogous to the other load conditions, the drag on adjacent bay cross bracing was accounted for by concentrated forces applied as nodes 14, 314, 334, 54 and 354.

v. Uplift Pressure Across Intermediate Deck

The uplift pressure acting on the intermediate deck plus hinge loads from the intermediate deck doors are as indicated in Table 6.5.10-1.

These loads are transmitted through the eight lattice columns to the lower support structure. These loads were applied as concentrated forces at nodes 1000, 1006, 1012, 1018, 1180, 1186, 1192 and 1198, the lattice column attachment points, assuming the end node columns 1000, 1018, 1180 and 1198 carry one-half the load of the center ones.

For the lattice columns attached to the outer circumferential beam, there is an offset from the base of the lattice column to the centroidal axis of the circumferential beam. Thus, concentrated torques were applied to the node points 1180, 1186, 1192 and 1198 on the outer circumferential beam.

Adjacent bay loading was accounted for as was other loads by applying concentrated forces at nodes 13, 314, 54 and 354, and a torque at nodes 14 and 314.

vi. Uplift on Lattice Frames and Lattice Columns

The force on the lattice frames and columns are as shown on Table 6.5.10-1. The total bay force for these lattice frames was assumed to distribute equally as concentrated vertical forces at the eight lattice column attachment points 1000, 1006, 1012, 1018, 1180, 1186, 1192 and 1198, assuming the end columns carry one-half the load of the remaining columns.

Torques were also applied to the outer circumferential beam nodes 1180, 1186, 1192 and 1198 to account for the offset, as discussed previously. Concentrated forces were applied to nodes 14, 314, 54 and 354 and torques at 14 and 314 to account for adjacent bay loading.

c. Horizontal Radial Blowdown Forces

i. General

The horizontal blowdown forces acting on the structure arise from the following phenomena:

a) Momentum forces on the middle circumferential beam turning vane
b) Momentum forces on the upper three turning vanes attached to the middle column
c) Momentum forces on the floor turning vane attached to the middle column
d) Momentum loading on the slotted impingement plate
e) Forces on the outer circumferential beam
f) Radial forces on the ice baskets

ii. Momentum Forces on Turning Vanes

The total load per vane is shown in Table 6.5.10-1. The force shown acts through the center of curvature of the vanes and at 45° with a vertical axis. The loads were applied as concentrated forces to the nodes contained in the beam representations of each vane. The total loads were assumed to distribute by the tributary length associated with each node. Adjacent bay loads were considered by applying one half the specified total bay force to the vane attachment points.

iii. Pressure on Slotted Impingement Plate

The jet impingement pressure acting on the slotted plate spanning the chord between the outer columns is given in Table 6.5.10-1. Similar to the vanes, the total force was assumed to distribute by the tributary length of beam element associated with each node of the beam simulation of the slotted plate. Adjacent bay loads were handled the same as the turning vanes.

iv. Forces on Outer Circumferential Beam

The radial outward force acting on the outer circumferential beam is shown in Table 6.5.10-1. These forces were applied as a distributed load to the beam element representing the circumferential beam. The adjacent bay loads were considered by applying concentrated forces at the outer circumferential beam reaction nodes 14 and 314.

v. Radial Forces on Ice Baskets

The radial force per ice basket was taken to be 17.9 lb/ft. Since there is a lattice frame six feet above the lower support structure, it was assumed that one-half of the load or three feet was carried by the lower support structure, giving a force of 53.7 lbs per ice basket. This gives a total radial force of 483 lbs per radial beam which was distributed among the nodes of each radial beam. The adjacent bay ice basket radial force was considered by applying concentrated radial forces at nodes 14, 314, 34, 334, 54 and 354, analogous to the seismic loads.

d. Lower Inlet Door Impact Load

From studies and tests performed on the peak force transmitted through the crushable material used to arrest the inlet door motion, at total static tangential load of 60 kips per door was applied to the lower support structure. The dynamic pulse characteristics of the force were accounted for by recommending a dynamic load factor of 2.0 for the rectangular pulse taken to represent the force versus time relationship for the crushable material.

From geometric layouts, it was determined that the force would be applied to approximately one-half of the plate box section between the inner and middle columns. The loaded area of flat triangular plate elements is shown shaded on Figure 6.5.10-8. Concentrated radial forces were applied at nodes 42 through 47, 72 through 77, and 372 through 377 for the door force.

The door impact load was applied simultaneously in the same direction at both column lines 1 and 2 as a worst case. Thus, the loading considered is antisymmetric tangential loading on the one bay model and creates an overturning moment about a radial axis through the lower support structure. In the design of the lower support structure, the bolt connections between the columns and the circumferential beams are designed to consider the possible loading from the door impact loads being applied in opposite tangential directions on the door arrestor plates.

e. Horizontal Tangential Forces

The tangential force acting on the ice baskets due to cross flow in the ice condenser chamber was taken to be 23.8 lbs. per linear foot. Similar to the radial forces, three feet of ice basket (one-half of the span between the top of the lower support structure and the attachment of the ice baskets to the first lattice frame) was considered. The loads were applied to the finite element model as uniformly distributed loads on each of the beam elements comprising a radial beam.

Analogous to the tangential seismic loads, the loads are applied at the top face of the radial beams where the ice baskets are attached, thereby applying torques to the radial beams. Therefore, concentrated torques are applied at each of the node points of the radial beams.

The adjacent bay loading was considered by concentrated forces at nodes 14, 314, 334 and 354.

3. <u>Dynamic Load Factors</u>

To account for the dynamic nature of the blowdown forces, dynamic load factors were applied to the DBA forces applied statically to the finite element representation of the lower support structure. The dynamic load factors (DLF) are as follows:

a.	Vertical Uplift Forces	DLF = 0 or 1.8
b.	Horizontal Radial Forces	DLF = 0 or 1.2
c.	Lower Inlet Door Impact Forces	DLF = 0 or 2.0
d.	Horizontal Tangential Forces	DLF = ± 1.2

<u>Transient Analysis of Blowdown Loads</u>

Following a LOCA, the inlet doors open admitting steam flow into the ice condenser chamber. The fluid flow through the lower support structure and upward through the ice bed cause time-dependent forces to be applied to the lower support structure. In general, there are four classifications of transient forces applied to the lower support structure: (1) vertical forces on the radial beams, ice baskets, lattice frames, lattice columns, and intermediate deck; (2) horizontal radial forces acting on the outer columns, the jet impingement plate, the outer circumferential beam, and turning vanes attached to the middle circumferential beam and middle column; (3) tangential forces, applied to the impact plates attached to the portal frames, resulting from arresting the motion of the inlet doors; and (4) tangential forces on the radial beams due to cross flow in the ice condenser compartment.

For the vertical forces, the time dependence of the forces on each ice basket is shown on Figure 6.5.10-9, and the time dependence of the pressure across the intermediate deck, thus the forces, is shown on Figure 6.5.10-10. The time dependence of the horizontal radial forces acting on the turning vanes, outer columns, jet impingement plate and outer circumferential beam are shown on Figure 6.5.10-11 for a cold let break and Figure 6.5.10-12 for a hot leg break. A cross flow force time dependence was not defined; however, it was assumed that the time dependence for the tangential forces is the same as for the radial forces. Since the actual magnitude of the cross flow forces is small, the time-dependence assumption will not greatly affect the results.

In arresting the motion of the inlet doors, a pulse-type loading is applied to the lower support structure, which is taken to be a regular pulse with maximum force equal to 60 kips with a duration of 16 milliseconds.

Single Degree of Freedom Representation

In general, the transient structural response of a multidegree of freedom system is given by the expression:

$$Y_i\ (t) = \sum_{J = i}^{N} \Gamma_j\ \eta_j\ (t)\ \psi_{ij} \qquad (1)$$

where,

$y_i(t)$ is the structural responser at any time t.

Γ_j is the jth mode shape of the structure.

Ψ_{ij} is the participation factor of the jth mode shape for the transient load.

η_j (t) is the generalized coordinate of the jth mode shape at any time (t).

The generalized coordinate η_j of the jth mode is given in terms of the forcing function f(t) by Duhamel's integral, or the convolution integral as:

$$\eta_j\ (t) = \omega \int_o^t f(\tau) \sin\ \omega (t - \tau)\ d\tau \qquad (2)$$

Thus, the expansion for the generalized coordinate for each mode, j, is the same as the amplification factor, or Dynamic Load Factor definition for a single degree of freedom system:

$$DLF(t) = \omega \int_o^t f(\tau)\ \sin\ \omega (t - \tau)\ d\tau \quad (3)$$

Assuming that $\Gamma j = 1$ for some $j = k$ and $\Gamma j \approx O$ for $j \neq k$, amounts to the assumption that only one mode dominates in the structural response to the transient. In this case, the structural response becomes:

$$y_i(t) = \eta k\ (t) \quad \psi ik \qquad (4)$$

or,

$$y_i(t) \cong D\ (t)\ \psi ik \qquad (5)$$

in which case the maximum structural response is given by:

$$y_{i\max} \cong DLF_{\max}\ \psi ik \qquad (6)$$

Assuming that the dominant mode ψik can be approximated by the static deflection shape due to the loads applied to the structure, the maximum structural response can be approximated by:

$$y_{i\max} \cong DLF_{\max}\ y_{i\,static} \qquad (7)$$

Thus, assuming that the response of the lower support structure to the transient blowdown forces may be represented by Equation (7), the dynamic effects of the transient may be investigated by evaluating the transient response spectra given by:

$$DLF_{\max}(\omega) = \max_{over\ t}\ \omega \int_{o}^{t} f(\tau)\ \sin\ \omega(t-\tau)d\tau \qquad (8)$$

evaluated for ω=Iωη where ωη is the natural frequency estimated for the lower support structure.

Computation of Transient Response Spectra

The development of the transient response spectra corresponding to the blowdown forces shown on Figures 6.5.10-9, -10, -11, and -12, was done by numerically evaluating the convolution integral given by Equation (2) for discrete values of time, t, then finding the maximum DLF(t*) over the range $0 \leq t^* \leq T$, where T was the end of the transient as determined from the TMD code as discussed in Paragraph 6.5.11.1. In the computations, the transient shown on Figures 6.5.10-9, -10, -11, and -12 are represented as a series of straight line segments.

The evaluation of the dynamic load factor as a function of time, was made at discrete time points with the interval Δt given as:

$$\Delta t < \frac{1}{10f_{max}} \qquad (9)$$

where f_{max} is the maximum frequency in Hz considered in the transient response spectra. Thus, the time interval was chosen sufficiently small so that it was no larger than 1/10 of the smallest period of free vibration considered in the transient response spectra.

Figures 6.5.10-13, -14, -15, and -16, show plots of the transient response spectra for the vertical ice basket forces, pressure across the intermediate deck, radial horizontal force due to a cold leg break and radial horizontal forces due to a hot leg break, respectively.

From the figures, it was decided that a dynamic load factor of 0 to 1.8 should be used for the two vertical uplift forces, and 0 to 1.2 should be used for the horizontal forces, including the circumferential (tangential) forces.

Since the transient for the forces applied to the structure in arresting the motion of the inlet doors was taken to be a rectangular pulse, the transient response spectra may be found in the literature.

Considering the frequency of the lower support structure, a Dynamic Load Factor of 0 to 2.0 was considered to represent a conservative design value for the effect of door impact on the structure. Also, in the design of the structure, a complete reversal of the door impact forces is considered.

<u>Discussion</u>

The recommended dynamic load factors are the maximum values from the transient response spectra for zero damping and for a frequency greater than 10 Hz. When evaluating the Dynamic Load Factor to be used, the combined dynamic action of the lower support structure and the supporting floor must be considered. Preliminary estimates of the lowest frequency for the coupled floor-structure system are in excess of 11 Hz.

As previously stated, transient response spectra used to determine the DLF are for zero damping, rather than, a damping of between 5 to 10 percent, which is appropriate for the highly stressed, bolted lower support structure. Damping will reduce the dynamic response as indicated on Figures 6.5.10-15 and 6.5.10-16 which show the response for horizontal forces for 0, 5, 10 and 20 percent damping; thus the DLF recommended are conservative from this standpoint.

For multi-degree of freedom systems, a single DLF cannot theoretically be specified. However, if the structure responds predominantly in a single mode that has a mode shape which approximates the static deflected shape resulting from the applied forces, a conservatively derived DLF can be used for practical design. For the lower support structure, preliminary estimates of the combined floor-lower support structure frequencies indicate that the lowest frequency will be greater than 11 Hz and the third mode will be in excess of 15 Hz. The DLF applicable to the higher modes, as indicated on Figures 6.5.10-13, -14, -15, and -16 will be 15 to 25 percent less than the DLF value specified for the DBA forces. Therefore, by specifying the peak DLF value for the transient, the actual forces applied to the structure will be conservative.

In addition to the conservatism used to derive the DLF's used for design, additional conservatism has been incorporated into the design by specifying that the forces scaled by the DLF's to be applied to the structure in the worst manner to determine the maximum member forces. Since the maximum DLF for each transient will not occur at the same time, combining the member forces derived for each transient in this manner is conservative. In particular, an RMS combination similar to that used in earthquake analysis could be justified because of the time separation of peak occurrence.

Also, as discussed in Section 4, below, the allowable stresses used for design load conditions which include the DBA have been specified as 0.9 times the yield stress of the lower support structure material after normalizing. This requirement is more conservative than that specified in Subsection 3.8.3.

Conclusion

The recommended DLF's have been conservatively derived and applied in the design of the lower support structure. Therefore, the resultant member forces determined for the DBA, using the recommended DLF, result in a conservative prediction of the stresses induced in the structure.

4. Design Load Case

It can be seen from the magnitude of forces shown in Table 6.5.10-1 that the proportions of all members and structural elements of the lower support structure are sized by the load combinations which include DBA forces. The DBA forces are 2 to 5 times larger than other forces that are applied to the lower support structure. Therefore, only the load combinations which include DBA forces are presented.

For design of the lower support structure, the following load condition was used:

DL + TN + EV + ER + ET + AV + AR + AT + LIDI $\leq$ 0.9 YIELD

where YIELD is defined as the yield strength of the material after normalizing.

DL	=	Gravity
TN	=	Thermal 70°F to 250°F
EV	=	Safe Shutdown Earthquake Forces in the Vertical Direction
ER	=	Safe Shutdown Earthquake Forces in Radial Direction
ET	=	Safe Shutdown Earthquake Forces in the Tangential Direction
AV	=	Vertical Forces Due to DBA as Defined in Paragraph 6.5.10.3
AR	=	Radial Horizontal Forces Due to DBA as Defined in Paragraph 6.5.10.3
AT	=	Tangential Horizontal Forces Due to DBA as Defined in Paragraph 6.5.10.3
LIDI	=	Lower Inlet Door Impact

Because of the oscillatory nature of the DBA forces, the above loading condition results in two maximum equivalent static design load cases which have different Dynamic Load Factors for DBA forces. The two load cases correspond to the maximum uplift condition on the lower support structure and a maximum down load on the lower support structure. For the maximum uplift case, the load equation including dynamic load factors (DLF) is:

DL + TN + EV(UP) + ER + ET + 1.8 AV + 1.2 AR + 1.2 AT +
2 LIDI $\leq$ 0.9 YIELD

The second load case, maximum down force is similar to the aforementioned load case, with the exception that the DLF for the vertical DBA is taken equal to zero and the vertical SSE forces (EV) are assumed to act downwards. The DBA forces used in the detailed analysis have been increased, as previously mentioned, by 40% from those listed in Table 6.5.10-1.

5. Results of Stress Analysis

Members

The stresses in the various structural members for the two design load cases specified are tabulated in Table 6.5.10-2. For each load case, the following format is used for the stresses tabulated in the table: the stresses induced in the member due to the axial member forces are shown in the first column; the stresses induced due to moment about the local member y axis are contained in the second column, and those induced in the member around the local member z axis are contained in the third column. The fourth column presents the maximum stresses in the member considering biaxial bending and the axial force.

Joints

The member forces at connections from the two load cases previously discussed that include DBA forces were used to proportion the connections. In the design of the connection for the load conditions including DBA, the recommendation of the AISC - 69 Code section 2.8 were followed. In summary, the normal allowable AISC - 69 Code limits for bolted and welded connections were increased by 1.7 to determine an equivalent yield point stress condition. To be consistent with the conservative approach used in proportioning members, the allowable stresses were scaled by 1.7 and then multiplied by 0.9 to determine the joints stress limits used in the design.

6.5.10.4 Testing and Inspection

A 100 percent inspection and evaluation for any gross ice buildup in the lower plenum will be performed. The lower plenum consists of the lower support structure, turning vanes, and associated components. Any identified ice buildup will be removed (Reference 29).

6.5.11 Top Deck and Doors

The top deck, intermediate deck, containment shell, crane wall and end walls form the boundaries of the ice condenser upper plenum. The upper plenum houses the air handling units and the distribution ducts to the wall panels and provides a working space for loading, weighing and maintaining the ice baskets.

6.5.11.1 Design Basis

Function

An array of blanket panels forms a thermal and vapor barrier atop the upper plenum, allowing limited movement of air through vents during plant operation and free outflow of air during DBA. A grating deck supports the blanket panels and accommodates traffic by inspectors. The top deck structure supports the grating as well as the bridge crane and rail assembly and the air handling units.

Loading Modes

The following loading conditions are considered in the design of the top deck: Deadweight, seismic loads, blowdown loads, and live loads. The top deck structure will withstand these loads and remain within the allowable limits established in the Design Criteria.

Design Considerations

1. The blanket panels are hinged on top of the crane wall. The major loads are applied directly into the crane wall.

2. A blanket panel must be flexible, i.e., be capable of deforming out of its plane in response to relatively low forces without disintegrating. Deformation of panels during DBA is permissible, but formation of missiles must be averted.

3. The deck forms an integral part of ice condenser performance during DBA. Structural loads are a function of air pressure and flow relationships, which in turn are affected by deck characteristics.

4. The top deck structures are subjected to loads from the air handling unit.

Material Consideration

1. Refer to Subsection 3.8.3 of the Design Criteria for steel structures.

2. Blanket material must be fire resistant by its own composition or by means of a suitable cover sheet.

3. Blanket material must not be significant source of halides in gaseous form, either by gradual diffusion of inherent ingredients or by radiolysis of component materials following a DBA.

4. Blanket material must not be a significant source of leachable halides during exposure to containment spray following a DBA.

Thermal and Hydraulic Performance Requirements

1. Heat input to the plenum through the top deck assembly is limited to 13.5 BTU/hr-ft^2.

2. Resistance to air flow during DBA is minimized, in terms of both inertia of panels and obstruction by grating. Panels may reclose or remain open following DBA. Panels open on low differential pressure for small flow rates.

3. A vapor barrier is established on the upper surface of the blanket panels.

Interface Requirements

1. In the process of opening, adjacent blanket panels will interfere with each other. This is acceptable in view of their flexibility.

2. Sealing strips are installed to connect panel vapor barrier to adjacent panels, to crane wall, to end walls and to containment shell, without transmitting appreciable loads to the containment shell.

3. The grating rests on, and is attached to, the cross beams between the top deck beams and transmits operating and drag loads to these structures. The structural members receive loads from bridge crane and air handling units as well as the deck itself.

Design Loads

Design loads used in the design of the top deck assembly are shown in Table 6.5.11-1.

6.5.11.2 System Design

The design of the top deck is shown in Figure 6.5.11-1.

The top deck doors consist of radially aligned flexible blanket panels resting on a grating deck and hinged on top of the crane wall.

A blanket pair covers one-half bay, extending from the radial centerline of a bay to the edge of the adjacent top deck beam. It consists of two blanket assemblies, one resting on the grating, the second one resting (mirror image) on the first one, with bands touching.

The parts of a blanket assembly and their respective functions are as follows:

1. Thermal insulation is provided by a flexible polyurethane foam blanket, 1 inch thick.

2. Approximately one-half of the centrifugal load is carried by bands of fully hardened stainless steel, 0.005 inch thick.

3. A stainless steel cover sheet ("skin") or similar material serves as a vapor barrier (top surface), protects the blanket against wear and fire (top and bottom surfaces) and provides all of the lateral and about one-half of the centrifugal strength.

4. Parts (2) and (3) are bonded to the faces of the foam and extended along one edge to form a hinge.

The grating deck performs the structural functions of the top deck during non-accident conditions. It is supported from pairs of cross beams spanning the top deck beams, and its upper surface is flush with the top of the top deck beams. The bearing bars of the grating run parallel to the centerline of the particular bay. They are 2 inches high, 3/16 inch thick, and spaced on 2-3/8 inch centers. This design satisfies all requirements for open area and upward drag loads during DBA as well as for normal traffic loads. A clearance of no less than 4.0 inches is maintained between the grating and the containment.

The grating is fabricated from carbon steel, ASTM-A569-72, and provided with trim banding adjacent to top deck beams. Completed grating sections are galvanized for corrosion protection.

A hinge bar clamps one edge of each blanket assembly to the top surface of the crane wall. Anchor bolts transmit the hinge loads into the crane wall.

Fixed insulation pads are tacked to the top of the radial beams.

Flexible seal membranes are attached between vapor barrier (top) surfaces of the blanket panels and against containment liner, end walls, and fixed insulation.

A pressure equalization vent curtain is installed around the periphery of the top deck. The curtain minimizes diffusion of air under steady state conditions while permitting free movement of air in or out during momentary periods of pressure imbalance.

Fabrication

1. Grating sections are fabricated to specific shapes, complete with trim handling. The finished assemblies are cleaned and hot dip galvanized.

2. Structurals are cut and welded to suit.

3. Blanket assemblies and fixed insulation are fabricated by an insulation contractor using specified bonding methods.

4. Hinge bars are machined from rectangular steel bars and painted or galvanized.

Installation

1. The grating sections are placed and bolted down.

2. New bolts are installed in top of crane wall.

3. Fixed insulation pads and bottom layer of blankets are placed in position all around top deck.

4. Top layer of blankets is placed in position all around top deck.

5. Hinge bars are installed. Blankets are clamped. Fixed insulation is attached.

6. Vent assemblies are installed.

7. Seals are installed.

6.5.11.3 Design Evaluation

Top Deck Blanket Doors

The top deck doors were dynamically analyzed to determine the loads and structural integrity of the door for the design basis load conditions.

Using TMD results as input, the door dynamic analysis was performed using a separate computer code named the "DOOR" Program. This computer program has been developed to predict door dynamic behavior under accident conditions. This program takes the door geometry and the pressures and calculates the flow conditions in the door port. From the flow are derived the forces on the door due to static pressure, dynamic pressure and momentum. These forces, plus

a door movement generated force, i.e., air friction, are used to find the moment on the door and from this are derived the hinge loads. Output from the program includes door opening angle, velocity and acceleration as functions of time as well as both radial and tangential hinge reactions.

Analysis Due to LOCA

The net load distributions on the door opening were determined by considering the applied pressures acting on the door and then solving the rigid body equations of motion such that the net forces and moments at the hinge point are zero. In the process, this produced expressions for the inertial forces in the door and the hinge bar reaction as functions of the applied pressure. The resultant horizontal and vertical hinge loads, calculated by subsequent stress analysis.

Using this input, the blanket assembly was analyzed with horizontal and vertical forces being taken by direct stress in the skin and bands.

As inertial forces are directly accounted for in the analysis, no dynamic load factor was applied.

The hinge bar and anchor bolt stresses were analyzed under hinge reactions considering the effects of the horizontal and vertical components of the tension band. For these components, no dynamic load factor was applied since the bars are very rigid themselves and are rigidly attached to the crane wall. Stresses in the blanket floor grating due to aerodynamic drag were also calculated. Loads used for stress calculations include 40% margin above computed TMD values. Certain aspects of the dynamic performance of a flexible door (e.g., tangential distortion, whipping, bowing) cannot be modeled with sufficient confidence.

A summary of the analysis performed and results are presented in Table 6.5.11-2. All portions of the door showed factors of safety equal to or greater than one. The general acceptance criterion was that stresses be within the allowable limits of the AISC-69 Structural Code. For materials and components not covered by the Code, i.e., spring temper stainless steel, non-metallic materials, floor grating, etc., conservative acceptance criteria were established on the basis of manufacturer's recommendations or ASTM minimum tensile specifications.

Dynamic Test

A full scale test of a blanket pair (one-half bay) was performed for verification of analysis. Observed dynamic characteristics were found to correlate well with computed TMD values, and integrity of blankets was maintained within acceptable limits.

Top Deck Structure

The top deck structure was analyzed using the ANSYS finite element computer program, with three-dimensional beams representing the structural members, three-dimensional lumped masses representing the mass elements, and a stiffness matrix to represent the flexible connections in the system. Geometric compatibility is maintained using three-dimensional rigid elements.

Two bays considered representative of the system were isolated and modeled. Conservatively, four air handling units were assumed to be located in the two-bay region, two next to the crane wall and two next to the containment wall.

Stresses were calculated for the various combinations of dead load, thermal, seismic and accident conditions. A modal analysis was performed to determine seismic amplification. Blowdown stresses were calculated using a computed dynamic load factor, and a 40% margin added to TMD loads. Maximum stresses produced in major members are all within the limits of the design criteria given in Subsection 3.8.3. The circumferential struts, AHU beams and crane rails have been analyzed and are structurally acceptable.

6.5.11.4 Testing and Inspection

Inservice inspection of the top deck doors is described in SQN Technical Specification 3.6.13.

6.5.12 Intermediate Deck and Doors

6.5.12.1 Design Basis

Function

The intermediate deck forms the ceiling of the ice bed region and the floor of the upper plenum. It serves as a thermal and vapor barrier, which allows limited air movement, through vents, between regions during normal plant operation and free out flow of air and steam following DBA.

Criteria

Refer to Design Criteria in Subsection 3.8.3 for structural design criteria.

Loading Modes

The following loading conditions are considered in the design of the intermediate deck: Deadweight, seismic loads, blowdown loads, and loads due to personnel traffic on deck. The intermediate deck structure will withstand these loads and remain within the allowable limits established in Subsection 3.8.3.

Design Criteria - Accident Conditions

1. Resistance to air flow during DBA shall be minimized, in terms of both inertia of the door panels and obstruction by the frames. Panels may reclose or remain open. Panels shall open on low pressure differential for small flow rates.

2. At the end of their movement, pairs of doors will collide. Distortion at the time is acceptable, provided doors do not become missiles.

3. The doors shall be of simple mechanical design to minimize the possibility of malfunction.

Design Criteria - Normal Conditions

1. Heat conduction through the intermediate deck shall be limited to 0.6 BTU/°F-hr-ft^2.

2. The design of the deck shall permit its use as a walking surface for maintenance of the air handling units and inspection of the ice bed.

3. The design of the deck shall provide a vapor barrier between the ice bed and upper plenum area.

4. The design of the upper deck shall provide convenient access to selected ice baskets for weighing and visual inspection.

Interface Requirements

1. Sealing strips will be installed to seal deck frames to wall panels as a continuation of the vapor barrier.

2. Hinge loads, drag loads, and live loads will be transmitted from the deck through support beams to the lattice frame support columns.

3. Instrumentation cables from the temperature monitoring system will penetrate the seal area of the deck.

Design Loads

Pressure loading during LOCA was provided by the Transient Mass Distribution (TMD) code from an analysis of a double-ended hot leg break in the corner formed by the refueling canal, with 100 percent entrainment of water in the flow. For conservatism, TMD results were increased by 40 percent in performing the design analysis.

The intermediate deck design parameters and loads are presented in Table 6.5.12-1 and on Figure 6.5.12-2.

6.5.12.2 System Design

The intermediate deck is shown in Figure 6.5.12-1. For ease of manufacture and installation, the deck is separated into 48 subsections. Each sub-section covers an area extending over a length of three lattice frames and width of approximately half the ice condenser annulus. Two types of subsections are used; the inner subsection have overall dimensions of 13 ft. long by 5 ft. 7 inches wide; and the outer subsection have dimensions of 12 ft. by 4 ft. 7 inches. Except for dimensional differences, the designs of inner and outer subsections are identical.

Each sub-section consists of four door panels mounted on a steel frame. The door panels are sandwich structures, consisting of 26 gauge galvanized steel sheets adhesively bonded to a 2.5 inch thick urethane foam core. Loads developed in the sandwich structures are transmitted to two panel hinge points by a 2.5 inch x 5 in. rectangular steel tube which forms a backbone for the panel. The panel is reinforced and sealed by a peripheral channel and two internal ribs, formed from 18 gauge steel sheet.

Plates, which are welded to the ends of the tubular backbone, are drilled to accommodate 1 in. diameter stainless steel hinge pins. These pins in turn are supported by welded steel support brackets which are bolted, through the door frame, to intermediate deck support beams. Thus, hinge loads are taken directly into the support beams and not into the frame itself.

The door frame is fabricated from steel angle and T-sections. A formed channel on the frame holds a compliant bulb-type rubber seal which is compressed by the door in its closed position. In addition to being clamped in place by the hinge support brackets as described above, additional bolts in the frame angles fasten the corners of the frame to the support beams and connect adjacent members of the inner and outer assemblies to each other.

The intermediate deck support beams are 8 inches wide flange steel members, which radially span the ice condenser annulus. They are bolted to the lattice frame support columns via welded plate bracket assemblies and compliant pads. The latter feature assures that beam end moments will not be transmitted to the relatively flexible support columns.

Flexible membranes are installed between the intermediate deck frame and adjacent wall panels to provide a continuous vapor barrier.

Pressure equalization vents are installed at selected door locations on the intermediate deck. Vertical flaps minimize diffusion of air under steady state conditions while permitting free movement of air in or out during momentary periods of pressure imbalance.

6.5.12.3 Design Evaluation

The intermediate deck doors were dynamically analyzed to determine the loads and structural integrity of the door for the design basis load conditions.

Using TMD results as input, the door dynamic analysis was performed using a separate computer code named the "DOOR" Program. This computer program has been developed to predict door dynamic behavior under accident conditions. This program takes the door geometry and the pressures and calculates flow conditions in the door port. From the flow are derived forces on the door due to static pressure, dynamic pressure and momentum. These forces, plus a door movement generated force, i.e., air friction, are used to find the moment on the door and from this are derived the hinge loads. Output from the program includes door opening angle, velocity and acceleration as functions of time as well as both radial and tangential hinge reactions.

Analysis Due to LOCA

The net load distributions on the door during opening were determined by considering the applied pressures acting on the door and utilizing an analysis similar to that derived for the lower inlet door (Subsection 6.5.9), to obtain shear, moment, and hinge reactions.

Using this input the door panel was analyzed as a sandwich panel; i.e., the outer steel skins are assumed to carry tensile and compressive membrane loads, while the urethane core carries transverse shear loads between the outer skins. The tubular backbone was analyzed as a beam with biaxial bending and torsion under the combined effects of panel shear loading, panel centrifugal loading and hinge reactions. Hinge pins and support brackets, including bolting, were analyzed by considering the effects of tension, shear, and bending as appropriate. No dynamic load factor was applied, as inertial forces are directly accounted for in the analysis.

The door frame and attachment bolting were analyzed under loadings created by the differential pressure acting on the frame members. The intermediate deck beams and attachments were analyzed under the effects of loads transmitted to them by the door hinges and frames. For these latter analyses, appropriate dynamic load factors were calculated and applied.

All results indicated positive margins of safety in comparison with the structural criteria contained in Subsection 3.8.3.

During a LOCA, stopping of the doors is accomplished by impacting adjacent door panels against each other. In the process, a significant portion of the door kinetic energy is absorbed through plastic deformation of the door panels. This is an acceptable mode of behavior as long as the doors do not break up and lose their insulation or otherwise generate missiles. During simulated blowdown tests on full-scale prototype doors at levels of up to 140% of maximum pressures predicted by TMD, the ability of the doors to withstand opening and stopping loads was confirmed. Only local deformation of the panels resulted and no missiles or insulation were released.

Seismic Analysis

A response spectra nodal analysis was performed on the intermediate deck structure to determine maximum seismic loadings during 1/2 SSE and SSE. Resultant loadings on the structure were found to be negligible in comparison with LOCA loadings. Further, calculations indicated the doors will not open during either earthquake.

6.5.12.4 Testing and Inspection

Inservice inspection of the intermediate deck doors, is described in SQN Technical Specification 3.6.13.

6.5.13 Air Distribution Ducts

6.5.13.1 Design Basis

Functional Requirements

The air distribution ducts distribute the cold air from all air handling units uniformly to the wall panels. The air distribution ducts also serve to return the warmer air which is discharged from the wall panels to the upper plenum. (See Figure 6.5.13-1) The loss of the air distribution function does not affect the safety of the plant as the ice bed is a passive component and can tolerate refrigeration system failures for a week to two weeks.

Design Criteria

The air distribution ducts are permitted to deform during accident conditions but must not affect any safety related components located nearby.

Design Conditions

Normal Operation

Design temperature normal	10°F - 15°F
ΔP normal	2'WG

Accident Conditions

Accident temperature maximum (without ΔP)	190°F

6.5.13.2 System Design

The air distribution ducts are located in the upper plenum. The ducts are made of galvanized sheet steel. The design includes flexible connections separating each duct and each AHU. The flexible connections also serve as vibration breaks.

6.5.13.3 Design Evaluation

The air distribution ducts are a part of the refrigeration system and serve to distribute cold air to the wall panels thereby maintaining the readiness of the ice in the ice bed. The air distribution ducts are not required to function during an accident. The air distribution ducts, are, therefore, non-safety related components. Refer to Subsection 6.5.6 for detailed discussions of the refrigeration system performance during normal operating conditions and of its ability to tolerate refrigeration component failures.

During a LOCA, the air distribution ducts are permitted to deform. A deformation will be outward toward the crane and liner wall insulation and therefore present no problem to nearby safety related components.

6.5.14 Equipment Access Door

6.5.14.1 Design Basis

Functional Requirements

The equipment access door permits movement of crane, equipment and personnel into and out of the ice condenser plenum for ice loading and maintenance.

In closed position, the door constitutes a thermal and vapor barrier (normal plant operation) and a pressure barrier (accident condition) between ice condenser air and upper containment atmosphere.

The basic functions of the equipment access door are non-safety related. It is important, however, to prevent failure of the door in any manner that may affect safety related components located nearby.

Design Criteria and Codes

The door is designed to comply with structural requirements in Subsection 3.8.3.

Design Conditions

Normal Operation

Design temperature inside	15°F
Design temperature outside	100°F

Accident Conditions

Maximum surface temperature (without ΔP)	190°F

6.5.14.2 System Design

An equipment access door is provided in each end wall thereby providing ample access to the upper plenum. The equipment access door includes: the insulated door panel, frame and hoist assembly, gasketing, and fasteners. The door frame slides from closed to open position within a fixed frame embedded in the concrete end wall. All exposed surfaces are protected against corrosion by appropriate coating.

Limit switches are provided to monitor movement of each door and to indicate position as a part of the door position monitoring system.

6.5.14.3 Design Evaluation

The equipment access door is a non-safety related component. The door stresses during SSE + DBA loadings are below the allowable levels.

6.5.15 Ice Technology, Ice Performance and Ice Chemistry

6.5.15.1 Design Basis

The operational principle of the ice condenser is the condensation of steam by means of melting ice. Approximately one and a half pounds of ice per pound of reactor coolant are required to absorb the coolant energy to prevent excessive containment pressure and temperature buildup. The liquid resulting from the thawing process drains to the containment sump where it is utilized during the recirculation phase of cooldown by the Emergency Core Cooling System. It is, therefore, necessary that the boron concentration of the recirculated primary coolant not be diminished through the action of the ice condenser. Hence, the ice condenser utilizes borated ice, which upon bulk melting delivers an aqueous solution containing boron to the containment sump.

The complete equilibrium freezing of this solution forms a eutectic composition with a melting point of -0.42°C (31.2°F).

On a macroscopic scale, the complete equilibrium freezing of an aqueous solution of boron as sodium tetraborate, results in a solid consisting of crystals of pure ice (approximately 91% of the original water), surrounded by frozen eutectic. Microscopically this eutectic solid consists of individual crystals of pure ice and pure $Na_2B_40_7$ $10H_20$ (Reference 13).

6.5.15.2 System Design

The ice for the ice condenser is produced in machines that yield ice in the form of a continuous ribbon, 3/16 inch thick which is deposited in a storage bin via gravity chutes.

The ice is kept at subcooled temperatures by chilled air flowing through the hollow walls and floor of the bin and over the exposed surface of the ice.

Ice is pushed out of the bin by a mechanized rake and carried to an ice chopper via two screw conveyor. The chopper reduces the size of the ice flakes to approximately 2 inch x 2 inch x 3/16 inch. The ice chopper discharges through a metering hopper into a pneumatic conveying valve.

