1.0 INTRODUCTION AND GENERAL DESCRIPTION OF PLANT

1.1 INTRODUCTION

This Final Safety Analysis Report is in support of the Tennessee Valley Authority (TVA) facility operating licenses for a two-unit nuclear power plant located approximately 7.5 miles northeast of Chattanooga at the Sequoyah site in Hamilton County, Tennessee.

This facility has been designated the Sequoyah Nuclear Plant (SNP). The plant has been designed, built, and is operated by TVA. Each of the two identical units employs a Pressurized Water Reactor Nuclear Steam Supply System with four coolant loops furnished by Westinghouse Electric Corporation. These units are similar to those of the Watts Bar Nuclear Plant, and other plants reviewed by the U.S. Nuclear Regulatory Commission.

Each of the two reactor cores is rated at 3,455 MWt and, at this core power, each NSSS will operate at 3,467 MWt. The additional 12 MWt is due to the contribution of heat of the Primary Coolant System from nonreactor sources, primarily reactor coolant pump heat. Each of the reactor cores has an Engineered Safeguards design rating of approximately 3565 MWt and each NSSS 3577 MWt. The total generator output is approximately 1,199 MWe for the rated core power.

The containment for each of the reactors consists of a freestanding steel vessel with an ice condenser and separate reinforced concrete shield building. The ice condenser was designed by the Westinghouse Electric Corporation. The freestanding containment vessel was designed by Chicago Bridge & Iron (CBI).

Unit 1 began commercial operation in July 1, 1981. Unit 2 began commercial operation on June 1, 1982.

1.1.1 LICENSING BASIS DOCUMENTS

The following documents are typical documents submitted periodically to NRC. Implementation of changes to these documents without NRC approval may be controlled by regulation or the plant operating license. The following list provides references on the review and approval requirements for the listed documents.

DOCUMENT	REGULATORY OR REQUIREMENT
Updated Final Safety Analysis Report	10 CFR 50.59 10 CFR 50.71(e)
Technical Requirements Manual	Technical Requirement 6.0 10 CFR 50.59 10 CFR 50.36(c)(2)(ii)
Technical Specification Bases	10 CFR 50.59
Organizational Topical Report	10 CFR 50.71(e)
Quality Assurance Plan	10 CFR 50.54(a)(3)

DOCUMENT	REGULATORY OR REQUIREMENT
Fire Protection Report	Unit 1 License Condition 2.C.16 Unit 2 License Condition 2.C.13
Offsite Dose Calculation Manual	Technical Specification 5.5.1
Physical Security Plan	10 CFR 50.54(p)
Radiological Emergency Plan	10 CFR 50.54(q)
Core Operating Limits Report	Technical Specification 5.6.3
Pressure Temperature Limits Report	Technical Specification 5.6.4
Licensing Requirements for the Independent Storage of Spent Nuclear Fuel and High-Level Radioactive Waste	10 CFR 72
General License Issued	10 CFR 72.210
Conditions of General License Issued Under 10 CFR 72.210	10 CFR 72.212

1.1.2 PROGRAMMATIC COMMITMENTS

The following programmatic commitments are incorporated to ensure control under the licensing basis process.

Technical Specification Change (TSC 04-08)

TVA is using an industry database (e.g., the industry's Consolidated Data Entry [CDE] program, currently being developed and maintained by the Institute of Nuclear Power Operations) to send to the NRC the operating data (for each calendar month) that is described in Generic Letter 97-02, "Revised Contents of the Monthly Operating Report," by the last day of the month following the end of each calendar quarter. This regulatory commitment will be implemented to prevent any gaps in the monthly operating statistics and shutdown experience provided to the NRC (i.e., data for all months will be provided using one or both systems monthly operating reports and CDE).

1.2 GENERAL PLANT DESCRIPTION

1.2.1 Site Characteristics

1.2.1.1 Location

The plant site, consisting of approximately 525 acres, is located in southeastern Tennessee on the west shore of Chickamauga Lake approximately 7.5 miles northeast of Chattanooga.

1.2.1.2 Demography

The population density of the area surrounding the site is relatively low. The site consists of an owner controlled exclusion area. A low population zone surrounds the plant site.

1.2.1.3 Meteorology

Meteorological data has been collected since April 1971 at the site. Selected data has been used for the description of the local weather and for the calculation of the dispersion factors. In addition, data from stations within 75 miles of the site was used to calculate the regional climatology. The probability of a tornado occurrence at the site is estimated to be about once in 6,000 years. Despite this low probability, the design of plant Category I structures included consideration of the effects of tornadic winds.

1.2.1.4 Hydrology

The Design Basis Flood could exceed plant grade at the plant site. The plant grade has been established at approximately elevation 705 feet. The flood elevation includes wave runup on vertical surfaces resulting from an over water wind. The plant design considered the effects of this flood and the plant can be placed in a safe shutdown condition before the flood exceeds plant grade. The potential for floods resulting from seismically induced dam failure and/or dam failure permutations has been investigated. The results indicate that floods of this type will exceed plant grade, but to an elevation lower than the Design Basis Flood.

1.2.1.5 Geology

The controlling feature of the geologic structure at the site is the Kingston thrust fault which developed some 250 million years ago. The fault has been inactive for many millions of years and recurrence of movement is not expected. The fault crosses to the northwest of the site area; however, it was not involved directly in the foundation for any of the major plant structures.

1.2.1.6 Seismology

The seismic history of the southeastern United States indicates that there has been no significant seismic activity originating in the site area. The Safe Shutdown Earthquake (SSE) for the plant has been established as having a maximum horizontal acceleration of 0.18g and a simultaneous maximum vertical acceleration of 0.12g.

1.2.2 Facility Description

1.2.2.1 Design Criteria

The design criteria for the Sequoyah Nuclear Plant are discussed in Section 3.1.

1.2.2.2 Nuclear Steam Supply System

The Nuclear Steam Supply System consists of a reactor and four closed reactor coolant loops connected in parallel to the reactor vessel. Each loop contains a reactor coolant pump, a steam generator, loop piping, and instrumentation. The Nuclear Steam Supply System also contains an electrically heated pressurizer and certain auxiliary systems.

High pressure water circulates through the reactor core to remove the heat generated by the nuclear chain reaction. The heated water exits the reactor vessel and passes via the coolant loop piping to the steam generators. Here it gives up its heat to the feedwater to generate steam for the turbine generator. The cycle is completed when the water is pumped back to the reactor vessel.

The inherent design of the pressurized water, closed-cycle reactor minimizes the quantities of fission products released to the atmosphere. Three barriers exist between the fission product accumulation and the environment. These are the fuel cladding, the reactor vessel and coolant loops, and the reactor containment. The consequences of a breach of the fuel cladding are greatly reduced by the ability of the uranium dioxide lattice to retain fission products. Escape of fission products through fuel cladding defect would be contained within the pressure vessel, loops and auxiliary systems. Breach of these systems or equipment would release the fission products to the reactor containment where they would be retained. The reactor containment is designed to adequately retain these fission products under the most severe accident conditions, as analyzed in Chapter 15.

The reactor core, with its related Control and Protection System, is designed to function throughout its design lifetime without exceeding the acceptable fuel damage limits defined in Section 4.2. The core design, together with process and residual heat removal systems, provides for this capability under all expected conditions of normal operation with appropriate margins for uncertainties and anticipated transient situations, including, as examples, the effects of the loss of reactor coolant flow, turbine trips due to steam and power conversion system malfunctions, and loss of external electrical load.

The reactor core is a multi-region cycled core. The fuel rods are zirconium alloy tubes containing slightly enriched uranium dioxide fuel. The fuel assembly is a canless type with the basic assembly consisting of the Rod Cluster Control (RCC) guide thimbles welded to the top nozzle and mechanically fastened to the grids and bottom nozzle. The fuel rods are held by the spring clip grids in this assembly. The internals, consisting of the upper and lower core support structure, are designed to support, align, and guide the core components, direct the coolant flow to and from the core components, and to support and guide the in-core instrumentation. Dissolved boric acid is used as reactivity control device to minimize the use of RCC assemblies and assist in the control of power peaking.

Full length RCC assemblies and burnable poison rods are inserted into the guide thimbles of the fuel assemblies. The control rod drive mechanisms for the full length RCC assemblies are of the magnetic latch type. The latches are controlled by three magnetic coils. They are so designed that upon a loss of power to the coils, the RCC assembly is released and falls into the core by gravity to shut down the reactor.

Pressure in the system is controlled by the pressurizer, where system pressure is maintained through the use of electrical heaters and sprays. Steam can either be formed by the heaters, or condensed by a pressurizer spray to minimize pressure variations due to contraction and expansion of the coolant. Instrumentation used in the Reactor Coolant system is described in Chapter 7. Spring-loaded safety valves and power-operated relief valves for overpressure protection are connected to the pressurizer and discharge to the pressurizer relief tank, where the discharge steam is condensed and cooled by mixing with water.

The reactor coolant pumps are Westinghouse vertical, single-stage, mixed flow pumps of the shaft-seal type. The power supply system to the pumps is designed so that adequate coolant flow is maintained to cool the reactor core under all credible circumstances.

The original steam generators (OSG) were Westinghouse vertical U-tube units which contain Inconel tubes. Integral moisture separation equipment reduces the moisture content of the steam. The replacement steam generators (RSG) for Unit 1and Unit 2 are similar in design and are supplied by Westinghouse Electric Company, Combustion Engineering Nuclear Power LLC (CENP). The RSG's on Unit 1 were installed during the U1C12 RFO (March - May 2003). The RSG's on Unit 2 were installed during the U2C18 RFO (October - December 2012).

The reactor coolant piping and the pressure-containing and heat transfer surfaces in contact with reactor water are stainless steel clad except the steam generator tubes and fuel tubes, which are Inconel and zirconium alloy, respectively. Reactor core internals, including control rod drive shafts, are stainless steel.

Auxiliary system components are provided to charge the Reactor Coolant System and add makeup water, purify reactor coolant water, provide chemicals for corrosion inhibition and reactor control, cool system components, remove decay heat when the reactor is shut down, and provide for emergency coolant injection.

1.2.2.3 Control and Instrumentation

The reactor is controlled by temperature coefficients of reactivity, control rod clusters, and a soluble neutron absorber, boron, in the form of boric acid.

Instrumentation and controls are provided to monitor and maintain essential reactor facility operating variables such as neutron flux, primary coolant pressure, temperature, and control rod positions within prescribed operating ranges.

The non-neutronic process and containment instrumentation measures temperatures, pressure, flows, and levels in the Reactor Coolant system, steam systems, containment, and auxiliary systems. Process variables which are required on a continuous basis for the startup, power operation, and shutdown of the plant are monitored in a controlled access area. The quantity and types of process instrumentation provided are adequate for safe and orderly operation of all systems and processes over the full operating range of the plant.

Reactor protection is achieved by defining a region of power and coolant temperature conditions allowed by the principal tripping functions: the overpower delta temperature trip, the overtemperature delta temperature trip, and the nuclear overpower trip. The allowable operating region within these trip settings is designed to prevent any combination of power, temperatures, and pressure which would result in exceeding departure from nucleate boiling ratio limits. Additional tripping functions such as a high-pressurizer pressure trip, low-pressurizer pressure trip, high-pressurizer water-level trip, loss of coolant flow trip, steam generator low-low water-level trip, turbine trip, safety injection trip, nuclear source and intermediate range trips, neutron flux rate trips, and manual trip are provided to support the principal tripping functions for specific accident conditions and mechanical failures. Independent and redundant channels are combined in logic circuits which improve tripping reliability and minimize trips from spurious causes. Protection interlocks, initiation signals to the Safety Injection System, containment isolation signals, and turbine runback signals further assist in plant protection during operation.

1.2.2.4 Fuel Handling System

New fuel assemblies are removed one at a time from the shipping cask and stored dry in the fuel storage racks located in the fuel storage area or wet in the spent fuel pool. New fuel is delivered to the reactor vessel by placing a fuel assembly into the new fuel elevator, lowering it into the transfer canal, storing it in the spent fuel pit or taking it through the fuel transfer system and placing it in the core by the use of the manipulator crane. Spent fuel is removed from the reactor vessel by the manipulator crane and placed in the Fuel Transfer System. In the spent fuel pool, the fuel is removed from the Transfer System and placed in the storage racks. After a suitable decay period, the fuel may be removed from storage and loaded in a shipping cask for removal from the site or the spent fuel assemblies may be placed in interim storage at SQN Independent Spent Fuel Storage Installation (ISFSI) (Section 9.1.5).

Spent fuel is handled entirely under water from the time it leaves the reactor vessel until it is placed in a cask for shipment from the site or the spent fuel assemblies may be placed in interim storage at SQN Independent Spent Fuel Storage Installation (ISFSI) (Section 9.1.5). Underwater transfer of spent fuel provides an effective, economic and transparent shield, as well as a reliable cooling medium for removal of decay heat.

1.2.2.5 Waste Processing Systems

The Waste Processing System provides equipment necessary for controlled treatment, and preparation for retention or disposal of liquid, gaseous, and solid wastes produced as a result of reactor operation. The Liquid Waste System collects and processes reactor grade water, removes or concentrates radioactive constituents and processes them until suitable for release or shipment offsite. The Gaseous Waste Processing System functions to remove fission product gases from the reactor coolant. The system also collects the gases from

various tanks and processes. The waste processing systems, including both liquid and gas, are designed to ensure that the quantities of radioactive releases from the total plant to the surrounding environment will not exceed the 10 CFR 20 limits and are as low as practicable.

The solid waste management system functions to prepare slurries and solid radwaste for shipment or for temporary onsite storage in compliance with the requirements in 10 CFR 61, 10 CFR 71, and 49 CFR 170 through 178. Waste inputs are divided into two categories: dry active waste (DAW) and wet active waste (WAW). DAW is further divided into compactible and non-compactible wastes. WAW is primarily composed of two types of waste: evaporator concentrates and spent resins.

1.2.2.6 Steam and Power Conversion System

The Steam and Power Conversion System consists of a turbine-generator, main condenser, vacuum pumps, Turbine Seal System, Turbine Bypass System, hot well pumps, condensate booster pumps, main feed pumps, main feed pump turbines (MFPT), condenser-feedwater heater, feedwater heaters, heater drain pumps, and Condensate Storage System. The system is designed to convert the heat produced in the reactor to electrical energy through conversion of a portion of the energy contained in the steam supplied from the steam generators, to condense the turbine exhaust steam into water, and to return the water to the steam generator as feedwater.

Each turbine generator unit consists of a tandem arrangement of one double-flow high-pressure turbine and three double-flow low-pressure turbines driving a direct-coupled generator at 1800 RPM. The generator has a nameplate rating of 1,356,200 KVA at 0.9 PF with 75 psig hydrogen pressure. Each unit employs a horizontal, single pressure, triple shell, single pass surface condenser. Return to the steam generator is through three stages of feedwater pumping and seven stages of feedwater heating. Safety relief valves and power operated relief valves, as well as a turbine bypass to the condenser are provided in the steam lines.

1.2.2.7 Plant Electrical System

For Unit 1 and 2, the Plant Electric Power System consists of the main generator, the generator circuit breaker, the unit station service transformers, the common station service transformers, the main bank transformers, the diesel generators, the batteries, and the electric distribution system. The main generator supplies electrical power through isolated-phase buses to the main bank transformers and the unit station service transformers located adjacent to the Turbine Building. The primaries of the unit station service transformers are connected to the isolated-phase bus at a point between the generator circuit breaker terminals and the low-voltage connection of the main bank transformers. During normal operations the auxiliary power is typically supplied by unit power through the unit station service transformers. During startup and shutdown the auxiliary power is typically supplied by the 500-kV system through the main bank and unit station service transformers for Unit 1 and the 161-kV system through the main bank and unit station service transformers for Unit 2. During startup, shutdown, and normal operations auxiliary power may be supplied by the 161-kV system through the common station service transformers.

The standby onsite power is supplied by four diesel generators. The power to the 6.9-kV common boards is supplied by the 161-kV system through the common station service transformers.

The Plant Distribution System can receive AC power from either the Unit 1 or 2 nuclear power unit, the two independent preferred (offsite) power circuits, or the four diesel-generator standby (onsite) power sources and distribute it to safety-related and nonsafety-related loads as required. The two preferred circuits have access to the TVA transmission network which in turn has multiple interties with other transmission networks.

The safety-related loads for the plant are divided into two redundant groups. Each load group has access to each of the two preferred offsite sources. One load group with its two associated diesel generators can provide all safety functions in each unit. The electrical systems are described in Section 8.2 and 8.3.

The vital AC and DC Control and Instrument Power system consists of four 125V batteries, four battery chargers and eight 120V AC inverters with their respective safety-related loads. A spare 125V battery and spare chargers are available as needed. Each channel has a spare inverter which can be manually aligned to replace the Unit 1 or Unit 2 inverter. The 125V DC Distribution System is a safety-related system which receives power from four independent battery chargers and four 125V DC batteries and distributes it to safety-related loads of both units. The 120V AC Distribution System receives power from eight independent inverters and distributes it to the safety-related loads of both units. These systems are described in Section 8.3.

1.2.2.8 Cooling Water

The Condenser Circulating Water System provides cooling water to the main turbogenerator condensers and auxiliary cooling equipment. Water from this system may also be used to dilute and disperse low level radioactive liquid waste. For each unit, three pumps are provided in the intake pumping station located at the land end of the intake channel. Water flows into the intake channel under a skimmer wall from the river. Each pump has a separate suction well with individual traveling screens and discharges through a motor-operated butterfly valve into a common single square conduit tunnel which carries the cooling water to the condensers. Unit 1 was started up before completion of the separate, permanent ERCW pumping station. Unit 1 startup utilized the ERCW pumps in the Intake Pumping Station which houses the permanent condenser circulating water (CCW) pumps. The Main Cooling Towers and the permanent ERCW pumping station were completed prior to startup of Unit 2. The new ERCW station is located offshore in the lake, at the skimmer wall, and is capable of taking suction from the river channel on loss of the downstream dam.

Unit 1 operation before startup of unit 2 utilized once-through CCW and ERCW cooling, the discharge water passing through an embayment and a diffuser discharge system in the lake. The transition to the Main Cooling Towers and the permanent ERCW pumping station was made prior to startup of Unit 2.