The pneumatic conveying valve feeds ice at a measured rate into a stream of chilled compressed air, which carries the ice through temporarily erected piping to either one of the ice condenser units where it is stored for manual loading or conveyed directly to the ice baskets. When directed to the baskets, the air/ice mixture is fed into a cyclone receiver atop the ice baskets where the ice drops into the basket while the air is released into the containment vessel. Air is removed during this procedure in order to maintain a stable containment vessel pressure.

6.5.15.3 Design Evaluation

As the ice condenser is to be available to perform its engineered safety feature function for the life of the plant, ice storage characteristics are an important consideration. Two mechanisms influence the long term storage of the ice, the diffusion of sodium borate crystals through the ice crystals, and the sublimation of the ice.

1. Diffusion

   For a discussion of the first mechanisms, it will be necessary to refer to the phase diagram presented in Figure 6.5.15-1. When the temperature of an aqueous sodium tetraborate solution is continuously lowered, freezing begins with the formation of crystals of pure water surrounded by the salt solution. The temperature at which the first ice crystals form (assuming no supercooling) depends on the initial concentration of the solution. For example, a solution of $Na_2B_40_7$ $10H_20$ containing 2000 ppm boron begins to freeze at - 0.41°C (+31.27°F), under one atmosphere pressure (Point A in Figure 6.5.15-1). If the freezing process is allowed to continue reversibly, i.e., under conditions of the thermodynamic equilibrium, more ice crystallizes and the surrounding solution increases in concentration according to line AB in Figure 6.5.15-1. Finally when the system temperature is -0.42°C (+31.24°F), the remaining liquid freezes to a solid with a boron concentration of 2220 ppm. The composition of this solid is known as the eutectic composition.

   If the borated ice is made by the very slow freezing process just described, the pure water crystals first formed will become the centers for further crystallization and will therefore grow until the liquid reaches the eutectic composition. The total number of these relatively large pure ice crystals will be determined by the number of nucleation sites available in the solution during the initial phase of the process. If the freezing rate is made extremely large i.e., the process is carried out in an irreversible manner, the initial crystals will not have time to grow appreciably before all the water and sodium borate have crystallized. Such a path is represented by the line CD in Figure 6.5.15-1. The solid obtained by this process will be a uniform mixture of very small crystals of two kinds, ice and sodium tetraborate.

When a collection of various-sized crystals of a substance are maintained at constant temperature and pressure in contact with a solution saturated with respect to the substance, two processes tend to occur. The larger crystals tend to grow at the expense of the smaller ones, and the crystals of irregular form tend to become regular of form. Both of these phenomena are manifestations of systems tending toward thermodynamic equilibrium where the total free energy of the system (in this case the surface free energy) is at a minimum. The solution referred to above can also be a vapor and in the simplest case can be the pure saturated vapor of the crystalline substance. Note that kinetically the two processes are competitive and that both are subject to diffusional control. Therefore, diffusion of molecules, from one site to an adjacent one of the same crystal would be favored over migration to another large crystal, in the case where rapid cooling of very dilute solutions causes many crystals to form that are small compared to the separation between them. Such is the case in practice with the ice condenser.

The driving force for diffusion between crystals of sodium borate through the pure ice matrix is a concentration gradient. If a large crystal is tending to grow, it will cause depletion of sodium and borate ions in the immediately surrounding ice. If a small crystal tends to give up sodium and borate ions to feed the growth of the larger crystal then there will be an increase in the concentrations of sodium borate surrounding the shrinking crystal. Since ice and sodium borate do not form an appreciable solid solution (note eutectic mixture of ice and sodium borated crystals), then the concentration of sodium borate around the shrinking crystal can not be large. For the sake of constructing an upper bound on diffusional effects in the borated ice, assume the maximum concentration to be ~ 10% of the eutectic solution concentration (i.e., 220 ppm).

Diffusion of sodium borate across a slab of pure ice can be determined as follows:

Data for the diffusion of sodium borate in ice are not available, but the self-diffusion coefficients for deuterium, tritium and oxygen (18) in ice have been reported by Franks. (Reference 14) At -11°C (+12°F) the value for all species is ~ 10^{-11} cm^2/sec. Assuming that the coefficient for sodium and borate ions is of the same order of magnitude, the rate of diffusion of sodium borate through a 1/32 inch slab of pure ice is estimated to be ~ 2 x 10^{-13} g/cm^2-sec. for an initial concentration of 220 ppm boron. If the concentration of boron in the ice phase on one face of the slab remained constant at 220 ppm while diffusion through the pure ice slab took place it would take over 100 years for an amount of boron in a single piece of condenser ice to diffuse 1/32 inch, or halfway through the ice flake.

Since the quick frozen borated ice is of stable uniform composition, then upon bulk melting there should be formed a solution of borax of uniform concentration. If the entire borated ice-mass were to be uniformly warmed above -0.42°C (+31.24°F) then melting would begin at the points of contact between water crystals and $Na_2B_40_7$ $10H_20$ crystals, and the ice-mass would lose structure. This is a phenomenon known as "rotting" and has been observed at times in sea-ice which has been subjected to slow (order of hours or days) temperature excursions to just above the melting point. If the melting process is rapid then the fact that the borated ice-mass is a mixture of crystals not a homogeneous solid solution will not affect the performance of the ice condenser.

Melting in the ice condenser will occur over a time span of the order of seconds, beginning at the contact between the steam and the ice-mass and progressing inwardly.

The above arguments are greatly simplified, but lead to conservative results. It can therefore be concluded from the above arguments that while some local changes will undoubtedly occur in the quick frozen borated ice, a maldistribution of the solute boron in the ice condenser, of such magnitude as to affect the operation of the condenser as described in the first paragraph, is extremely remote. Furthermore, the microscopically heterogeneous composition of the borated ice-mass will not reflect itself in the ice condenser performance.

2. Sublimation

The other mechanism that affects the long term storage of the ice is sublimation. Sublimation has several effects inside the ice condenser. The geometry of the ice mass changes where sublimation occurs, and the resulting vapor is deposited on a colder surface at another location inside the ice condenser.

In normal cold storage room application, the cooling coil is exposed to the air in the room, and moisture in the air will freeze on the coil. If ice is stored in the room, all of the ice will eventually migrate to the coil (which will be defrosted periodically, draining the water outside the room) through a sublimation-mass transfer mechanism.

To avoid the mechanism, and maintain a constant mass of ice, the ice condenser is provided with double wall insulation. The annular gap between the insulated walls is provided with a heat sink in the form of a flow of cool, dry air that enters and leaves through the insulated panels.

However, a small amount of heat enters the system through the inlet doors, which are not double insulated, and also through the double layer insulation system. The effect of this heat gain on the ice condenser has been examined analytically and experimentally through testing.

An analytical model of the sublimation process has been developed to provide an estimate of the expected sublimation rate as well as identify the significant parameters affecting the sublimation rate. The model developed a relationship identifying the fraction of total heat input which sublimes ice (the rest of the heat raises the temperature of the air, which transports the vapor to the cold surface where it freezes). The sublimation fraction depends on the difference in vapor pressure between warmest and coldest air temperatures within the ice condenser. The sublimation fraction decreases as the ΔT decreases and also as the average ice condenser temperature decreases. For an average temperature of 15°F in the ice condenser compartment, the analytical model predicts a sublimation rate of about 1 percent of the ice mass sublimed per year per ton (12,000 BTU/hr) of heat gain to the ice storage compartment. The final heat gain calculations identified a heat gain into the ice storage compartment of 1 to 1.5 tons, most of which will enter the compartment through the doors. For the purposes of this report, it is assumed that the reference heat gain for the plant is 1 ton, and therefore, the calculated reference sublimation rate would be 1 percent of the ice weight per year and provides a basis of comparison with test results.

3. Chemical Additives

Sodium tetraborate will be used as a chemical additive to the ice in the plant. The boron is needed for recirculation through the core and the tetraborate is used for iodine removal and containment sump pH control. Boron or sodium tetraborate was also added to the ice used in the long-term storage tests. Chemical analyses were performed before and after certain storage tests to identify any change in boron concentration in the ice. These chemical tests showed that the boron concentration did not significantly change during long-term ice storage. Also, the tests proved that the boron is not transferred with the ice during the sublimation process. It remains as a residue at the original point of sublimation.

Samples of flake ice with sodium tetraborate additive were laced in the cold storage room at Waltz Mill on August 29, 1969, and chemical analyses were made of the ice used in the test samples. The samples were suitably isolated so that sublimation would be minimized or prevented. The tests were terminated on June 19, 1970, approximately 9-1/2 months after initiation, and chemical analyses were again made of several samples taken from different locations in the test section. These analyses indicated that there was essentially no change in the boron concentration from beginning to end of testing, confirming the diffusion theory discussed in paragraph 1 above.

6.5.15.4 Testing and Inspection

1. General

The ice condenser design consists of 48 foot long columns of ice contained within perforated metal baskets.

In the long-term storage of ice, the compression, shear, and creep characteristics are important considerations. Several years of testing at the Waltz Mill facility in these areas of interest has indicated that the ice bed will maintain its geometry for its design life. While the construction of the ice baskets has changed since these tests were performed, the data is still applicable as the basic geometric configuration of the baskets has remained the same, and the same type of ice to be used in the plant was incorporated in the final series of tests. These Waltz Mill tests provide background on the testing that has been done to date, and presented in the next section is a discussion of planned tests that will provide additional information to further evaluate the mechanical performance of ice.

A number of mechanical loading test series have been performed at Waltz Mill to determine compaction, shear, or creep rates in the ice bed. The first series of tests initiated in 1966 used tube ice (hollow cylinders, 1.50 inch O.D. by 0.5 inch I.D. by 2 inch length) produced in a commercial ice machine. The ice used in the above tests was made with no chemical additive, or with boron as a chemical additive to the ice. In some of these tests lead weights were placed on top of the ice samples to simulate the weight of various ice column heights.

The final series of tests initiated in 1969 used flake ice in the same type of baskets to determine the compaction and shear rates of the ice. As the flake ice represents the basis for the configuration used in the ice condenser, only those tests results applicable for this ice form will be discussed.

2. Compaction Tests

Table 6.5.15-1 lists and describes the flake ice compaction tests performed, the duration of the tests, and the resulting compaction after one year of testing for these tests. The results of all of the tests showed that the greatest amount of compaction occurred during the first several months of testing. The amount of compaction varied with the equivalent height of the ice column and depended on the type of ice employed. Figure 6.5.15-2 presents the percent compaction versus time for flake ice test D'. Compaction of flake ice occurs much more rapidly than the other forms of ice due to the smaller and random size of the individual pieces of ice. After the initial year of compaction, the rate of compaction reduces significantly. The rate of compaction reduces almost to zero as the ice density approaches some value close to the density of solid ice. Inspection of the compaction tests indicated no evidence of ice being extruded out through the sides of the baskets.

For these tests the compaction measured is for the bottom section of the ice bed only; the ice above this level (simulated by lead blocks) would be compacted to a lesser extent since it is loaded with less weight. Therefore, the tests results were corrected for the effect of continuously reducing load from bottom to top of the ice column. When this correction was made, the results of the flake ice tests (D',E') suggest that the amount of compaction of an increment in the ice bed varies linearly with the height of the ice bed above the increment, as shown by Figure 6.5.15-3. For flake ice the comparison rate must eventually change, as indicated by the dotted line, as the density of solid ice is approached. Application of this relationship would result in the estimated compaction relationship, shown in Figure 6.5.15-4, for total compaction (in the first year) versus unsupported height of the ice bed. Since the basket provides support for the ice every 6 feet, the compaction of any 6-foot section of the ice bed would be limited to less than 4 inches.

3. Shear Tests

In these tests, ice was loaded into the basket on top of the temporary bottom support which was removed within one or two weeks after loading. The initial series of tests employed tube ice in expanded metal baskets with lead weights added to simulate additional weight of ice. All of the tests experienced an initial settlement within the first two months (after the temporary support was removed). Afterwards, the results show very low creep rates, which appear to be proportional to the weight added. Subsequently it was concluded that each increment of ice in the basket would support its own weight by shear on the adjacent basket walls.

To evaluate this theory with flake ice, additional shear tests (G', H', I') were initiated. In these tests, unsupported ice bed heights of 1 foot, 3 feet, and 5 feet were tested with no lead weights added. In theory, the shear rate should be the same since each foot of ice column had the same shear support.

The results presented in Table 6.5.15-1, confirmed that the shear rates for the three ice bed heights were of similar magnitude for a period of about 6 months. The rate measured was about 1 inch per year and was about 10 times the rate measured in the previous tests with tube ice in expanded metal baskets. From this information it is concluded that the shear capability of flake ice on the sides of the wire baskets is small. However, in the plant design the ice will be supported by the horizontal supports at the bottom and center of each 12-foot section of ice column, so the stability of the ice bed will not depend on the shear forces existing between the ice and the baskets.

51	4095	2047	819	1228
57	3748	1874	750	1124
TOTALS	47,889	23,945	9,578	14,367

NOTE: A design margin of 40% and a dynamic load factor of 1.53 is used in the above values.

TABLE 6.5.3-6

MAXIMUM LATTICE FRAME STRESS SUMMARY

Criteria	D+1/2 SSE S per AISC-69	D+DBA 1.33S	D+SSE 1.33S	D+DB+SSE 1.33S
Bending Allowable Stress** (psi)	37,500	49,875	49,875	61,875
Max Calculated Stress (psi)				
Member No./stress	71/33,360	71/25,640	71/36,850	71/49,330
	63/30,590	72/22,900	63/33,770	63/43,720
	79/28,360	80/22,300	79/31,320	72/42,870
	72/28,160	63/22,040	72/31,110	79/42,160
	78/27,780	79/22,030	78/30,690	75/41,600
Interaction Factor:				
Calculated Member No/value:	71/.92	71/.81	71/1.02	78/1.46
Allowable:	1.0	1.33*	1.33*	1.65*

Note: The interaction factor considers the combined effect of vertical and horizontal stresses. It is the product of the increase in allowable stresses and the limit for S per AISC-69.

** ASTM-A441 not normalized. Yield Stress = 50,000 psi

TABLE 6.5.3-7

SUMMARY OF FATIGUE ANALYSIS [(1)]
FOR LATTICE FRAMES

Member Number/ Joint Number	Calculated Stress range, psi (in welded location)	Allowable Stress range [(2)], psi
127/67	2000	22,500
128/68	2300	22,500
130/130	2000	22,500
131/72	2200	22,500
133/92	2200	22,500
134/73	2300	22,500

(1) - Based on 400 1/2 SSE cycles.
(2) - AISC-69 specification, Appendix B.

TABLE 6.5.5-1

CRANE AND RAIL ASSEMBLY DESIGN LOADS

A. Normal Operation

Crane Weight (excluding rails)	7200 lbs
Maximum Capacity During Plant Erection	6000 lbs (each of two cranes)
Maximum Capacity	6000 lbs (one crane)
Maximum Load Expected	2400 lbs

Note: Seismic loading is not considered as crane is parked outside of Ice Condenser section during normal operation.

TABLE 6.5.6-1 (Sheet 1)

REFRIGERATION SYSTEM PARAMETERS

1.0 General - per twin unit plant

Cooling Water Temperature, maximum design	95°F
Number of ice condenser units	2

2.0 Refrigeration - per twin unit plant

2.1 Glycol chilling machines - 5 dual packages installed

Refrigeration capacity per chiller (half pkg), nominal	6 at 25 tons* / 4 at 25 tons**
Total plant capacity, 5 x 2 x 25	250 tons
Glycol flow per evaporator, normal	≅127 gpm
Glycol flow per evaporator at max. ΔP	200 gpm
Glycol pressure, maximum design	150 psig
Pressure drop through evaporator, normal	16 feet
Maximum allowable ΔP through evaporator	17 psig
Glycol entering temperature, nominal	2°F
Glycol exit temperature, nominal	-5°F (25 ton* units) / -5.2°F (25 ton** units)
Cooling water flow per condenser, normal	110 gpm
Cooling water pressure, maximum design	150 psig
Pressure drop through condenser	3.6 feet
Approximate refrigerant charge per chiller	150 lb (25 ton* units) / 150 lb (25 ton** units)
Refrigerant	R-502 (25 ton* units) / R-404A (25 ton** units)

2.2 Glycol circulation pumps - 6 installed 4-Required

Design flow per pump	190 gpm
Normal flow per containment, 2 x 190	380 gpm
TDH at design flow	220 feet
Shut-off head	250 feet
NPSH required at design point	9 feet

2.3 Pressure relief valves

2.3.1 External headers 2 - installed

Set pressure (for thermal expansion of glycol)	150 psig
Capacity at set pressure (each)	2.9 gpm

2.3.2 Floor cooling system header (2 per unit) Set pressure — 180 psig

2.4 Refrigeration medium (glycol) - UCAR Thermofluid 17 or equal

Concentration, ethylene glycol in water-50 weight % or 47.8 volume %

At temperature:	-10°F	-5°F	0°F	100°F
Specific gravity	1.084	1.083	1.082	1.056
Absolute viscosity, centipoise	29.5	25.0	20.5	2.3
Kinematic viscosity, centistokes	27.2	23.1	18.9	2.18

*Nominal refrigeration rating of original chillers based on 85°F RCW Condenser inlet temperature.
**Nominal refrigeration rating of replacement chillers based on 88°F RCW Condenser inlet temperature.

TABLE 6.5.6-1 (Sheet 2)

REFRIGERATION SYSTEM PARAMETERS

3.0 Ice Condenser - per one containment unit

3.1 Ice Bed

Amount of ice initially stored per unit, nominal, lbs	2.98×10^6
Minimum amount of ice in storage, lbs	1.930×10^6
Estimated ice displacement per year	1-2%
Ice melt during maximum LOCA, calculated, approx.	10^6 lbs
Temperature of ice & static air, (optimum 19°F)	18-20°F
Assumed ambient temperature (external)	100°F
Pressure at lower doors due to cold head, nominal	0.68 psf
Inlet door opening pressure	0.68 psf

3.2 Air Handling Units - 30 dual packages installed per containment

Refrigeration requirements per containment, calculated nominal	51.5 tons
Gross capacity per dual package rated	2.5 tons
Glycol entering temperature, nominal	-5°F
Glycol exit temperature, approx.	0°F
Glycol flow per air handler (1/2 package)	6 gpm
Total glycol flow, 30x2x6	360 gpm
Glycol pressure drop, estimated	50 feet
Air flow per single air handler (1/2 package) (nominal)	1,200 cfm
Total cooling air flow, 30x2x1200	72,000 scfm
Air blower head	2" H_20
Air entering temperature, estimated	19°F
Air exit temperature, nominal	10°F

TABLE 6.5.9-1

LOWER INLET DOOR DESIGN PARAMETERS AND LOADS

A. Normal Operation	
Temperature, Lower Compartment, °F	120 Maximum
Temperature, Ice Bed, °F	10 Minimum
Pressure across Doors, psf	1.0 Nominal
B. Seismic	
Response of Crane Wall at Door Elevation	
Horizontal, 1/2 SSE,g	0.015
Vertical, 1/2 SSE, g	0.087
Horizontal, SSE,g	0.27
Vertical, SSE g	0.18
C. Accident Conditions	
Temperature, Lower Compartments, °F	250 Maximum
Pressure across Doors as shown in Figure 6.5.9-7. For design purposes a 40% margin shall be applied to differential pressure given in this figure.	

TABLE 6.5.10-1 (Sheet 1)

DESIGN LOADS THREE PIER LOWER SUPPORT STRUCTURE
(See Figure 6.5.10-4)

		LOAD DESCRIPTION	BASIC VALUE
I.	Gravity		
	Structural and Ice Weight (2000 lbs/Ice Basket)		1.0 g
	Wall Panel Weight (lbs/Lattice Frame Bay*)		4000
	Lattice Frames (for eight/Lattice Frame Bay) in lbs.		9600
	Intermediate Deck (lbs/LSS** Bay)		2200
	Lattice Frame Colums each in lbs.		989
II.	Thermal Loads		
	Normal Operating		70°F to 10°F
	DBA Thermal Loading		70°F to 250°F
III.	(A)	Seismic Vertical SSE	
		Vertical Seismic Load	0.55 g
III.	(B)	Seismic Vertical 1/2 SEE	
		Vertical Seismic Load	0.35 g
IV.	(A)	Radial Horizontal SSE Seismic	
		Radial Direction - Structural Acceleration	0.37 g
		Seismic Load on Ice Basket (lbs/Lattice Frame Bay)	13000
IV.	(B)	Radial 1/2 SSE Seismic	
		Radial Direction Structural Acceleration	0.24 g
		Seismic Ice Basket Loads (lbs/Lattice Frame Bay)	11000
V.	(A)	Tangential Horizontal SSE Seismic	
		Tangential Direction Structural Acceleration	0.56 g
		Seismic Load on Ice Basket (lbs/Lattice Frame Bay)	9000
V.	(B)	Tangential 1/2 SSE Seismic	
		Tangential Direction Structural Acceleration	0.36 g
		Seismic Load on Ice Basket (lbs/Lattice Frame Bay)	8000

*One Lattice Frame Bay in Plan is equivalent to 1/3 of the Lower Support Structure bay or three radial beams.
**Lower Support Structure.

TABLE 6.5.10-1 (Sheet 2)

DESIGN LOADS THREE PIER LOWER SUPPORT STRUCTURE
(See Figure 6.5.10-4)

		LOAD DESCRIPTION	BASIC VALUE
VI.	(A)	Vertical Blowdown	
		Drag on Inner Radial Beam (kips/ft)	0.0567
		Drag on Outer Radial Beam (kips/ft)	0.0885
		Drag on Ice Basket (kips/Basket)	2.354
		Drag on Horizontal Platform Inner & Outer Bracking (kips/LSS Bay)	2.192
		Drag on Lattice Frame - Eight Frames (kips/LSS Bay)	31.727
		Drag on Intermediate Deck (kips/LSS Bay)	116
		Drag Upward on Outer Circumferential Beam (kips/ft)	.758
VI.	(B)	Horizontal Blowdown	
		Horizontal Load on Middle Circumferential Beam (kips/LSS Bay) at 45^{o} Angle	31.114
		Floor Turning Vane on Middle Column (kips/LSS Bay)	9.911
		Upper Turning Vanes each (kips/LSS Bay)	15.221
		Slotted Plate (kips/LSS Bay)	36.391
		Outer Circumferential Beam Load (kips/ft)	1.728
		Radial Load on Ice Basket (kips/Basket)	0.054
VI.	(C)	Impact Loading for Inner Portal	
		Tangential (kips/Column Line)	60
		Radial (kips/Column Line)	48.2
VI.	(D)	Tangential Blowdown Force	
		Tangential Drag Force (kips/Basket)	.071

TABLE 6.5.10-2 (Sheet 1)

SUMMARY OF STRESSES MAJOR STRUCTURAL COMPONENTS LOWER SUPPORT STRUCTURE ICE CONDENSER

Definition of Terms

M_y = Moment about local y axis

M_z = Moment about local z axis

C_y = Distance from local y neutral axis to extreme fiber

C_z = Distance from local z neutral axis to extreme fiber

I_{yy} = Moment of inertia about local y axis

I_{zz} = Moment of inertia about local z axis

$$\sigma_y = \frac{M_z c_y}{I_{zz}} \pm \sigma_{axial}$$

$$\sigma_z = \frac{M_y c_z}{I_{yy}} \pm \sigma_{axial}$$

$$\sigma_{max} = \frac{M_z c_y}{I_{zz}} \pm \frac{M_y c_z}{I_{yy}} \pm \sigma_{axial}$$

σ_{max}, σ_{min}, Tau_{max} = Maximum principal stresses through the plate thickness

6.6 AIR RETURN FANS

6.6.1 Design Bases

The primary purpose of the Air Return Fan System is to enhance the ice condenser and containment spray heat removal operation by circulating air from the upper compartment to the lower compartment, through the ice condenser, and then back to the upper compartment. The operation will take place at the appropriate time (Section 6.5) following the design basis accident including LOCA. The secondary purpose of the system is to limit hydrogen concentration in potentially stagnant regions by ensuring a flow of air from these regions.

6.6.2 System Description

There are two 100 percent capacity air return fans. Each will remove air at the rate of approximately 40,000 cfm from the upper compartment through a main duct to an accumulator room of the lower compartment. (See Figure 9.4.7-1.) The discharged air will flow from each accumulator room through the annular equipment areas into the lower compartment. Any steam produced by residual heat will mix with the air and flow through the lower inlet doors of the ice condenser. The steam portion of the mixture will condense as long as ice remains in the ice condenser and the air will continue to flow into the upper compartment through doors at the top of the ice condenser. Each main duct contains a nonreturn damper which prevents excessive reverse flow.

The fans will start approximately 10 minutes after receipt of a Phase B containment isolation signal. In addition, either fan may be controlled manually from the main control room. Each fan can develop sufficient head to keep the nonreturn dampers and ice condenser inlet doors open after blowdown is complete.

System components are environmentally qualified (EQ) per the requirements of 10CFR50.49 to function during the conditions resulting from a DBA LOCA or MSB. These conditions as well as the normal and abnormal operating conditions are defined in appropriate EQ design criteria. During accident conditions, the system is capable of operating continuously with temperatures ranging up to 327°F for the first hour, and at 250°F and 100 percent relative humidity for 100 days, with a total radiation dose of up to 10^8 rads. See Section 15.5.8, Reference 17. The fan motors contain motor space heaters which operate normally to prevent condensation within the motor even when the ambient relative humidity is at 100 percent. Materials of the system are essentially steel, coated to prevent corrosion.

The Air Return Fan System is an engineered safety feature and meets the qualification requirements for seismic Category I. The main duct through the divider deck between the upper and lower compartments meets the requirements of ANSI Safety Class 2A. The remainder of the system meets the requirements of ANSI Safety Class 2B.

The design of the fans and controls of each 100 percent capacity system meets the intent of Regulatory Guides 1.29 and 1.53.

Each air return fan is direct drive, vaneaxial, with a capacity of not less than 40,000 cfm against a static pressure of 5 inches water gauge; each is driven by a 460-volt, 3-phase electric motor which develops 50 horsepower at 1,170 r/min. The non-return dampers are heavy duty and are designed to prevent flow from the lower compartment to the upper compartment under a

differential pressure of 12 lb/in^2. The dampers are controlled to open when the differential pressure across the operating fan assures flow from the upper to lower compartment. The gravity-loaded damper will fail in the closed position upon loss of necessary flow head, and has a leakage area at 12 lb/in^2 differential pressure of not more than 4 square inches. The position of the damper is monitored in the control room.

Simultaneously with the return of air from the upper compartment to the lower compartment, post-LOCA hydrogen mixing capability is provided by the Air Return Fan System in the following regions of the containment: containment dome, each of the four steam generator enclosures, pressurizer enclosure, upper reactor cavity, each of the four accumulator rooms, and the instrument room. These regions are served by hydrogen collection headers which terminate on the suction side of either of the two air return fans as shown in Figure 9.4.7-1. The minimum design flow from each region is sufficient to limit the local concentration of hydrogen to not more than 3 percent when the containment average is 2 percent.

The header system was adjusted prior to initial plant operation to assure that the actual flows are at least equal to the minimum design flow when either or both fans are in operation.

6.6.3 Safety Evaluation

In order to assure the rapid return of air to the lower compartment after the initial blowdown, air return fans are provided. The design basis of the fans is described in Section 6.2.1.3. The fans also provide a continuous mixing of containment compartment atmosphere for the long-term postblowdown environment. This mixing flow is to bring fission products in contact with the ice bed and/or the upper compartment spray for removal from the containment atmosphere, as described in Section 6.2.3. The fans also aid in mixing the containment atmosphere to preclude hydrogen pocketing, which is assumed to be produced as a result of the accident. A fully redundant system is provided by the design.

Each fan located in the lower compartment, when operating alone, will circulate air at approximately 40,000 cfm from the upper compartment into the lower compartment. A back-draft damper, usually closed, is located upstream of each deck fan to prevent reverse flow during the initial loss-of-coolant blowdown. In addition, each fan will mix air from the enclosed areas in the lower volume to the general lower volume atmosphere to prevent excessive localized hydrogen buildup following a DBA.

The air return fans have sufficient head to overcome the compartment differentials that occur after the Reactor Coolant System blowdown. The fan head is sufficient to overcome steam generation by decay heat, plus air flow into the ice condenser inlet doors, ice condenser cold head differential, flow through the ice condenser and other system losses. In the event that the top and intermediate deck doors should all reclose after blowdown, each fan has sufficient head to overcome the increased pressure to pass the required flow. After complete ice bed melt out, each fan has sufficient head to flow a minimum of 40,000 cfm with the containment pressurized to the design pressure rating.

Two 100 percent capacity air return systems are provided. Thus, if one fan should fail, the other will provide the necessary air flow from the upper to lower compartment. The fans are designed to withstand the post-accident containment environment. To preclude the flooding of containment air return fan A-A, curbs or "kick plates" are installed about the fan. These curbs

will cause spray water runoff to flow into the sump through the refueling canal, rather than the equipment hatch, personnel access hatch, or fan A-A. In addition, system redundancy assures that the minimum design flows required for hydrogen mixing capability are achieved even during operation of only one air return fan. As seen in Figure 9.4.7-1, the headers which serve the steam generator enclosures, pressurizer enclosure, accumulator rooms, and instrument room are interconnected on the suction side of each fan (downstream of the nonreturn damper). This arrangement permits flow in either direction depending on the fan in operation. The upper reactor cavity and containment dome areas have separate headers connected to each fan which accomplishes the same objective when only one fan is in operation.

6.6.4 Inspection and Testing

Preoperational performance tests are addressed in Chapter 14. Inservice tests and inspections are provided in Technical Specifications.

6.7 AUXILIARY FEEDWATER SYSTEM

The auxiliary Feedwater System is discussed in Paragraph 10.4.7.2.

6.8 PUMP AND VALVE INSERVICE TESTING PROGRAM

The ASME SECTION XI Pump and Valve Inservice Testing Programs were completed for the first ten year inspection interval on December 12, 1995. Unit 1 pump and valve testing was performed to the requirements of ASME Section XI 1974 Edition through the Summer 1975 Addenda. Unit 2 pump and valve testing was performed to the requirements of ASME Section XI 1977 Edition through the Summer 1978 Addenda. The first ten year interval was greater in length due to the lengthy shutdown periods of the units during this interval.

The second ten year interval was based upon the 1989 Edition of the ASME Section XI Code and utilizes OM Part 6 for pumps and OM Part 10 for valves and OM Part 1 for relief valves. Information relative to the scope, exemptions, relief requests, and program basis information is contained in the Sequoyah ASME Inservice Pump Testing Program Basis Document and the ASME Inservice Valve Testing Program Basis Document.

The third ten-year interval is based upon the ASME OM Code 2001 Edition through the 2003 Addenda. The OM Code provides the rules for the selection and testing of pumps, valves, and relief devices. Information relative to the scope, exemptions, relief requests, and program basis information is contained within SQN site technical procedures.

6.9 MOTOR-OPERATED VALVE PROGRAM - GENERIC LETTER 89-10

6.9.1 Program Description

NRC Generic Letter (GL) 89-10, "Safety-Related Motor Operated Valve Testing and Surveillance," requests that holders of nuclear power plant operating licenses and construction permits establish a program to provide for testing, inspection, and maintenance of safety-related motor-operated valves (MOVs) and certain other MOVs in safety-related systems so as to provide the necessary assurance that they will function when subjected to the design basis conditions that are to be considered during both normal operation and abnormal events within the design basis of the plant.

GL 89-10, GL 95-07; Pressure Locking and Thermal Binding of Safety-Related Power-Operated Gate Valves, and GL 96-05; Periodic Verification of Design-Basis Capability of Safety-Related MOVs, are described in the Motor-Operated Valve Program.

IODINE REMOVAL IN THE ICE CONDENSER SYSTEM

6A.1 INTRODUCTION

Following a postulated loss of coolant accident, fission products are assumed to be released from the reactor fuel elements in accordance with the model outlined in TID-14844. This model is used as a basis for determining if the iodine removal systems installed in the nuclear power plant are adequate to insure that the off-site doses do not exceed 10 CFR 100 reference values.

As a result of experimental and analytical efforts by Westinghouse, the ice condenser system has been proven to be an effective passive system for removing elemental iodine from the containment atmosphere and thereby reducing the off-site doses following a Loss of Coolant Accident. The experimental program and results of the ice condenser system effectiveness in removal of elemental iodine is reported in WCAP 7426, a non-proprietary topical report. The results of these extensive bench scale tests clearly indicated that an ice condenser system containing sodium tetraborate ice could effectively remove elemental iodine from the containment atmosphere.

In order to apply the results of the bench scale experimental program, an analytical model applicable to the plant ice condenser system has been developed from the data of the experimental program. The purpose of this appendix is to describe the analytical model and present the results of the ice condenser iodine removal effectiveness analysis.

6A.2 ANALYTICAL MODEL

Following a LOCA a large volume of steam would discharge into the containment lower compartment. Pressure and temperature would rise immediately. At first the increased pressure in the lower compartment would force steam through the ice condenser sections and later recirculation fans would circulate the iodine-air-steam mixture through the ice condenser.

The ice condenser serves primarily as a large heat sink to readily reduce the containment temperature and pressure and condense the steam. In addition to steam, iodine as gaseous elemental iodine may be liberated into the containment. It is also assumed that a fraction of the iodine in the containment atmosphere exists as methyl iodine. Elemental iodine, being readily soluble in aqueous solutions will be removed from the air-steam mixture by the ice condenser. Methyl iodide, however, is assumed not to be removed by the ice condenser.

The ice in the ice condenser will contain sodium tetraborate normally referred to as alkaline ice by virtue of the alkalinity of the ice melt.

Data obtained from the experimental program as reported in WCAP 7426 can be classified as (1) alkaline ice and (2) acid ice. Since alkaline ice will be used in the ice condenser the iodine removal efficiency from those tests results were correlated. The theoretical analysis for iodine removal by alkaline ice treats the ice condenser as consisting of two distinct compartments, an ice section and a rain section. Melt, falling from the ice into the sump comprises the rain section (see Figure 6A-1). Steam condenses from the air-steam of melt mixture in both sections. In the ice section $(1+\lambda_v/\lambda_f)$ grams of melt mixture are formed per gram of steam condensed, where λ_v is latent heat of vaporization of water and λ_f is latent heat of fusion of water. In the rain section, however, only 1 gram of melt mixture is formed per gram of steam

condensed. Melt temperature rises above 32°F as steam condenses in the rain. As time progresses more ice melts, and the rain section plays a more significant role in iodine removal.

An equation for iodine removal efficiency is obtained by solving the multi-component diffusion equations for steam-air-iodine mixtures in both ice condenser sections. In the rain section iodine is treated as a trace component with air and steam as the bulk constituents. Iodine from the bulk vapor diffuses through a gaseous boundary layer into the spherical drop as it falls through the rain section. Condensation of water vapor and absorption of iodine in the ice sections were treated in a similar manner. Ice is modeled as a flat plate surrounded by an essentially stagnant air-steam-iodine boundary layer through which steam and iodine diffuse.

The solution of the diffusion equations based on the above assumptions results in the following relationship:

$$\eta_I = Y_s \, \eta_s$$

Where:

η_I is the iodine removal efficiency, $\dfrac{\text{gm iodine removed}}{\text{gm iodine fed to condenser}}$,

Y_s is the mole fraction steam in inlet gas stream, and

η_s is the steam condensation efficiency, $\dfrac{\text{gm steam condensed}}{\text{gm steam fed to condenser}}$

Since the steam condensation efficiency in an ice condenser is nearly 100% the iodine removal efficiency is directly related to the mole fraction of steam in the inlet gas steam.

6A.3 APPLICATION OF ICE CONDENSER IODINE REMOVAL MODEL

The ice condenser iodine removal model has been applied to an ice condenser containment. The model assumes iodine is released from the reactor system after blowdown and mixed with steam from boiloff and is swept to the ice condenser by the recirculation fans. The vapor composition of the lower compartment is homogenous mixture of iodine, steam from core boiloff, and air.

The ice bed iodine removal efficiency, η_I, has been computed on a time dependent basis for Sequoyah with the results provided in Table 15.5.3-2.

The results of the ice condenser iodine removal efficiency are applied in Chapter 15 in evaluating the off-site doses.

7.0 INSTRUMENTATION AND CONTROLS

7.1 INTRODUCTION

This chapter presents the various plant Instrumentation and Control Systems by relating the functional performance requirements, design bases, system descriptions, design evaluations, and tests and inspections for each. The information provided in this chapter emphasized those instruments and associated equipment which constitute the protection system as defined in IEEE Std. 279-1971 "IEEE Standard: Criteria for Protection Systems for Nuclear Power Generating Stations."

The primary purpose of the Instrumentation and Control Systems is to provide automatic protection against unsafe and improper reactor operation during steady state and transient power operations (Conditions I, II, III) and to provide initiating signals to mitigate the consequences of faulted conditions (Condition IV). For a discussion of the four conditions see Chapter 15. The information presented in this chapter emphasizes those Instrumentation and Control Systems which are central to assuring that the reactor can be operated to produce power in a manner that insures no undue risk to the health and safety of the public.

It is shown that the applicable criteria and codes, such as the Nuclear Regulatory Commission's General Design Criteria and IEEE Standards, concerned with the safe generation of nuclear power are met by these systems.

Definitions

The definitions below establish the meaning of words in the context of their use in Chapter 7.

Channel - An arrangement of components and modules or software as required to generate a single protective action signal when required by a plant condition. A channel loses its identity where single action signals are combined.

DCS - (Distributed Control System) - Non-safety related arrangement of processing groups that contain redundant digital processor pairs that perform many plant functions - controls, interlocks, alarms, etc. Each processing pair (or group or controller) are separate and independent of the others.

DNBR - (Departure From Nucleate Boiling Ratio) - The ratio of the critical heat flux (defined as the transition from nucleate boiling to film boiling) to the actual local heat flux.

Module - Any assembly of interconnected components which constitutes an identifiable device, instrument, or piece of equipment. A module can be disconnected, removed as a unit, and replaced with a spare. It has definable performance characteristics which permit it to be tested as a unit. A module could be a card or other subassembly of a larger device, provided it meets the requirements of this definition.

Components - Items from which the system is assembled (e.g., resistors, capacitors, wires, connectors, transistors, tubes, switches, springs, etc.).

Single Failure - Any single event which results in a loss of function of a component or components of a system. Multiple failures resulting from a single event will be treated as a single failure.

Protective Action - A protective action can be at the channel or the system level. A protective action at the channel level is the initiation of a signal by a single channel when the variable sensed exceeds a limit. A protective action at the system level is the initiation of the operation of a sufficient number of actuators to effect a protective function.

Protective Function - A protective function is the sensing of one or more variables associated with a particular generating station condition signal processing and the initiation and completion of the protective action at values of the variable established in the design basis.

Type Tests - Tests made on one or more units to verify adequacy of design.

Degree of Redundancy - The difference between the number of channels monitoring a variable and the number of channels which when tripped, will cause an automatic system trip.

Minimum Degree of Redundancy - The degree of redundancy below which operation is prohibited, or otherwise restricted by the Technical Specifications.

Reproducibility - This definition is taken from SAMA Standard PMC-202-1970. Process Measurement and Control Terminology: "the closeness of agreement among repeated measurements of the output for the same value of input, under normal operating conditions over a period of time, approaching from both directions." It includes drift due to environmental effects, hysteresis, long-term drift, and repeatability. Longterm drift (aging of components, etc.) is not an important factor in accuracy requirements since, in general, the drift is not significant with respect to the time elapsed between testing. Therefore, long-term drift may be eliminated from this definition. Reproducibility, in most cases, is a part of the definition of accuracy (see below).

Accuracy - This definition is derived from SAMA Standard PMC-202-1970, Process Measurement and Control Terminology. An accuracy statement for a device falls under Note 2 of the definition of accuracy, which means reference accuracy or the accuracy of that device at reference operating conditions: "Reference accuracy includes conformity, hysteresis and repeatability." To adequately define the accuracy of a system, the term reproducibility is useful as it covers normal operating conditions. The following terms, "trip accuracy" and "indicated accuracy" etc., will then include conformity and reproducibility under normal operating conditions.

Where the final result does not have to conform to an actual process variable but is related to another value established by testing, conformity may be eliminated, and the term reproducibility may be substituted for accuracy.

Readout Devices - For consistency the final device of a complete channel is considered a readout device. This includes indicators, recorders, isolators (nonadjustable), and controllers.

Channel Accuracy - This definition includes accuracy of primary element, transmitter and rack modules. It does not include readout devices or rack environmental effects, but does include process and environmental effects on field mounted hardware. Rack environmental effects are included in the next two definitions to avoid duplication due to dual inputs.

Indicated and/or Recorded Accuracy - This definition includes channel accuracy, accuracy of readout devices and rack environmental effects.

Trip Accuracy - This definition includes comparator accuracy, channel accuracy, for each input, and rack environmental effects. This is the tolerance expressed in process terms (or percent of span) within which the complete channel must perform its intended trip function. This includes all instrument errors but no process effects such as streaming. The term "actuation accuracy" may be used where the word "trip" might cause confusion (for example, when starting pumps and other equipment).

Actuation Accuracy - Synonymous with trip accuracy, but used where the word "trip" may cause ambiguity.

Cold Shutdown - The reactor is in the cold shutdown condition when the reactor is subcritical by at least 1 percent $\Delta k/k$ and T_{avg} is $\leq$200°F with T_{avg} defined as the average temperature across the reactor vessel as measured by the hot and cold leg temperature detectors.

Hot Shutdown - The reactor is in the hot shutdown condition when the reactor is subcritical by an amount greater than or equal to the margin as specified in the SQN Technical Specifications and T_{avg} is greater than 200°F but less than or equal to T_{oper} where T_{oper} is defined as any temperature at which the reactor is critical, limited by the SQN Technical Specifications.

Phase A Containment Isolation - Closure of all non-essential process lines which penetrate containment initiated by the safety injection signal.

Phase B Containment Isolation - Closure of remaining process lines, initiated by containment high-high pressure.

Key Variables

A key variable is that single variable (or minimum number of variables) that provides primary information and most directly indicates the accomplishment of a safety function (in the case of types B and C) or the operation of a safety system (for type D) or radioactive material release (for type E). All type A variables are key variables.

Backup Information

That information, made up of additional variables, that provides supplemental information for diagnosis, backup, system status, and/or confirmatory information to the operator.

Critical Safety Function

Those safety functions that are essential to prevent a direct and immediate threat to the health and safety of the public. These are the accomplishing and maintaining of:

1. Reactivity control

2. Reactor core cooling and heat removal from the primary system

3. Reactor coolant system integrity

4. Containment integrity (Including radioactive effluent control)

Primary Information

Primary information is information that is essential for the direct accomplishment of specified safety functions; it does not include variables that may be associated with contingency actions that may also be identified in written plant procedures.

7.1.1 Identification of Safety Related Systems

7.1.1.1 Safety Related Systems

The instrumentation required to function to achieve the system responses assumed in the safety evaluations, and those needed to shut down the plant safely are given in this section.

7.1.1.1.1 Reactor Trip System

The Reactor Trip System is a functionally defined system described in Section 7.2. The equipment which provides the trip functions is identified and discussed in Section 7.2. Design bases for the Reactor Trip System are given in Paragraph 7.1.2.1.

7.1.1.1.2 Engineered Safety Features Actuation System

The Engineered Safety Features Actuation System is a functionally defined system described in Section 7.3. The equipment which provides the actuation functions is identified and discussed in Section 7.3. Design bases for the Engineered Safety Features Actuation System are given in Paragraph 7.1.2.1.

7.1.1.1.3 Vital Power Supply System

Design bases for the Vital Power Supply System are given in Paragraph 7.1.2.1. Further description of the system is provided in Section 7.6.

7.1.1.1.4 Auxiliary Control Air System

The Auxiliary Control Air System supplies essential control air to safety related items such as the auxiliary feedwater control valves; the Vacuum Relief System containment isolation valves; and dampers in the Auxiliary Building Gas Treatment System, the Emergency Gas Treatment System, and the Control Building HVAC system. Further description of the system is given in Subsection 9.3.1.

7.1.1.2 Safety Related Display Instrumentation

Display instrumentation provides the operator with information to enable him to monitor the results of Engineered Safety Features actions following a Condition II, III or IV event. Section 7.5 and Table 7.5-2 provide information required to assess plant conditions during and following an event and to maintain the plant in a hot shutdown condition, or to proceed to cold shutdown.

7.1.1.3 Instrumentation and Control System Designers

All systems discussed in Chapter 7 have definitive functional requirements developed on the basis of the Westinghouse NSSS design. The systems are supplied by Westinghouse with the exception of the vital power, auxiliary control air, and post accident monitoring systems that were designed and supplied by TVA and the DCS, which was supplied by Invensys (Foxboro Company).

7.1.1.4 Plant Comparison

A detailed comparison is provided in Section 1.3 for initial plant design and major changes from the PSAR.

7.1.2 Identification of Safety Criteria

Paragraph 7.1.2.1 gives design bases for the systems given in Paragraph 7.1.1.1. Design bases for non-safety related systems are provided in the sections which describe the systems. Conservative considerations for instrument errors are included in the accident analyses presented in Chapter 15. Functional requirements, developed on the basis of the results of the accident analyses, which have utilized conservative assumptions and parameters are used in designing these systems and a pre-operational testing program verifies the adequacy of the design. Accuracies are given in Sections 7.2, 7.3, and 7.5.

The documents listed below were considered in the design of the systems given in Subsection 7.1.1. In general, the scope of these documents is given in the document itself. This determines the systems or parts of systems to which the document is applicable. A discussion of compliance with each document for systems in its scope is provided in the referenced sections.

Because some documents were issued after design and testing had been completed, the equipment documentation may not meet the format requirements of some standards. The documents considered are:

1. "General Design Criteria for Nuclear Power Plants," Appendix A to Title 10 CFR Part 50, July 7, 1971. (See Sections 7.2, 7.3, 7.4, and 7.7).

2. "Regulatory Guide 1.11 (March, 1971) -Instrument Lines Penetrating Primary Reactor Containment," Regulatory Guides for Water Cooled Nuclear Power Plants, Division of Reactor Standards, Atomic Energy Commission, (See Paragraph 6.2.4.1 and 6.2.4.3).

3. "Regulatory Guide 1.22 (February, 1972) -Periodic Testing of Protection System Actuation Functions," Regulatory Guides for Water Cooled Nuclear Power Plants, Division of Reactor Standards, Atomic Energy Commission, (See Paragraph 7.1.2.8).

4. The Institute of Electrical and Electronic Engineers, Inc., "IEEE Standard: Criteria for Protection Systems for Nuclear Power Generating Stations," IEEE Std. 279-1971. (See Sections 7.2, 7.3, 7.6).

19. The Institute of Electrical and Electronic Engineers, Inc., "IEEE Standard for Electric Penetration Assemblies in Containment Structures for Nuclear Fueled power Generating Stations," IEEE Std. 317-1976. (See Paragraph 7.1.2.4).

20. Regulatory Guide 1.105, "Instrument Setpoints for Safety-Related Systems", Revision 2 February 1986.

21. The Institute of Electrical and Electronic Engineers, Inc., “IEEE Standard for Electric Penetration Assemblies in Containment Structures for Nuclear Fueled Power Generating Stations,” IEEE Std. 317-1983. (See paragraph 7.1.2.4).

7.1.2.1 Design Bases

The technical design bases for the protection systems are provided by Westinghouse equipment specifications which consider the functional requirements for these systems and applicable criteria such as IEEE 279-1971, IEEE 317-1971, IEEE 323-1971 and the NRC General Design Criteria.

7.1.2.1.1 Reactor Trip System

The Reactor Trip System acts to limit the consequences of Condition II events (faults of moderate frequency such as loss of feedwater flow) by, at most, a shutdown of the reactor and turbine, with the plant capable of returning to operation after corrective action. The Reactor Trip System features impose a limiting boundary region to plant operation which ensures that the reactor safety limits analyzed in Chapter 15 are not exceeded during Condition II events and that these events can be accommodated without developing into more severe conditions.

The design requirements for the Reactor Trip System are derived by analyses of plant operating and fault conditions where automatic rapid control rod insertion is necessary in order to prevent or limit core or reactor coolant boundary damage. The design limits for this system are:

1. Minimum DNBR will not be less than limit value as a result of any anticipated transient or malfunction (Condition II faults).

2. Power density will not exceed the rated linear power density for Condition II faults. See Chapter 4 for fuel design limits.

3. The stress limit of the Reactor Coolant System for the various conditions will be as specified in Chapter 5.

4. Release of radioactive material will not be sufficient to interrupt or restrict public use of those areas beyond the exclusion distance or to exceed the guidelines of 10 CFR 20, "Standards For Protection Against Radiation," as a result of any Condition III fault.

5. For any Condition IV fault, release of radioactive material shall not result in an undue risk to public health and safety nor will it exceed the guidelines of 10 CFR 100, "Reactor Site Criteria."

7.1.2.1.2 Engineered Safety Features Actuation System

The Engineered Safety Features Actuation System acts to limit the consequences of certain Condition II (upset conditions such as credible small steamline breaks) and Condition III events (infrequent faults such as primary coolant spillage from a small rupture which exceeds normal charging system makeup and requires actuation of the safety injection system). The Engineered Safety Features Actuation System acts to mitigate Condition IV events (limiting faults, which include the potential for significant release of radioactive material).

The design bases for the Engineered Safety Features Actuation System are derived from the design bases given in Chapter 6 for the Engineered Safety Features. Design bases requirements of IEEE 279-1971 are addressed in Paragraph 7.3.1.2. General design requirements are given below.

1. Automatic Actuation Requirements

   The primary functional requirement of the Engineered Safety Features Actuation System is to receive input signals (information) from the various on-going processes within the reactor plant and containment and automatically provide, as output, timely and effective signals to actuate the various components and subsystems comprising the Engineered Safety Features System. These signals must assure that the Engineered Safety Features System will meet its performance objectives as outlined in Chapter 6.

   The functional diagrams presented in Figure 7.2.1-1, Sheets 5, 6, 7 and 8 provide a graphic outline of the logic associated with the ESF actuation system.

2. Manual Actuation Requirements

   The Engineered Safety Features Actuation System has provisions for manually initiating from the control room all of the functions of the Engineered Safety Features System. Manual actuation serves as backup to the automatic initiation and provides selective control of Engineered Safety Features service features.

7.1.2.1.3 Vital Power Supply System

The Vital Power Supply System provides continuous, reliable, regulated single phase AC power to all instrumentation and control equipment required for plant safety. Details of this system are provided in Section 7.6. The design bases are given below:

1. The inverter shall have the capacity and regulation required for the AC output for proper operation of the equipment supplied.

2. Redundant loads shall be assigned to different distribution panels which are supplied from different inverters.

3. Auxiliary devices that are required to operate dependent equipment will be supplied from the same distribution panel to prevent the loss of electric power in one protection set from causing the loss of equipment in another protection set. No single failure shall cause a loss of power supply to more than one distribution panel.

4. Each of the distribution panels will have access to an inverter and a standby power supply.

7.1.2.1.4 Emergency Power

Design bases and system description for the emergency power supply are provided in Chapter 8.

7.1.2.1.5 Interlocks

Interlocks are discussed in Sections 7.2, 7.3, 7.6, and 7.7. The protection (P) interlocks are given on Tables 7.2.1-2 and 7.3.1-3. These interlocks are designed to meet the requirements of paragraph 4.12 of IEEE 279-1971. Control interlocks are identified on Table 7.7.1-1. Because control interlocks are not safety related, they have not been specifically designed to meet the requirements of IEEE Protection System Standards.

7.1.2.1.6 Bypasses

Bypasses are designed to meet the requirements of IEEE 279-1971, paragraphs 4.11, 4.12, 4.13 and 4.14. A discussion of bypasses provided is given in Sections 7.2 and 7.3.

7.1.2.1.7 Equipment Protection

The criteria for equipment protection are given in Chapter 3. Equipment related to safe operation of the plant is designed, constructed and installed to protect it from damage. This is accomplished by working to accepted standards and criteria aimed at providing reliable instrumentation which is available under varying conditions. As an example, certain equipment is seismically qualified in accordance with IEEE 344-1971 (Reference 10). During construction, independence and separation is achieved, as required by IEEE 279-1971, either by barriers or physical separation. This serves to protect against complete destruction of a system by fires, missiles or other natural hazards.

7.1.2.1.8 Diversity

Functional diversity has been designed into the system. Functional diversity is discussed in Reference 1. The extent of diverse system variables has been evaluated for a wide variety of postulated accidents as discussed in Reference 2. Generally, two or more diverse protection functions would automatically terminate an accident before unacceptable consequences could occur.

For example, there are automatic reactor trips based upon nuclear flux measurements, reactor coolant loop temperature measurements, pressurizer pressure and level measurements, and reactor coolant pump underfrequency and under voltage measurements, as well as manually, and by initiation of a safety injection signal.

Regarding the Engineered Safety Features Actuation System for a LOCA, a safety injection signal can be obtained manually or by automatic initiation from diverse parameter measurements as shown in Table 7.3.1-1.

7.1.2.1.9 Setpoints

The Technical Specifications for the Sequoyah Nuclear Plant incorporate the Nominal Trip Setpoint (NTSP) and the Allowable Value (AV) for setpoints within the reactor protection system (RPS) which includes the Reactor Trip System (RTS) and the Engineering Safety Features Actuation System (ESFAS). These setpoints were analytically determined in accordance with the methodology described in references 22 and 23. Instrument spans are selected such that the AVs are at least 5 percent from the end of the instrument span. Automatic initiation of protective functions occurs at the NTSP (plus or minus the allowed tolerances). The reactor trip setpoints have been selected to ensure that core damage and loss of integrity of the reactor coolant system are prevented during anticipated operational events. The ESFAS setpoints have been selected to protect against violating core design limits and the

Reactor Coolant System (RCS) pressure boundary, and to mitigate accidents. These NTSPs are monitored and adjusted as necessary by periodic performance of surveillance tests in accordance with Technical Specification requirements.

NTSPs are chosen, in conjunction with the AV, to ensure that the Analytical Limits will not be exceeded during either accidents or anticipated operational occurrences, the NTSP is more conservative than the Analytical Limit. The AV provides an allowance to the Analytical Limit to account for unmeasurable uncertainties such as process effects to ensure that the protective action is performed under worst case conditions before the Analytical Limit is exceeded. To ensure the AV protects the Analytical Limit, the channel must be reset or confirmed to be within the As Left (AL) tolerance during periodic surveillance testing. The AL is the tolerance band on either side of the NTSP within which an instrument or instrument loop is left after calibration or setpoint verification to ensure future operability. The As Found (AF) is the tolerance band on either side of the NTSP which defines the limits of acceptable instrument performance, beyond which the channel may be considered degraded and must be evaluated for operability prior to returning to service. Conditions where the device is found outside the AF will be entered into the corrective action program for further evaluation.

The methodologies used for the determination of the AF and AL tolerances for the functions defined to be within the scope of TSTF 493 are described as follows:

> As Found tolerance is determined to be the Square Root Sum of the Squares (SRSS) combination of Reference Accuracy, Measurement and Test Equipment (M&TE) error, M&TE readability error and Drift. Other uncertainties may be included if applicable and are technically justified. As Left tolerance is determined to be the SRSS combination of Reference Accuracy, M&TE error and M&TE readability error (Reference 24). The Technical Specifications are annotated with the functions that fall under the scope of these AF and AL tolerances.

7.1.2.2 <u>Independence of Redundant Safety Related Systems</u>

The safety related systems in Paragraph 7.1.1.1 are designed to meet the independence and separation requirements of criterion 22 of the 1971 General Design Criteria and Paragraph 4.6 of IEEE 279- 1971. The administrative responsibility and control provided during the design and installation is discussed in Chapter 17 which address the Quality Assurance programs applied by Westinghouse and TVA.

The electrical power supply, instrumentation, and control conductors for redundant circuits of a nuclear plant have physical separation to preserve the redundancy and to ensure that no single credible event will prevent operation of the associated function due to electrical conductor damage. Critical circuits and functions include power, control and analog instrumentation associated with the operation of the Reactor Trip System or Engineered Safety Features Actuation System. Credible events shall include, but not be limited to, the effects of short circuits, pipe rupture, missiles, etc. and are considered in the basic plant design. Control board details are given in Paragraph 7.7.1.10. Detailed information pertaining to electrical cable for safety related systems is given in Paragraph 8.3.1.4 (including exceptions to the following general requirements).

7.1.2.2.1 General

1. Cables of redundant circuits will be run in separate cable trays, conduits, ducts, penetrations, etc.

2. Circuits for non-redundant functions should be run in cable trays or conduit separated from those used for redundant circuits. Where this cannot be accomplished, non-redundant circuits may be run in a cable tray, conduit, etc., assigned to a redundant function. When so routed, it must remain with that particular redundant circuit routing and will not cross-over to other redundant groups.

3. Horizontal and vertical separation will be maintained between cable trays, associated with redundant circuits.

4. Where it is impractical for reasons of equipment arrangement to provide separate cable trays, cables of redundant circuits may be isolated by physical barriers or be installed in separate metallic conduit.

5. Power and control conductors rated at 600 volts or below should not be placed in cable trays with conductors rated above 600 volts.

6. Analog or other low level type signal conductors will not be routed in cable trays containing power or control cables

7.1.2.2.2 Specific Systems

Channel independence is carried throughout the system, extending from the sensor through to the devices actuating the protective function. Physical separation is used to achieve separation of redundant transmitters. Separation of wiring is achieved using separate wireways, cable trays, conduit runs and containment penetrations for each redundant channel set. Redundant process equipment is separated by locating modules in different protection rack sets. Each redundant channel set is energized from a separate AC power feed.

There are four separate process protection rack sets. Separation of redundant process channels begins at the process sensors and is maintained in the field wiring, containment penetrations and process protection racks to the redundant trains in the logic racks. Redundant process channels are separated by locating electronics in different rack sets. Since all equipment within any rack is associated with a single protection channel set, there is no requirement for separation of wiring and components within the rack.

Independence of the logic trains is discussed in Reference 11. Two reactor trip breakers are actuated by two separate logic matrices which interrupt power to the control rod drive mechanisms. The breaker main contacts are connected in series with the power supply so that opening either breaker interrupts power to all full length shutdown and control rod drive mechanisms, permitting the rods to free fall into the core.

1. Reactor Trip System

    a. Separate routing is maintained for the four basic Reactor Trip System channel sets process sensing signals, comparator output signals and power supplies for such systems. The separation of these four channel sets is maintained from sensors to instrument racks to logic system cabinets.

    b. Separate routing of the reactor trip signals from the redundant logic system cabinets is maintained, and in addition, they are separated from the four process channel sets.

2. Engineered Safety Features Actuation System

    a. Separate routing is maintained for the four basic sets of ESF Actuation System process sensing signals, comparator output signals and power supplies for such systems. The separation of these four channel sets is maintained from sensors to instrument racks to logic system cabinets.

    b. Separate routing of the ESF actuation signals from the redundant logic system cabinets is maintained and is separated from the four process channel sets.

    c. Separate routing of control and power circuits associated with the operation of engineered safety features equipment is required to retain redundancies provided in the system design and power supplies.

3. Vital Power Supply System

   The separation criteria presented also apply to the power supplies for the load centers and busses distributing power to redundant components and to the control of these power supplies.

Reactor Trip System and Engineered Safety Features Actuation System process circuits may be routed in the same wireways provided circuits have the same power supply and channel set identity (I, II, III or IV).

7.1.2.2.3 Fire Protection

Details of fire protection are provided in the Fire Protection Report (see 9.5.1).

7.1.2.3 Physical Identification of Safety Related Equipment

Adequate identification is provided to distinguish Reactor Trip, Engineered Safety Features and Instrumentation and Control Power Supply Systems as safety related. As previously stated there are four protection channel set racks. A color coded nameplate on each rack of each set is used to identify the protection sets. The color coding of the protection set nameplates is given in section 8.3.1.4.5.

All non-rack mounted protective equipment and components are provided with an identification tag or nameplate. Small electrical components such as relays have nameplates on the enclosure which house them. All cables are numbered with identification tags. In congested areas, such as under or over the control boards, instrument racks, etc., cable trays and conduits containing redundant circuits shall be identified using permanent markings. The purpose of such markings, discussed in detail in Chapter 8, Paragraph 8.3.1.4, is to facilitate cable routing identification of future modification or additions.

Positive permanent identification of cables and/or conductors shall be made at all terminal points. There are also identification nameplates on the input panels of the solid state logic protection system.

7.1.2.4 Conformance to IEEE 317-1971 (Reference 3), IEEE 317-1976 (Reference 21), and IEEE 317-1983 (Reference 25).

Electrical penetrations and conformance with IEEE 317-1971, 317-1976, or 317-1983 "Electrical Penetration Assemblies in Containment Structures for Nuclear Fueled Power Generating Stations" are discussed in Chapter 8, Subparagraph 8.3.1.2.3.

7.1.2.5 Conformance to IEEE 323-1971 (Reference 4) and IEEE 323-1974 (Reference 16)

Reactor Trip System equipment is type tested to substantiate the adequacy of design. This is the preferred method as indicated in IEEE 323-1971. Type tests may not conform to the format guidelines set forth in Section 5.2 of IEEE 323-1971, since type tests on some equipment were performed prior to issuance of the standard. However, it has been determined by Westinghouse that the testing and documentation was comparable to that required by IEEE 323-1971.

The Eagle 21 Process Protection System has been environmentally qualified in accordance with 10CFR50.49 and IEEE 323-1974. "Topical Report Eagle 21 Microprocessor - Based Process Protection System," WCAP-12374, September 1989, provides additional qualification information for the Eagle 21 System.

7.1.2.6 Conformance to IEEE 336-1971 (Reference 5)

A discussion of conformance to IEEE 336 is given in Paragraph 8.3.1.2.2.

7.1.2.7 Conformance to IEEE 338-1971 (Reference 6)

1. The reliability goals specified in Paragraph 4.2 of Reference 6 are being developed, and adequacy of test frequencies will be demonstrated.

2. The periodic test frequency discussed in Paragraph 4.3 of Reference 6 and specified in the plant Technical Specifications, is conservatively selected to assure that equipment associated with protection functions has not drifted beyond its minimum performance requirements. If any protection channel appears to be marginal or requires more frequent adjustments due to plant condition changes, the test frequency is accelerated to accommodate the situation until the marginal performance is resolved.

3 The test interval discussed in Paragraph 5.2, Reference 6, is developed primarily on past operating experience and modified if necessary to assure that system and subsystem protection is reliably provided.

7.1.2.8 Conformance to Regulatory Guide 1.22 (February, 1972) (Reference 7)

Periodic testing of the Reactor Trip and Engineered Safety Features Actuation Systems, as described in Subsections 7.2.2 and 7.3.2, complies with NRC Regulatory Guide 1.22, "Periodic Testing of Protection System Actuation Functions." Under the present design, there are functions which are not tested at power, because to do so would render the plant in a less-safe condition. These are as follows:

1. Generation of a reactor trip by tripping the turbine;

2. Generation of a reactor trip by use of the manual trip switch;

3. Generation of a reactor trip by use of the manual safety injection switch;

4. Closing the main steam line stop valves;

5. Closing the feedwater control valves;

6. Closing of FW pump discharge valves.

The actuation logic for the functions listed is tested as described in Sections 7.2 and 7.3. As

required by Regulatory Guide 1.22, where actuated equipment is not tested during reactor operation it has been determined that:

1. There is no practicable system design that would permit operation of the equipment without adversely affecting the safety or operability of the plant;

2. The probability that the protection system will fail to initiate the operation of the equipment is, and can be maintained, acceptably low without testing the equipment during reactor operation; and

3. The equipment can routinely be tested when the reactor is shut down. Where the ability of a system to respond to a bona fide accident signal is intentionally bypassed for the purpose of performing a test during reactor operation, each bypass condition is automatically indicated to the reactor operator in the main control room by a separate annunciator for the train in test. Test circuitry does not allow two trains to be tested at the same time so that extension of the bypass condition to redundant systems is prevented.

7.1.2.9 <u>Conformance of IEEE 308-1971</u> (Reference 9)

See Section 7.6 for a discussion of the power supply for the Reactor Trip System and compliance with IEEE 308.

7.1.2.10 <u>Conformance to IEEE 334-1971</u> (Reference 8)

There are no Class I motors in the Reactor Trip System, thus IEEE 334 does not apply.

7.1.2.11 <u>Conformance to IEEE 344-1971</u> (Reference 10) and <u>IEEE 344-1975</u> (Reference 20)

The seismic testing as discussed in Section 3.10 and the references of Chapter 3 conform to the guidelines set forth in IEEE 344-1971 with the exceptions noted in Section 3.10.

The Eagle 21 Process Protection System Seismic Testing was performed in accordance with IEEE-344-1975. "Topical Report Eagle 21 Microprocessor - Based Process Protection System," WCAP-12374, September 1989, provides additional qualification information for the Eagle 21 System.

7.1.2.12 <u>Conformance to IEEE 379-1972 and Regulatory Guide 1.53 (June, 1973)</u>
(References 1, 12 and 13)

The principles described in IEEE Std. 379-1972 were used in the design of the Westinghouse protection system. The system complies with the intent of this standard and the additional requirements of Regulatory Guide 1.53. The formal analyses required by the standard have not been documented exactly as outlined although parts of such analyses are published in various documents such as References 1, 12 and 13. Westinghouse has gone beyond the required analyses and has performed a fault tree analysis (Reference 1).

The referenced Topical Reports provide details of the analyses of the protection systems previously made to show conformance with single failure criterion set forth in Paragraph 4.2 of IEEE Std. 279-1971. The interpretation of a single-failure criterion provided by IEEE-379 does not indicate substantial differences with the Westinghouse interpretation of the criterion except in the methods used to confirm design reliability.

Established design criteria in conjunction with sound engineering practices form the bases for the Westinghouse protection systems. The Reactor Trip and Engineered Safeguards Actuation Systems are each redundant safety systems. The required periodic testing of these systems will disclose any failures or loss of redundancy which could have occurred in the interval between tests, thus ensuring the availability of these systems.

7.1.3 Electrical Penetrations

7.1.3.1 Design Bases

The electrical penetration assemblies are designed to maintain containment integrity during all design basis events including temperature rise under fault-current conditions. To assure that electric power is continuously available to operate required equipment, penetrations for redundant cables are located in two or more separate areas in the containment structure.

7.1.3.2 System Description

Either modular or canister type penetrations are used for all electrical conductors passing through the primary containment. A double pressure barrier is formed by a header plate at the end of the penetration nozzle through which the conductors pass. There are three basic types of electrical penetration assemblies: high-voltage, instrumentation, and low-voltage type. These three types are tabulated into five categories: high-voltage power, nuclear instrumentation system, control rod position indication, low-voltage power, control and indication, and thermocouple. An example of each category of canister-type penetration assembly is shown in Figures 7.1.3-1 through 7.1.3-5, respectively.

The penetration assembly is designed for insertion from the outboard end of the primary containment nozzle and is welded to the nozzle by a weld ring. Leak test equipment (valve and pressure gauge) is provided on the outboard end of each assembly. The assemblies are designed to remain functional during and after design basis events. For additional details, see Section 8.3.1.2.3.

7.1.3.3 Tests and Inspections

The original Westinghouse canister-type electrical penetration assemblies have been prototype tested, production tested, and field tested after installation for leakage. Prototype leak rate test results were comparable to the specified test requirement and found acceptable. The leak rate did not exceed 1.0×10^{-6} cubic centimeters per second of dry helium total for the prototype assembly when pressurized to 12 lb/in^2g with dry helium in an ambient temperature of 150°F.

Each original Westinghouse canister-type penetration assembly is provided with a pressure connection and gauge to allow pressurization of the assembly from outside the primary containment. Refer to Figures 7.1.3-1 through 7.1.3-5 for the location of the gauge-valve assembly on each of the five categories of electrical penetration assemblies. Each penetration assembly has passed the factory production leak rate test. This requires the assemblies to be pressurized with helium out in the open and tested for individual leaks using a sniffer type leak detector.

After all of the original Westinghouse canister-type electrical penetration assemblies were installed and became an integral part of the primary containment system, they were leak rate tested. The installed penetration assemblies were backfilled with dry nitrogen at approximately 12 lb/in^{2}g and tested to the following requirements:

Pressure	12 lb/in^{2}g for 24 hours
Temperature	Ambient (50°F to 120°F)
Maximum leakage rate for each assembly	1 x 10^{-2} cubic centimeters per second of dry nitrogen

Subsequent replacement electrical penetrations are tested per Appendix J of 10CFR50. In addition, each conductor was given an insulation resistance test and an electrical continuity test after installation of the penetration assemblies.

7.1.4 Control Room Displays and Controls

7.1.4.1 Control Room Panels

The control room panels are shown in Figure 7.1.4-1.

7.1.4.2 Safety Parameter Display System

7.1.4.2.1 System Description

The principal purpose and function of the Safety Parameter Display System (SPDS) is to aid control room personnel during abnormal and emergency conditions in determining the safety status of the plant and in assessing whether abnormal conditions warrant corrective action by operators to avoid a degraded core. During emergencies the SPDS serves as an aid to evaluating the current safety status of the plant, executing function-oriented emergency procedures, and monitoring the impact of engineered safeguards or mitigation activities. The SPDS also operates during normal operations, continuously displaying information from which the plant safety status can be readily and reliably assessed.

Each unit has its own SPDS running on the Plant Computer System. These plant computer systems also drive display equipment in the Technical Support Center (TSC) and provides plant data to the off-site computer located at the Emergency Operations Facility (EOF). Each unit's plant computer system has two color graphic monitors in the control room, which continuously display information on the Critical Safety Functions (CSF) for the SPDS.

The operators use keyboards and touch screens to request additional detailed information about the parameters used to determine the CSF status as well as other plant conditions. This information is provided in three formats: mimic, tabular, and trend displays.

The data undergoes several validation steps before being presented to the operators. When redundant sensors are used, the data received by the computer can be processed by software to determine if the quality of one or more points is questionable.

7.1.4.2.2 Design Bases

Location of SPDS

The SPDS is conveniently located to control room operators. Both units' plant computer systems main monitor and SPDS is located inside the horseshoe on panel M-19A. A second monitor located at panel M-19B also provides access to SPDS.

Continuous and Reliable Display of Plant Safety Status Information

The SPDS displays information from which the plant safety status can be readily and reliably assessed by control room personnel responsible for the avoidance of degraded and damaged core events. This is accomplished by presenting the status of each CSF on every SPDS display. Redundant sensor algorithms are used to aid the operators in determining if displayed information is reliable.

The quality of the information is identified as being good, suspect, bad, or substituted. Data is tagged as suspect if it is inconsistent with redundant sensors. Data is tagged as bad if it is outside the process sensor limits, or data acquisition system span, or because hardware checks indicate a malfunctioning input device. Data is tagged as substituted when the value is operator entered. If a point is not suspect, bad, or substituted, it is considered good. Pseudo-points are tagged as suspect if any of their constituent points are not good.

A general "health indicator" is provided on every SPDS display which provides an overall SPDS condition (operating or failed).

Concise Display of Critical Plant Variables

The SPDS parameters are from the augmented Westinghouse Owners Group (WOG) status tree displays. The six standard trees have been modified to function under both pre and post trip conditions. Two additional trees have been added to meet NUREG 0737, Supplement 1. The SPDS provides a concise display of critical plant variables which provide information to plant operators about the following critical safety functions:

Critical Safety Function	SPDS Parameter(s)
Reactivity Control	Subcriticality
Reactor Core Cooling and Heat Removal from the Primary System	Core Cooling Heat Sink Decay Heat Removal
Reactor Coolant System Integrity	Pressurized Thermal Shock Inventory
Radioactivity Control	Effluent and Area Radioactivity Containment

Critical Safety Function (continued)	SPDS Parameter(s)
Containment Conditions	Effluent and Area Radioactivity Containment

When the SPDS logic determines the plant may not be in a safe condition, the operator is informed of the problem. The operator verifies the SPDS indication is correct.

Human Factors

Human factors are taken into account in the design of the SPDS. Color coding is used to inform operators of the severity of SPDS alarm condition. Flashing is used to draw operator attention to new alarm conditions. Page keys, touch screens, or mouse commands are used for screen navigation. Alarms are acknowledged with a keystroke or touch screen at the plant computer system monitor located on panel M-19A.

Alpha-numeric information is input from a standard QWERTY keyboard.

Additional information is presented to control room personnel in various standard formats.

Electrical and Seismic Qualification

The SPDS is not qualified 1E and is not powered from a 1E power source. As such the SPDS is suitably isolated from equipment and sensors used in safety systems.

The SPDS has three power sources:

Normal: Rectified station unit board AC power inverted to 120V AC

Alternate: Station battery 250V DC inverted to 120V AC

Maintenance: Regulated 120V AC from 480V AC station unit board

The SPDS is not required to operate during or after a seismic event. SPDS equipment is designed so that it will not adversely affect any equipment important to safety, either during or after a seismic event.