With the Main Cooling Towers operable, the CCW System may be operated in any of three modes as follows:

1. Once-through as described above, with the discharge stream passing through the Cooling Tower supply pumping station.

2. Helper mode in which the main condenser discharge stream is pumped by the Cooling Tower supply pumps into one or both natural draft Cooling Towers where the heat load is dumped to the atmosphere. Seven pumps are provided. The cooled stream then passes through the holding pond and diffuser pipes as in the once-through mode.

3. Closed cycle, in which the discharge stream is returned from the Cooling Towers to the CCW intake pumping station forebay, from which it is recycled.

1.2.2.9 Component Cooling System & Essential Raw Cooling Water

The Component Cooling system (CCS) is the intermediate, closed-loop cooling water between various components handling Reactor Coolant system fluids, and the Essential Raw Cooling Water (ERCW). Two basic purposes of the CCS are:

1. To remove heat from the components and heat exchangers that are handling radioactive fluids.

2. To serve as a buffer against leakage from the nuclear systems to the ERCW and thus to the environment.

The CCS system is vital to plant operation. The system is designed as a safety system with components necessary for heat removal from other safety systems.

The ERCW system is the cooling water supply and discharge to the ultimate heat sink, the Tennessee River.

1.2.2.10 Chemical and Volume Control System

The Chemical and Volume Control System (CVCS) performs the following functions:

1. Fills the Reactor Coolant system (RCS).

2. Provides a source of high pressure water for pressurizing the RCS when cold.

3. Maintains the water level in the pressurizer when the RCS is hot.

4. Reduces the concentration of corrosion and fission products in the reactor coolant.

5. Adjusts the boric acid concentration of the reactor coolant for chemical shim control.

6. Provides high pressure seal water for the reactor coolant pump seals.

7. Provides a means of reactor coolant water chemistry control.

During power operation, a continuous feed-and-bleed stream is normally maintained to and from the RCS. Letdown water leaves the RCS and flows through the shell side of the regenerative heat exchanger where it gives up its heat to makeup water being returned to the RCS. The letdown water then flows through the orifices where its pressure is reduced, then through the letdown heat exchanger, followed by a second pressure reduction by a

low-pressure letdown valve. The letdown normally flows through a mixed bed demineralizer, where ionic impurities are removed, then flows either through the cation demineralizers or directly through the reactor coolant filter, and into the volume control tank via a spray nozzle. The vapor space in the volume control tank normally contains hydrogen which dissolves in the coolant. Fission gases can be removed from the system by venting of the volume control tank.

The charging pumps take the coolant from the volume control tank and send it along two parallel paths: (1) to the RCS through the tube side of the regenerative heat exchanger and (2) to the seals of the reactor coolant pumps. Some RCS seal water flows into the RCS and the remainder leaves the pumps as seal leakage. From the pumps, the leakage water goes to the seal water heat exchanger and then returns for another circuit. If the normal letdown and charging path through the regenerative heat exchanger is not operable, water injected into the RCS through the reactor coolant pump seals is returned via the excess letdown heat exchanger.

Surges from the RCS accumulate in the volume control tank unless a high water level in the tank causes flow to be diverted to the Hold Up Tanks.

Makeup to the CVCS comes from the following sources:

1. Demineralized and deaerated water supply, when the concentration of the dissolved neutron absorber is to be reduced.

2. Boric acid tank, when the concentration of dissolved neutron absorber is to be increased.

3. A blend of demineralized and deaerated water and concentrated boric acid to match or regulate the reactor coolant boron concentration for normal plant makeup.

4. Refueling water storage tank for emergency makeup of borated water.

5. Chemical mixing tank for small quantities of hydrazine for oxygen scavenging or lithium hydroxide for pH control.

1.2.2.11 <u>Sampling and Water Quality System</u>

The Sampling and Water Quality System provides the equipment necessary to provide required process samples for laboratory analysis. These analyses provide the essential chemical and radiochemical data required for the operation of the various process systems in each of the two units.

1.2.2.12 <u>Ventilation</u>

The internal environments of the various buildings of the plant are controlled within acceptable limits for safety, comfort, and equipment protection by several heating, cooling, and ventilating systems. Filtration is provided in exhaust systems as required to reduce contaminants.

Heating systems involve both electric and hot water systems while cooling utilizes fan coil units supplied with direct expansion, chilled water, or raw water coils.

Ventilation is, for the most part, by both supply and exhaust with central intakes and exhausts for proper treatment of the air.

Redundant equipment is provided for safety-related equipment.

1.2.2.13 Fire Protection System

The Fire Protection system will provide a reliable water and CO2 system to extinguish fires both inside and outside the buildings. The systems are designed to provide early detection and extinguishing of fires with an overall objective of minimizing fire hazards and limiting the consequences in the event of a fire. The Fire Protection System is discussed in the Fire Protection Report (see 9.5.1).

1.2.2.14 Compressed Air System

The Compressed Air System is common to both units and is divided into two subsystems: the station control and service air system, and the auxiliary control air system. The station control and service air system supplies compressed air for general plant service, instrumentation, testing, and control. The auxiliary air systems provide, as a minimum, sufficient air for an orderly plant shutdown, including Safe Shutdown Earthquake and Maximum Possible Flood. Only the auxiliary air systems are considered to be Engineered Safety Features. For detailed description see Subsection 9.3.1.

1.2.2.15 Engineered Safety Features

Several Engineered Safety Features have been incorporated into the plant design to reduce the consequences of a loss-of-coolant accident. One of these safety features is an Emergency Core Cooling System (ECCS) which automatically delivers borated water via the cold legs to the reactor core for continued cooling and for negative reactivity insertion following an accidental steam release. Another safety feature which has been included is the Ice Condenser Containment system. Basically, this system provides for very rapid absorption of the energy released from the Reactor Coolant System in the improbable event of a loss-of-coolant accident. The energy is absorbed by condensing steam in a low temperature heat sink, consisting of a suitable quantity of ice permanently stored inside the containment. The ice containment system markedly reduces the peak containment pressure that would otherwise result in the event of a loss-of-coolant accident. The peak pressure is reduced to an even lower value within a few minutes. The system also removes radioactive iodine from the containment atmosphere by the action of sodium tetraborate impregnated ice.

There are several other systems which help mitigate the consequences of a LOCA by aiding the systems mentioned above or by the performance of other specific functions. The first of these is the Containment Spray System which sprays cool water into the containment atmosphere to insure that the containment pressure limit is not exceeded. The air return

fans also aid in the operation of the Containment Spray System and the ice condenser by returning to the lower compartment air which is displaced through the ice condenser into the upper compartment. This system also limits hydrogen concentration by ensuring a flow of air in potentially stagnated regions. The containment isolation systems maintain containment integrity by isolating systems that pass through the containment as required. The radioactivity that may be released in the containment will be confined there by this system.

To help reduce radioactive nuclide releases to the atmosphere, this plant is provided with gas treatment systems. The Emergency Gas Treatment System and the Auxiliary Building Gas Treatment System establish and maintain the air pressure below atmospheric in the Shield Building annulus and the Auxiliary Building Secondary Containment Enclosure (ABSCE), respectively. These systems reduce the concentration of radioactive nuclides in the air released from the annulus and the ABSCE.

1.2.2.16 Shared Facilities and Equipment-Safety Related

Separate and similar systems and equipment are provided for each unit of the two unit Sequoyah Nuclear Plant when required. In certain instances, systems or some components of a system are shared by both units. A common control room and Auxiliary Building is provided with shared HVAC and air cleanup systems. Other principal components/systems which are shared are identified below.

System	Components Shared	Quantity Provided
Chemical and Volume	Boric Acid Tanks	3
Control System	Boric Acid Transfer Pumps	4
Component Cooling System	Pump	Total of 5, up to 3 shared
	Heat Exchangers	Total of 6- two are shared.
Spent Fuel Pit Cooling System	Spent Fuel Pit	1
	Spent Fuel Pit Pumps	3
	Spent Fuel Pit Filter	1
	Spent Fuel Pit Heat Exchanger	2
	Refueling Water Purification Pumps	2
	Refueling Water Filters	2
Waste Disposal System	A common Waste Disposal System is used for the two units. Each containment structure has its own reactor coolant drain tank and containment sump and each is serviced by two reactor coolant drain tank pumps. All other waste disposal equipment is sized to or contracted to adequately serve two units and common Auxiliary and Service Building.	

System	Components Shared	Quantity Provided
Emergency Gas Treatment Systems and Air Cleanup Systems	Portions of the Air Cleanup Subsystem of the Gas Treatment Systems shared components include ducting, air purification filter and absorbers, fans and flow control dampers.	
Essential Raw Cooling Water System	The water supply and distribution system is essentially common to both units.	
Standby AC power System	The Standby AC Power System supplies power to both units.	
Vital 125V DC Control Power System	Four 125V Vital Batteries and Boards, each supply two static inverters of the Vital 120V AC Control Power system on each unit. Each channel has a spare inverter which can be manually aligned to replace the Unit 1 or Unit 2 Inverter. A spare vital battery is also provided as needed.	
Offsite Power System (Preferred Power Supply)	The offsite power grid serves as the preferred power supply for both units.	

1.2.3 General Arrangement of Major Structures and Equipment

The major structures are two Reactor Buildings, a Turbine Building, Auxiliary Building, a Control Building, a Service and Office Building, a Diesel Generator Building, an Intake Pumping Station, ERCW Pumping Station, two natural draft Cooling Towers, and an Independent Spent Fuel Storage Installation (ISFSI) (Section 9.1.5). The arrangement of these structures is shown in Figure 2.1.2-1. Plant arrangement plans and cross sections are presented in Figures 1.2.3-1 through 1.2.3-19.

TABLE 1.3.2-1 (Sheet 1)

MAJOR DESIGN CHANGES SINCE SUBMITTAL OF THE PSAR

System	Reference Section	Changes
Containment	3.8.2	The steel containment was modified as a result of analyses to include stiffeners in both the vertical and horizonal directions.
Fuel	4.2.1	The reactors will be fueled with 17 x 17 fuel assemblies in lieu of 15 x 15 fuel assemblies.
Reactor Internals	4.2.2	The reactor internals have been modified to accept 17 x 17 fuel assemblies.
Reactor	5.0	The Unit 1 and Unit 2 Steam Generators have been replaced.
	5.5.15	A Reactor Vessel Head Vent System has been provided.
Containment Ice Condenser	6.2	Design of the following has been modified: (1) Ice Baskets (2) Lower inlet door and hinges (3) Lower support structure (4) Lattice Frames (5) Lattice frame support columns (6) Wall panels (7) Intermediate deck doors (8) Top deck doors (9) Air handling unit supports (10) Top deck beams (11) Ice Condenser crane, crane rail, and supports (12) Stud material and diameter in containment, end walls, and crane wall (13) Number of air handling units (14) Number of refrigeration packages and associated hardware The following have been deleted: (1) Floor air-cooling duct (2) Access platform to lower inlet doors

TABLE 1.3.2-1 (Sheet 2)

MAJOR DESIGN CHANGES SINCE SUBMITTAL OF THE PSAR

System	Reference Section	Changes
Containment (Cont.)		The following have been added: (1) Ice basket tie-down (2) Lattice frame tangential-tie-member (3) Closer spacing of lattice frames (4) Lower inlet door arrester (5) Turning vanes on lower support structure and floor (6) Jet impingement plate (7) Foam concrete in floor (8) Glycol cooling of floor (9) Defrosting capability of wall panels and floor (10) Floor support columns (11) Wall panel cradle (12) Rounded entrance to lower doors
Containment		Carbon absorbers added to containment purge exhaust.
		The pressure vessels of the containment spray heat exchangers will conform to ASME Boiler and Pressure Vessel Code, Section VIII.
	6.2.5	Electric recombiners for post LOCA hydrogen control have been added.
	6.2.4	A Reactor Vessel Level Indicating System has been provided.
	6.2.6	A containment vacuum relief system has been added to limit pressure differential across the steel containment vessel.

TABLE 1.3.2-1 (Sheet 3)

MAJOR DESIGN CHANGES SINCE SUBMITTAL OF THE PSAR

System	Reference Section	Changes
Emergency core cooling System	6.3	Safety injection pumps will normally inject into the four cold legs of the reactor coolant system but provision for injection into the hot legs has been retained.
		An UHI Accumulator System was added and the Reactor head and internals modified. The UHI system was later deleted.
Cables	7.1.2, 8.3.1.2	Tray loading has been modified to 30 percent of the cross-section area for low-voltage power trays (except when a single layer of cables are used) and to 60 percent for control and instrument cables trays to reflect current design practices (unless evaluated as a design criteria exception).
Instrument & Controls	7.1	The process protection system has been replaced by a Westinghouse Eagle 21 System.
		The Main Control Room has undergone a Control Room Design Review and layout modifications.
Reactor trip system	7.2	Protection system logic design has been changed from relay to solid state.
Engineered safety features	7.3	Increased online testability has been provided for the Engineered Safety Features.
Onsite AC power	8.3.1	A fourth diesel generator has been added to the plant.
		The capacity of each diesel generator has been increased.
Onsite DC power	8.3.2	The two 250-volt battery systems have been replaced by four 125-volt battery systems shared between the two nuclear generating units to achieve greater diversity of the onsite dc power supplies. A fifth vital battery has been added as a spare.

TABLE 1.3.2-1 (Sheet 4)

MAJOR DESIGN CHANGES SINCE SUBMITTAL OF THE PSAR

System	Reference Section	Changes
Component cooling	9.2.1	During normal full power operation with maximum spent fuel pit cooling available, two CCS pumps and one heat exchanger pair may be required for the unit assigned the spent fuel pit load and one CCS pump and heat exchanger pair for the other unit. It was indicated in the PSAR that two pumps and one heat exchanger were capable of serving all operating components in both units, but that two pumps and heat exchangers would normally be operated. Two CCS pumps and one heat exchanger pair and not three CCS pumps and two heat exchanger pairs may be required to remove the residual and sensible heat load plus the aligned component loads for minimum cooldown rate. However, unit cooldown operations design allows assignment of a pump and heat exchanger pair to each train of the safeguards systems thereby increasing cooldown capability. Normal alignment of the CCS has been changed to assure two independent trains of cooling. Automatic actuation has been added to start any standby pumps on the normally operating headers to help assure a continuous supply of cooling water to all loads. The following equipment is no longer served by the CCS: (1) Reactor coolant pump bearing coolers (2) Reactor vessel supports (3) Safety injection pump oil coolers (4) Charging pump oil coolers

TABLE 1.3.2-1 (Sheet 5)

MAJOR DESIGN CHANGES SINCE SUBMITTAL OF THE PSAR

System	Reference Section	Changes
Component Cooling (cont)	9.2.1 (cont)	The following equipment is served by the CCS: (1) Reactor coolant pump thermal barriers and motor oil coolers (2) Residual heat removal pump seal water heat exchangers (3) Safety injection pump mechanical seal coolers (4) Charging pumps mechanical seal coolers (5) Waste gas compressors The water temperature detectors have been repositioned to the outlet of each heat exchanger pair or heat exchanger group and to the main return headers to the CCS pumps. Radiation monitors have been provided at each CCS heat exchanger pair outlet. Four booster pumps (two per unit) have been included to provide the additional head necessary to overcome the high head loss through the RCS thermal barriers. A seal collection station has been provided to collect seal leakage from the CCS pumps. The three shell and tube CCS HTXs have been replaced by six plate heat exchangers.

TABLE 1.3.2-1 (Sheet 6)

MAJOR DESIGN CHANGES SINCE SUBMITTAL OF THE PSAR

System	Reference Section	Changes
Spent fuel storage pool	9.1.2	The pool in the Auxiliary Building has been modified by the addition of a concrete wall separating the cask set down area from the fuel area to protect the spent fuel from an accidental drop of the cask. The storage capacity of the spent fuel pool has increased.
	9.1.3	The volume of the pool has been modified.
Essential raw	9.2.2	A new ERCW pump station has been provided. The AERCW system has been deleted. The auxiliary charging pumps and auxiliary letdown heat exchangers are no longer served by the ERCW system. The reactor coolant pump motor coolers and the control rod drive motor coolers are additional equipment served by the ERCW system. Sodium hypochlorite can be injected into the ERCW system in the pumping station ERCW pump compartment to control Asiatic clams.
Demineralized	9.2.3	A new makeup water treatment was provided and a Contractor supplied source of makeup water can be provided.
Auxiliary control air	9.3.1	Credit is now taken for auxiliary air system as a safety feature.

TABLE 1.3.2-1 (Sheet 7)

MAJOR DESIGN CHANGES SINCE SUBMITTAL OF THE PSAR

System	Reference Section	Changes
Heating, ventilation, and air conditioning	9.4.1	Two redundant emergency cleanup air supply fans have been provided to recirculate a portion of the main control room air through the HEPA-charcoal filter trains during control room isolation.
		A capability to isolate major sections of the Auxiliary Building during emergencies and keep it at a slight negative pressure is provided.
	9.4.7	An annulus vacuum control subsystem was included in the emergency gas treatment system to continuously maintain the Shield Building annulus space at a negative pressure during plant operation.
Fire Protection	9.5.1	$C0_2$ storage has been moved outside the Control Building.
Post Accident Sampling Facility	9.5.10	A post accident sampling facility has been provided.
Main steam supply	10.3	32” OD piping has been used instead of the 33” ID indicated in the PSAR.
Main condenser evacuation	10.4.2	An optional HEPA filter-charcoal adsorber system was provided to restrict radioactive effluents to a level as low as practicable.
Condenser circulating water	10.4.5	Cooling towers and a cooling tower supply pumping station have been provided.

TABLE 1.3.2-1 (Sheet 8)

MAJOR DESIGN CHANGES SINCE SUBMITTAL OF THE PSAR

System	Reference Section	Changes
Condensate-feedwater	10.4.7	Bypass feedwater regulator valves have been included to provide additional feedwater stability during startup conditions. A motor-operated feedwater isolation valve in the piping to each steam generator was included to provide redundant valve closure in feedwater isolation signal. This system has been modified to provide the capability of restoring 85 percent of the feedwater flow to the steam generators within 20 seconds after the loss of a main feed pump by: (1) Increasing rated speed of drive turbine, and (2) Starting all auxiliary feedwater pumps. The main feed pump turbine condenser cooling is performed by the condensate instead of the raw water as indicated in the PSAR. Secondary side heat exchanger components have undergone a copper reduction program.
Auxiliary Feedwater Systems	10.4.8	A steam driven turbine auxiliary feedwater pump system has been added to each unit. Redundant and independent isolation valves have been added to guard against a loss of auxiliary feedwater during a major accident.