7.1.4.3 Bypassed and Inoperable Status Indication

The Bypassed and Inoperable Status Indication (BISI) system is a computer-based system which provides indication and annunciation of the abnormal status of certain safety related systems which have been bypassed or deliberately placed in an abnormal condition. The BISI system meets the intent of Reg Guide 1.47 for selected ESFAS components.

The BISI system is an aid to MCR operating crews; it supplements plant administrative procedures by supplying plant safety system status. The BISI is not a safety grade system and is not required to operate after an accident. The BISI system is not required to prevent or

mitigate the consequences of any accidents. As such, the BISI system is properly isolated and separated from safety systems.

The BISI system provides component level, system level, and train level indication of ESFAS actuated components which do not fail in their ESFAS actuated condition. When a BISI monitored component or required support system is determined to be in a non-safe (abnormal) condition, MCR personnel are alerted visually and audibly to the situation. The final determination of the bypassed or inoperable status of the system, and any associated action, is left up to the licensed reactor operators.

The following systems are monitored by BISI: 1) Chemical and Volume Control; 2) Component Cooling; 3) Containment Spray; 4) Control Air; 5) Diesel Generator; 6) Containment Air Return Fans; 7) Essential Raw Cooling Water; 8) Main and Auxiliary Feedwater; 9) Residual Heat Removal; 10) Safety Injection; and 11) Air Cleanup Systems.

Components must meet all three of the following conditions for the device to be monitored by the BISI system:

1. Could render inoperable a redundant portion of the protection system, or systems related to the protection system required to be operable to perform their safety-related functions; and
2. Is expected to be rendered inoperable more frequently than once a year; and
3. Is expected to occur when the affected system is normally required to be operable per Technical Specifications.

Note: The safety related room coolers are not monitored by BISI. The operable status of these components/systems are controlled by administrative procedures.

The BISI system software is executed on the same plant computer system used for the Safety Parameter Display System (SPDS) and Technical Support Center (TSC). The computer inputs consist of signals which reflect the status of monitored components. The initial signal may be generated by a limit switch, relay contact, or similar device. The computer processes the incoming signals and generates appropriate outputs on the monitors located in the MCR.

In accordance with Section D.4 of Reg Guide 1.47, the operator has the capability to manually declare a BISI system abnormal for cases where a system is inoperable but the computer software algorithms do not make the same determination. The operator cannot defeat the BISI indication for a system determined to be in an abnormal condition by the computer but determined to be normal by the operator. Some BISI monitored system alarms will be inhibited based on the plant mode as indicated by the plant computer system.

7.1.4.4 <u>Distributed Control System Displays</u>

The Distributed Control System (DCS) utilizes four flat panel display control areas, one on M-3, one on M-14, one on M-19A and one on M-19B along with their associated keyboard or numeric key pads and point/click devices. These display controls are connected to their respective independent display servers located in the Auxiliary Instrument Room. These servers, through an independent computer network, access the various control processing groups that make up the DCS. The failure of one display processor will fail it’s associated displays, leaving the second redundant processor and its associated displays fully capable of providing the operator with display and control functions needed to fully operate the plant.

Through these DCS displays the operator may control and monitor the various plant processes or variables that are controlled by the DCS system. These displays, using their keyboards or numeric key pads along with their point/click devices, provide a secondary control access point for the plant controls systems that have manual-auto stations in the Main Control Room. Should a manual-auto control station fail or be removed from service for maintenance, any DCS display can then be used to provide operator access to make necessary control functions if necessary.

These displays are powered by reliable power from the 120 VAC Vital Instrument Power Boards and the Technical Support System inverters. The plant can typically be operated without these displays being in service as the manual-auto stations provide the primary main control room access. The displays provide parameter display values and provide process trends in monitoring plant operations. When maintenance is required for DCS components, affected channels or inputs may be taken out of scan by the operator at any of the MCR DCS display stations to prevent plant upsets by the maintenance activity.

The displays use similar graphics color coding and symbols as the design of the SPDS and plant Integrated Computer System. The background color of the DCS displays differ from the ICS/SPDS background to ensure they are not mistaken for each other. Access to the DCS control functions is controlled by user name and password. To enact a control action from the display, the operator has to acknowledge a two-step process to help prevent inadvertent system operation.

7.2 REACTOR TRIP SYSTEM

7.2.1 Description

7.2.1.1 System Description

The Reactor Trip System automatically keeps the reactor operating within a safe region by shutting down the reactor whenever the limits of the region are approached. The safe operating region is defined by several considerations such as mechanical/hydraulic limitations on equipment, heat transfer phenomena and nuclear phenomena. Therefore, the Reactor Trip System keeps surveillance on process variables which are directly related to equipment mechanical limitations, such as pressure, pressurizer water level (to prevent water discharge through safety valves, and uncovering heaters) and also on variables which directly affect the heat transfer capability of the reactor (e.g., flow, reactor coolant temperatures). Still other parameters utilized in the Reactor Trip System are calculated from various process variables. In any event, whenever a direct process or calculated variable exceeds a setpoint the reactor will be shut down in order to protect against either gross damage to fuel cladding or loss of system integrity which could lead to release of radioactive fission products into the containment.

The following systems make up the Reactor Trip System:

1. Process Instrumentation and Control System (References 1 and 17)

2. Nuclear Instrumentation System (Reference 2)

3. Solid State Logic Protection System (Reference 3)

4. Reactor Trip Switchgear (Reference 3)

5. Manual Actuation Circuit

The Reactor Trip System consists of up to four redundant sensors and associated process protection circuitry and two redundant digital logic trains. The process protection circuitry monitors various plant parameters and provides inputs to the digital logic trains. The digital logic trains develop the logic necessary to automatically open the reactor trip breakers.

Each of the two trains, A and B, is capable of opening a separate and independent reactor trip breaker, RTA and RTB, respectively. The two trip breakers in series connect three phase AC power from the rod drive motor generator sets to the rod drive power cabinets, as shown on Figure 7.2.1-1, Sheet 2. During plant power operation, a DC undervoltage coil on each reactor trip breaker holds a trip plunger out against its spring, allowing the power to be available at the rod control power supply cabinets.

For a reactor trip, 1) a loss of DC voltage to the undervoltage coil releases the trip plunger and 2) the shunt trip coil energizes, either of which will trip open the breaker. When either of the trip breakers opens, power is interrupted to the rod drive power supply, and the control rods fall, by gravity, into the core. The rods cannot be withdrawn until an operator resets the trip breakers. The trip breakers cannot be reset until the bistable which initiated the trip is re-energized. Bypass breakers BYA and BYB are provided to permit testing of the trip breakers, as discussed in 7.2.2.2.3.

7.2.1.1.1 Functional Performance Requirements

The Reactor Trip System automatically initiates reactor trip:

1. Whenever necessary to prevent fuel damage for an anticipated transient (Condition II).

2. To limit core damage for infrequent faults (Condition III).

3. So that the energy generated in the core is controlled to limit fuel damage such that 10 CFR 100 dose limits are met and peak clad temperature is less than the maximum allowed value for limiting faults (Condition IV).

The Reactor Trip System initiates a turbine trip signal whenever reactor trip is initiated to prevent the reactivity insertion that would otherwise result from excessive reactor system cooldown and to avoid unnecessary actuation of the Engineered Safety Features Actuation System.

The Reactor Trip System provides for manual initiation of reactor trip by operator action.

7.2.1.1.2 Reactor Trips

The various reactor trip circuits automatically open the reactor trip breakers whenever a condition monitored by the Reactor Trip System reaches a preset level. To ensure a reliable system, high quality design, components, manufacturing, quality control and testing is used. In addition to redundant channels and trains, the design approach provides a reactor trip system which monitors numerous system variables by different means, i.e., protection system functional diversity. The extent of this diversity has been evaluated for a wide variety of postulated accidents and is detailed in Reference 7.

Table 7.2.1-1 provides a list of reactor trips which are described below.

1. Nuclear Overpower Trips

   The specific trip functions generated are as follows:

   a. Power range high neutron flux trip.

      The power range high neutron flux trip circuit trips the reactor when two of the four power range channels exceed the trip setpoint.

      There are two independent bistables each with their own trip setting (a high and a low setting) per channel (four channels total). The high trip setting provides protection during normal power operation and is always active. The low trip setting, which provides protection during startup, can be manually bypassed when two out of the four power range channels read above approximately 10 percent power (P-10). Three out of the four channels below 10 percent automatically reinstates the trip function. Refer to Table 7.2.1-2 for a listing of all protection system interlocks.

   b. Intermediate range high neutron flux trip

      The intermediate range high neutron flux trip circuit trips the reactor when one out of the two intermediate range channels exceed the trip setpoint. This trip, which provides

protection during reactor startup, can be manually blocked if two out of four power range channels are above approximately 10 percent power (P-10). Three out of the four power range channels below this value automatically reinstates the intermediate range high neutron flux trip. The intermediate range channels (including detectors) are separate from the power range channels. The intermediate range channels can be individually bypassed at the nuclear instrumentation racks to permit channel testing at any time under prescribed administrative procedures and only under the direction of authorized supervision. This bypass action is annunciated on the control board.

c. Source range high neutron flux trip

The source range high neutron flux trip circuit trips the reactor when one of the two source range channels exceeds the trip setpoint. This trip, which provides protection during reactor startup and plant shutdown, can be manually bypassed when one of the two intermediate range channels reads above the P-6 setpoint value (source range outputs disabled and intermediate range on scale power level) and is automatically reinstated when both intermediate range channels decrease below the P-6 value. This trip is also automatically bypassed by two out of four logic from the power range permissive (P-10).

This trip function can also be reinstated below P-10 by an administrative action requiring manual actuation of two control board mounted switches. Each switch will reinstate the trip function in one of the two protection logic trains. The source range trip is set between the P-6 setpoint and the maximum source range level. The channels can be individually blocked at the nuclear instrumentation racks to permit channel testing at any time under prescribed administrative procedures and only under the direction of authorized supervision. This blocking action is annunciated on the control board.

d. Power range high positive neutron flux rate trip

This circuit trips the reactor when an abnormal rate of increase in nuclear power occurs in two out of four power range channels. This trip provides protection against rod ejection accidents of low worth from mid-power and is always active.

e. Power range high negative neutron flux rate trip

This circuit trips the reactor when an abnormal rate of decrease in nuclear power occurs in two out of four power range channels. This trip provides protection against dropped rods and is always active.

Figure 7.2.1-1, Sheets 3, 4 and 5 show the logic for all of the nuclear overpower and rate trips. A detailed functional description of the equipment associated with this function is given in Reference 2.

2. Core Thermal Overpower Trips

The specific trip functions generated are as follows:

a. Overtemperature ΔT trip

This trip protects the core against low DNBR and trips the reactor on coincidence logic as listed in Table 7.2.1-1 with one set of temperature measurements per loop. The setpoint for this trip is continuously calculated by process circuitry for each loop by solving the following equation:

Overtemperature ΔT

$$\Delta T \frac{[1+\tau_4 s]}{[1+\tau_5 s]} \leq \Delta T_0 [K_1 - K_2 \frac{(1+\tau_1 s)}{(1+\tau_2 s)} (T - T') + K_3 (P - P') - f_1(\Delta I)]$$

Where:

ΔT = Difference between hot leg and cold leg

T = Average temperature, °F

T'= nominal T_{avg} at rated thermal power

$\Delta T°$ = indicated ΔT at Rated Thermal Power

$K_1 \leq 1.15$

$K_2 \geq 0.011$

$\frac{1+\tau_1 s}{1+\tau_2 s}$	= The function generated by the lead-lag controller for T_{avg} dynamic compensation
τ_1 & τ_2	= Time constants utilized in the lead-lag controller for T_{avg}, $\tau_1 \geq 33$ secs., $\tau_2 \leq 4$ secs.
$\frac{1+\tau_4 s}{1+\tau_5 s}$	= The function generated by the lead-lag controller for measured ΔT
τ_4 & τ_5	= Time constants utilized in the lead-lag controller for measured ΔT, $\tau_4 \geq 5$ secs., $\tau_5 \leq 3$ secs.
K_3	= 0.00055
P	= Pressurizer pressure, lb/in^{2}g
P'	= 2235 lb/in^{2}g (Nominal RCS operating pressure)
S	= Laplace transform operator (sec^{-1})

f_1 (ΔI) is a function of the indicated difference between top and bottom detectors of the power-range nuclear ion chambers; with gains to be selected based on measured instrument response during plant startup tests such that (reference Figure 7.2.1-2):

(i) For $q_t - q_b$ between QTNL* and QTPL* $f_1(\Delta I) = 0$ (where q_t and q_b are percent RATED THERMAL POWER in the top and bottom halves of the core respectively, and $q_t + q_b$ is total THERMAL POWER in percent of RATED THERMAL POWER).

(ii) For each percent that the magnitude of (q_t - q_b) exceeds -29 percent, the ΔT trip setpoint shall be automatically reduced by QTNS* of its value at RATED THERMAL POWER.

(iii) For each percent that the magnitude of (q_t -q_b) exceeds +5 percent, the ΔT trip setpoint shall be automatically reduced by QTPS* of its value at RATED THERMAL POWER.

* These values can be found in the Technical Specification/COLR for the applicable fuel cycle.

The one pressurizer pressure parameter required per loop is obtained from separate sensors which are connected to three pressure taps at the top of the pressurizer. The four pressurizer pressure signals are obtained from the three taps by connecting one of the taps to two pressure transmitters. Refer to Subparagraph 7.2.2.3.3 for an analysis of this arrangement.

Figure 7.2.1-1, Sheet 5, shows the logic for the overtemperature ΔT trip function. A detailed functional description of the process equipment associated with this function is contained in Reference 1.

b. Overpower ΔT trip

This trip protects against excessive power (fuel rod rating protection) and trips the reactor on coincidence as listed in Table 7.2.1-1, with one set of temperature measurements per loop. The setpoint for each channel is continuously calculated using the following equation:

Overpower ΔT

$$\Delta T \frac{[1+\tau_4 s]}{[1+\tau_5 s]} \leq \Delta T_0 [K_4 - K_5 \frac{(\tau_3 s)}{(1+\tau_3 s)}(T) - K_6(T - T'') - f_2(\Delta I)]$$

Where:

$\Delta T°$ = Indicated ΔT at RATED THERMAL POWER

$K_4 \leq 1.087$

$K_5 \geq 0.02/°F$ for increasing average temperature and 0 for decreasing average temperature

$\frac{\tau_3 s}{1 + \tau_3 s}$ = The function generated by the rate-lag controller for T_{avg} dynamic compensation

τ_3 = Time constant utilized in the rate-lag controller for T_{avg}, $\tau_3 \geq 10$ secs.,

$K_6 \geq 0.0011$ for $T > T''$ and $K_6 \geq 0$ for $T \leq T''$

T" = Indicated T_{avg} at rated thermal power

S = Laplace transform operator (sec $^{-1}$)

$f_2(\Delta I)$ is a function of the indicated difference between top and bottom detectors of the power-range nuclear ion chambers; with gains to be selected based on measured instrument response during plant startup tests such that:

(i) for q_t - q_b between QPNL* and QPPL* $f_2(\Delta I) = 0$ (where q_t and q_b are percent RATED THERMAL POWER in the top and bottom halves of the core, respectively, and $q_t + q_b$ is total THERMAL POWER in percent of RATED THERMAL POWER).

(ii) for each percent that the magnitude of (q_t - q_b) exceeds QPNL* the ΔT trip setpoint shall be automatically reduced by QPNS* of its value at RATED THERMAL POWER.

(iii) for each percent that the magnitude of (q_t - q_b) exceeds QPPL* the ΔT trip setpoint shall be automatically reduced by QPPS* of its value at RATED THERMAL POWER.

* These values can be found in the Technical Specification/COLR for the applicable fuel cycle.

T = As defined for overtemperature ΔT trip

$\frac{1 + \tau_4 s}{1 + \tau_5 s}$ = The function generated by the lead-leg controller for measured ΔT.

The source of temperature and flux information is identical to that of the overtemperature ΔT trip and the resultant ΔT setpoint is compared to the same ΔT. Figure 7.2.1-1 Sheet 5 shows the logic for this trip function. The detailed functional description of the process equipment associated with this function is contained in Reference 17.

3. Reactor Coolant System Pressurizer Pressure and Level Trips

The specific trip functions generated are as follows:

a. Pressurizer low pressure trip

The purpose of this trip is to protect against low pressure which could lead to DNB and limit the necessary range of protection afforded by the overtemperature ΔT trip. The parameter being sensed is reactor coolant pressure as measured in the pressurizer. Above P-7 the reactor is tripped when the compensated pressurizer pressure measurements fall below preset limits. This trip is blocked below P-7 to permit startup. The trip logic and interlocks are given in Table 7.2.1-1.

The trip logic is shown on Figure 7.2.1-1, Sheet 6.

b. Pressurizer high pressure trip

The purpose of this trip is to protect the Reactor Coolant System against system overpressure.

The same sensors and transmitters used for the pressurizer low pressure trip are used for the high pressure trip except that separate bistables are used for trip. These comparators trip when uncompensated pressurizer pressure signals exceed preset limits on coincidence as listed in Table 7.2.1-1. There are no interlocks or permissives associated with this trip function.

The logic for this trip is shown on Figure 7.2.1-1, Sheet 6.

c. Pressurizer High Water Level Trip

This trip is provided as a backup to the high pressurizer pressure trip and serves to prevent water relief through the pressurizer safety valves. This trip is blocked below P-7 to permit startup. The coincidence logic and interlocks of pressurizer high water level signals are given in Table 7.2.1-1.

The trip logic for this function is shown on Figure 7.2.1-1, Sheet 6.

4. Reactor Coolant System Low Flow Trips

These trips protect the core from DNB in the event of a loss of coolant flow situation. The means of sensing the loss of coolant flow are as follows:

a. Low reactor coolant flow

The parameter sensed is reactor coolant flow. Three elbow taps in each coolant loop are used as a flow device that indicates the status of reactor coolant flow. The basic function of this device is to provide information as to whether or not a reduction in flow rate has occurred. An output signal from two out of the three comparators in a loop would indicate a low flow in that loop. This trip is blocked below P-7 to permit startup.

The coincidence logic and interlocks are given in Table 7.2.1-1.

Figure 7.2.1-1, Sheet 5, shows the logic for the Reactor Coolant System low flow trips.

At power levels above P-7 and below P-8, low flow in two or more loops causes a reactor trip. Above P-8, low flow in one loop causes a reactor trip.

b. Reactor coolant pump undervoltage trip

This trip is required in order to protect against low flow which can result from loss of voltage to more than one reactor coolant pump (e.g. from plant blackout). There is one undervoltage sensing relay connected to the load side of each reactor coolant pump breaker. These relays provide an output signal when the pump voltage goes below approximately 70 percent of rated voltage. Signals from these relays are time delayed to prevent spurious trips caused by short term voltage perturbations. The coincidence logic and interlocks are given in Table 7.2.1-1. This trip is blocked below P-7 to permit startup.

c. Reactor coolant pump underfrequency trip

This trip is required to protect against low flow resulting from bus underfrequency; for example, a major power grid frequency disturbance. The function of this trip is to open the reactor coolant pump (RCP) breakers and trip the reactor for an underfrequency condition.

There is one underfrequency sensing relay connected to the load side of each reactor coolant pump breaker. Power level above the P-7 setpoint and an underfrequency condition sensed by more than one reactor coolant pump motor results in the tripping of all of the reactor coolant pump breakers as well as directly tripping the reactor. Signals from these relays are time delayed to prevent spurious trips caused by short-term frequency perturbations. Undervoltage sensing relays are provided across the power feed to each underfrequency sensor in order to ensure that each underfrequency input to the Reactor Protection System will indicate an underfrequency condition exists on loss of power to the sensing device. The contacts of this undervoltage relay are in series with the output of the underfrequency sensing relays in each channel. Figure 7.2.1-1, Sheet 5 shows the logic.

As shown in Figure 7.2.1-1, Sheet 5, the only inputs to the Reactor Protection System (RPS), associated with the RCP come from the undervoltage and underfrequency sensors. These sensors are located on the load side of the RCP breakers, within a Seismic Category I structure, and are designed in accordance with the requirements of IEEE 279-1971.

The trip signal for the reactor trip breakers, associated with the underfrequency condition, is an output from the RPS, as shown in Figure 7.2.1-1, Sheet 5.

The Westinghouse analysis of the loss of flow accident has shown that for frequency decay rates less than 6.8 Hz per sec. no RCP trip is necessary. TVA has performed an analysis to confirm that the worst case frequency decay rate at the RCP input terminals is below this limit. The results of the TVA analysis shows a frequency decay rate of less than 5 Hz/sec.

5. Low-Low Steam Generator Water Level Trip (Including Environmental Allowance Modifier and Trip Time Delay)

   This trip protects the reactor from loss of heat sink in the event of a loss of feedwater to one or more steam generators or a major feedwater line rupture. This trip is actuated on two out of three low-low water level signals occurring in any steam generator. If a low-low water level condition is detected in one steam generator, signals shall be generated to trip the reactor and start the motor driven auxiliary feedwater pumps. If a low-low water level condition is detected in two or more steam generators, a signal is generated to start the turbine driven auxiliary feedwater pump as well.

   This trip includes an Environmental Allowance Modifier (EAM) which distinguishes between normal and adverse containment environmental conditions. The EAM selects a low setpoint for the steam generator low-low level trip which includes an environmental uncertainty associated with normal plant conditions. In the event that an adverse containment condition is sensed by the EAM, a higher steam generator low-low level trip setpoint is automatically selected to account for larger environmental uncertainties associated with the harsh environmental conditions due to a feedwater rupture inside containment. By utilizing the two different setpoints, more operational flexibility is provided during normal conditions, while adequate protection is still provided during accident/adverse conditions.

   In addition, the signals to actuate reactor trip and start auxiliary feedwater pumps are delayed through the use of a Trip Time Delay (TTD) system for reactor power levels below 50% of RTP. Low-low water level in any protection set in any steam generator will generate a signal which starts an elapsed time trip delay timer. The allowable trip time delay is based upon the prevailing power level at the time the low-low level trip setpoint is reached and the

number of steam generators that are affected. If power level rises after the trip time delay setpoints have been determined, the trip time delay is re-determined (i.e., decreased) according to the increase in power level. However, the trip time delay setpoints are not to be changed if the power level decreases after the setpoints have been determined. The use of this delay allows added time for natural steam generator level stabilization or operator intervention to avoid an undesirable inadvertent protection system actuation.

The logic is shown on Figure 7.2.1-1, Sheets 17, 18 and 19.

6. Turbine Trip-Reactor Trip

The turbine trip-reactor trip is actuated by two out of three logic from emergency trip header pressure signals or by all closed signals from the turbine steam stop valves. A turbine trip causes a direct reactor trip above P-9 setpoint.

The reactor trip on turbine trip is an anticipatory trip input signal to the reactor protection system. This trip is anticipatory in that it is not assumed to occur in any of the Chapter 15 accident analysis. This trip meets all of the requirements of IEEE 279-1971 including separation, redundancy, single failure, and testability. Seismic location, qualification, or mounting of the sensors is not practical because of their location in the nonseismic Turbine Building.

High-high steam generator level signals in two out of three channels for any steam generator will actuate a turbine trip, trip the main feedwater pumps and close the main and bypass feedwater control valves and main feedwater isolation valves. The purpose is to protect the turbine and steam piping from excessive moisture carryover caused by high-high steam generator level. Other turbine trips are discussed in Chapter 10.

The logic for this trip is shown on Figure 7.2.1-1, Sheet 7.

The analog portion of the trip shown on Figure 7.2.1-1, Sheet 16, is represented by dashed (- - -) lines. When the turbine is tripped, turbine emergency trip header pressure drops, and the pressure is sensed by three pressure sensors. A digital output is provided from each sensor when the oil pressure drops below a preset value. These three outputs are transmitted to two redundant two out of three logic matrixes, either of which trips the reactor if above P-9 setpoint.

The emergency trip header pressure signal also dumps the emergency header closing all of the turbine steam stop valves. When all stop valves are closed a reactor trip signal will be initiated if the reactor is above P-9 setpoint. This trip signal is generated by redundant (two each) limit switches on the stop valves.

7. Safety Injection Signal Actuation Trip

A reactor trip occurs when the Safety Injection System is actuated. The means of actuating the Safety Injection System are described in Section 7.3. This trip protects the core against a loss of primary or secondary coolant.

Figure 7.2.1-1, Sheet 8, shows the logic for this trip.

8. Manual Trip

   The manual trip consists of two switches with two outputs on each switch. One output is used to actuate the train A trip breaker, the other output actuates the train B trip breaker. Operating a manual trip switch removes the voltage from the undervoltage trip coil and energizes the reactor trip breaker shunt trip coil.

   There are no interlocks which can block this trip. Figure 7.2.1-1, Sheet 3, shows the manual trip logic.

7.2.1.1.3 Reactor Trip System Interlocks

1. Power Escalation Permissives

   The overpower protection provided by the out of core nuclear instrumentation consists of three discrete, but overlapping, levels. Continuation of startup operation or power increase requires a permissive signal from the higher range instrumentation channels before the lower range level trips can be manually blocked by the operator.

   A one out of two intermediate range permissive signal (P-6) is required prior to source range level trip blocking and source range outputs disabled. Source range level trips are automatically reactivated and outputs restored when both intermediate range channels are below the permissive (P-6) level. There is a manual reset switch for administratively reactivating the source range level trip and outputs when between the permissive P-6 and P-10 level, if required.

   Source range level trip block and outputs disabled are always maintained when above the permissive P-10 level.

   The intermediate range level trip and power-range (low setpoint) trip can only be blocked after satisfactory operation and permissive information are obtained from two of four power range channels. Individual blocking switches are provided so that the low-range power range trip and intermediate range trip can be independently blocked for each train. These trips are automatically reactivated when any three of the four power range channels are below the permissive (P-10) level, thus ensuring automatic activation to more restrictive trip protection.

   The development of permissives P-6 and P-10 is shown on Figure 7.2.1-1, Sheet 4. All of the permissives are digital; they are derived from bistable signals from the four power range and the two intermediate range channels.

   See Table 7.2.1-2 for the list of protection system interlocks.

2. Blocks of Reactor Trips at Low Power

   Interlock P-7 blocks a reactor trip below approximately 10 percent of full power on a low reactor coolant flow in more than one loop, reactor coolant pump undervoltage and under frequency, pressurizer low pressure or high water level. See Figure 7.2.1-1, Sheets 5 and 6.

   Interlock P-8 blocks a reactor trip on 2/3 low reactor coolant flow in any one loop. When the plant is below approximately 35 percent of full power, the block action (absence of the

P-8 interlock signal) occurs when three out of four neutron flux power range signals are below the setpoint. Thus, below the P-8 setpoint, the reactor will be allowed to operate with one loop indicating low flow and trip will not occur until two loops are indicating low flow. See Figure 7.2.1-1, Sheet 4, for derivation of P-8, and Sheet 5 for applicable logic.

Interlock P-9 blocks a reactor trip following a turbine trip below 50 percent power. The block action (absence of the P-9 interlock signal) occurs when three out of four neutron flux power range signals are below the setpoint. Thus, below the P-9 setpoint, the reactor will not be directly tripped by a turbine trip, but instead the reactor control system and the steam dump system will automatically control the reactor to zero power conditions. See Figure 7.2.1-1 Sheet 16 for the implementation of the P-9 interlock. See Figure 7.2.1-1 Sheet 4 for the derivation of P-9.

See Table 7.2.1-2 for the list of protection system blocks.

7.2.1.1.4 Coolant Temperature Sensor Arrangement and Calculational Methodology

The individual narrow range cold and hot leg temperature signals required for input to the reactor trip circuits and interlocks are obtained using RTD's installed in each reactor coolant loop.

The cold leg temperature measurement on each loop is accomplished with two RTDs mounted in thermowells. The cold leg sensors are inherently redundant in that either sensor can adequately represent the cold leg temperature measurement.

The hot leg temperature measurement on each loop is accomplished with three RTDs mounted in thermowells spaced 120 degrees apart around the circumference of the reactor coolant pipe for spatial variations.

These cold and hot leg RTD signals are input to the protection system digital electronics and processed as follows:

The two cold leg temperature signals are subjected to range and consistency checks and then averaged to provide a group value for T cold.

If either T cold input signal is out of range high or low, it will be set to the high or low limit, respectively.

Next, a consistency check is performed on the T cold input signals. If these signal agree within an acceptance interval (DELTAC), the group quality is set to GOOD. If the signals do not agree within the acceptance tolerance DELTAC, the group quality is set to BAD, and the individual signal qualities are set to POOR. The average of the two signals is used to represent the group in either case.

DELTAC is a fixed input parameter based on operating experience. One DELTAC value is required for each protection set.

Each of the three hot leg temperature signals is subjected to a range check, and utilized to calculate an estimated average hot leg temperature which is then consistency checked against the other two estimates for average hot leg temperature.

If any T hot input signal is out of range high or low, it will be set to the offscale high or low limit respectively. Next, an estimated average hot leg temperature is derived from each T hot input signal as follows:

$$\overline{T}_{hji} = T^{f}_{hji} - P_{\beta i}\, S^{\circ}_{ji}$$

where

T^{f}_{hji} is the filtered T hot signal for the jth RTD (j = 1 to 3) in the ith loop (i = 1 to 4)

S°_{ji} = manually input bias which corrects the individual T hot RTD value to the loop average.

$P_{\beta i}$ = Power fraction being used to correct the bias value being used for any power level.

$$P_{\beta i} = \left(T^{f}_{havei} - T^{f}_{ci}\right) / \Delta T^{o}_{i}$$

where

ΔT^{o}_{i} is the full power ΔT in the ith loop

Then, an average of the three estimated hot leg temperatures is computed and the individual signals are checked to determine if they agree within ± DELTA of the average value. If all of the signals do agree within ± DELTA of the average value, the group quality is set to GOOD. The group value T^{f}_{havei} is set to the average of the three estimated average hot leg temperatures.

If the signal values do not all agree within ± DELTA of the average, the algorithm will delete the signal value which is furthest from the average. The quality of this signal will be set to POOR and a consistency check will then be performed on the remaining GOOD signals. If these signals pass the consistency check, the group value will be taken as the average of these GOOD signals and the group quality will be set to POOR. However, if these signals again fail the consistency check (within ± DELTA), then the group value will be set to the average of these two signals; but the group quality will be set to BAD. All of the individual signals will have their quality set to POOR.

DELTA is a fixed input parameter based upon temperature distribution tests within the hot leg. One DELTA value is required for each protection set.

Delta T and T average are calculated as follows:

$$\Delta T = T^{f}_{have} - T^{f}_{c}$$

$$T_{avg} = \left(T^{f}_{have} + T^{f}_{c}\right) / 2.0$$

The calculated values for Delta T and T Average are then utilized for both the remainder of the Overtemperature and Overpower Delta T protection channel and channel outputs for control purposes.

7.2.1.1.5 Pressurizer Water Level Reference Leg Arrangement

The design of the pressurizer water level instrumentation includes a slight modification of the usual tank level arrangement using differential pressure between an upper and a lower tap. The modification consists of the use of a sealed reference leg instead of the conventional open column of water. Refer to 7.2.2.3.4 for an analysis of this arrangement.

7.2.1.1.6 Process System

The process system is described in Reference 17.

7.2.1.1.7 Solid State Logic Protection System

The solid state logic protection system takes binary inputs (voltage/no voltage) from the process protection and nuclear instrument channels corresponding to conditions (normal/abnormal) of plant parameters. The system combines these signals in the required logic combination and generates a trip signal to the undervoltage and shunt trip coils of the reactor trip circuit breakers when the necessary combination of signals occur. The system also provides annunciator, status light and computer input signals which indicate the condition of bistable input signals, partial trip and full trip functions and the status of the various blocking, permissive (see Section 10.4.4.3 for exception on P-12) and actuation functions. In addition the system includes means for semi-automatic testing of the logic circuits. A detailed description of this system is given in Reference 3.

7.2.1.1.8 Isolation Devices

In certain applications, Westinghouse considers it advantageous to employ control signals derived from individual protection channels through isolation devices contained in the protection channel, as permitted by IEEE-279.

In all of these cases, analog signals derived from protection channels for non-protective functions are obtained through isolation devices located in the process protection racks. By definition, non-protective functions include those signals used for control, remote process indication, and computer monitoring.

Isolation device qualification tests are described in References 4, 5, and 17.

7.2.1.1.9 Energy Supply and Environmental Variations

The energy supply for the Reactor Trip System, including the voltage and frequency variations, is described in Section 7.6. The environmental variations, throughout which the system will perform, are given in Section 3.11.

7.2.1.1.10 Trip Levels (Setpoints)

The levels that, when reached, will require trip action are given in the SNP Technical Specifications. (Refer also to Subparagraph 7.1.2.1.9)

7.2.1.1.11 Seismic Design

The seismic design considerations for the Reactor Trip System are given in Section 3.10. This design meets the requirements of Criterion 2 of the 1971 General Design Criteria (GDC).

7.2.1.2 Design Bases Information

The information given below presents the design bases information per Section 3 of IEEE 279-1971 Reference 8. Functional logic diagrams are presented in Figure 7.2.1-1.

7.2.1.2.1 Generating Station Conditions

The following are the generating station conditions requiring reactor trip.

1. DNBR approaching limit value.

2. Power density (kilowatts per foot) approaching rated value for Condition II faults (See Chapter 4 for fuel design limits).

3. Reactor Coolant System overpressure creating stresses approaching the limits specified in Chapter 5.

7.2.1.2.2 Generating Station Variables

The following are the variables required to be monitored in order to provide reactor trips. (See Table 7.2.1-1)

1. Neutron flux

2. Reactor Coolant temperature

3. Reactor Coolant System pressure (pressurizer pressure)

4. Pressurizer water level

5. Reactor Coolant flow

6. Reactor Coolant pump operational status (voltage and frequency, and breaker position)

7. Steam generator water level

8. Turbine-generator operational status (emergency trip header pressure and stop valve position)

7.2.1.2.3 Spatially Dependent Variables

The following variable is spatially dependent:

1. Reactor coolant narrow range hot leg temperature: See Paragraph 7.3.1.2 for a discussion of this variable spatial dependence.

7.2.1.2.4 Limits, Margins and Levels

The parameter values that will require reactor trip are given in the SNP Technical Specifications, and in Chapter 15, Safety Analysis. Chapter 15 demonstrates that the setpoints used in the SNP Technical Specifications are conservative. (Refer also to Subparagraph 7.1.2.1.9)

The setpoints for the various functions in the Reactor Trip System have been analytically determined such that the operational limits so prescribed will prevent fuel rod clad damage and loss of integrity of the Reactor Coolant System as a result of any Condition II incident (anticipated malfunction). As such, the Reactor Trip System limits the following parameters:

1. Minimum DNBR
2. Maximum System Pressure
3. Fuel rod maximum linear power

The accident analyses described in Section 15.2 demonstrate that the functional requirements as specified for the Reactor Trip System are adequate to meet the above considerations, even assuming, for conservatism, adverse combinations of instrument errors (Refer to Table 15.1.3-1). Safety limits associated with the reactor core and Reactor Coolant System, plus the Limiting Safety System Setpoints, are presented in the SNP Technical Specifications.

The Technical Specifications incorporate both nominal and limiting setpoints. Nominal settings of the setpoints are more conservative than the limiting settings. This allows for calibration uncertainty and instrument channel drift without violating the limiting setpoint. Automatic initiation of protective functions occurs at the nominal setpoints (plus or minus the allowed tolerances). The methodology used to derive the setpoints is documented in references 16 and 20.

7.2.1.2.5 Abnormal Events

The malfunctions, accidents or other unusual events which could physically damage Reactor Trip System components or could cause environmental changes are as follows:

1. Earthquake (discussed in Chapter 2 and Chapter 3).
2. Fire (See Section 9.5).
3. Explosion (Hydrogen buildup inside containment). (See Section 6.2).
4. Missiles (See Sections 3.5 and 10.2.3).
5. Flood (See Chapter 2 and 3).
6. Wind and Tornadoes (See Section 3.3).

All instrumentation, control and communication lines that will be required for operation in the flood mode are either above the design basis flood (DBF) or within a nonflooded structure or are designed for submerged operation.

7.2.1.2.6 Minimum Performance Requirements

The performance requirements are as follows:

1. System response times:

   The reactor trip system response time shall be the time interval from when the monitored parameter exceeds its trip setpoint at the channel sensor until loss of stationary gripper coil voltage.

The reactor trip system instrumentation response time values are provided in Table 7.2.1-5.