TABLE 1.3.2-1 (Sheet 9)

MAJOR DESIGN CHANGES SINCE SUBMITTAL OF THE PSAR

System	Reference Section	Changes
Heater, drains, and vents	10.4.9	The Unit Main Turbine Generator will receive a signal to run the unit back to approximately 78% (Unit 2) and 76.6% (Unit 1) if: load (a) either No. 3 Heater Drain Tank bypass valve is open, (b) the main turbine generator is loaded to greater than 83%, (Unit 2) and 81.6% (Unit 1) and (c) after receiving a delayed indication of low flow from the discharge header of the No. 3 Heater Drain Tank Pumps.
		Additional logic has been provided to close level control valve at No. 3 heater drain pump discharge on loss of one drain pump to protect the remaining operating pumps when required.
Waste disposal	11.2	The drains have been segregated into tritiated and non-tritiated systems.
	11.3	Holdup time for the gaseous waste system has been increased to 60 days.
	11.2	Provisions have been made to supply nitrogen to the steam generators when they are drained to inert them.
		A mobile waste system is provided as needed to process radwaste.

1.4 IDENTIFICATION OF AGENTS AND CONTRACTORS

The Westinghouse Electric Corporation contracted the design and fabrication of NSSS components at the Sequoyah Nuclear Plant including the two reactors. In addition, they supplied the initial fuel loading. TVA has also contracted with Framatome for replacement core fuel starting with the Cycle 9 reloads for both units. TVA contracted with Westinghouse Electric Company, Combustion Engineering Nuclear Power LLC for the design and fabrication of replacement steam generators (RSG) on Unit 1and Unit 2. Removal and installation construction work associated with the Unit 1 RSG’s was performed by Bechtel. Removal and installation construction work associated with the Unit 2 RSG’s was performed by SGT LLC. TVA's Nuclear Engineering Group (formerly the Division of Engineering Design (EN DES) in the Office of Engineering Design and Construction) had the responsibility for the design of the remainder of the plant plus additional design changes as they became necessary. TVA's Nuclear Construction Group (formerly the Division of Construction in the Office of Engineering Design and Construction) had the responsibility for construction of the plant. TVA Nuclear has the responsibility for operating the plant.

TVA utilizes consultants, as necessary, to perform selected design work and to obtain specialized services. Weston Geophysical Engineering, Inc., was contracted to assist in soil foundation dynamic analyses. Engineering Data Systems, Inc., of San Francisco, assisted in seismic analysis of piping. Chicago Bridge and Iron Company, Chicago, Illinois, was contracted to design and construct the free standing steel containments for both units. Certification of material used for containment flexible seals to withstand extreme radiation and temperature conditions was done by the Presray Corporation, Pawling, New York.

1.5 REQUIREMENTS FOR FURTHER TECHNICAL INFORMATION

The design of the Sequoyah Nuclear Plant is based upon proven concepts which have been developed and successfully applied to the design of pressurized water reactor systems.

The term "research and development" as used in this section is the same as that used by the Commission in Section 50.2 of 10 CFR Part 50 as follows:

(n) "Research and development" means (1) theoretical analysis, exploration or experimentation; or (2) the extension of investigative findings and theories of a scientific nature into practical application for experimental and demonstration purposes including the experimental production and testing of models, devices, equipment, materials and processes."

The research and development discussed in the FSAR is to confirm the engineering and design values normally used to complete equipment and system designs. It does not involve the creation of new concepts or ideas.

The technical information generated by these research and development programs are used either to demonstrate the safety of the design and more sharply define margins of conservatism, or to lead to design improvements.

Each research and development program is briefly summarized for identification and its relationship to the Sequoyah Nuclear Plant is discussed. Detailed discussions of each program are available in a more expanded summary form in the references incorporated throughout this section.

Information regarding the Mark-BW fuel assembly is provided in the referenced Topical Reports in Section 1.6 and the text in Chapter 4.5.

1.5.1 Programs Required for Plant Operation

In the PSAR, the following programs were identified as required for plant design and operation:

1. Core Stability Evaluation (Item 1 in Reference 1)

The purpose of this program was to establish means for the detection and control of potential xenon oscillations and for the shaping of the axial power distribution for improved core performance. The research and development portions of this program have been completed, as discussed below.

The development program for power distribution control is divided into four general areas, namely:

a. Confirmation of the capability of the out-of-core detector system to indicate axial and diametrical gross core power distributions sufficiently to permit control of xenon oscillations within specified operating limits.

b. Development of a control system utilizing the out-of-core detector system for axial power shaping (such a system is used in the Robert Emmett Ginna, Indian Point Unit 2, and all subsequent Westinghouse reactors).

c. Verification, during startup tests of other Westinghouse reactors, that the control system specified in Item b can control the core power distribution.

d. Verification that adequate margin exist to operate the Sequoyah Nuclear Plant at the licensed power rating by measurements taken during prior operation of other Westinghouse reactors.

Items a and b of this program have been completed satisfactorily. Items c and d were evaluated on Westinghouse reactors going into operation prior to the Sequoyah Nuclear Plant. These include Donald C. Cook Units 1 and 2 (Docket Nos. 50-315 and 50-316), Zion Units No. 1 and 2 (Docket Nos. 50-295 and 50-304) and Trojan (Docket No. 50-344).

Safe operation at the design power level experimentally demonstrated, at the time of Sequoyah's initial startup, that the actual power shapes at full power are no worse than those used in the calculation of core integrity. The analytical model used to predict these power shapes has been justified by these and earlier measurements.

2. Fuel Rod Burst Program (Item 2 in Reference 1)

The original rod burst program, a study of the performance of Zircaloy cladding under simulated loss-of-coolant accident (LOCA) conditions, has been completed. It has supplied empirical data from which the effect of geometry distortion on the ability of the emergency core cooling system (ECCS) to meet the LOCA design criteria has been determined using present analytical design techniques.

The program included burst and quench tests on single rods and burst tests on rod bundles. As a result of single rod tests, specific design limits have been established on peak clad temperature and allowable maximum metal-water reaction to assure effective core cooling. The multi-rod burst tests demonstrated that even when rod-to-rod contact does occur after burst, the remaining flow area is always sufficient to ensure adequate core cooling.

The single rod burst test program for the 17 x 17 fuel pin array is discussed in Section 1.5.5.3.

3. Ice Condenser Containment Program (Item 4 in Reference 1)

In order to confirm the functional adequacy and the structural integrity of the designed ice condenser components, an extensive test program was performed. This program confirmed the prototype design, and was validated by additional confirmatory tests on selected production components.

A summary of the completed test program is presented below, the results of which are reported in the indicated References.

Title	Reference
ICE BASKET TESTS	
Static Load Test of Ice Basket	2, 8, 10
Failure Load Test of Ice Basket	2
Dynamic Load Test of Ice Basket	2
Ice Fallout from Seismic Loading	9
Stress Analysis Report	8
WALL PANEL TESTS	
Wall Panel Leak Test	2
Wall Panel Radial Load Test	2
Wall Panel Shear Test	2
LATTICE FRAME TESTS	
Lattice Frame Load-Deflection Test	2
LOWER INLET DOOR TESTS	
Lower Inlet Door Dynamic Load Test	3
Lower Inlet Door Heat Transfer and Leak Rate Test	4
Lower Inlet Door Shock Absorber Dynamic Tests	5, 6
TOP DECK DOOR TESTS	
Dynamic Load Tests	4, 6
INTERMEDIATE DOOR TESTS	
Intermediate Door Dynamic Test	5
PERFORMANCE TESTS	
Full Scale Section Test	7, 11, 12, 14
ICE TECHNOLOGY	
Iodine Removal Effectiveness	13

1.5.2 Programs Not Required for Plant Operation

Other areas of research and development, as outlined below, are those which give added confirmation that the designs are conservative.

1.5.2.1 Burnable Poison Program (Item 7 in Reference 1)

Burnable poison rod program is complete. The burnable poison rods are borosilicate glass encased in stainless steel tubes. The fixed rods are used in the first core to reduce the concentration of boric acid poison in the moderator, thereby ensuring that the moderator coefficient of reactivity is always negative at operating temperature.

1.5.2.2 Fuel Development Program for Operation at High Power Densities (Item 8 in Reference 1)

To demonstrate satisfactory operation of fuel at high burnup and power densities, and to define design margins, a program was designed to test fuel in both the Saxton and Zorita reactors. The Saxton loose-lattice irradiation program was designed to demonstrate fuel performance at conditions significantly in excess of PWR design limits, and would establish power burnup limits for the fuel. The Zorita reactor is the first PWR with a Zircaloy core to operate at similar core conditions as the current design units. Because of the timely manner in which fuel can be irradiated in Zorita, four fuel assemblies are being tested there to demonstrate satisfactory operation of the fuel in a commercial PWR environment.

Sustained successful operation of special Zorita fuel rods at peak design power levels, in excess of those planned for the Sequoyah Nuclear Plant, will increase assurance that the fuel has adequate performance margins to accommodate transient overpower operation.