2. Reactor Trip accuracies are given in Table 7.2.1-4.

3. Protection system ranges:

		Range
a.	Power range nuclear power	1 to 120% full power
b.	Neutron flux rates (positive and negative)	+5% to -5% of full power for rapid changes in power.
c.	Overtemperature ΔT:	
	T_{hot} leg	530 to 650°F
	T_{cold} leg	510 to 630°F
	T_{avg}	530 to 630°F
	Pressurizer pressure	1700 to 2500 psig
	F(Δ>)	-60 to +60%
	ΔT setpoint	0 to 150% power

d.	Overpower ΔT	(See Overtemperature ΔT)
e.	Pressurizer Pressure	1700 to 2500 psig
f.	Pressurizer water level	Entire distance between level taps
g.	Reactor coolant flow	0 to 120% of rated flow
h.	Reactor coolant pump bus underfrequency	50 to 65 Hz
i.	Reactor coolant pump bus undervoltage	0 to 100% rated voltage
j.	Steam generator water level	± ~ 6 ft. from nominal full load

7.2.2 Analyses

7.2.2.1 Failure Mode and Effects Analyses

A failure mode and effects analysis of the Reactor Trip System has been performed. Results of this study and a fault tree analysis are presented in WCAP-7706, "An Evaluation of Solid State Logic Reactor Protection In Anticipated Transients," (Reference 6).

7.2.2.2 Evaluation of Design Limits

While most setpoints used in the Reactor Protection System are fixed, there are variable setpoints, most notably the overtemperature ΔT and overpower ΔT setpoints. All setpoints in the Reactor Trip System have been selected on the basis of detailed safety analyses and engineering design studies. The capability of the Reactor Trip System to prevent loss of integrity of the fuel clad and/or Reactor Coolant System pressure boundary during Condition II and III transients is demonstrated in the Safety Analysis, Chapter 15. These safety analyses are carried out using those setpoints determined from results of the engineering design studies. Setpoint limits are presented in the Technical Specifications. A discussion of the intent for each of the various reactor trips and the accident analysis (where appropriate) which utilizes this trip is presented in Subparagraph 7.2.1.1.2. It should be noted that the selected trip setpoints all provide for margin before protection action is actually required to allow for uncertainties and instrument errors (Reference 16). The design meets the requirements of Criteria 16 and 22 of the 1971 GDC.

7.2.2.2.1 Trip Setpoint Discussion

It has been noted in Subparagraph 7.2.1.2.4 that below the minimum allowable DNBR there is likely to be significant local fuel clad failure. The DNBR existing at any point in the core for a given core design can be determined as a function of the core inlet temperature, power output, operating pressure and flow. Consequently, core safety limits in terms of a DNBR equal to the minimum value for the hot channel can be developed as a function of core ΔT, T_{avg} and pressure for a specified flow as illustrated by the solid lines in Figure 7.2.2-1. Also shown as solid lines in Figure 7.2.2-1 are the loci of conditions equivalent to 116.5 percent of power as a function of ΔT and T_{avg} representing the overpower (kW/ft) limit on the fuel. The dashed lines indicate the

maximum permissible setpoint (ΔT) as a function of T_{avg} and pressure for the overtemperature and overpower reactor trip. Actual setpoint constants in the equation representing the dashed lines are as given in the SNP Technical Specifications. These values are conservative to allow for instrument errors. The design meets the requirements of Criteria 16, 20, 22 and 27 of the 1971 GDC.

DNBR is not a directly measurable quantity; however, the process variables that determine DNBR are sensed and evaluated. Small isolated changes in various process variables may not individually result in violation of a core safety limit, whereas the combined variations, over sufficient time, may cause the overpower or overtemperature safety limit to be exceeded. The design concept of the reactor trip system takes cognizance of this situation by providing reactor trips associated with individual process variables in addition to the overpower/overtemperature safety limit trips. The process variable trips prevent reactor operation whenever a change in the monitored value is such that a core or system safety limit is in danger of being exceeded should operation continue. Basically, the high pressure, low pressure and overpower/overtemperature ΔT trips provide sufficient protection for slow transients as opposed to such trips as low flow or high flux which will trip the reactor for rapid changes in flow or flux, respectively, that would result in fuel damage before actuation of the slower responding ΔT trips could be effected.

Therefore, the Reactor Trip System has been designed to provide protection for fuel clad and RCS pressure boundary integrity where: (a) A rapid change in a single variable of factor which will quickly result in exceeding a core or a system safety limit, and (b) A slow change in one or more variables will have an integrated effect which will cause safety limits to be exceeded. Overall, the Reactor Trip System offers diverse and comprehensive protection against fuel clad failure and/or loss of Reactor Coolant System integrity for Condition II and III accidents. This is demonstrated by Table 7.2.1-3 which lists the various trips of the Reactor Trip System, the corresponding Technical Specification on Safety Limits and Safety System Settings and the appropriate accident discussed in the Safety Analyses in which the trip could be utilized.

The nuclear power plant Reactor Trip System design employed by Westinghouse was evaluated in detail with respect to common mode failure and is presented in References 6 and 7. The design meets the requirements of Criterion 21 of the 1971 GDC.

Preoperational testing is performed on Reactor Trip System components and systems to determine equipment readiness for startup. This testing serves as a very real evaluation of the system design.

Analyses of the results of Condition I, II, III and IV Events, including considerations of instrumentation installed to mitigate their consequences, are presented in Chapter 15. The instrumentation installed to mitigate the consequences of load rejection and turbine trip is given in Section 7.7.

7.2.2.2.2 Reactor Coolant Flow Measurement

The elbow taps used on each loop in the primary coolant system are instrument devices that indicate the status of the reactor coolant flow. The basic function of this device is to provide information as to whether or not a reduction in flow has occurred. The correlation between flow and elbow tap signal is given by the following equation:

$$\frac{\Delta P}{\Delta P_0} = \left(\frac{w}{w_0}\right)^2$$

Where ΔP_o is the pressure differential at the reference flow, w_o, and ΔP is the pressure differential at the corresponding flow, w. The full flow reference point is established during initial plant startup. The low flow trip point is then established by extrapolating along the correlation curve. The expected absolute accuracy of the channel is within $\pm$ 10 percent of full flow and field results have shown the repeatability of the trip point to be within $\pm$ 1 percent.

7.2.2.2.3 Evaluation of Compliance to Applicable Codes and Standards

The Reactor Trip System meets the requirements of IEEE-Standard 279, Reference 8, as indicated below.

1. Single Failure Criterion

   The protection system is designed to provide redundant (one out of two, two out of three or two out of four) instrumentation channels for each protective function and one out of two logic train circuits. These redundant channels and trains are electrically isolated and physically separated. Thus, any single failure within a channel or train will not prevent protective action when required. This meets the requirements of Criterion 22 of the GDC. Loss of input power, the most likely mode of failure, to a channel or logic train will result in a signal calling for a trip. This meets the requirements of Criterion 23 of the 1971 GDC.

   To prevent the occurrence of common mode failures, such additional measures as functional diversity, physical separation, and testing as well as administrative control during design, production, installation and operation are employed, as discussed in References 6 and 7. This meets the requirements of Criterion 21 of the 1971 GDC.

2. Quality of Components and Modules

   For a discussion of the quality of the components and modules used in the Reactor Trip System, refer to Chapter 17. The quality used meets the requirements of Criterion 1 of the 1971 GDC.

3. Equipment Qualification

   For a discussion of the type of tests made to verify the performance requirements, refer to Section 3.11. The test results demonstrate that the design meets the requirements of Criterion 22 of the 1971 GDC.

4. Independence

   Each individual channel is assigned to one of four channel designations, e.g., Channel I, II, III, IV. See Figure 7.2.2-2. Channel independence is carried throughout the system, extending from the sensor through to the devices actuating the protective function. Physical separation is used to achieve separation of redundant transmitters. Separation of wiring is achieved using separate wireways, cable trays, conduit runs and containment penetrations for each redundant channel. Redundant process equipment is separated by locating electronics in different protection rack sets. Each redundant channel is energized from a separate AC power feed. This meets the requirements of Criterion 22 of the 1971 GDC.

5. Control and Protection System Interaction

   The protection system is designed to be independent of the control system. In certain applications the control signals and other non-protective functions are derived from individual

protective channels through isolation devices. The isolation devices are classified as part of the protection system and are located in the process protective racks. Non-protective functions include those signals used for control, remote non-IE process indication, and computer monitoring. The isolation devices are designed such that a short circuit, open circuit, or the application of the maximum credible fault voltage on the isolated output portion of the circuit (i.e., the non-protective side of the circuit) will not affect the input (protective) side of the circuit.

The signals obtained through the isolation devices are never returned to the protective racks. This meets the requirements of Criterion 24 of the 1971 GDC.

A detailed discussion of the design and testing of the isolation devices is given in References 4 and 5. These reports include the results of applying various malfunction conditions on the output portion of the isolation devices. The results show that no significant disturbance to the isolation device input signal occurred.

Where failure of a protection system component can cause a process excursion, which requires protective action, the protection system can withstand another independent failure without loss of protective action. This is normally achieved by means of two-out-of-four (2/4) trip logic for each of the protective functions except the Steam Generator Level and Pressure and the Pressurizer Level and Pressure Protections. The Steam Generator and Pressurizer Low Water Level as well as the Steam Generator Pressure and Pressurizer Pressure (Low Pressure Safety Injection Initiations) protective functions rely upon two-out-of-three (2/3) trip logic and a control system Median Signal Selector (MSS). The use of a control system MSS prevents any protection system failure from causing a control system reaction resulting in a need for subsequent protective action. This meets the requirements of Criterion 25 of the 1971 GDC.

6. Capability for Testing

The Reactor Trip System is capable of being tested during power operation. Where only parts of the system are tested at any one time, the testing sequence provides the necessary overlap between the parts to assure complete system operation.

The protection system is designed to permit periodic testing of the process channel portion of the Reactor Trip System during reactor power operation without initiating a protective action unless a trip condition actually exists. This is because of the "AND" logic required for reactor trip. Note that the source and intermediate range high neutron flux trips must be bypassed during testing.

The operability of the process sensors is ascertained by comparison with redundant channels monitoring the same process variables or those with a fixed known relationship to the parameter being checked. The sensors can be calibrated during plant shutdown.

The Process Protection System performs automatic surveillance testing of the digital process protection racks via a portable Man Machine Interface (MMI) test cart. The MMI test cart is connected to a process rack by inserting a connector into the process rack test panel. Using the MMI, the "Surveillance Test" option is then selected. Following instructions entered through the MMI, the rack test processor automatically performs the following operations:

1. Selection of the individual process channel to be tested.

2. Calibration of the test reference signals and verification of the tester time base.

3. Placement of the Individual channel trip outputs in either "Channel Trip" or "Bypass" (password protected) mode.

   A. Bypass Mode -- disables the individual channel comparator trip circuitry which forces the associated logic input relays to remain in the non-tripped state until the "bypass" is removed.

   B. Channel Trip Mode – Usually interrupts the individual channel comparator outputs to the logic circuitry to de-energize the associated logic input relay(s) (some channel trip functions are energize to trip).

4. Activation of the test injection signal.

5. Performance of Analog to Digital (A/D) converter test, and engineering unit values conversion tests.

6. Performance of comparator functional tests.

7. Performance of channel time response test.

8. Completion of test cycle and automatically remove "Channel Trips" or “Bypass” signals.

9. Verify calibration of the test injection signals.

10. Display of test results on the MMI screen.

Interruption of the comparator output to the logic circuitry for any reason (test, maintenance purposes, or removed from service) causes that portion of the logic to be actuated and accompanied by a channel trip alarm and channel status light in the control room. Status lights on the process rack test panel indicate when the associated comparators have tripped. Each channel is fully testable via the portable MMI test cart.

The power range channels of the Nuclear Instrumentation System are tested by superimposing a test signal on the actual detector signal being received by the channel at the time of testing. The output of the bistables is not placed in a tripped condition prior to testing. Also, since the power range channel logic is two out of four, bypass of this reactor trip function is not required.

To test a power range channel, a "TEST-OPERATE" switch is provided to require deliberate operator action and operation of which will initiate the "CHANNEL TEST" annunciator in the control room. Bistable operation is tested by increasing the test signal level up to its trip setpoint and verifying bistable relay operation by control board annunciator and trip status lights.

It should be noted that a valid trip signal would cause the channel under test to trip at a lower actual reactor power level. A reactor trip would occur when a second bistable trips. No provision has been made in the channel test circuit for reducing the channel signal level below that signal being received from the Nuclear Instrumentation System detector.

A Nuclear Instrumentation System channel which can cause a reactor trip through one of two protection logic (source or intermediate range) is provided with a bypass function which prevents the initiation of a reactor trip from that particular channel during the short period that it is undergoing test. These bypasses initiate an alarm in the control room.

For a detailed description of the Nuclear Instrumentation System see Reference 2.

The logic trains of the Reactor Trip System are designed to be capable of complete testing at power, except for those trips listed in Subsection 7.1.2.8. Annunciation is provided in the control room to indicate when a train is in test, when a reactor trip is bypassed and when a reactor trip breaker is bypassed. Details of the logic system testing are given in Reference 3.

The reactor coolant pump breakers cannot be tripped at power without causing a plant upset by loss of power to a coolant pump. However, the reactor coolant pump breaker open trip logic and continuity through the shunt trip coil can be tested at power. Manual trip cannot be tested at power without causing a reactor trip since operation of either manual trip switch actuates both Train A and Train B. Note, however, that manual trip could also be initiated from outside the control room by manually tripping one of the reactor trip breakers. Initiating safety injection or opening the turbine trip breakers cannot be done at power without upsetting normal plant operation. However, the logic for these trips is testable at power.

Testing of the logic trains of the Reactor Trip System includes a check of the SSPS input relays and a logic matrix check. The following sequence is used to test the system:

a. Check of input relays

   During testing of the process instrumentation system and nuclear instrumentation system bistables, each channel bistable is placed in a trip mode causing one SSPS input relay in Train A and one in Train B to de-energize. A contact of each relay is connected to a universal logic printed circuit card. This card performs both the reactor trip and monitoring functions. The contact that creates the reactor trip also causes a status lamp and an annunciator on the control board to operate. Either the Train A or Train B input relay operation will light the status lamp and annunciator.

   Each train contains a multiplexing test switch, one of which (either train) normally remains in the A + B position. The A + B position alternately allows information to be transmitted from the two trains to the control board. During process or nuclear instrumentation testing, a steady status lamp and annunciator indicates that input relays in both trains have been de-energized. A flashing lamp means that the input relays in the two trains did not both de-energize. Contact inputs to the logic protection system such as reactor coolant pump bus under frequency relays operate input relays which are tested by operating the remote contacts as described above and using the same type of indications as those provided for bistable input relays.

Actuation of the SSPS input relays provides the overlap between the testing of the logic protection system and the testing of those systems supplying the inputs to the logic protection system. Test indications are status lamps and annunciators on the control board. Inputs to the logic protection system are checked one channel at a time, leaving the other channels in service. For example, a function that trips the reactor when two out of four channels trip becomes a one out of three trip when one channel is placed in the trip mode. Both trains of the logic protection system remain in service during this portion of the test.

b. Check of Logic Matrixes

Logic matrixes are checked one train at time. Input relays are not operated during this portion of the test. Reactor trips from the train being tested are inhibited with the use of the input error inhibit switch on the semi-automatic test panel in the train. Details of

semi-automatic tester operation are given in Reference 3. At the completion of the logic matrix tests, one comparator/bistable in each channel of process instrumentation or nuclear instrumentation is tripped to check closure of the input error inhibit switch contacts.

The logic test scheme uses pulse techniques to check the coincidence logic. All possible trip and non-trip combinations are checked. Pulses from the tester are applied to the inputs of the universal logic card at the same terminals that connect to the input relay contacts. Thus there is an overlap between the input relay check and the logic matrix check. Pulses are fed back from the reactor trip breaker undervoltage coil to the tester. The pulses are of such short duration that the reactor trip breaker undervoltage coil armature cannot respond mechanically.

Test indications that are provided are an annunciator in the control room indicating that reactor trips from the train have been blocked and that the train is being tested, and green and red lamps on the semi-automatic tester to indicate a good or bad logic matrix test. Protection capability provided during this portion of the test is from the train not being tested.

The general design features and details of the testability of the logic system are described in Reference 3, thus this testing capability meets the requirements of Criterion 21 of the 1971 GDC.

7. Testing of Reactor Trip Breakers

Normally, reactor trip breakers 52/RTA and 52/RTB are in service, and bypass breakers 52/BYA and 52/BYB are withdrawn (out of service). In testing the protection logic, pulse techniques are used to avoid tripping the reactor trip breakers thereby eliminating the need to bypass them during this testing. The following procedure describes the method used for testing the trip breakers:

a. With bypass breaker 52/BYA in the test position, manually close and trip it to verify its operation.

b. Rack in and close 52/BYA. Place test block hand switch (S1) in the test position (not blocked). Manually trip 52/RTA through a protection system logic matrix.

c. Reset 52/RTA.

d. Trip and rackout 52/BYA.

e. Repeat above steps to test trip breaker 52/RTB using bypass breaker 52/BYB.

Auxiliary contacts of the bypass breakers are connected into the alarm system of their respective trains, as described in Reference 3 such that if either train is placed in test while the bypass breaker of the other train is closed, both reactor trip breakers and both bypass breakers will automatically trip.

Auxiliary contacts of the bypass breakers are also connected in such a way that if an attempt is made to close the bypass breaker in one train while the bypass breaker of the other train is already closed, both bypass breakers will automatically trip.

The Train A and Train B alarm systems operate separate annunciators in the control room. The two bypass breakers also operate an annunciator in the control room. Bypassing of a protection train with either the bypass breaker or with the test switches will result in audible and visual indications.

The complete Reactor Trip System is normally required to be in service. However, to permit online testing of the various protection channels or to permit continued operation in the event of a subsystem instrumentation channel failure, Technical Specification, 3.3.1 defines the required number of operable channels and the minimum degree of channel redundancy has been formulated. This Technical Specification also defines the required restriction to operation in the event that the channel operability and degree to redundancy requirements cannot be met.

The Reactor Trip System is designed in such a way that response time tests can only be performed during shutdown. However, the safety analyses utilize conservative numbers for trip channel response time. The measured channel response times are compared with those used in the safety evaluations. On the basis of startup tests conducted on several plants, the actual response times measured are less than the times used in the safety analyses. Refer to Table 15.1.3-1.

8. Bypasses

The process protection system is designed to permit an inoperable channel to be placed in a bypasss condition for the purpose of trouble shooting or periodic test of a redundant channel.

Where operating requirements necessitate automatic or manual bypass of a protective function (see Section 10.4.4.3 for exception on P-12), the design is such that the bypass is removed automatically whenever permissive conditions are not met. Devices used to achieve automatic removal of the bypass of a protective function are considered part of the protective system and are designed in accordance with the criteria of this section. Indication is provided in the control room if some part of the system has been administratively bypassed or taken out of service.

9. Multiple Setpoints

For monitoring neutron flux and steam generator level, multiple setpoints are used. When a more restrictive trip setting becomes necessary to provide adequate protection for a particular mode of operation or set of operating conditions, the protective system circuits are designed to provide positive means or administrative control to assure that the more restrictive trip setpoint is used. The devices used to prevent improper use of less restrictive trip settings are considered part of the protective system and are designed in accordance with the criteria of this section.

10. Completion of Protective Action

The protection system is so designed that, once initiated, a protective action goes to completion. Return to normal operation requires action by the operator.

11. Manual Initiation

Switches are provided on the Control Board for manual initiation of protective action. Failure in the automatic system does not prevent the manual actuation of the protective functions. Manual actuation relies on the operation of a minimum of equipment.

12. Access

The design provides for administrative control of access to all set point adjustments, module calibration adjustments, test points, and the means for manually bypassing channels or protective functions. For details refer to Reference 17.

13. Information Read Out

The protective system provides the operator with complete information pertinent to system status and safety. All transmitted signals (flow, pressure, temperature, etc.) which can cause a reactor trip is either indicated or recorded for every channel, including all neutron flux power range currents (top detector, bottom detector, algebraic difference and average of bottom and top detector currents). Any reactor trip will actuate an alarm and an annunciator. Such protective actions are indicated and identified down to the channel level.

Alarms and annunciators are also used to alert the operator of deviations from normal operating conditions so that he may take appropriate corrective action to avoid a reactor trip. Actuation of any rod stop or trip of any reactor trip channel will actuate an alarm.

14. Identification

The identification described in Section 7.1 provides immediate and unambiguous identification of the protection equipment.

7.2.2.3 Specific Control and Protection Interactions

7.2.2.3.1 Neutron Flux

Four power range neutron flux channels are provided for overpower protection. If any channel fails in such a way as to produce a low output, that channel is incapable of overpower protection but will not cause control rod movement because of the auctioneer. Two out of four overpower trip logic will ensure an overpower trip if needed even with an independent failure in another channel.

The high median signal of the four power range neutron flux channels is selected by DCS to automatically control the control rods. If any channel fails and produces a low output, DCS utilizes the median signal of the three remaining channels, thereby limiting rod movement due to a failed channel.

In addition, channel deviation signals in the control system will give an alarm if any power range neutron flux channel deviates significantly from any of the other channels. Also, the automatic rod control system (contained within the DCS) will respond only to rapid changes in indicated neutron flux; slow changes or drifts are compensated by the temperature control signals. Finally, an overpower signal from any intermediate or power range nuclear channel will block automatic rod withdrawal. The setpoint for this rod stop is below the reactor trip setpoint.

7.2.2.3.2 Coolant Temperature

The accuracy of the resistance temperature detector measurements is demonstrated during plant startup tests by comparing temperature measurement from all resistance temperature detectors with one another.

The comparisons are done with the Reactor Trip System in an isothermal condition. The linearity of the ΔT measurements obtained from the hot leg and cold leg resistance temperature

detectors as a function of plant power is also checked during plant startup tests. The absolute value of ΔT versus plant power is not important as far as reactor protection is concerned. Reactor Trip System setpoints are based upon percentages of the indicated ΔT at nominal full power rather than on absolute values of ΔT. For this reason, the linearity of the ΔT signals as a function of power is of importance rather than the absolute values of the ΔT. As part of the plant startup tests, the loop resistance temperature detector signals will be compared with the core exit thermocouple signals. Note also that reactor temperature control is based upon signals derived from protection system channels after isolation by isolation devices such that no feedback effect can perturb the protection channels. Since control is based on the highest average temperature of the loops, the control rods are always moved based upon the most pessimistic temperature measurement with respect to margins to DNBR. A spurious low average temperature measurement (at power) from any loop temperature control channel will cause no control action. A spurious high average temperature measurement will cause rod insertion (safe direction).

In addition, channel deviation signals in the control system will give an alarm if any temperature channel deviates significantly from the auctioneered (highest) value. Automatic rod withdrawal blocks will also occur if any two of the temperature channels indicate overtemperature or overpower condition.

7.2.2.3.3 Pressurizer Pressure

The pressurizer pressure protection channels signals are used for high and low pressure protection and as inputs to the overtemperature ΔT trip protection function. Isolated output signals from these channels are used for pressure control in the DCS. These signals are used to control pressurizer spray and heaters and power operated relief valves. A coincident high pressure signal from two independent DCS processing groups is needed for the actuation of each pressurizer PORV. Pressurizer pressure is sensed by fast response pressure transmitters with a time response of better than 0.2 seconds.

The four pressurizer pressure signals pass through a Median-Low Signal Selector in the DCS preventing a spurious signal from one channel causing a control system pressure perturbation.

Units 1 and 2

The pressurizer heaters are incapable of overpressurizing the Reactor Coolant System. The rate of pressure rise achievable with heaters is slow, and ample time and pressure alarms are available to alert the operator of the need for appropriate action.

Overpressure protection is based upon the positive surge of the reactor coolant produced as a result of turbine trip under full load, assuming the core continues to produce full power.

The self-actuated safety valves are sized on the basis of steam flow from the pressurizer to accommodate this surge at a setpoint of 2500 psia and an accumulation of 3 percent. Note that no credit is taken for the relief capability provided by the power operated relief valves during this surge. In addition, operation of any one of the power operated relief valves can maintain pressure below the high pressure trip point for most transients.

The four pressurizer pressure signals are obtained from the three taps by connecting one of the taps to two pressure transmitters. Redundancy is not impaired by having a shared tap since the logic for this trip is two out of four. If the shared tap is plugged, the affected channels will remain static. If the impulse line bursts, the indicated pressure will drop to zero. In either case the fault is easily detectable, and the protective function remains operable.

7.2.2.3.4 Pressurizer Water Level

Three pressurizer water level channels are used for reactor trip. Isolated signals from these channels are used for pressurizer water level control (control contained within the plant Distributed Control System). A failure in the level control system could fill or empty the pressurizer at a slow rate (on the order of half an hour or more).

Experience has shown that hydrogen gas can accumulate in the upper part of the condensate pot on conventional open reference leg systems in pressurizer water level service. At Reactor Coolant System operating pressures, high concentrations of dissolved hydrogen in the reference leg water are possible. To eliminate the possibility of such effects, a bellows is used in a pot at the top of the reference leg to provide an interface seal and prevent dissolving of hydrogen gas into the reference leg water. Supplier tests were run which confirmed a time response of less than 1.0 second. A major section of the vertical portion of the sealed sense line is outside the cavity that shields the pressurizer and therefore is not subject to short-term heatup. Since Sequoyah is an ice condenser plant, it does not experience peak temperatures in the upper compartment as high as non-ice condenser plants. The long-term heatup is the only concern. The reference leg is uninsulated and will remain at local ambient temperature. This temperature will vary somewhat over the length of the reference leg piping under normal operating conditions but will not exceed 140°F. During a blowdown accident, any reference leg water flashing to steam will be confined to the condensate steam interface in the condensate pot at the top of the temperature barrier leg and will have only a small (about one inch) effect on measured level. Some additional variance may be expected due to effervescence of hydrogen in the temperature barrier water. However, even if complete loss of this water is assumed, the variance will tend to increase the margin of safety.

The sealed reference leg design has been installed in various plants since early 1970 and operational accuracy was verified at the Robert Ginna Station by use of the sealed reference leg system in parallel with an open reference leg channel. No effects of operating pressure variations on either the accuracy or integrity of the channel have been observed.

Calibration of the sealed reference leg system is done in place after installation by application of known pressure to the low pressure side of the transmitter and measurement of the transmitter output. The effects of static pressure variations are predictable. The largest effect is due to the density change in the saturated fluid in the pressurizer itself. The effect is typical of level measurements in all tanks with two phase fluid and is not peculiar to the sealed reference leg technique. In the sealed reference leg, there is a slight compression of the fill water with increasing pressure, but this is taken up by the flexible bellows. A leak of the fill water in the sealed reference leg can be detected by comparison of redundant channel readings on line and by physical inspection of the reference leg off line. Leaks of the reference leg to atmosphere will be immediately detectable by off scale indications and alarms on the control board. A closed pressurizer level instrument shut off valve would be detected by comparing the level indications from the redundant level channels (three channels). In addition, there are alarms on each one of the three channels to indicate an error between the measured pressurizer water level and the programmed pressurizer water level. There is no single instrument valve which could affect more than one of the three level channels.

The high level trip setpoint provides sufficient margin such that the undesirable condition of discharging liquid coolant through the safety valves is minimized. Even at full power conditions, which would produce the worst thermal expansion rates, a failure of the level control would not lead to any liquid discharge through the safety valves. This is due to the automatic high pressurizer pressure reactor trip actuating at a pressure sufficiently below the safety valve setpoint.

7.2.2.3.5 Steam Generator Water Level

The basic function of the reactor protection circuits associated with low steam generator water level is to preserve the steam generator heat sink for removal of long term residual heat. Should a complete loss of feedwater occur, the reactor would be tripped on low-low steam generator water level. In addition, redundant auxiliary feedwater pumps are provided to supply feedwater in order to maintain residual heat removal after trip preventing eventual thermal expansion and discharge of the reactor coolant through the pressurizer relief valves into the relief tank even when main feedwater pumps are incapacitated. This reactor trip acts before the steam generators are dry to reduce the required capacity and starting time requirements of these auxiliary feedwater pumps and to minimize the thermal transient on the Reactor Coolant System and steam generators. Therefore, a low-low steam generator water level reactor trip is provided for each steam generator to ensure that sufficient initial thermal capacity is available in the steam generator at the start of the transient. It is desirable to minimize thermal transients on a steam generator for a credible loss of feedwater accident.

It should be noted that a single protection system failure that potentially could cause a control system reaction is eliminated by the DCS (Distributed Control System) using a Median Signal Selection (MSS) function. The system checks the quality of the instrument signal inputs and if all are of a good quality, the median signal is then selected for control. Should one of the signal inputs fail, the remaining signals are then averaged to provide the control function. The prime reason for the MSS feature is to prevent a failed protection system instrument channel from causing a disturbance in the feedwater control system requiring subsequent protective system action. All three narrow range steam generator water level channels for each steam generator, which also provide a reactor protection system reactor trip, are applied to the DCS MSS circuitry for feedwater control for its respective feedwater regulating valve. Upon a failure of one steam generator level signal, the remaining level signals for that generator are averaged in the DCS for its feedwater regulating valve control. Since no adverse control system action may now result from a single failed protection instrument channel, a second random protection system failure (as would otherwise be required by IEEE 279-1971) need not be considered.

7.2.2.4 Additional Postulated Accidents

Loss of plant auxiliary control air or loss of component cooling water is discussed in Paragraph 7.3.2.3. Load rejection and turbine trip are discussed in further detail in Section 7.7.

The control interlocks, called rod stops, that are provided to prevent abnormal power conditions which could result from excessive control rod withdrawal are discussed in 7.7.1.4.1 and listed on Table 7.7.1-1. Excessively high power operation (which is prevented by blocking of automatic rod withdrawal), if allowed to continue, might lead to a safety limit (as given in the Technical Specifications) being reached. Before such a limit is reached, protection will be available from the Reactor Trip System. At the power levels of the rod block setpoints, safety limits have not been reached; and therefore these rod withdrawal stops do not come under the scope of safety related systems, and are considered as control systems.

7.2.3 Tests and Inspections

The Reactor Trip System meets the testing requirements of Reference 9. The testability of the system is discussed in 7.2.2.2.3. The test intervals are specified in the Technical Specifications. Written test procedures and documentation, conforming to the requirements of Reference 9, are available for audit by responsible personnel.

Reference 15 documents a methodology to be used to justify revisions to the technical specifications. The methodology consists of the deterministic and numerical evaluation of the effects of particular technical specification changes with consideration given to such things as safety, equipment requirements, human factors and operational impacts. The technical specification revisions evaluated were increased test and maintenance times, less frequent surveillance and testing in bypass.

7.2.3.1 Inservice Tests and Inspections

Periodic surveillance of the Reactor Trip System is performed to ensure proper protective action. This surveillance consists of channel checks, channel calibrations, channel operational testing, and response time testing which are summarized as follows:

1. Channel Checks

   A channel check consists of a qualitative determination of acceptability by observation of channel behavior during operation. It includes comparison of the channel indication and/or status indications and/or status derived from independent channels measuring the same variable. Failures such as blown instrument fuses, defective indicators, or faulted amplifiers which result in "upscale" or "downscale" indication can be easily recognized by simple observation of the functioning of the instrument or system. Furthermore, in many cases such failures are revealed by alarm or annunciator action, and a check supplements this type of surveillance.

2. Channel Calibration

   A channel calibration consists of adjustment of channel output such that it responds, within acceptable range and accuracy, to known values of the parameter which the channel measures. Calibration encompasses the entire channel including the sensor, alarm and/or trip function, and includes the channel operational test discussed below. Thus, the calibration ensures the acquisition and presentation of accurate information.

3. Channel Operational Test

   A channel operational test consists of:

   a. Analog channels - the injection of a simulated signal into the channel as close to the sensor as practicable to verify operability including alarm and/or trip functions.

   b. Bistable channels - the injection of a simulated signal into the sensor to verify operability including alarm and/or trip functions.

   c. Digital channels - the injection of a simulated signal into the channel as close to the sensor input to the process racks as practicable to verify operability including alarm and/or trip functions.

4. Response Time Test

   A response time verification demonstrates that the protective function associated with each applicable channel is completed within the required time limit. The response time verification may consist of any series of sequential, overlapping, or total channel measurements such that the total channel response time is verified to be within the acceptable limits (Table 7.2.1-5).

The minimum frequencies for the surveillance items listed above are defined in the plant technical specifications.

As a result of TS Change No. 99-08 and WCAP-13632 R1, the following requirements must be applied in order to eliminate sensor Response Time Test.

1. Pressure sensor response times must be verified by performance of an appropriate response time test prior to placing a new sensor in to operational service and reverified following maintenance that may adversely affect sensor response time.

2. Pressure sensors (transmitters and switches) utilizing capillary tubes must be subjected to response time testing after initial installation and following any maintenance or modification activity that could damage the transmitter capillary tubes.

3. Pressure transmitters equipped with variable damping capability in reactor trip system or engineered safety feature actuation system response time applications, which required periodic response time test, must be subjected to response time testing after initial installation or following any maintenance or modification activity. Administrative controls may include use of pressure transmitters that are factory set and hermetically sealed to prohibit tampering or in situ application of a tamper seal (or sealant) on the potentiometer to secure and give visual indication of the potentiometer position.

4. Periodic drift monitoring will be performed for all Model 1151, 1152, 1153, and 1154 Rosemount pressure and differential pressure transmitters for which periodic response time testing is required, in accordance with guidance contained in Rosemount Technical Bulletin No. 4 and will continue to remain in full compliance with any prior commitments to Bulletin 90-01, Supplement 1, “Loss of Fill-Oil in Transmitters Manufactured by Rosemount.”

7.2.3.2 <u>Periodic Testing of the Nuclear Instrumentation System</u>

The following periodic tests of the Nuclear Instrumentation System are performed:

1. Testing at plant shutdown

    a. Source range testing
    b. Intermediate range testing
    c. Power range testing

2. Testing between P-6 and P-10 permissive power levels

    a. Intermediate range testing
    b. Power range testing

3. Testing above P-10 permissive power level

    a. Intermediate range testing
    b. Power range testing

Any deviations noted during the performance of these tests are investigated and corrected in accordance with the established calibration and trouble shooting procedures provided in the manufacturer's technical manual for the Nuclear Instrumentation System. Control and protection trip settings are indicated in the plant Technical Specifications and the Precautions, Limitations and Setpoints documents.

7.2.3.3 <u>Periodic Testing of the Process Channels of the Protection Circuits</u>

The following periodic tests of the process channels of the protection circuits are performed:

1. T_{avg} and ΔT protection channel testing
2. Pressurizer pressure protection channels
3. Pressurizer level protection channels
4. Environmental Allowance Modifier and Trip Time Delay Protection Channels
5. Steam generator level protection channels
6. Reactor coolant flow protection channels
7. Impulse chamber pressure channels

The following conditions are incorporated into the procedures for these tests:

1. These tests may be performed at the required frequencies and for the required operational modes as defined in the plant technical specifications.

2. Before starting any of these tests with the plant at power, all redundant reactor trip channels associated with the function to be tested must be in the normal (untripped) mode in order to avoid spurious trips. In accordance with the provisions of the plant technical specifications, certain inoperable channels may be placed in the bypassed mode to accommodate testing of the remaining channels.

3. Setpoints are verified.

Median Signal Selector Testing

The median signal selectors (MSS) that are used for feedwater control (and pressurizer (level and pressure) and steam generator pressure controls as well as in other systems) exist as software modules or blocks in the Distributed Control System (DCS). Prior to maintenance or testing of an individual DCS input channel, the MSS function can be validated that it is working properly. The signals that are applied to the MSS can be compared to the resultant output by reviewing the various signal values in the DCS. The MSS function will then allow testing or maintenance of individual DCS input channels while at power without causing a control system disturbance as long as the other channels are functioning properly and their channels are not tripped or bypassed. The MSS would simply ignore the channel under test.

The DCS has the option to manually remove a channel to be tested from providing input into the DCS control, forcing the DCS logic to ignore the channel to be tested. If two input channels of the same parameter are removed for maintenance at the same time, the DCS will cause the control affected by those signals to shift to manual and initiate an alarm. If the DCS detects a hardware problem with two channels of the same parameter at the same time, the associated control is switched to manual, initiating an alarm to warn the operators.