The Saxton Loose Lattice Irradiation and Saxton Parametric Irradiation subprograms have been completed. It is concluded that the loose lattice program has satisfactorily completed the test objective. The work of the loose lattice assemblies was partly performed under USAEC Contract AT (11-1)-3044 and has been reported on a quarterly basis (Reference 15); a fuel materials performance report has been published (Reference 16).

1.5.2.3 FLECHT (Full Length Emergency Core Cooling Heat Transfer Test) (Item 12 in Reference 1)

The objective of the FLECHT program was to obtain experimental reflooding heat transfer data under simulated loss-of-coolant accident conditions for use in evaluating the heat transfer capabilities of pressurized water reactor emergency core cooling systems. The test results verified the ability of a bottom flooding ECCS design to terminate the temperature increase during a LOCA. The LOCA evaluation presented in this application utilizes the results of the FLECHT Program for the analysis of the reflooding phase of the accident.

1.5.2.4 Loss of Coolant Analysis Program (Item 14 in Reference 1)

This program has been completed with the results of the Flashing Heat Transfer Program (Item 13 in Reference 1) being incorporated in the core thermal design codes used in the LOCA analysis presented in this application.

The loss of coolant analysis program was established to integrate, as appropriate, the more realistic heat transfer models obtained from experimental and analytical development programs into the core thermal design codes used to evaluate the loss-of-coolant accident.

1.5.2.5 Reactor Vessel Thermal Shock (Item 16 in Reference 1)

The effects of safety injection water on the integrity of the reactor vessel following a postulated loss-of-coolant accident, has been analyzed using data on fracture toughness of heavy section steel both at beginning of plant life and after irradiation corresponding to approximately 40 years of equivalent plant life. The results show that under the postulated accident conditions, the integrity of the reactor vessel is maintained.

Fracture toughness data are obtained from a Westinghouse experimental program which is associated with the Heavy Section Steel Technology (HSST) Program at ORNL and from Euratom programs. Since results of the analyses are dependent on the fracture toughness of irradiated steel, efforts are continuing to obtain additional confirmatory data. Data on two-inch thick specimens became available in 1970 from the HSST Program. Their data indicated a strong temperature dependence with a rapid increase in toughness at approximately NDT. For results obtained in the HSST Program, the HSST Semiannual Progress Report, issued by the Oak Ridge National Laboratory (quarterly, beginning in 1974), should be consulted.

1.5.2.6 Blowdown Forces Program (Item 15 in Reference 1)

The objective of the Blowdown Forces Program was to develop a digital computer program for the calculation of pressure, velocity, and force transients in the Reactor Coolant System during a loss-of-coolant accident, and to utilize this code in the calculation of blowdown forces on the fuel assemblies and reactor internals to ensure that the stress and deflection criteria used in the design of these components are met.

Westinghouse has completed the development of BLODWN-2, an improved digital computer program for the calculation of local fluid pressure, flow and density transients in the Primary Coolant System during a loss of coolant accident.

Extensive comparisons have been made between BLODWN-2 and test data. Agreement between code predictions and data has been good.

Analyses using the BLODWN-2 Program to evaluate the effects of Blowdown Forces are presented in Section 3.9 of the Sequoyah FSAR. It was concluded from the analysis that the design of this reactor meets the established design criteria. The validity of the BLODWN-2 Code has been demonstrated, therefore the program is considered to be complete.

1.5.3 17 x 17 Fuel Assembly Verification Tests (Item 23 in Reference 1)

A comprehensive test program for the 17 x 17 assembly has been successfully completed by Westinghouse. Reference 1 contains a summary discussion of the program.

Some of the verification work described herein was conducted using 17 x 17 assemblies of seven grid design whereas the selected 17 x 17 assembly design has eight grids. Tabulated below are those 17 x 17 tests which utilized a seven grid geometry and the effect of adding an eighth grid.

Test	Parameter	Effect
Fuel Assembly Structural Test	Axial Stiffness	Negligible effect at blowdown Structural Test impact forces (Reference 17)
	Lateral Impact	Additional grid shares impact load (Reference 17)

Test	Parameter	Effect
Prototype Assembly Test	Pressure Drop	The margin between 7 grid design ∆P and D loop results (Reference 18) is adequate to cover the additional ∆P resulting from the additional grid (< 5% increase in ∆P).
	Lift Force	The margin between 7 grid design lift force and D loop results (Reference 18) is adequate to cover the additional lift force resulting from the additional grid.
	Rod Vibration	Decreased span length results in improved vibration characteristics and reduced rod wear.
Departure from Nucleate Boiling	DNB Correlation	Addition of a grid increases mixing which increases DNB margin
Incore Flow Mixing	TDC	TDC increases as grid spacing decreases (Reference 19)

The above tabulation shows that (1) additional design changes are not required (e.g. no new fuel assembly holddown spring) due to the addition of a grid and (2) seven grid test information can be used to assess the adequacy of the eight grid design. Additional testing to specifically investigate the eight grid assembly is not required.

1.5.3.1 Rod Cluster Control Spider Tests

The 17 x 17 rod cluster control (RCC) spider is conceptually similar to, but geometrically different from the 15 x 15 spider. The 17 x 17 spider supports 24 rodlets (the 15 x 15 design supports 20) with no vane supporting more than two rodlets (same as the 15 x 15 design). The RCC spider tests verified the structural adequacy of the design.

The RCC Spider tests have been completed. A vertical static load test approximately seven times the design dynamic load did not result in spider vane to hub joint failure. A spider was tested to 2.8 x 106 steps without failure. The spider loading was 110% of the design value for 1.8 x 106 cycles and 220% of the design loading for 1 x 106 cycles. Design load is 3600 pounds compression and 1800 pounds tension. The spring test resulted in negligible preload loss.

1.5.3.2 Grid Tests

The 17 x 17 grid is conceptually similar but geometrically different from the 15 x 15 "R" grid. The purpose of the grid tests is to verify the structural adequacy of the grid design.

The grid tests have been completed. Test results are in agreement with pretest design values. The test results, along with fuel assembly structural test results, were factored into the seismic analysis (Reference 17).

1.5.3.3 Fuel Assembly Structural Tests

The 17 x 17 fuel assembly tests were performed to determine mechanical strength and properties. The fuel assembly parameters obtained were as follows: lateral and axial stiffness, impact and internal structural damping coefficients, vibrational characteristics and the lateral and axial impact response for postulated accident loads. The parameters obtained from the lateral dynamic tests are used for seismic analysis, while those obtained from the axial tests are incorporated in the loss-of-coolant (blowdown) accident analysis.

There is a general axial test buckling criterion which does not allow local buckling of components which could preclude control rod insertion during an accident. The fuel assembly overall buckling and component local buckling is checked during the axial static and dynamic tests. The lateral displacement associated with the fuel assembly overall (beam type) buckling is constrained by the reactor internals and therefore does not reduce the fuel assembly ultimate strength. Local component buckling was not experienced during either the static or dynamic tests for loads well in excess of the design values. The general acceptance was not violated. These tests were completed at the Westinghouse Engineering Mechanics Laboratory. A general description of the test procedure, including a description of use of the parameters as related to seismic and blowdown is presented in Reference 17.

1.5.3.4 Guide Tube Tests

To verify the structural adequacy of the guide tubes, an extensive series of tests were conducted to determine guide tube deflection with simulated blowdown forces comparable to those expected during a loss-of-coolant accident and to determine the maximum acceptable deflection which assures insertion of a control rod by free fall. Additional tests were conducted to determine fatigue strength, displacement as a function of strain and the natural frequencies of the guide tubes for use in dynamic analyses. Refer to References 19 and 20 for a discussion of these tests.

1.5.3.5 Prototype Assembly Tests

The purpose of these tests was to demonstrate that the 17 x 17 fuel assembly and control rod hardware designs will perform as predicted. Two prototype assemblies were sequentially tested in order to obtain the required experimental data. A single set of control rod hardware, including driveline, was used in the tests. The fuel assemblies were subjected to flow and system conditions covering those most likely to occur in a plant during normal operation as well as during a pump overspeed transient. Seismic testing is not included in the test sequence.

These tests were used to verify the integrated fuel assembly and RCC performance in several areas. Data obtained included pressures and pressure drops throughout the system, hydraulic loadings on the fuel assembly and drive line, control rod drop time and stall velocity, fuel rod vibration and control rod, drive line, guide tube, and guide thimble wear during a lifetime of operation.

The D-Loop testing has been completed. The results of the testing are given in Reference 18.

1.5.3.6 Departure from Nucleate Boiling (DNB)

The effect of the 17 x 17 fuel assembly geometry on the DNB heat flux has been determined experimentally and has been incorporated in a modified spacer factor for use with the W-3 correlation. The effect of cold-wall thimble cells in the 17 x 17 geometry has also been quantified.

A similar program was conducted to quantify the DNB performance of the R-type mixing vane grid as developed for the 15 x 15 fuel assembly design (References 21 and 22). The results of that program were used to develop a modified spacer factor which quantifies the power capability associated with the use of the R mixing vane grid as well as the change in power capability due to the axial spacing of the grids. The modified spacer factor, along with the W-3 correlation with the cold-wall factor, was shown to be applicable to cold-wall thimble cells in the 15 x 15 geometry (Reference 22).