TABLE 7.2.1-1 (Sheet 1)

LIST OF REACTOR TRIPS

	Reactor Trip	Coincidence Logic	Interlocks	Comments
1.	High neutron flux (Power Range)	2/4	Manual block of low setting permitted by P-10	High and low settings: manual block and automatic reset of low setting by P-10
2.	Intermediate range neutron flux	1/2	Manual block permitted by P-10	Manual block and automatic reset
3.	Source range neutron flux	1/2	Manual block permitted by P-6, interlocked with P-10	Manual block and automatic reset. Automatic block above P-10
4.	Power range high positive neutron flux rate	2/4	No interlocks	
5.	Power range high negative neutron flux rate	2/4	No interlocks	
6.	Overtemperature ΔT	2/4	No interlocks	
7.	Overpower ΔT	2/4	No interlocks	
8.	Pressurizer low pressure	2/4	Interlocked with P-7	Blocked below P-7
9.	Pressurizer high pressure	2/4	No interlocks	
10.	Pressurizer high water level	2/3	Interlocked with P-7	Blocked below P-7
11.	Low reactor coolant flow	2/3 per loop	Interlocked with P-7 and P-8	Low flow in 1 loop will cause a reactor trip when above P-8 and low flow in two loops will cause a reactor trip when above P-7. Blocked below P-7.
12.	Reactor coolant pump undervoltage	2/4	Interlocked with P-7	Low voltage on all buses permitted below P-7

TABLE 7.2.1-1 (Sheet 2)

LIST OF REACTOR TRIPS

	Reactor Trip	Coincidence Logic	Interlocks	Comments
13.	Reactor coolant pump underfrequency	2/4	Interlocked with P-7	Under frequency on 2 buses will cause reactor trip; reactor trip blocked below P-7
14.	Low-low steam generator water level	2/3 per loop	No interlocks	
15.	Safety injection signal	Coincident with actuation of safety injection	No interlocks	(See Section 7.3 for Engineered Safety Features actuation conditions)
17.	Turbine-generator trip			
	a) Low emergency trip header pressure	2/3	Interlocked with P-9	Blocked below P-9
	b) Turbine stop valve	4/4	Interlocked with P-9	Blocked below P-9
18.	Manual	1/2	No interlocks	

Note: See Table 7.2.1-2 Protection System Interlocks for definition of designations.

TABLE 7.2.1-2

PROTECTION SYSTEM INTERLOCKS

Designation	Derivation	Function
	POWER ESCALATION PERMISSIVES	
P-6	1/2 Neutron flux (intermediate range) above setpoint	Allows manual block of source range reactor trip
	2/2 Neutron flux (intermediate range) below setpoint	Defeats the block of source range reactor trip
P-10	2/4 Neutron flux (power range) above setpoint	Allows manual block of power range (low setpoint reactor trip)
		Allows manual block of intermediate range reactor trip and intermediate range rod stops (C-1)
		Blocks source range reactor trip (back-up for P-6)
	3/4 Neutron flux (power range) below setpoint	Defeats the block of power range (low setpoint) reactor trip
		Defeats the block of intermediate range reactor trip and intermediate range rod stops (C-1)
		Input to P-7
	BLOCKS OF REACTOR TRIPS	
P-7	3/4 Neutron flux (power range) below setpoint (from P-10) and 2/2 Turbine impulse chamber pressure below setpoint (from P-13)	Blocks reactor trip on: Low flow, reactor coolant pump, under-voltage, and under-frequency, pressurizer low pressure, and pressurizer high level
P-8	3/4 Neutron flux (power range) below setpoint	Blocks low primary coolant flow reactor trip for low flow in a single loop
P-9	Absence of P-9: 3/4 neutron flux (power range) below setpoint	Blocks reactor trip on turbine trip
P-13	2/2 Turbine impulse chamber pressure below setpoint	Input to P-7

Note: See Table 7.7.1-1 Plant Control System Interlocks for explanation of C-1.

13. RCP undervoltage	(1)
14. RCP underfrequency	(1)

NOTES
(1) See Reference 16 for System Accuracy

SQN

TABLE 7.2.1-5 (Sheet 1)

REACTOR TRIP SYSTEM INSTRUMENTATION RESPONSE TIMES

FUNCTIONAL UNIT			RESPONSE TIME
1.	Manual Reactor Trip		Not Applicable
2.	Power Range Neutron Flux		≤ 0.5 seconds *
3.	Power Range, Neutron Flux, High Positive Rate		Not Applicable
4.	Power Range, Neutron Flux, High Negative Rate		≤ 0.5 seconds *
5.	Intermediate Range, Neutron Flux		Not Applicable
6.	Source Range, Neutron Flux		Not Applicable
7.	Overtemperature Delta T		≤ 8.0 seconds *
8.	Overpower Delta T		≤ 8.0 seconds *
9.	Pressurizer Pressure -- Low		≤ 2.0 seconds
10.	Pressurizer Pressure -- High		≤ 2.0 seconds
11.	Pressurizer Water Level -- High		Not Applicable
12.	Loss of Flow - Single Loop (Above P-8)		≤ 1.0 seconds
13.	Loss of Flow - Two Loops (Above P-7 and below P-8)		≤ 1.0 seconds
14.	Main Steam Generator Water Level -- Low - Low		
	A.	RCS Loop _T (P ≤ 50% RTP: P > 50% RTP)	≤ 8.0 seconds (1)
	B.	Steam Generator Water Level -- Low-Low (Adverse EAM)	≤ 2.0 seconds (1)
	C.	Containment Pressure (EAM)	≤ 2.0 seconds (1)
15.	Deleted		
16.	Undervoltage - Reactor Coolant Pumps		≤ 1.2 seconds
17.	Underfrequency - Reactor Coolant Pumps		≤ 0.6 seconds
18.	Turbine Trip		
	A.	Low Fluid Oil Pressure	Not Applicable
	B.	Turbine Stop Valve	Not Applicable

TABLE 7.2.1-5 (Sheet 2)

REACTOR TRIP SYSTEM INSTRUMENTATION RESPONSE TIMES

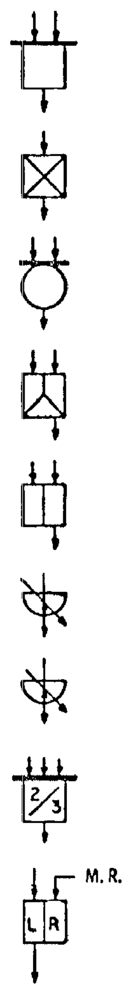
FUNCTIONAL UNIT	RESPONSE TIME
19. Safety Injection Input from ESF	Not Applicable
20. Reactor Trip Breakers	Not Applicable
21. Automatic Trip Logic	Not Applicable
22. Reactor Trip System Interlocks	Not Applicable

* Neutron detectors are exempt from response time testing. Response time of the neutron flux signal portion of the channel shall be measured from detector output or input of first electronic component in channel.

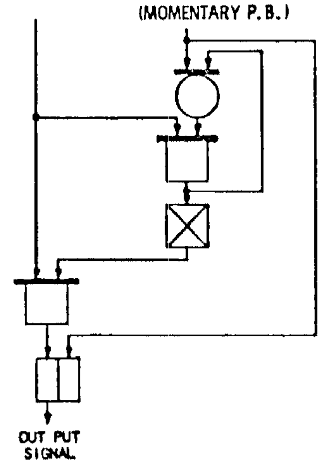
(1) Does not include Trip Time Delays. Response times noted include the transmitters, Eagle-21 process protection cabinets, solid state protection cabinets, and actuation devices. This reflects the response time necessary for THERMAL POWER in excess of 50% RTP.

Note: Not Applicable indicates that this is not used in the Chapter 15 analysis.

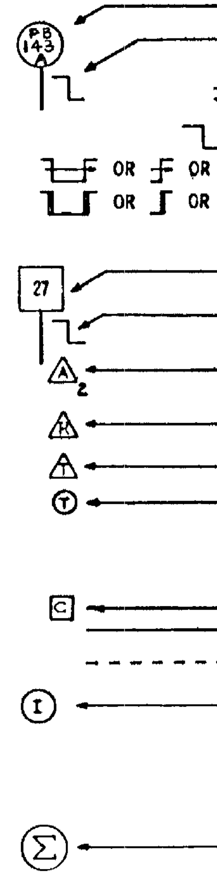
LOGIC SYMBOLS



SYMBOL	LOGIC FUNCTION	
	AND	A DEVICE WHICH PRODUCES AN OUTPUT ONLY WHEN EVERY INPUT EXISTS.
	NOT	A DEVICE WHICH PRODUCES AN OUTPUT ONLY WHEN THE INPUT DOES NOT EXIST.
	OR	A DEVICE WHICH PRODUCES AN OUTPUT WHEN ONE INPUT (OR MORE) EXISTS.
	OFF RETURN MEMORY	A DEVICE WHICH RETAINS THE CONDITION OF OUTPUT CORRESPONDING TO THE LAST ENERGIZED INPUT, EXCEPT UPON INTERRUPTION OF POWER IT RETURNS TO THE OFF CONDITION.
	RETENTIVE MEMORY	A DEVICE WHICH RETAINS THE CONDITION OF OUTPUT CORRESPONDING TO THE LAST ENERGIZED INPUT (ALSO UPON INTERRUPTION OF POWER).
	ADJUSTABLE TIME DELAY ENERGIZING	A DEVICE WHICH PRODUCES AN OUTPUT FOLLOWING DEFINITE INTENTIONAL TIME DELAY AFTER RECEIVING AN INPUT.
	ADJUSTABLE TIME DELAY DE-ENERGIZING	A DEVICE WHICH CONTINUES TO PRODUCE AN OUTPUT FOR A DEFINITE INTENTIONAL PERIOD OF TIME AFTER THE INPUT HAS BEEN REMOVED.
	COINCIDENCE (2 OUT OF 3 SHOWN)	A DEVICE WHICH PRODUCES AN OUTPUT WHEN THE PRESCRIBED NUMBER OF INPUTS EXIST (EXAMPLE 2 INPUTS MUST EXIST FOR AN OUTPUT).
	RETENTIVE MEMORY WITH MANUAL RESET	A DEVICE HAVING THE LOGICAL FUNCTION AS INDICATED BY THE DIAGRAM BELOW



ADDITIONAL SYMBOLS



INSTRUMENT CHANNEL BISTABLE

INDICATES THAT THE DEVICE OR INSTRUMENT CHANNEL HAS A BISTABLE LOGIC "1" OUTPUT WHEN:

- PARAMETER MEASURED IS GREATER THAN A PRESET VALUE
- PARAMETER MEASURED IS LESS THAN A PRESET VALUE
- PARAMETER MEASURED DEVIATES FROM A PRESET VALUE BY MORE THAN A PRESET AMOUNT.
- OR OR SAME AS ABOVE EXCEPT WITH AN AUTOMATICALLY SET VARIABLE VALUE
- OR OR SAME AS ABOVE EXCEPT WITH REQUIRED HYSTERESIS BETWEEN TURN ON AND TURN OFF.

NON-INSTRUMENT BISTABLE

OUTPUT INDICATOR SAME AS EXPLAINED ABOVE

ALARM ANNUNCIATOR (ALARMS ON THE SAME SHEET WITH THE SAME SUBSCRIPT SHARE A COMMON ANNUNCIATOR WINDOW)

REACTOR TRIP "FIRST OUT" ANNUNCIATOR

TURBINE TRIP "FIRST OUT" ANNUNCIATOR

INDICATOR LAMP

- A ACTUATION STATUS LIGHTS
- T TRIP STATUS LIGHTS
- P PERMISSIVE STATUS LIGHTS
- B BYPASS STATUS LIGHTS

COMPUTER INPUT

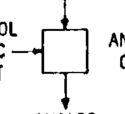
LOGIC INFORMATION TRANSMISSION

ANALOG INFORMATION TRANSMISSION

ANALOG DISPLAY

- I ANALOG INDICATOR
- R RECORDER
- R2 RECORDER 2 CHANNEL
- R3 RECORDER 3 CHANNEL
- R8 RECORDER 8 POINT

ANALOG SUMMER



A DEVICE WHICH PERMITS AN ANALOG SIGNAL TO PASS IN AN ISOLATED CIRCUIT IF THE CONTROL LOGIC INPUT EXISTS.

NOTES:

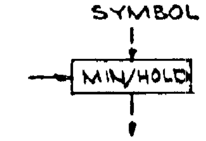
1. EXCEPT WHERE INDICATED OTHERWISE, THE FOLLOWING IS TRUE: ALL LOGIC CIRCUITS ARE REDUNDANT. ALL BISTABLES, CIRCUIT BREAKERS, ANNUNCIATORS AND INDICATOR LAMPS ARE NOT REDUNDANT. MANUAL CONTROLS DO NOT HAVE REDUNDANT ACTUATORS, BUT DO HAVE REDUNDANT CONTACTS WHERE LOGIC IS REDUNDANT.
2. THIS SET OF DRAWINGS IS IDENTICAL FOR UNITS 1 & 2 EXCEPT FOR THE TAG NUMBERS.
   FOR UNIT 1, TAG NUMBERS ADD A "1". EXAMPLE: 1PC-455E.
   FOR UNIT 2, TAG NUMBERS ADD A "2". EXAMPLE: 2PC-455E.
3. WHENEVER A PROCESS SIGNAL IS USED FOR CONTROL AND IS DERIVED FROM A PROTECTION CHANNEL, ISOLATION MUST BE PROVIDED.
4. THIS SET OF DRAWINGS ILLUSTRATES THE FUNCTIONAL REQUIREMENTS OF THE REACTOR CONTROL AND PROTECTION SYSTEM. THESE DRAWINGS DO NOT REPRESENT ACTUAL HARDWARE IMPLEMENTATION.
5. SHEET NUMBERS REFER TO THE FSAR FIGURE 7.2.1-1 SHEET #.

DEVICE FUNCTION LETTERS AND NUMBERS

FB	FLOW CHANNEL
LB	LEVEL CHANNEL
NC	NUCLEAR CHANNEL
PB	PRESSURE CHANNEL
RC	RADIATION CHANNEL
SB	SPEED CHANNEL
TB	TEMPERATURE CHANNEL
ZB	POSITION CHANNEL
20	ELECTRIC OPERATED VALVE
27	UNDERVOLTAGE RELAY
33	POSITION SWITCH
52	AC CIRCUIT BREAKER
63	PRESSURE SWITCH
71	LEVEL SWITCH
80	FLOW SWITCH
81	UNDERFREQUENCY RELAY

ADDITIONAL LOGIC SYMBOLS

SYMBOL LOGIC FUNCTION

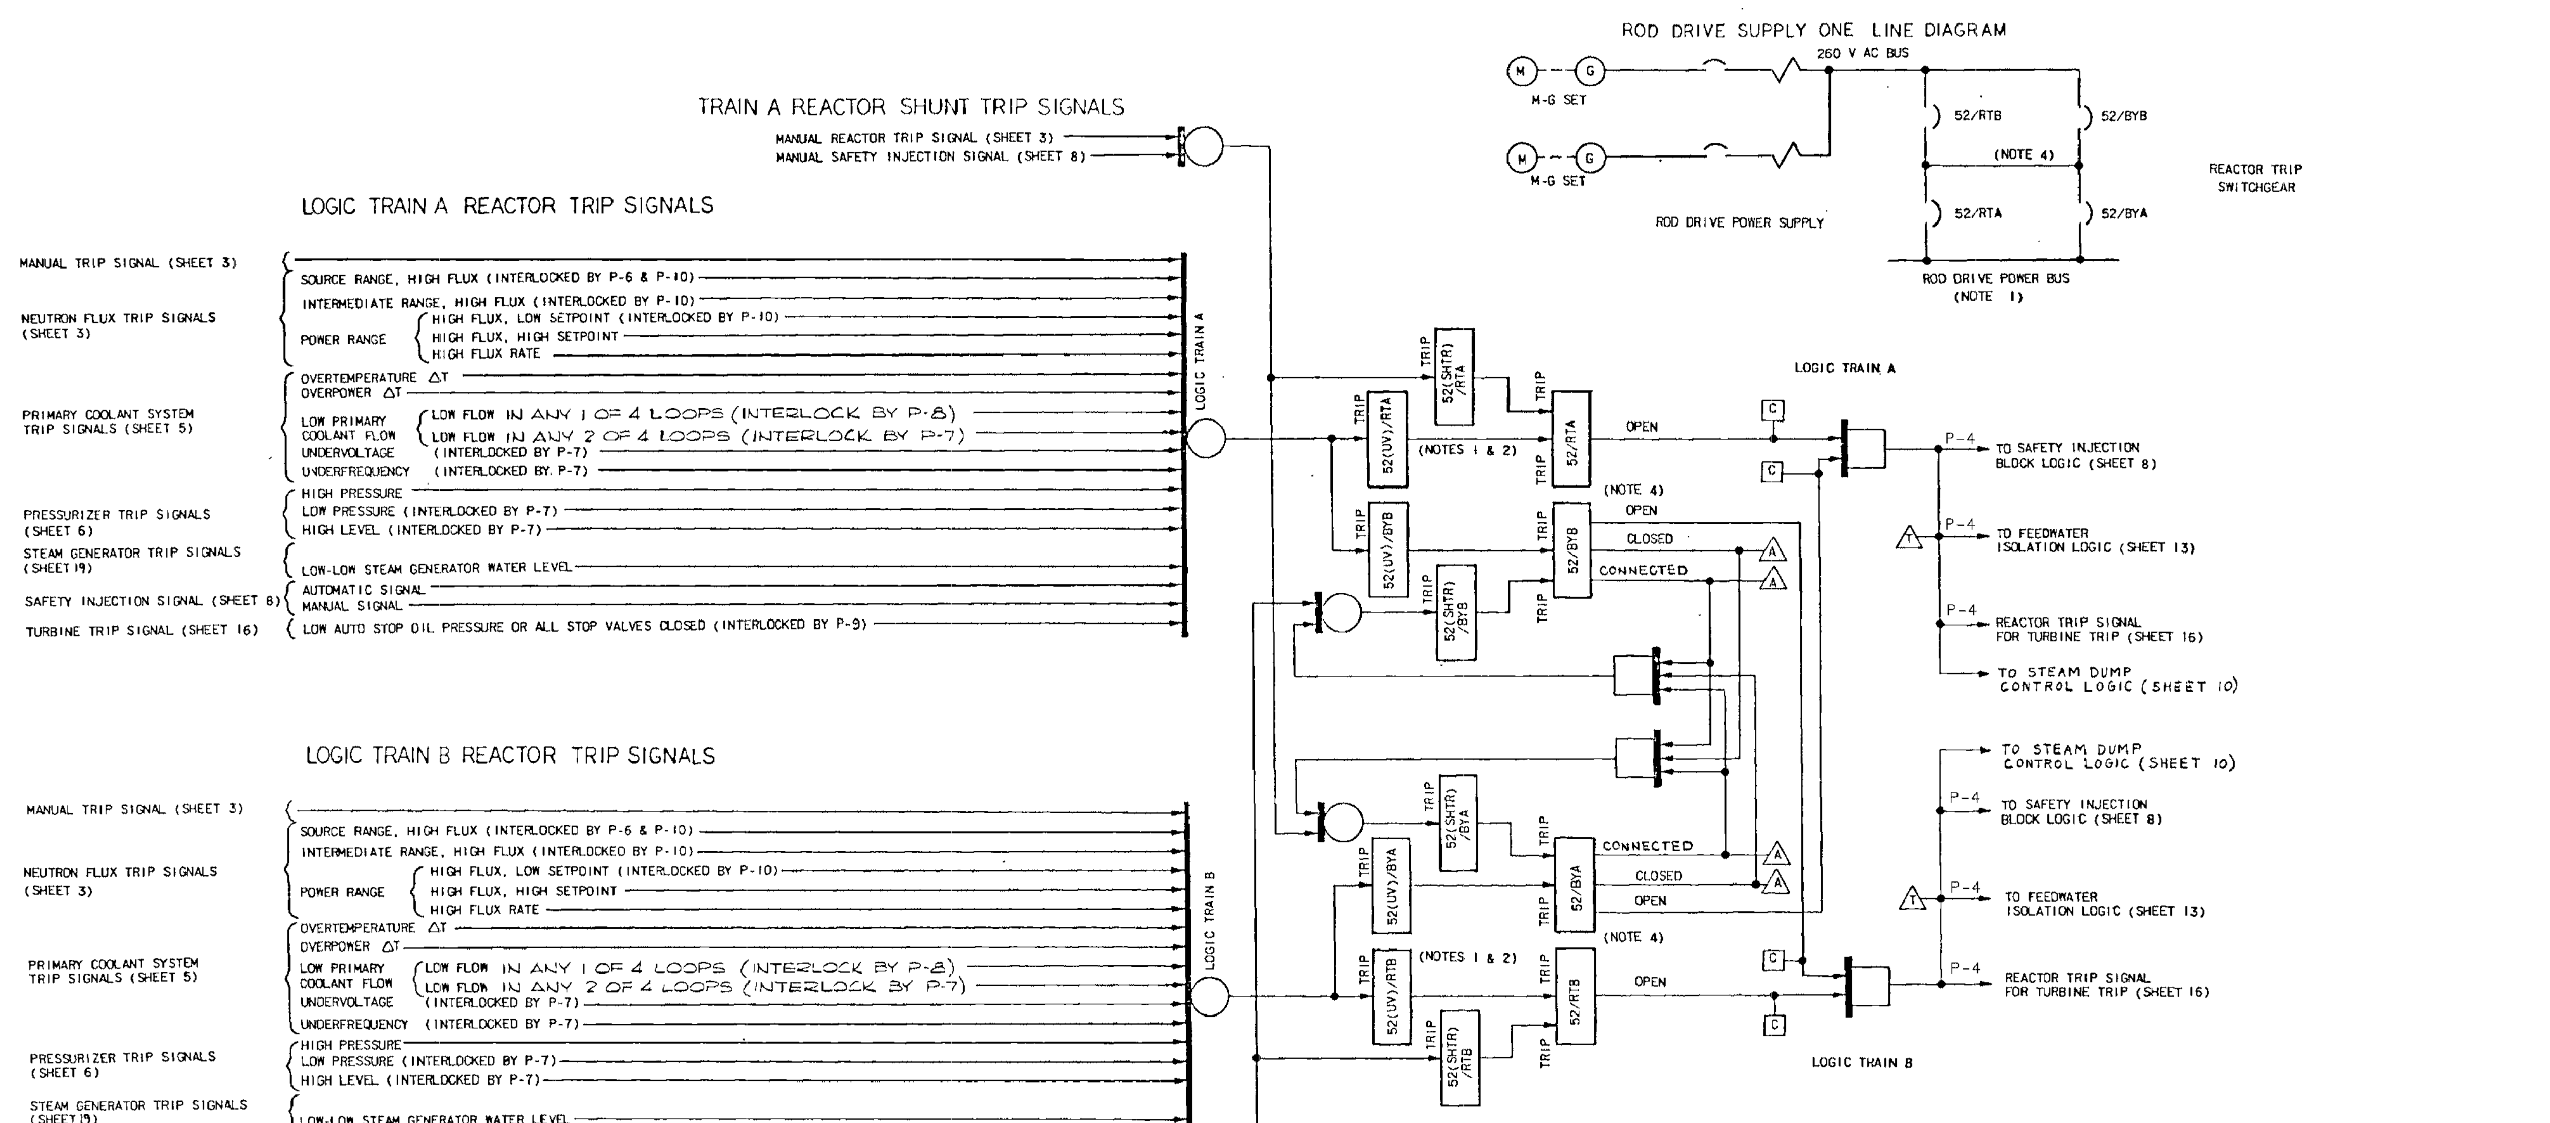


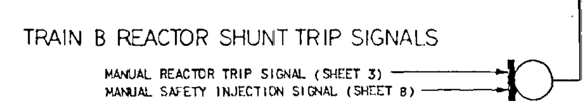
AFTER RECEIPT OF THE CONTROL LOGIC INPUT THE MIN/HOLD UNIT OUTPUT WILL BE ALLOWED TO DECREASE IF THE UNIT INPUT DECREASES. IF THE INPUT TO THE UNIT INCREASES, THE UNIT OUTPUT WILL HOLD THE MINIMUM VALUE SINCE RECEIPT OF CONTROL LOGIC.

SEQUOYAH NUCLEAR PLANT
FINAL SAFETY
ANALYSIS REPORT

FIGURE 7.2.1-1 SHEET 1

FUNCTIONAL DIAGRAMS-INDEX AND SYMBOLS
(REVISED BY AMENDMENT 13)





NOTES:

1. TRIPPING THE REACTOR TRIP BREAKERS 52/RTA AND 52/RTB REDUNDANTLY DE-ENERGIZES THE ROD DRIVES. ALL FULL LENGTH CONTROL RODS AND SHUTDOWN RODS ARE THEREBY RELEASED FOR GRAVITY INSERTION INTO THE REACTOR CORE.
2. NORMAL REACTOR OPERATION IS TO BE WITH REACTOR TRIP BREAKERS 52/RTA AND 52/RTB IN SERVICE AND BY-PASS BREAKERS 52/BYA AND 52/BYB WITHDRAWN.
   DURING TEST, ONE BY-PASS BREAKER IS TO BE PUT IN SERVICE AND THEN THE RESPECTIVE REACTOR TRIP BREAKER IS OPERATED USING A SIMULATED REACTOR TRIP SIGNAL IN THE TRAIN UNDER TEST. THE REACTOR WILL NOT BE TRIPPED BY THE SIMULATED SIGNAL SINCE THE BY-PASS BREAKER IS CONTROLLED FROM THE OTHER TRAIN. ONLY ONE REACTOR TRIP BREAKER IS TO BE TESTED AT A TIME.
3. ALL CIRCUITS ON THIS SHEET ARE NOT REDUNDANT BECAUSE BOTH TRAINS ARE SHOWN.
4. OPEN/CLOSED INDICATION FOR EACH TRIP BREAKER AND EACH BYPASS BREAKER IN CONTROL ROOM.
5. CLOSING A BYPASS BREAKER WILL ACTUATE THE SOLID STATE PROTECTION SYSTEM GENERAL WARNING ALARM SYSTEM FOR THAT TRAIN. ACTUATION OF THE GENERAL WARNING ALARM SYSTEM ON BOTH TRAIN A AND TRAIN B WILL SEND TRIP SIGNALS TO ALL FOUR BREAKERS (RTA, RTB, BYA, BYB,) THROUGH THE UNDERVOLTAGE COILS.
6. SHEET NUMBERS REFER TO FIGURE 7.2.1-1 (SHEET NUMBER).

FINAL SAFETY
ANALYSIS REPORT

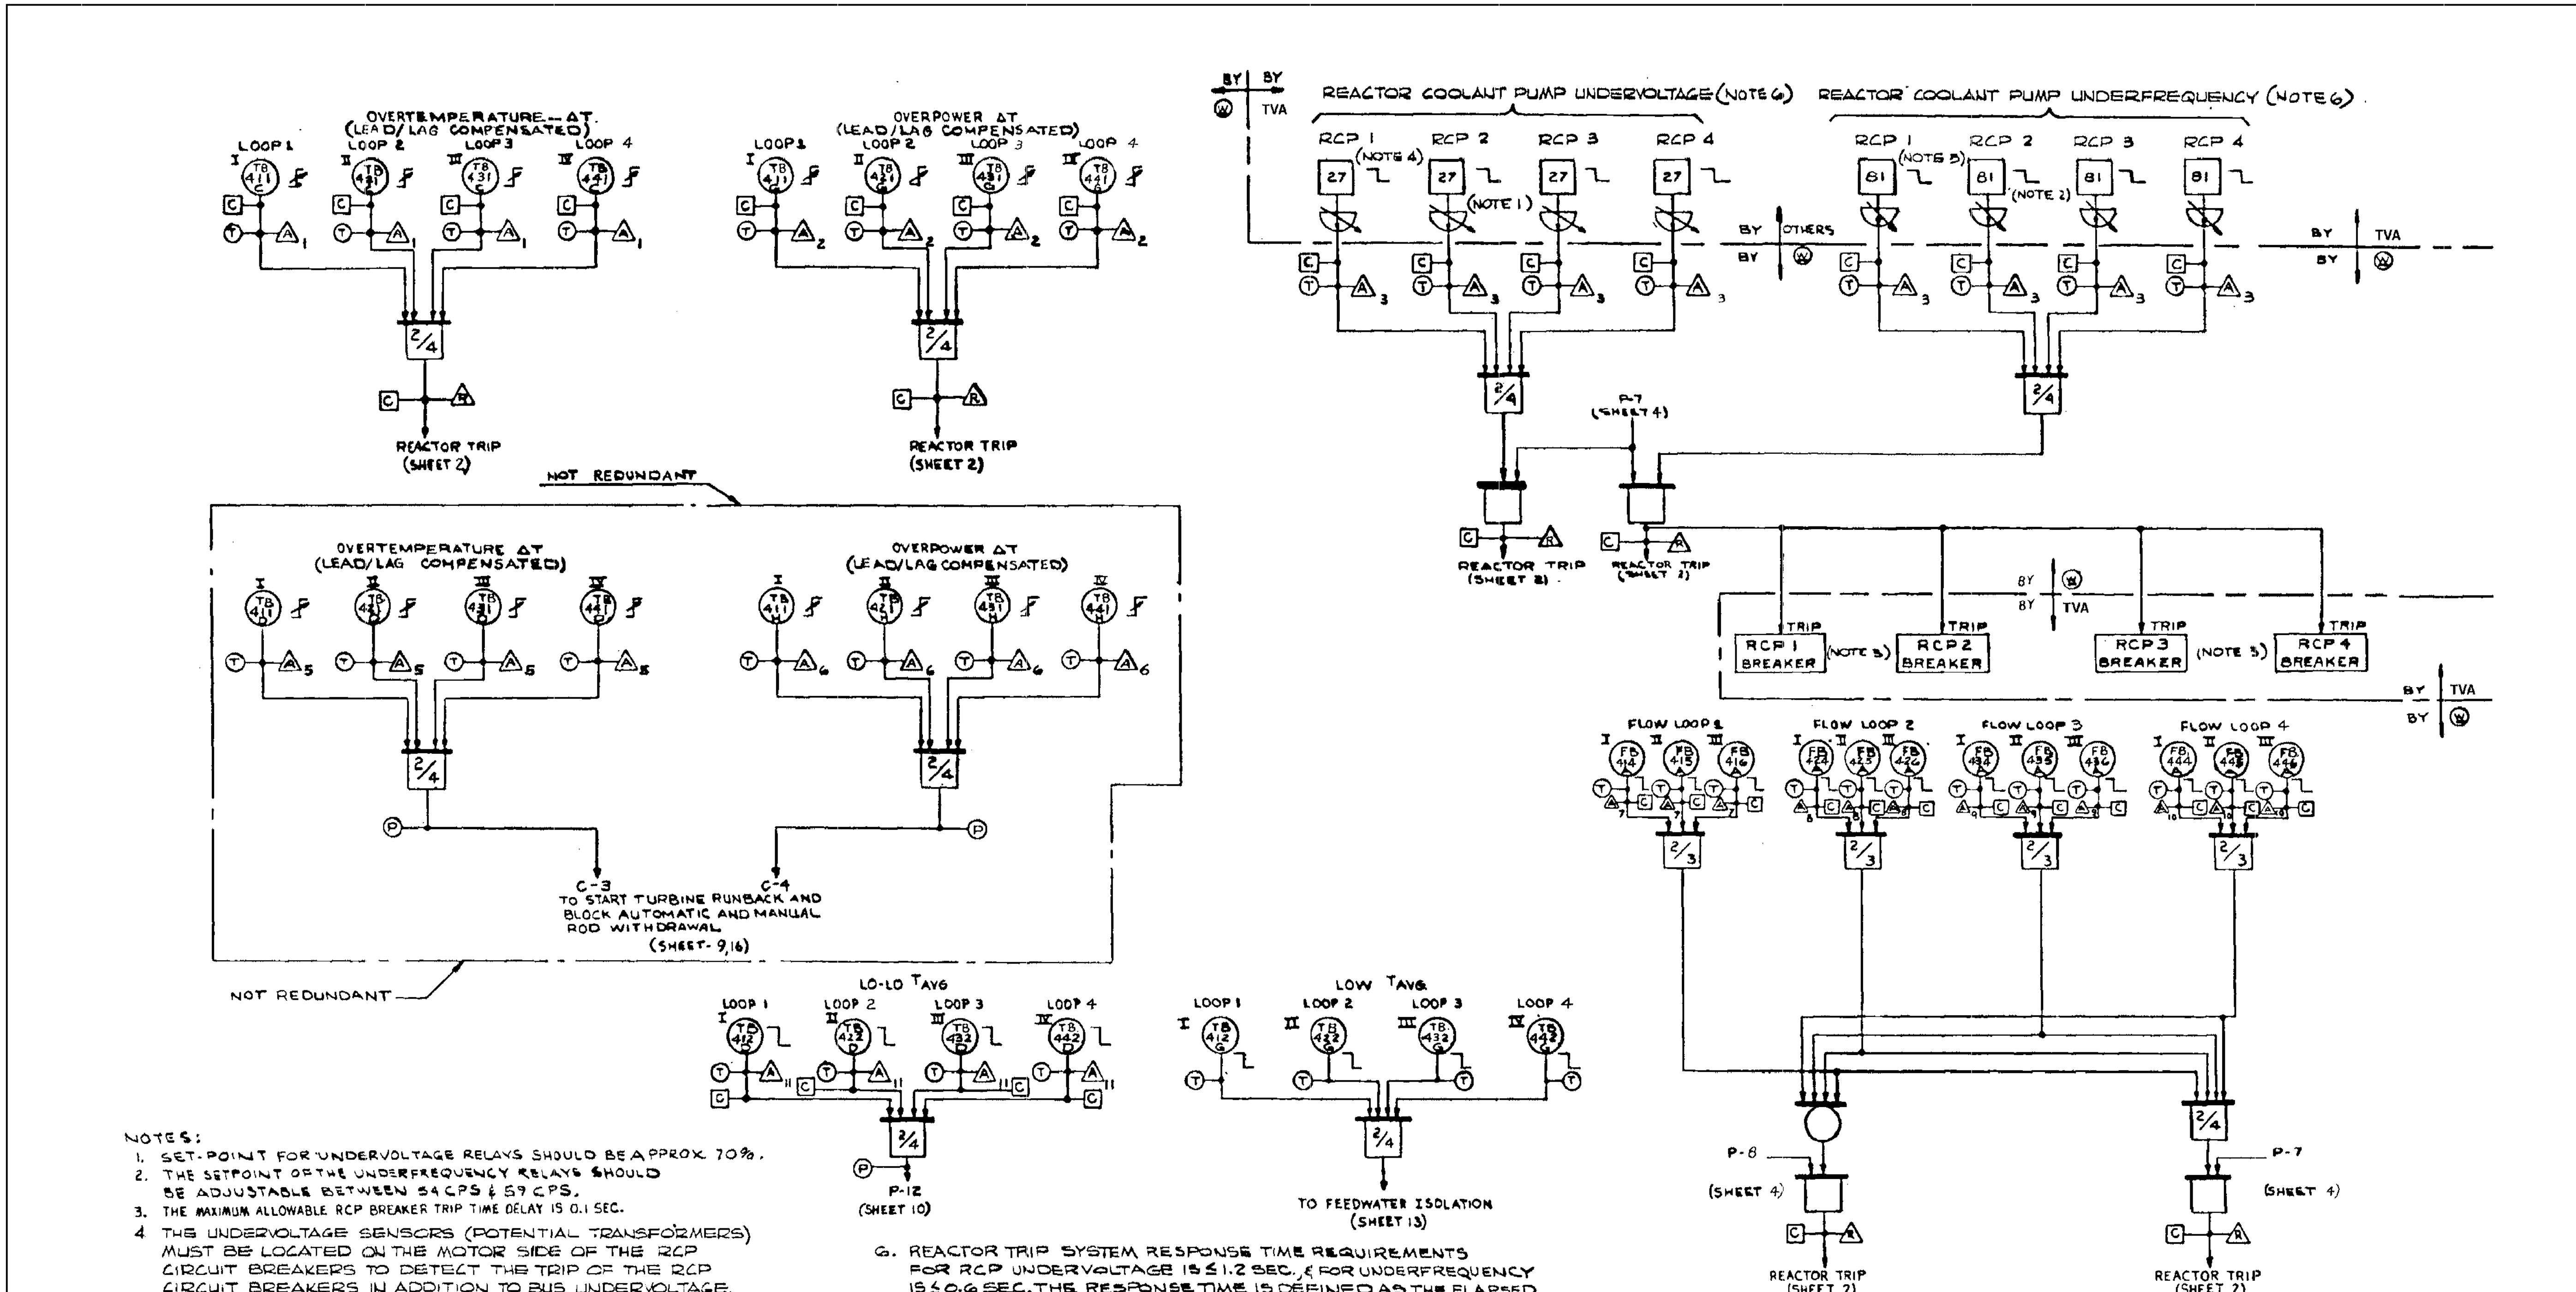
FIGURE 7.2.1-1 SHEET 4
FUNCTIONAL DIAGRAMS-NUCLEAR
INSTR PERMISSIVES & BLOCKS
(REVISED BY AMENDMENT 13)



NOTES:

1. SET-POINT FOR UNDERVOLTAGE RELAYS SHOULD BE APPROX. 70%.
2. THE SETPOINT OF THE UNDERFREQUENCY RELAYS SHOULD BE ADJUSTABLE BETWEEN 54 CPS & 57 CPS.
3. THE MAXIMUM ALLOWABLE RCP BREAKER TRIP TIME DELAY IS 0.1 SEC.
4. THE UNDERVOLTAGE SENSORS (POTENTIAL TRANSFORMERS) MUST BE LOCATED ON THE MOTOR SIDE OF THE RCP CIRCUIT BREAKERS TO DETECT THE TRIP OF THE RCP CIRCUIT BREAKERS IN ADDITION TO BUS UNDERVOLTAGE.
5. THE UNDERFREQUENCY SENSORS MAY BE LOCATED ON THE MOTOR SIDE OF THE RCP CIRCUIT BREAKERS.
6. REACTOR TRIP SYSTEM RESPONSE TIME REQUIREMENTS FOR RCP UNDERVOLTAGE IS ≤ 1.2 SEC. & FOR UNDERFREQUENCY IS ≤ 0.6 SEC. THE RESPONSE TIME IS DEFINED AS THE ELAPSED TIME FROM THE BISTABLE CHANGE OF STATE TO THE BEGINNING OF CONTROL ROD MOTION.