The program has been completed and the results are reported in Reference 23.

1.5.3.7 Incore Flow Mixing

In the thermal-hydraulic design of a reactor core, the effect of mixing or turbulent energy transfer within the hot assembly is evaluated using the THINC code. The rate of turbulent energy transfer is formulated in the THINC analysis in terms of a thermal diffusion coefficient (TDC).

A program (Reference 19) to determine the proper value of TDC for the R grid vane, as used in the 15 x 15 fuel assembly design, has been completed and showed that a design value of 0.038 (for 26 inch spacing) can be used for TDC. These results also showed that TDC was independent of Reynold's number, mass velocity, pressure, and quality over the ranges tested.

A similar TDC experimental program employed a geometry typical of the 17 x 17 fuel assembly to determine the effects of the geometry on mixing and to determine an appropriate value for TDC. A uniform axial heat flux was used. There is no analytical reason to expect that the mixing coefficient would be affected by a non-uniform axial heat flux. The THINC computer code considers the mixing in each increment along the heated length and within that increment the heat flux is considered uniform. The tests reported by Cadek (Reference 24) indicate that there was no difference, within experimental accuracy, between a test section with a uniform flux (Pitt) and one half of a cosine flux (Columbia). The heat flux will vary between the simulated fuel rods in the test section to create a thermal gradient in the radial direction. Using different flow rates and inlet temperatures, the TDC for the 17 x 17 geometry will be determined.

The TDC tests are completed and the results are reported in Reference 25.

1.5.4 Inpile Fuel Densification (Item 22 in Reference 1)

Operating experience with uranium dioxide fuel has indicated that the fuel may densify under irradiation, to a greater density than that to which it was manufactured. This densification can lead to shorter active fuel length stacks, increased initial rod-to-clad radial gaps, and pellet-to-

pellet axial gaps. The shorter fuel stack length gives rise to a small increase in overall, average linear power density (kW/ft). Increased radial gap dimensions result in reduced gap conductance and lead to higher pellet temperatures. Axial gaps give rise to local power peaking due to decreased neutron absorption.

Westinghouse fuel densification research was directed toward producing fuel with a structure which minimizes inpile densification (hereafter called stable fuel). The objective of the program was to define material characteristics and manufacturing processes which lead to stable fuel. Stable fuel is defined as fuel whose densification is small. Residual effects of densification were evaluated on a model developed by this program. A more detailed description of the program and results is presented in Reference 26.

1.5.5 LOCA Heat Transfer Tests (17 x 17)

Extensive experimental programs have been completed to determine the thermal hydraulic characteristics of 15 x 15 fuel assemblies, and to obtain experimental heat transfer data under simulated loss-of-coolant accident conditions.

Complementary experimental programs were completed with a simulated 17 x 17 assembly to determine its behavior under similar loss-of-coolant accident (LOCA) conditions.

Results from the 17 x 17 programs were compared with data from the 15 x 15 assembly test programs and were used to confirm predictions made by correlations and codes based on the 15 x 15 test results. Refer to Reference 27 for a more detailed discussion of these results.

1.5.5.1 Blowdown Heat Transfer Testing (Formerly Titled Delayed Departure From Nucleate Boiling)

The NRC Acceptance Criteria for Emergency Core Cooling Systems for Light-Water Power Reactor was issued in Section 50.4. of 10 CFR 50 on December 28, 1973. It defines the basis and conservative assumptions to be used in the evaluation of the performance of Emergency Core Cooling Systems (ECCS). Westinghouse believes that some of the conservatism of the criteria is associated with the manner in which transient DNB phenomena are treated in the evaluation models. Transient critical heat flux data presented at the 1972 specialists meeting of the Committee on Reactor Safety Technology (CREST) indicated that the time to DNB can be delayed under transient conditions. To demonstrate the conservatism of the ECCS evaluation models, Westinghouse initiated a program to experimentally simulate the blowdown phase of a LOCA. This testing is part of the Electric Power Research Institute (EPRI) sponsored Blowdown Heat Transfer Program, which was started early in 1976. Testing was completed in 1979. A DNB correlation will be developed by Westinghouse from these test results for use in the ECCS analyses.

Objective

The objective of the Blowdown Heat Transfer Test was to determine the time that DNB occurs under LOCA conditions. This information will be used to confirm the existing, or develop a new Westinghouse transient DNB correlation. The steady state DNB data obtained from 15 x 15 and 17 x 17 test programs can be used to assure that the geometrical differences between the two fuel arrays can be correctly treated in the transient correlations.

Program

The program was divided into two phases. The Phase I tests started from steady state conditions, with sufficient power to maintain nucleate boiling throughout the bundle, controlled ramps of decreasing test section pressure or flow initiated DNB. By applying a series of controlled conditions, investigation of the DNB was studied over a range of qualities and flows, and at pressures relevant to a PWR blowdown.

Phase I provided separate-effects data for heat transfer correlation development.

Typical parameters used for Phase I testing are shown below.

Parameters	Nominal Value
Initial Steady State Conditions	
Pressure	1250 to 2250 psia
Test section mass velocity	1.12 to 2.5 x 10^6 lb/hr-ft^2
Core inlet temperature	550 to 600°F
Maximum heat flux	306,000 to 531,000 Btu/hr-ft^2
Transient Ramp Conditions	
Pressure decrease depressurization from 2250 psia	0 to 350 psi/sec and subcooled
Flow decrease	0 to 100 percent/sec
Inlet enthalpy	Constant

Phase II simulates PWR behavior during a LOCA to permit definition of the time delay associated with onset of DNB. Tests in this phase covered the large double-ended guillotine cold leg break. All tests in Phase II were also started after establishment of typical steady state operating conditions. The fluid transient was then initiated, and the rod power decay was programmed in such a manner as to simulate the actual heat input of fuel rods. The test was terminated when the heater rod temperatures reach a predetermined limit.

Typical parameters used for Phase II testing are shown below.

Parameter	Nominal Value
Initial Steady State Conditions	
Pressure	2250 psia
Test section mass velocity	2.5×10^6 lb/hr-ft^2
Inlet coolant temperature	545°F
Maximum heat flux	531,000 Btu/hr-ft^2
Transient Conditions	
Simulated break	Double-ended cold leg guillotine breaks

Test Description

The experimental program was conducted in the J-Loop at the Westinghouse Forest Hills Facility with a full length 5 x 5 rod bundle simulating a section of a 15 x 15 assembly to determine DNB occurrence under LOCA conditions.

The heater rod bundles used in this program were internally-heated rods, capable of a maximum power of 18.8 kW/ft, with a total power of 135 kW (for extended periods) over the 12-foot heated length of the rod. Heat was generated internally by means of a varying cross-sectional resistor which approximates a chopped cosine power distribution. Each rod was adequately instrumented with a total of 12 clad thermocouples.

1.5.5.2 Results

The experiments in the DDNB Facility resulted in cladding temperature and fluid properties measured as a function of time throughout the blowdown range from 0 to 20 seconds.

Facility modifications and installation of the initial test bundle were completed. A series of shakedown tests in the J-Loop were performed. These tests provided data for instrumentation calibration and check-out, and provided information regarding facility control and performance. Initial program tests were performed during the first half of 1975. Under the sponsorship of EPRI, testing was reinitiated during 1976 on the same test bundle. The testing was terminated in November and plans were made for a new test bundle and further testing during 1978-1979. These tests were completed in December of 1979. A DNB correlation will be developed from these test results for use in Westinghouse ECCS analyses.

1.5.5.3 Single Rod Burst Test (SRBT)

The single rod burst test results were used to quantify the maximum assembly flow blockage which is assumed in LOCA analyses.

The single rod burst test program for the 17 x 17 fuel assembly rods consisted of testing specimens, at the two internal pressures and the three heating rates listed below in a steam atmosphere.

Heating Rate (725°F to 1940°F)	Internal Pressure psi
5°F/sec	1200, 1800
25°F/sec	1200, 1800
100°F/sec	1200, 1800

All specimens were then heated 5°F/sec from 1940°F to about 2300°F, held for a short time and then cooled 5°F/sec to 1200°F.

Metallography was done on specimens to determine the degree of wall thinning and the extent of oxygen embrittlement.

In addition, tests were run on 15 x 15 fuel assembly rods to insure reproducibility of the 1972 single rod burst test results.

The single rod burst tests are complete. The tests showed that the LOCA behavior of 17 x 17 clad in comparison to that of 15 x 15 clad exhibited no significant differences in failure ductility. Because of the results and the geometric scaling, the flow blockage as determined by 15 x 15 MRBT simulation can be used for 17 x 17 fuel geometry.

1.8 TECHNICAL QUALIFICATIONS OF APPLICANT (HISTORICAL)

The TVA power system is one of the largest in the United States with hydro, fossil and nuclear generating capability. TVA is primarily a wholesaler of power, operating generating plants, and transmission facilities, but no retail distribution systems. The TVA transmission system contains over 17,000 miles of lines. TVA supplies power over an area of about 80,000 square miles in parts of seven southeastern states, containing more than 2.3 million residential, farm, commercial and industrial customers.