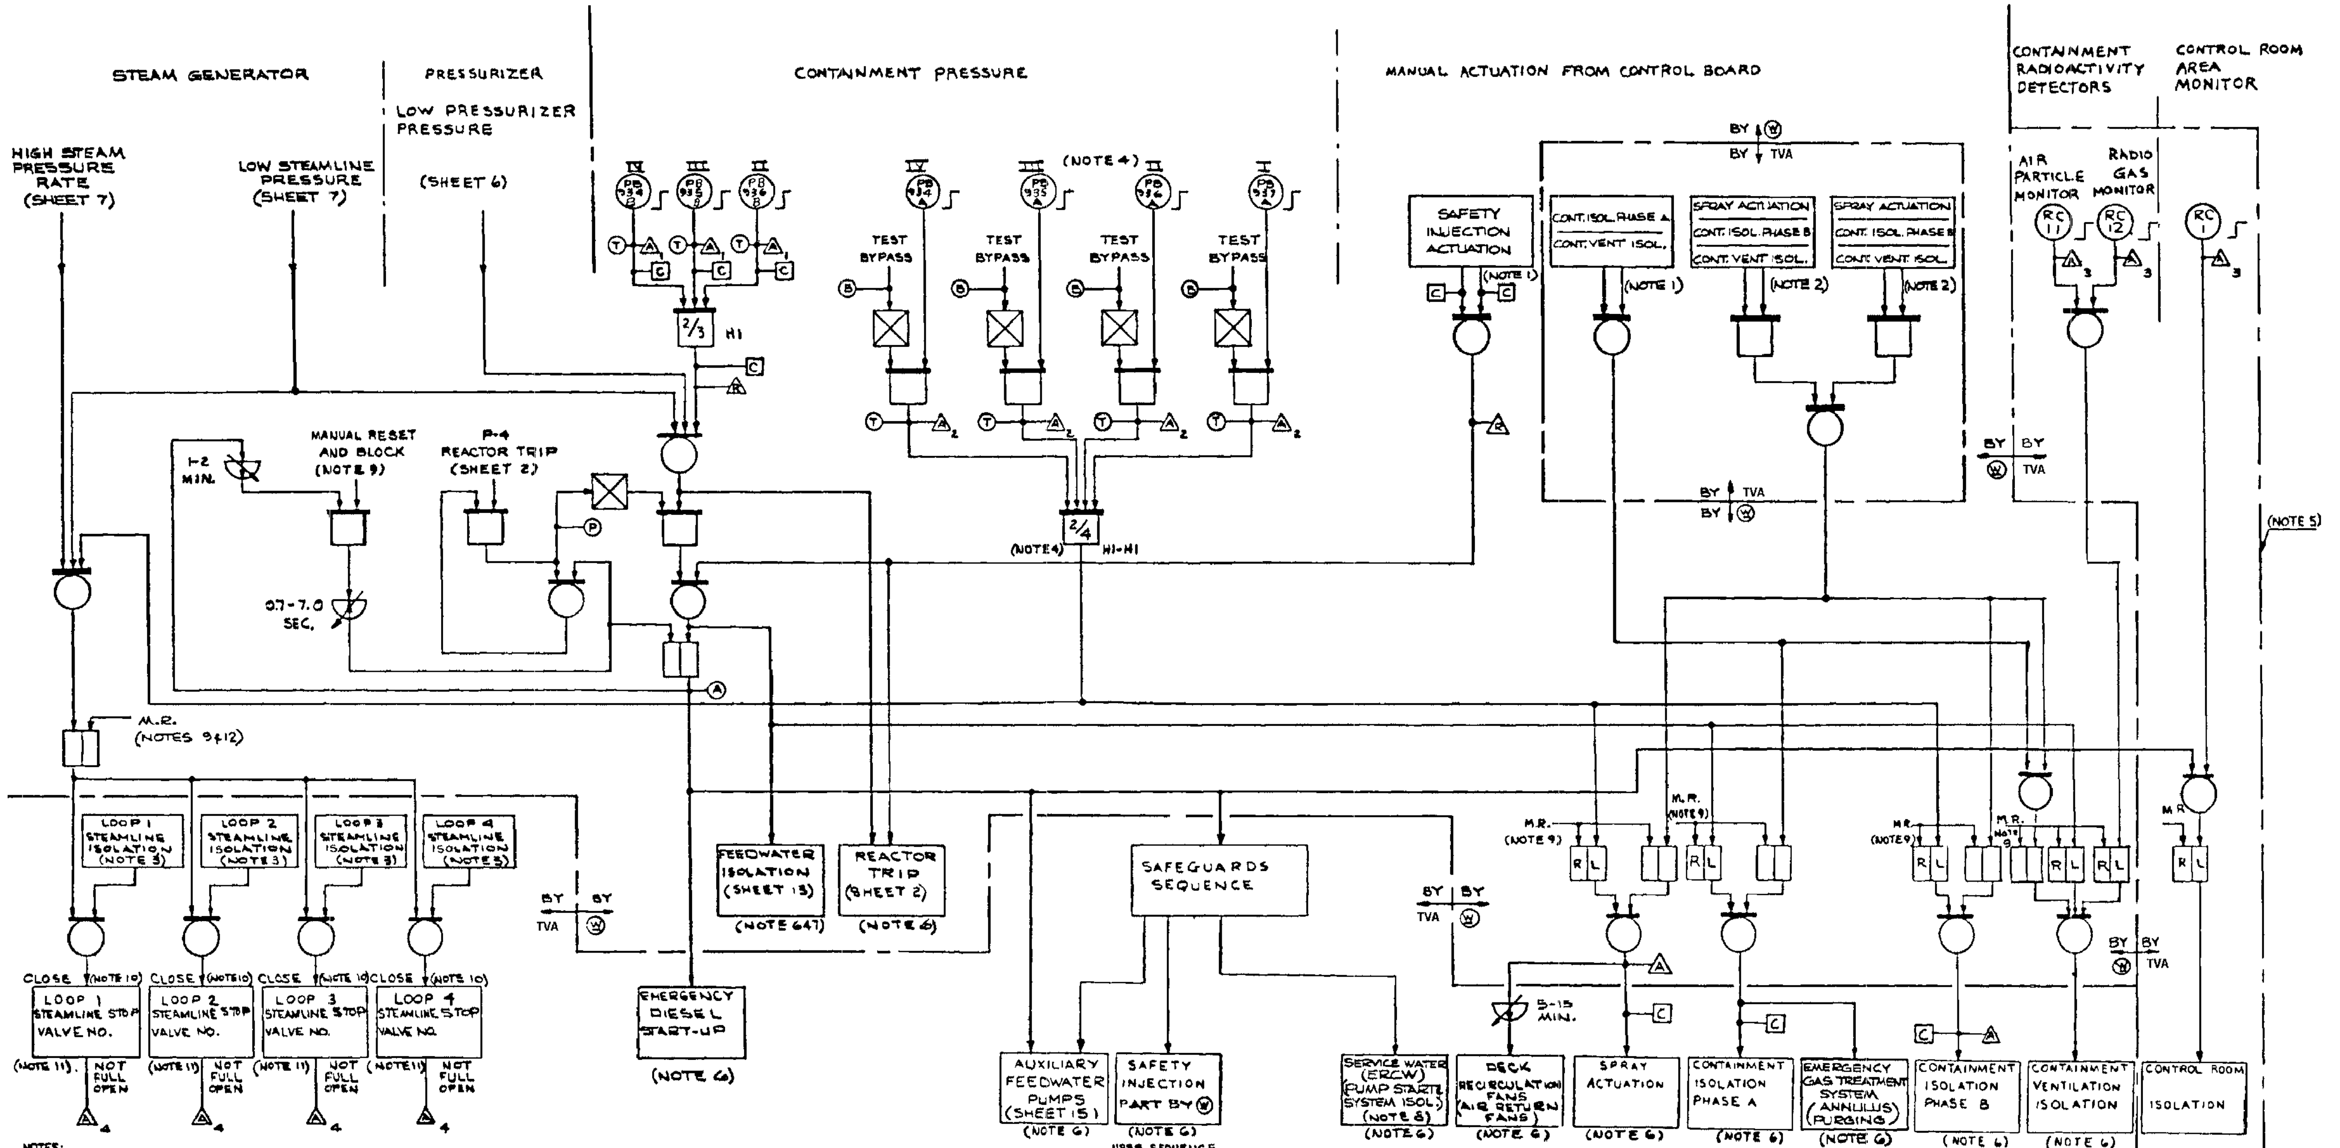
PROCAD MAINTAINED DRAWING
THIS CONFIGURATION CONTROL DRAWING IS MAINTAINED BY THE SQN CAD UNIT AND IS PART OF THE TVA PROCADAM DATABASE



NOTES:

1. TWO MOMENTARY CONTROLS; OPERATING EITHER CONTROL WILL ACTUATE.
2. THE MANUAL SPRAY ACTUATION CONSISTS OF FOUR MOMENTARY CONTROLS, ACTUATION WILL OCCUR ONLY IF TWO ASSOCIATED CONTROLS ARE OPERATED SIMULTANEOUSLY.
3. ONE MAINTAINED CONTROL PER LOOP.
4. CONTAINMENT PRESSURE BISTABLES FOR SPRAY ACTUATION ARE ENERGIZE TO ACTUATE (OTHER BISTABLES ARE DE-ENERGIZE TO ACTUATE).
5. ENCLOSED CIRCUITRY IS NOT PART OF THE SAFEGUARDS SYSTEM AND IS NOT REDUNDANT.
6. COMPONENTS ARE ALL INDIVIDUALLY SEALED IN (LATCHED), SO THAT LOSS OF THE ACTUATION SIGNAL WILL NOT CAUSE THESE COMPONENTS TO RETURN TO THE CONDTTION HELD PRIOR TO THE ADVENT OF THE ACTUATION SIGNAL.
7. FEEDWATER ISOLATION (SHEET 13) INCLUCES THE TRIPPING OF ALL MAIN FEEDWATER PUMPS.
8. SERVICE WATER SYSTEM ISOLATION IS USED ONLY IF REQUIRED.
9. THE REDUNDANT MANUAL RESET CONSISTS OF TWO MOMENTARY CONTROLS ON THE CONTROL BOARD, ONE FOR EACH TRAIN.
10. ALSO CLOSES THE BYPASS VALVE IN PARALLEL WITH THE ASSOCIATED STEAM LINE STOP VALVE.
11. LIGHTS SHOULD BE PROVIDED IN THE CONTROL ROOM FOR EACH STEAMLINE STOP VALVE TO INDICATE WHEN THE VALVE IS FULLY CLOSED OR FULLY OPEN.
12. MANUAL RESET IS EFFECTED ONLY IF ALL INDIVIDUAL VALVE CONTROLS ARE IN THE CLOSED POSITION.

SEQUOYAH NUCLEAR PLANT
FINAL SAFETY
ANALYSIS REPORT

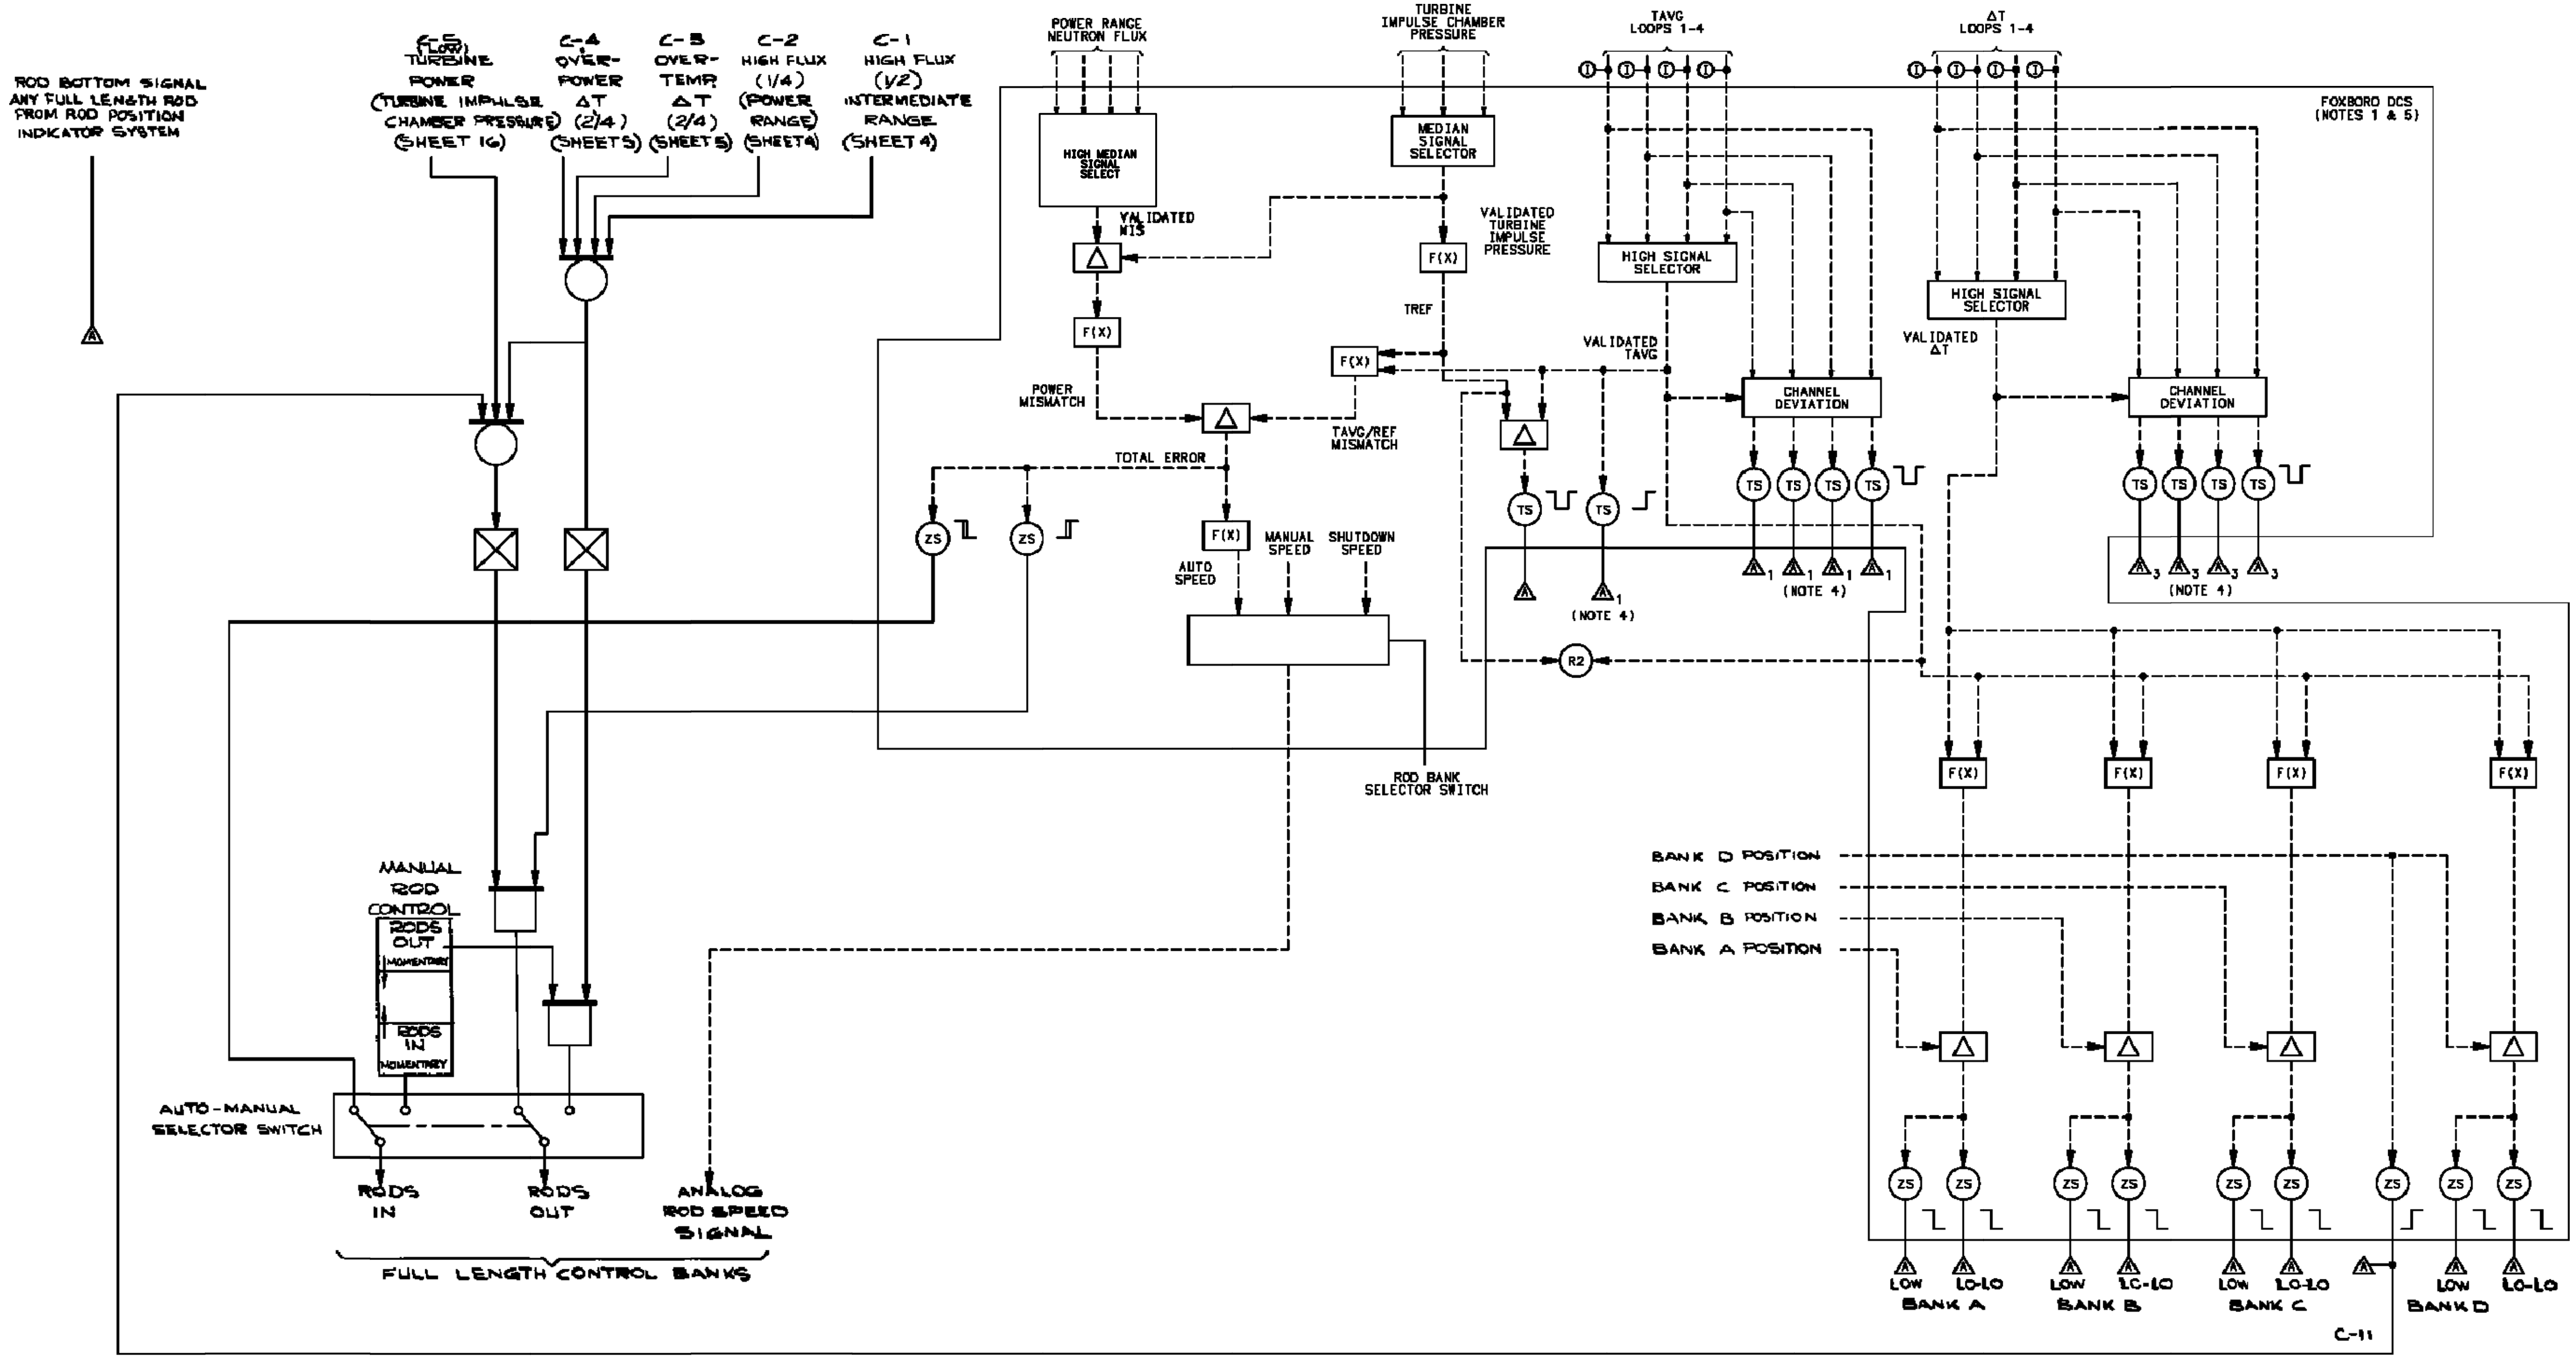
FUNCTIONAL DIAGRAMS-SAFEGUARDS ACTUATION SIGNALS
(REVISED BY AMENDMENT 13)



NOTES-

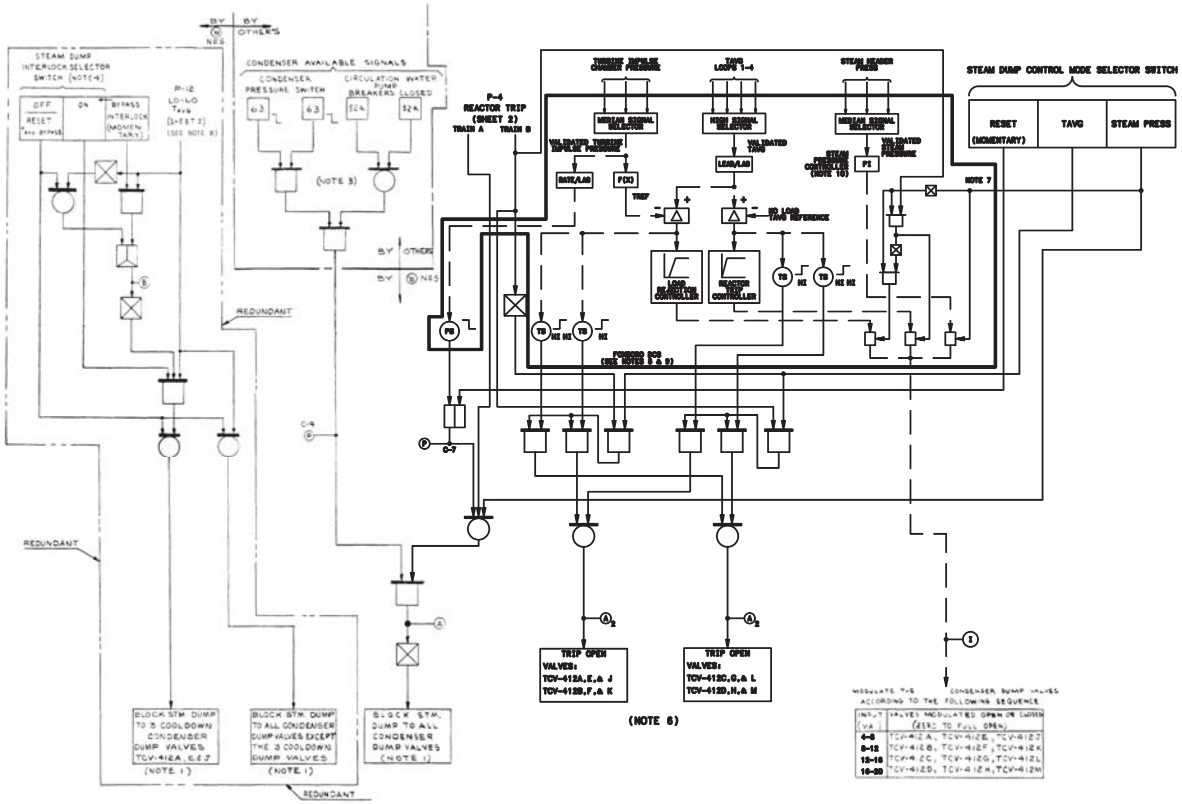
1. FOXBORO DCS CIRCUITS ARE FAULT TOLERANT AND REDUNDANT OTHER CIRCUITS ARE NOT REDUNDANT
2. NOT USED
3. NOT USED
4. ALARM 1 AND ALARM 3 MUST HAVE REFLASH CAPABILITY
5. REFER TO TVA DRAWING 1,2-47W611-99-1 FOR DCS FUNCTION DIAGRAM DRAWING REFERENCES

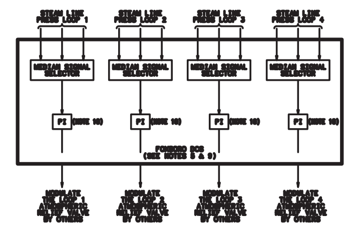
SEQUOYAH NUCLEAR PLANT
FINAL SAFETY
ANALYSIS REPORT

FIGURE 7.2.1-1 SHEET 9

FUNCTIONAL DIAGRAMS-ROD CONTROLS & ROD BLOCKS
(REVISED BY AMENDMENT 29)

CAD MAINTAINED DRAWING



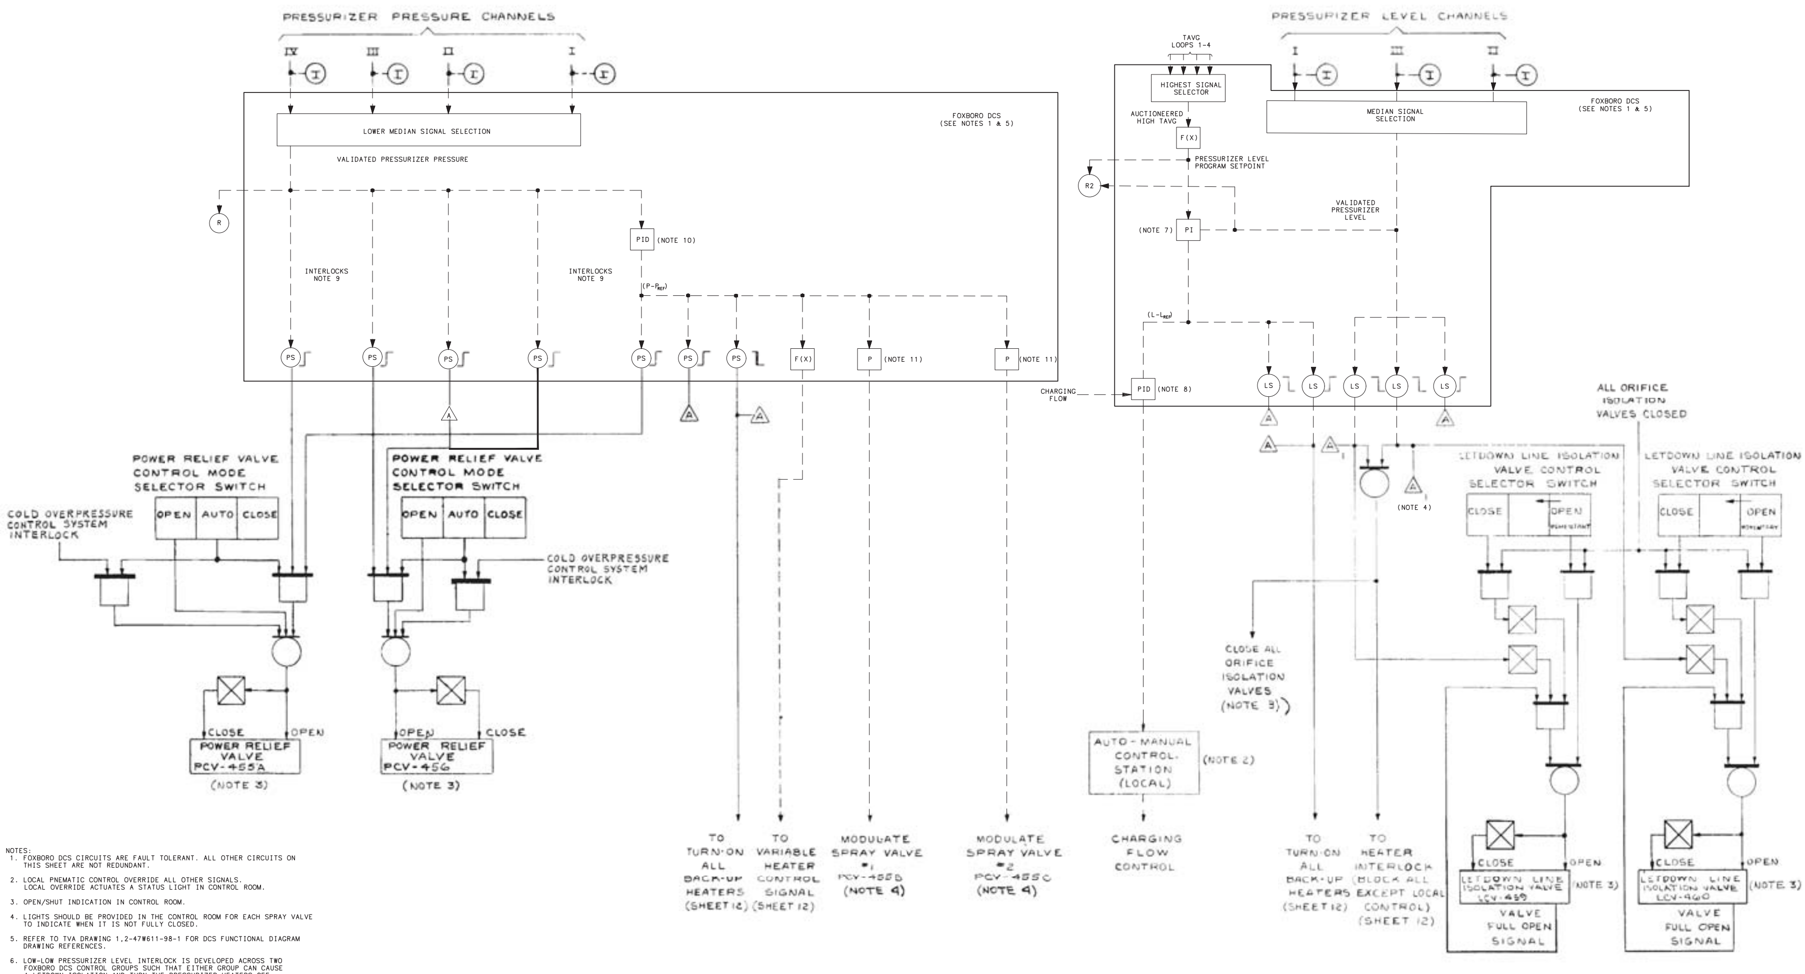


1. STEAM DUMP IS BLOCKED BY BLOCKING AIR TO THE DUMP VALVES AND VENTING THE DIAPHRAGMS. THE REDUNDANT LOGIC OUTPUT OPERATES TWO SOLENOID VENT VALVES IN SERIES TO REDUNDANTLY INTERLOCK THE AIR LINE BETWEEN EACH VALVE DIAPHRAGM AND ITS ASSOCIATED POSITIONER. THE NON-REDUNDANT LOGIC OUTPUT OPERATES ONE SOLENOID VENT VALVE TO INTERLOCK THE AIR LINE BETWEEN EACH VALVE DIAPHRAGM AND ITS ASSOCIATED POSITIONER. THE SOLENOID VALVES ARE DE-ENERGIZE TO VENT CAUSING THE MAIN DUMP VALVE TO CLOSE IN FIVE SECONDS. EITHER OF THE TWO REDUNDANT BLOCK SIGNALS OR THE NON-REDUNDANT BLOCK SIGNAL WILL BLOCK STEAM DUMP INDEPENDENT OF THE OTHERS.
2. CIRCUITRY ON THIS SHEET IS NOT REDUNDANT EXCEPT WHERE INDICATED REDUNDANT.
3. THE CONDENSER AVAILABLE SIGNAL LOGIC IS TYPICAL. ACTUAL IMPLEMENTATION MAY BE DIFFERENT.
4. SELECTOR SWITCH WITH THE FOLLOWING 3 POSITIONS
   ON -STEAM DUMP IS PERMITTED
   BYPASS -T AVG INTERLOCK IS BYPASSED FOR LO-LO T AVG SPRING RETURN TO ON POSITION.
   OFF -STEAM DUMP IS NOT PERMITTED AND RESET T AVG BYPASS.
5. FOXBORO DCS CIRCUITS ARE FAULT TOLERANT AND REDUNDANT. THE SOFTWARE USED TO DEVELOP THE LOSS OF LOAD SIGNAL AND THE STEAM DUMP DEMAND SIGNAL MUST BE ON SEPARATE, INDEPENDENT PROCESSOR PAIRS.
6. LIGHTS SHOULD BE PROVIDED IN THE CONTROL ROOM FOR EACH DUMP VALVE TO INDICATE WHEN THE VALVE IS FULLY CLOSED OR FULLY OPEN.
7. ONLY THE STEAM PRESS CONTACT OF THE STEAM DUMP CONTROL MODE SELECTOR SWITCH IS AN INPUT INTO DCS. DCS USES THE STATUS OF THE STEAM PRESS CONTACT INPUT TO DEDUCE THE STATE OF THE SWITCH (EITHER STEAM PRESS OR TAVG/RESET).
8. SEE NOTE 7 ON LOGIC DRAWING 1,2-47W611-1-2.
9. REFER TO TVA DRAWING 1,2-47W611-88-1 FOR DCS FUNCTIONAL DIAGRAM DRAWING REFERENCES.
10. PROPORTIONAL+INTEGRAL (PI) CONTROLLER LOGIC IS INTERNAL TO FOXBORO DCS. REMOTE CONTROLLER SETPOINT AND MANUAL DEMAND SIGNALS ARE PROVIDED FROM ASSOCIATED MAIN CONTROL ROOM HANDSTATION.

SEQUOYAH NUCLEAR PLANT
FINAL SAFETY
ANALYSIS REPORT

FIGURE 7.2.1-1 SHEET 10
FUNCTIONAL DIAGRAMS-STEAM DUMP CONTROL
(REVISED BY AMENDMENT 28)

CAD MAINTAINED DRAWING



NOTES:

1. FOXBORO DCS CIRCUITS ARE FAULT TOLERANT. ALL OTHER CIRCUITS ON THIS SHEET ARE NOT REDUNDANT.
2. LOCAL PNEMATIC CONTROL OVERRIDE ALL OTHER SIGNALS. LOCAL OVERRIDE ACTUATES A STATUS LIGHT IN CONTROL ROOM.
3. OPEN/SHUT INDICATION IN CONTROL ROOM.
4. LIGHTS SHOULD BE PROVIDED IN THE CONTROL ROOM FOR EACH SPRAY VALVE TO INDICATE WHEN IT IS NOT FULLY CLOSED.
5. REFER TO TVA DRAWING 1,2-47W611-98-1 FOR DCS FUNCTIONAL DIAGRAM DRAWING REFERENCES.
6. LOW-LOW PRESSURIZER LEVEL INTERLOCK IS DEVELOPED ACROSS TWO FOXBORO DCS CONTROL GROUPS SUCH THAT EITHER GROUP CAN CAUSE A LETDOWN ISOLATION AND TURN THE PRESSURIZER HEATERS OFF.
7. PROPORTIONAL+INTEGRAL (PI) CONTROLLER LOGIC IS INTERNAL TO FOXBORO DCS. CONTROLLER MANUAL DEMAND SIGNALS ARE PROVIDED FROM ASSOCIATED MAIN CONTROL ROOM HANDSTATION.
8. PROPORTIONAL+INTEGRAL+DERIVITIVE (PID) CONTROLLER LOGIC IS INTERNAL TO FOXBORO DCS. CONTROLLER MANUAL DEMAND SIGNALS ARE PROVIDED FROM ASSOCIATED MAIN CONTROL ROOM HANDSTATION.
9. PORV OPEN INTERLOCK REQUIRES 2/2 MI PRESSURE SIGNALS-ONE FROM EACH INDEPENDENT DCS PROCESSOR CONTROL GROUP.
10. PROPORTIONAL+INTEGRAL+DERIVITIVE (PID) CONTROLLER LOGIC IS INTERNAL TO FOXBORO DCS. REMOTE CONTROLLER SETPOINT AND MANUAL DEMAND SIGNALS ARE PROVIDED FROM ASSOCIATED MAIN CONTROL ROOM HANDSTATION.
11. PROPORTIONAL (P) CONTROLLER LOGIC IS INTERNAL TO FOXBORO DCS. CONTROLLER MANUAL DEMAND SIGNALS ARE PROVIDED FROM ASSOCIATED MAIN CONTROL ROOM HANDSTATION.

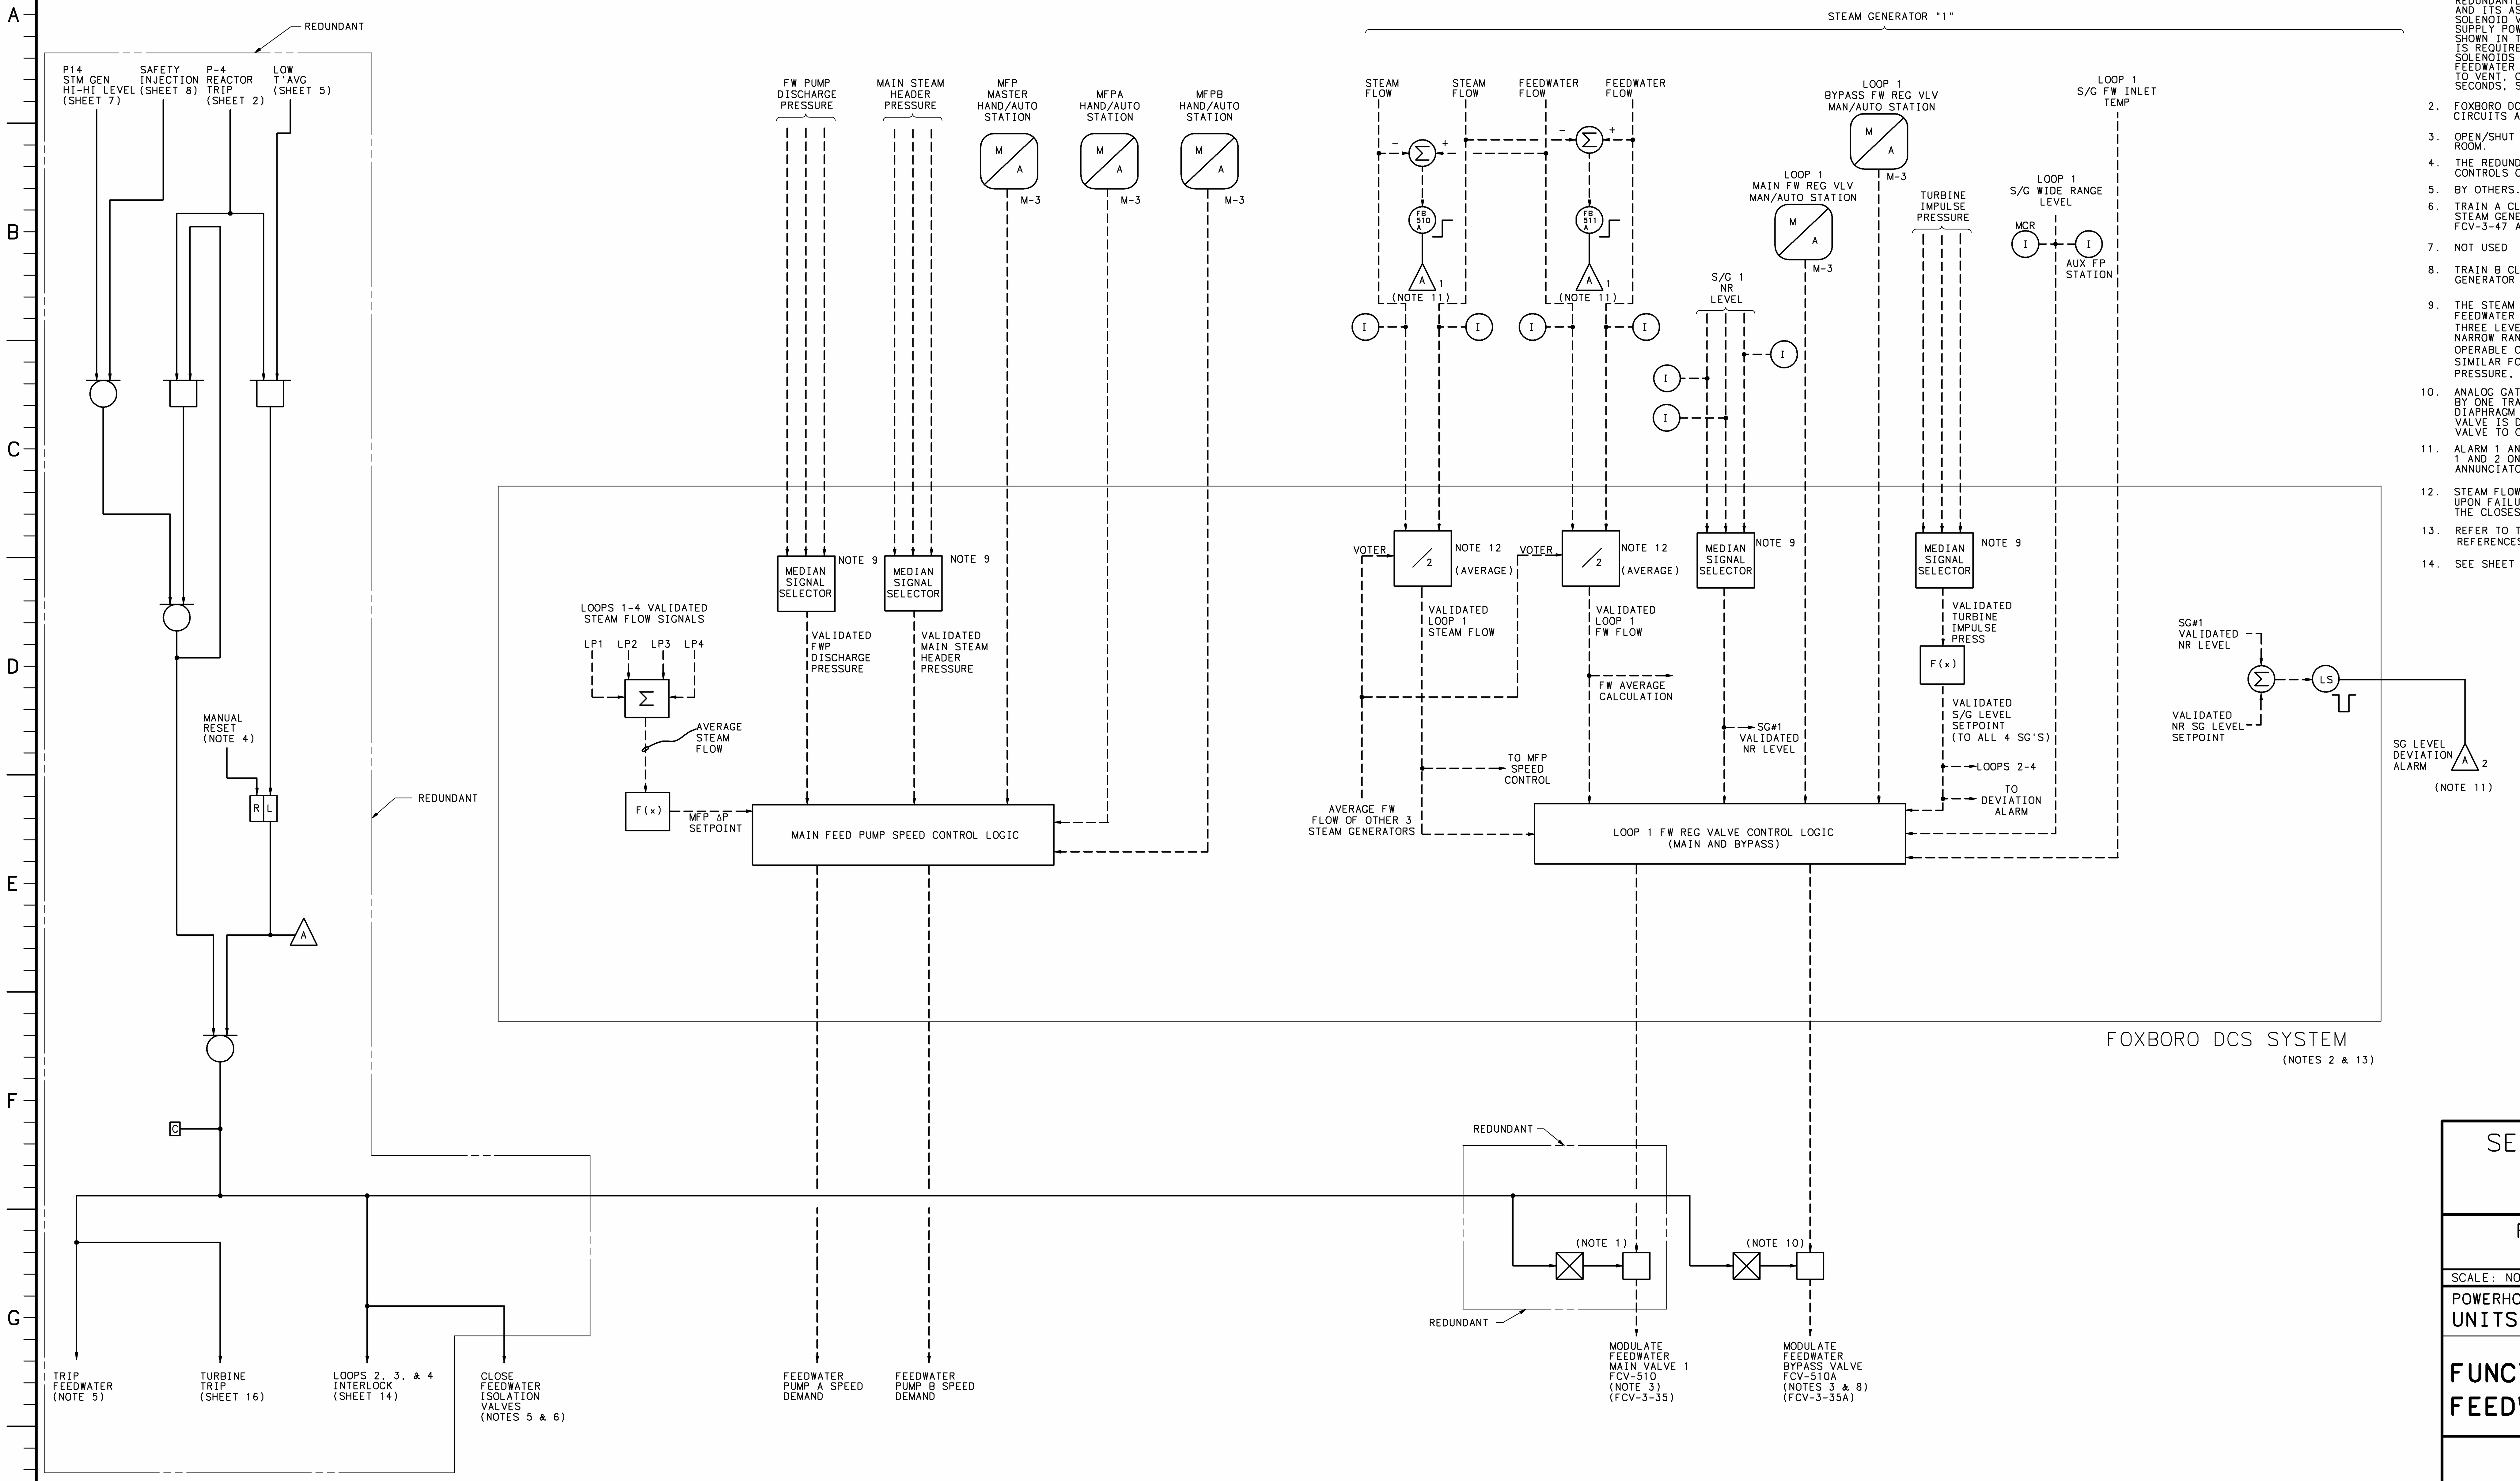
FUNCTIONAL DIAGRAMS-PRESSURIZER HEATER CONTROL
(REVISED BY AMENDMENT 28)

CAD MAINTAINED DRAWING



NOTES:

1. ANALOG GATE CONSISTS OF 2 SOLENOID ASSEMBLIES IN SERIES TO REDUNDANTLY INTERLOCK THE AIR LINE BETWEEN EACH VALVE DIAPHRAGM AND ITS ASSOCIATED POSITIONER. EACH ASSEMBLY CONTAINS TWO SOLENOID VALVES POWERED FROM DIFFERENT POWER SUPPLIES. EACH DC SUPPLY POWERS TWO SOLENOIDS, BUT FOR DIFFERENT ASSEMBLIES AS SHOWN IN THE LOGIC. ONE OF TWO SOLENOIDS WITHIN EACH ASSEMBLY IS REQUIRED FOR MAIN FEEDWATER VALVE MODULATION. BOTH SOLENOIDS WITHIN AN ASSEMBLY ARE REQUIRED FOR VENTING AND MAIN FEEDWATER VALVE CLOSURE. THE SOLENOID VALVES ARE DE-ENERGIZE TO VENT, CAUSING THE MAIN FEEDWATER VALVE TO CLOSE IN 7 SECONDS, SEE 1,2-45N603-1.
2. FOXBORO DCS CIRCUITS ARE FAULT TOLERANT AND REDUNDANT, OTHER CIRCUITS ARE NOT REDUNDANT EXCEPT WHERE INDICATED "REDUNDANT".
3. OPEN/SHUT INDICATION FOR EACH FEEDWATER VALVE IN CONTROL ROOM.
4. THE REDUNDANT MANUAL RESET CONSISTS OF TWO MOMENTARY CONTROLS ON THE CONTROL BOARD, ONE FOR EACH TRAIN.
5. BY OTHERS.
6. TRAIN A CLOSES VALVES NUMBER FCV-3-33 AND FCV-3-87 FOR STEAM GENERATORS 1 AND 3 . TRAIN B CLOSES VALVES NUMBER FCV-3-47 AND FCV-3-100 FOR STEAM GENERATORS 2 AND 4.
7. NOT USED
8. TRAIN B CLOSES BYPASS VALVE NUMBER FCV-510A FOR STEAM GENERATOR 1.
9. THE STEAM GENERATOR NARROW RANGE LEVEL SIGNAL USED FOR FEEDWATER CONTROL IS THE MEDIAN (MIDDLE) SIGNAL FOR THE THREE LEVEL CHANNELS. UPON FAILURE OF ONE STEAM GENERATOR NARROW RANGE LEVEL CHANNEL, THE AVERAGE OF THE REMAINING TWO OPERABLE CHANNELS IS USED FOR CONTROL. THIS FUNCTION IS SIMILAR FOR FW PUMP DISCHARGE PRESSURE, MAIN STEAM HEADER PRESSURE, AND TURBINE IMPULSE PRESSURE SIGNALS.
10. ANALOG GATE CONSISTS OF ONE SOLENOID VENT VALVE CONTROLLED BY ONE TRAIN TO INTERLOCK THE AIR LINE BETWEEN EACH VALVE DIAPHRAGM AND ITS ASSOCIATED POSITIONER. THE SOLENOID VALVE IS DE-ENERGIZE TO VENT, CAUSING THE BYPASS FEEDWATER VALVE TO CLOSE IN 5 SECONDS.
11. ALARM 1 AND ALARM 2 MUST HAVE REFLASH CAPABILITY. ALARMS 1 AND 2 ON THIS SHEET SHARE THE SAME RESPECTIVE COMMON ANNUNCIATOR WINDOWS WITH ALARMS 1 AND 2 ON SHEET 14.
12. STEAM FLOW AND FW FLOWS UTILIZE THE AVERAGE SIGNAL FOR CONTROL. UPON FAILURE OF ONE FW OR SF SIGNAL, THE VOTER SIGNAL SELECTS THE CLOSEST SIGNAL TO THE VOTER FOR CONTROL.
13. REFER TO TVA DRAWING 47W611-98-1 FOR FUNCTIONAL DIAGRAM DRAWING REFERENCES.
14. SEE SHEET 14 FOR LOOPS 2-4.

UPON FAILURE OF ONE STEAM GENERATOR NARROW RANGE LEVEL CHANNEL, THE AVERAGE OF THE REMAINING TWO OPERABLE CHANNELS IS USED FOR CONTROL. THIS FUNCTION IS SIMILAR FOR FW PUMP DISCHARGE PRESSURE, MAIN STEAM HEADER PRESSURE, AND TURBINE IMPULSE PRESSURE SIGNALS.
7. ANALOG GATE CONSISTS OF ONE SOLENOID VENT VALVE CONTROLLED BY ONE TRAIN TO INTERLOCK THE AIR LINE BETWEEN EACH VALVE DIAPHRAGM AND ITS ASSOCIATED POSITIONER. THE SOLENOID VALVE IS DE-ENERGIZE TO VENT, CAUSING THE BYPASS FEEDWATER VALVE TO CLOSE IN 5 SECONDS.
8. ALARM 1 AND ALARM 2 MUST HAVE REFLASH CAPABILITY, ALARMS 1 AND 2 ON THIS SHEET SHARE THE SAME RESPECTIVE COMMON ANNUNCIATOR WINDOWS WITH ALARMS 1 AND 2 ON SHEET 13.
9. STEAM FLOW AND FW FLOW UTILIZE THE AVERAGE SIGNAL FOR CONTROL. UPON FAILURE OF ONE FW OR SF SIGNAL, THE VOTER SIGNAL SELECTS THE CLOSEST SIGNAL TO THE VOTER FOR CONTROL.
10. LOOP 2 REPRESENTED FOR FOXBORO DIGITAL CONTROL SYSTEM EXCEPT AS SHOWN. LOOPS 3 AND 4 SIMILAR.
11. REFER TO TVA DRAWING 47W611-98-1 FOR FUNCTIONAL DIAGRAM REFERENCES.
12. SEE SHEET 13 FOR LOOP 1.

LOOP	STEAM FLOW SWITCH	FW FLOW SWITCH
2	FB 520A	FB 521A
3	FB 530A	FB 531A
4	FB 540A	FB 541A

NOTES:

1. ANALOG GATE CONSISTS OF TWO SOLENOID ASSEMBLIES IN SERIES TO REDUNDANTLY INTERLOCK THE AIR LINE BETWEEN EACH VALVE DIAPHRAGM AND ITS ASSOCIATED POSITIONER. EACH ASSEMBLY CONTAINS TWO SOLENOID VALVES POWERED FROM DIFFERENT POWER SUPPLIES. EACH DC SUPPLY POWERS TWO SOLENOIDS, BUT FOR DIFFERENT ASSEMBLIES AS SHOWN IN THE LOGIC. ONE OF TWO SOLENOIDS WITHIN EACH ASSEMBLY IS REQUIRED FOR MAIN FEEDWATER VALVE MODULATION. BOTH SOLENOIDS WITHIN AN ASSEMBLY ARE REQUIRED FOR VENTING AND MAIN FEEDWATER VALVE CLOSURE. THE SOLENOID VALVES ARE DE-ENERGIZE TO VENT, CAUSING THE MAIN FEEDWATER VALVE TO CLOSE IN SEVEN SECONDS. SEE 1,2-45N603-1.
2. CIRCUITS INSIDE FOXBORO DCS ARE FAULT TOLERANT AND REDUNDANT. THE DCS CIRCUITS ARE TYPICAL IN CONTROL GROUPS 2 - 4 ON THIS DRAWING. OTHER CIRCUITS ARE NOT REDUNDANT EXCEPT WHERE INDICATED.
3. OPEN/SHUT INDICATION FOR EACH FEEDWATER MAIN VALVE IN CONTROL ROOM.
4. NOT USED
5. TRAIN B CLOSES BYPASS VALVE NUMBER FCV-530A FOR STEAM GENERATOR 3. TRAIN A CLOSES BYPASS VALVE NUMBER FCV-520A FOR STEAM GENERATOR 2, AND FCV-540A FOR STEAM GENERATOR 4.
6. THE STEAM GENERATOR NARROW RANGE LEVEL SIGNAL USED FOR FEEDWATER CONTROL IS THE MEDIAN (MIDDLE) SIGNAL FOR THE THREE LEVEL CHANNELS. UPON FAILURE OF ONE STEAM GENERATOR NARROW RANGE LEVEL CHANNEL, THE AVERAGE OF THE REMAINING TWO OPERABLE CHANNELS IS USED FOR CONTROL. THIS FUNCTION IS SIMILAR FOR FW PUMP DISCHARGE PRESSURE, MAIN STEAM HEADER PRESSURE, AND TURBINE IMPULSE PRESSURE SIGNALS.
7. ANALOG GATE CONSISTS OF ONE SOLENOID VENT VALVE CONTROLLED BY ONE TRAIN TO INTERLOCK THE AIR LINE BETWEEN EACH VALVE DIAPHRAGM AND ITS ASSOCIATED POSITIONER. THE SOLENOID VALVE IS DE-ENERGIZE TO VENT, CAUSING THE BYPASS FEEDWATER VALVE TO CLOSE IN 5 SECONDS.
8. ALARM 1 AND ALARM 2 MUST HAVE REFLASH CAPABILITY, ALARMS 1 AND 2 ON THIS SHEET SHARE THE SAME RESPECTIVE COMMON ANNUNCIATOR WINDOWS WITH ALARMS 1 AND 2 ON SHEET 13.
9. STEAM FLOW AND FW FLOW UTILIZE THE AVERAGE SIGNAL FOR CONTROL. UPON FAILURE OF ONE FW OR SF SIGNAL, THE VOTER SIGNAL SELECTS THE CLOSEST SIGNAL TO THE VOTER FOR CONTROL.
10. LOOP 2 REPRESENTED FOR FOXBORO DIGITAL CONTROL SYSTEM EXCEPT AS SHOWN. LOOPS 3 AND 4 SIMILAR.
11. REFER TO TVA DRAWING 47W611-98-1 FOR FUNCTIONAL DIAGRAM REFERENCES.
12. SEE SHEET 13 FOR LOOP 1.

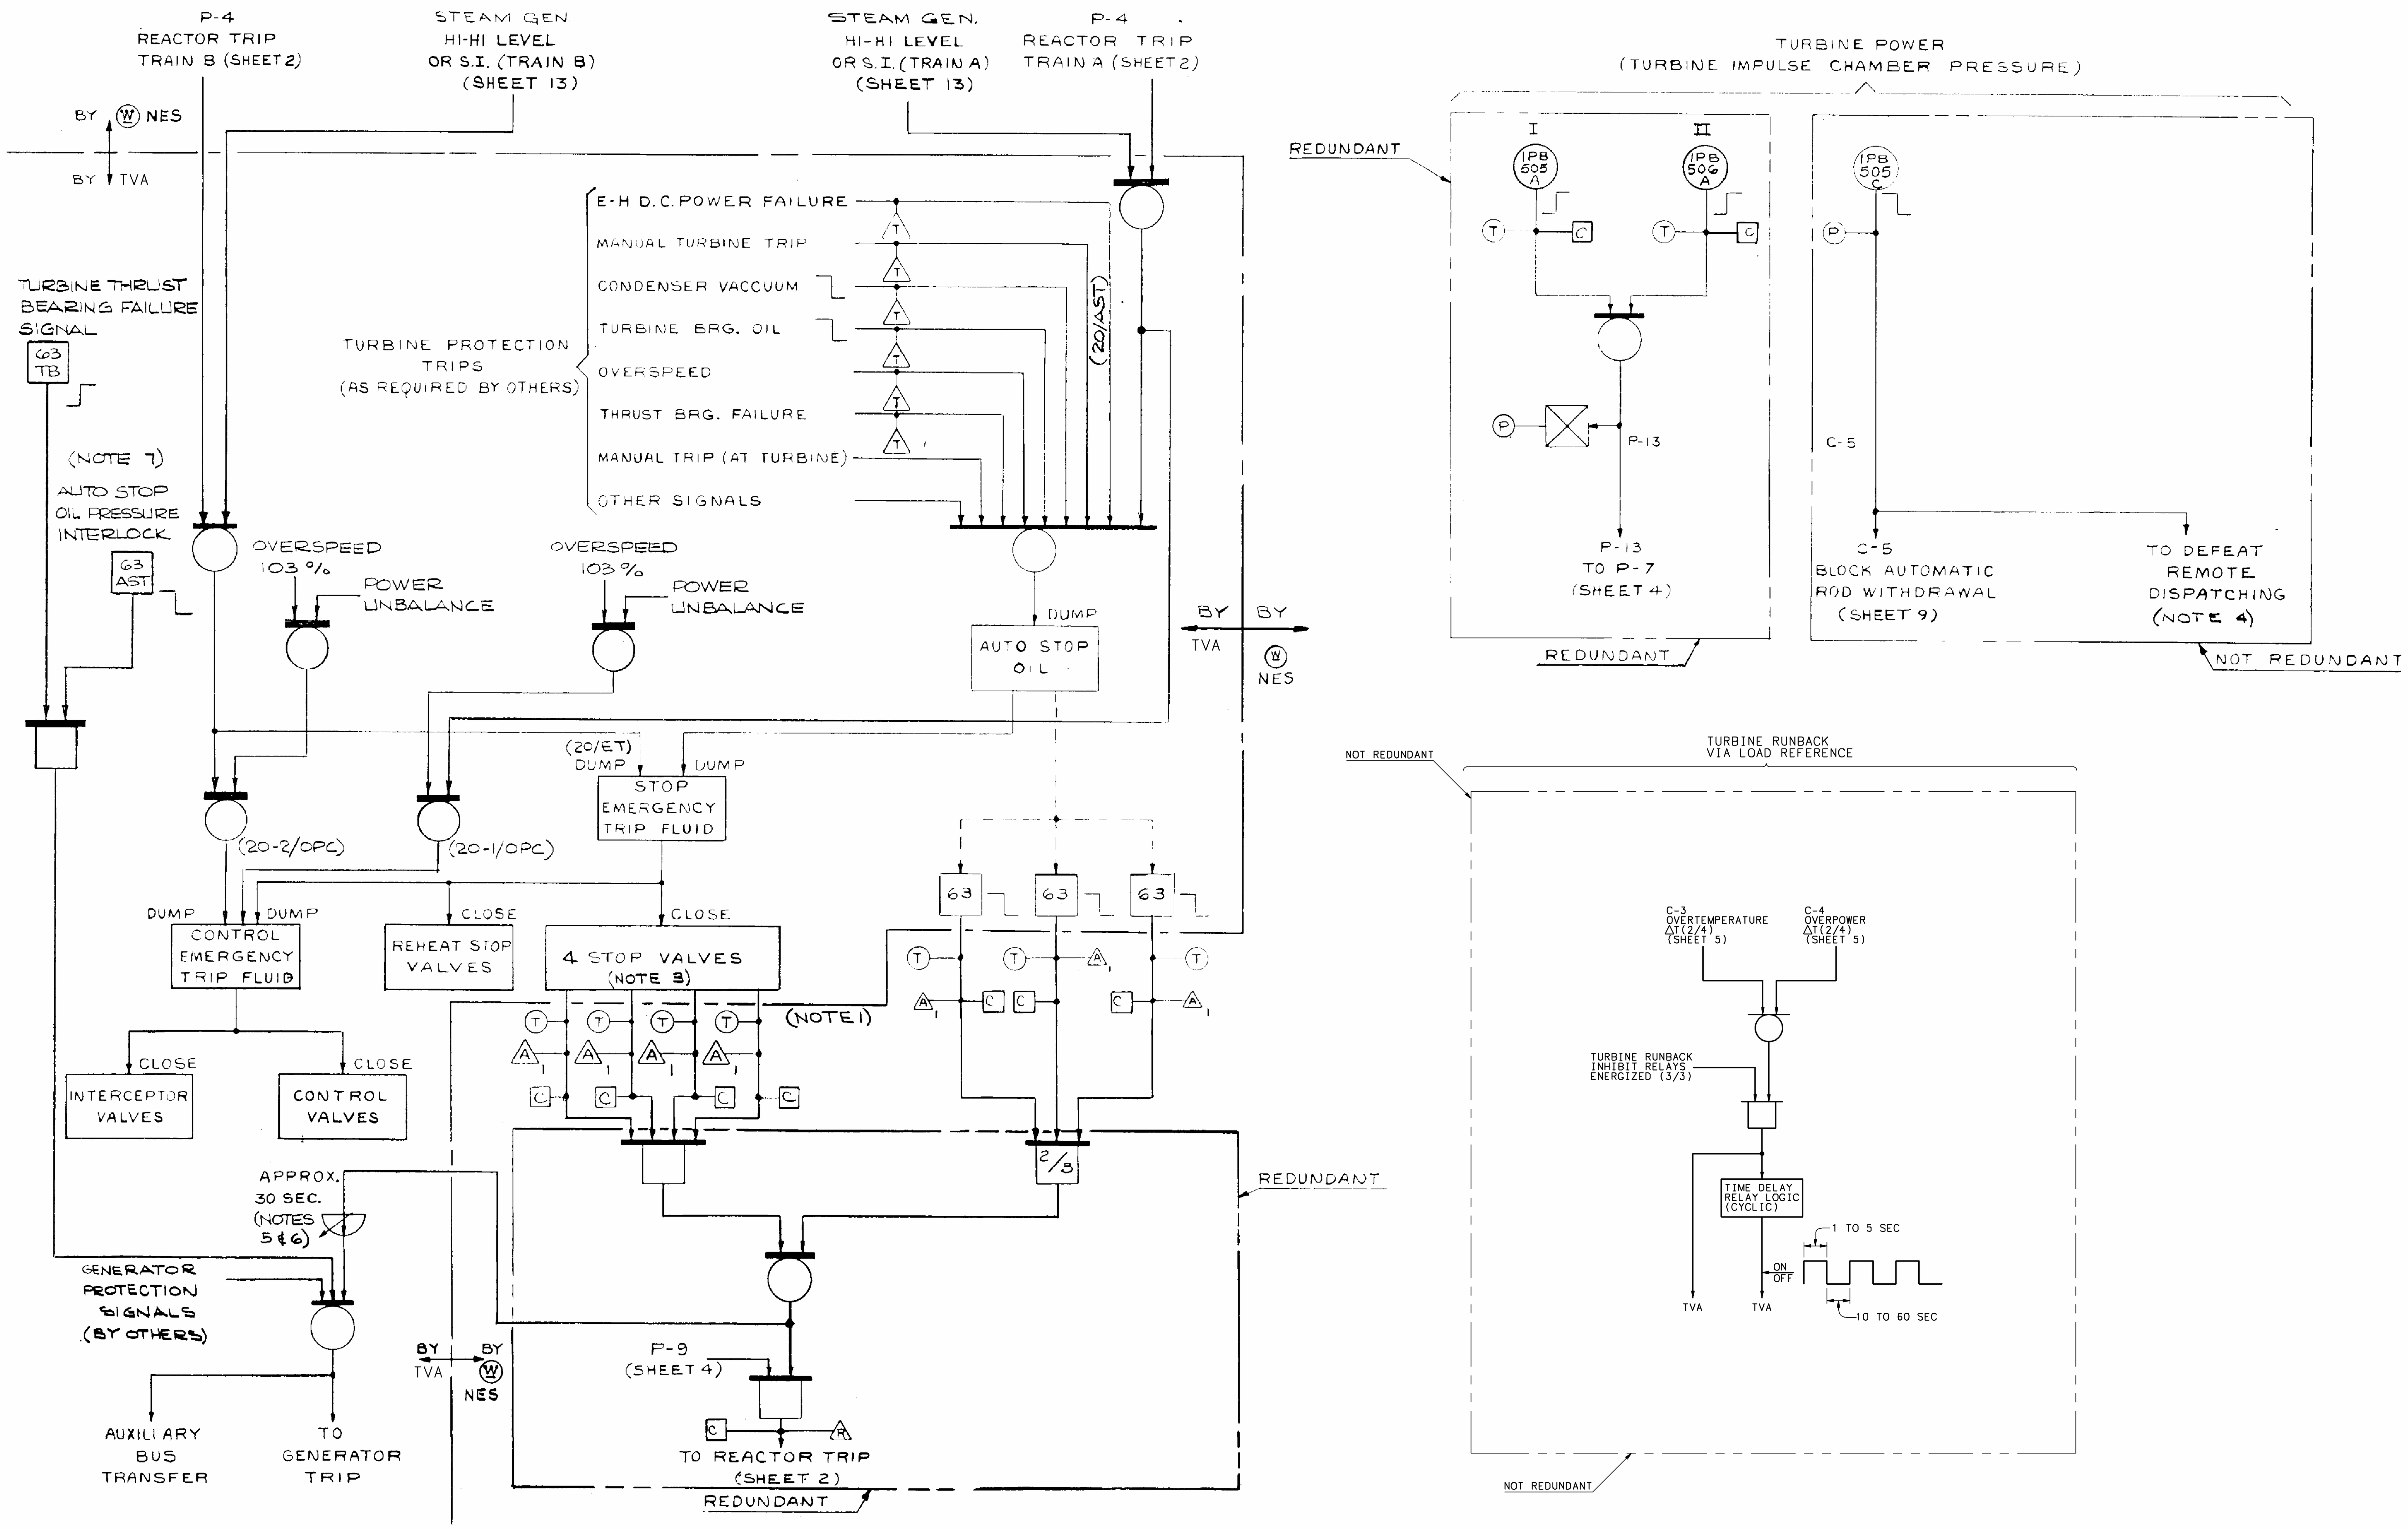
(REVISED BY AMENDMENT 13)



NOTES:

1. THESE SIGNALS INDICATE THE CLOSING OF THE STOP VALVES. POSITION DETECTION IS ACCOMPLISHED BY TWO CONTACTS PER STOP VALVE, ONE FOR EACH TRAIN. THE LOGIC SHOWN IS FOR FOUR STOP VALVES.
2. REDUNDANCY IS INDICATED AS REGARDS TO W REQUIREMENTS ONLY.
3. OPEN/SHUT INDICATION IN CONTROL ROOM.
4. THE REMOTE DISPATCHING IS TYPICAL. ACTUAL IMPLEMENTATION MAY NOT INCLUDE REMOTE DISPATCHING.
5. GENERATOR MOTORING PROTECTION SHOULD NOT DEFEAT THE 30 SEC. DELAY.
6. W S.T.D. REQUIRES THE THIRTY SECOND TIME DELAY TO BE REDUNDANT. ONE TIMER IS CONNECTED TO THE TRAIN A OUTPUT OF THE PROTECTION LOGIC SYSTEM AND THE OTHER TIMER IS CONNECTED TO THE TRAIN B OUTPUT. THE TIMER OUTPUTS ARE WIRED SO THAT EITHER WILL ACTUATE A GENERATOR TRIP.
7. THE "AND" LOGIC AND THE ASSOCIATED PRESSURE SWITCHES (63/TB AND 63/AST) MUST BE TESTED PERIODICALLY, WHILE ON LINE AT POWER, WITHOUT PLANT TRIP. TEST VALVES AND TEST LIGHTS ARE REQUIRED TO PROVIDE THOROUGH TESTING AND TO VERIFY PRESSURE SWITCH CONTACT STATUS.