The Tennessee Valley Authority has been engaged in the business of designing, constructing, and operating large power-producing hydro and steam units for over 50 years. TVA's technical qualifications to construct and operate Sequoyah units 1 and 2 are evidenced by the skills and experience gained over many years in the power business. This experience is supplemented by the skills and experience of TVA's consultants and its contractors in assisting in the design, construction, and operation of the Sequoyah Nuclear Plant.

TVA acts as its own engineer-constructor and as such has pioneered in erecting large generating units. Examples are the 1,150 megawatt electric (MWe) unit placed in operation at the Paradise Steam Plant; the 1,300 MWe units in operation at the Cumberland Steam Plant; the three 1,100 MWe units at the Browns Ferry Nuclear Plant; and one 1,170 MWe unit at the Watts Bar Nuclear Plant. A total of over 67 individual steam generating units have been designed, constructed, and placed in operation by TVA in the past 35 years.

TVA has an experienced, competent nuclear plant design organization, including a large number of engineers with many years of steam plant experience in the design and construction of large steam plants, including the design of the Browns Ferry (completed), Sequoyah (completed), and Watts Bar (Unit 1 completed), and Watts Bar Unit 2 and Bellefonte Nuclear Plants which are now in a deferred status. Hartsville, Phipps Bend, and Yellow Creek Nuclear Plants have been canceled.

Much of TVA's experience has been gained from early and continuing participation in nuclear power studies. In 1946, TVA took part in the Daniels Power Pile Study at Oak Ridge and the work of the Parker Committee, which surveyed prospects of nuclear power application. In 1953, TVA started developing a nuclear power staff and began a more detailed study of possible uses of nuclear power on its system.

In 1960, TVA agreed to operate the Experimental Gas-Cooled Reactor for the Atomic Energy Commission at Oak Ridge, Tennessee and developed a technical and operating staff. Many of these trained and experienced people were assigned to TVA engineering and operating organizations were directly involved in the planning, design, construction, and operation of the Sequoyah Nuclear Plant.

2.0 SITE CHARACTERISTICS

Chapter 2 provides information on the Sequoyah Nuclear Plant site, its environs and environment, and presents the results of studies that have been made to evaluate the physical characteristics of the site which influence the safety-related design bases of the plant.

The minimum exclusion and low population zone distances as defined by 10 CFR Part 100 are approximately 1825 feet and three miles respectively. The population center distance which is the distance to the nearest corporate limit of the city of Chattanooga, Tennessee, is approximately 7.5 miles southwest.

2.1 GEOGRAPHY AND DEMOGRAPHY

2.1.1 Site Location

The Sequoyah Nuclear Plant is located on a site near the geographical center of Hamilton County, Tennessee, on a peninsula on the western shore of Chickamauga Lake at Tennessee River mile (TRM) 484.5. The coordinates of the plant site are given in Table 2.1.1-1. Figure 2.1.1-1 shows the site in relation to other TVA projects. The Sequoyah site is approximately 7.5 miles northeast of the nearest city limit of Chattanooga, Tennessee, 14 miles west-northwest of Cleveland, Tennessee, and approximately 31 miles south-southwest of TVA's Watts Bar Nuclear Plant. Refer to Figure 2.1.1-2 for the regional features within 50 miles of the site.

2.1.2 Site Description

The Sequoyah Nuclear Plant site comprises approximately 525 acres (land above normal pool elevation of 683.0 ft MSL) which are owned, including mineral rights, by the United States and in the custody of TVA. A general plan of the plant layout is shown in Figure 2.1.2-1. The distance from the reactor building (containment) to the nearest point on the boundary of the exclusion area (minimum exclusion area distance) is approximately 1825 feet (556 meters). The site boundary is considered to be the boundary of the exclusion area.

2.1.2.1 Exclusion Area Control

There are no residences, commercial operations, or public recreational areas within the Sequoyah Nuclear Plant exclusion area boundary shown in Figure 2.1.2-2. The Sequoyah Training Center is within the TVA exclusion area and outside the security barrier. No public railroads or major highways penetrate the exclusion area boundary. Two rural county roads, Igou Ferry and Stonesage, penetrate the western boundary of TVA property and run adjacent to it for a short distance before leaving the site. Igou Ferry Road connects with Hixson Pike which follows the western shore of Chickamauga Lake and joins state route 153 just north of Chickamauga Dam. The plant access road crosses Igou Ferry Road at the exclusion area boundary and eventually connects with US Highway 27 near Soddy-Daisy, Tennessee. TVA has absolute authority for the exclusion of personnel and property within the exclusion area which includes marking of the

boundaries per 10 CFR 73. The control of personnel access to the exclusion area during emergencies is discussed in the Radiological Emergency Plan for the Sequoyah Nuclear Plant.

2.1.2.2 Boundaries for Establishing Effluent Release Limits

The effluent boundary (or unrestricted area boundary) is shown in Figure 2.1.2-2. The boundary of the Unrestricted Area (as defined in 10 CFR 20) is the same as the site boundary, but does not include the area over bodies of water. In accordance with the SQN Technical Specifications, limits for gaseous effluent releases are established for areas at or beyond the unrestricted area boundary using the methodology of the Offsite Dose Calculation Manual (ODCM). The distances from the plant to these areas are listed in Table 11.3.9-1 consistent with the ODCM. Routine releases of radioactivity meet the requirements of 10 CFR 20 and 10 CFR 50, Appendix I.

2.1.2.3 The Restricted Area

An area inside the exclusion area boundary is designated as the Restricted Area (as defined in 10 CFR 20). Access to this area is controlled for the purpose of protection of individuals from exposure to radiation and radioactive materials. The restricted area boundary can be adjusted, or temporary restricted areas established, as necessary, for the purpose of radiation protection.

2.1.3 Population and Population Distribution

Present and projected population information is contained in this section. Population data for 1985 are based on the Provisional Estimates of the Population of Counties, July 1, 1985. Population data for 1990 are based on the "1990 Census of Population" for Tennessee, North Carolina, Georgia, and Alabama. Projected population data are based on "County Projection to 2040" by the Regional Economic Analysis Division, Bureau of Economic Analysis, U.S. Department of Commerce, 1992. The allocation of county population into the various segments was based on a count of dwelling units from 1985 low-level aerial photography within ten miles of the site and census and 1:250,000 topographic maps for the remaining area.

2.1.3.1 Population Within 10 Miles

Population is distributed rather unevenly within 10 miles of the Sequoyah Nuclear Plant site. Over 50 percent of the 1990 population was in only seven sectors of the 5- to 10-mile range. These sectors are from S to and including NW (going clockwise around the compass). This concentration is a reflection of suburban Chattanooga and the town of Soddy-Daisy. Resident population in the remaining area is sparse and scattered with the exception of the 4-5 WSW annular segment. This pattern is projected to continue in the future with 55 percent of the total 2020 population being contained in this same portion of the 10-mile area. In addition, the 3-4 WSW annular segment is also projected for significant growth. The 0-10 mile population distributions for 1970 through 2020 are given in Tables 2.1.3-1 through 2.1.3-6a and are keyed to the various distances and directions shown on Figure 2.1.1-3.

2.1.3.2 Population Within 50 Miles

Although the site is located in southeastern Tennessee, the area within a 50-mile radius of the site encompasses portions of northwestern Georgia, northeastern Alabama, and a small portion of southwestern North Carolina.

The largest population concentration within 50 miles of the site is the city of Chattanooga, with a 1990 population of 152,466. The northernmost limits of the urbanization around Chattanooga are approximately four miles west-southwest of the plant site. Four smaller population centers (population of 10,000 to 50,000) are scattered around the area. The closest is Cleveland, Tennessee, about 13 miles east-southeast of the plant site with 1990 population of 30,354. In the 30- to 40-mile range are Dalton, Georgia, to the south-southeast (1990 population 21,761) and Athens, Tennessee, to the east-northeast (1990 population 12,054). McMinnville, Tennessee, with a 1990 population of 11,194, is 50 miles northwest of the plant site. In addition, the town of Soddy-Daisy (1990 pop. 8400) is located approximately 6 miles from the site. Development throughout the rest of the region consists primarily of smaller towns dispersed throughout low density rural development. Most of them serve as small retail or service centers for the surrounding farms, although a number are developing an industrial base. Tables 2.1.3-7 through 2.1.3-12a show the 0-50 mile population distributions for the year 1970 through 2020 for various distances and directions shown on Figure 2.1.1-2.

2.1.3.3 Low Population Zone

The low population zone distance as defined in 10 CFR Part 100 has been chosen to be three miles (4,828 meters). The population of this area (2,005 in 1970) and the population density (71 people per square mile in 1970) are both low. In addition, this area is of such size that in the unlikely event of a serious accident there is a reasonable probability that appropriate measures could be taken to protect the health and safety of the residents. Specific provisions for the protection of this area were considered in the development of the Sequoyah Nuclear Plant site emergency plan. The present and projected population figures for this area are included in Tables 2.1.3-1 through 2.1.3-6. Features of the area within the low population zone distances are shown on Figure 2.1.3-1.

2.1.3.4 Transient Population

Transient population within 10 miles of the plant is made up primarily of visitors to the various recreation facilities along the shoreline of the Chickamauga Reservoir. Figure 2.1.1-3 shows the location of the three primary public recreation facilities: Harrison Bay and Booker T. Washington State Parks and the Chester Frost County Park. In addition, there are many commercial marinas, group camps, and cottage developments as well as small formal and informal public access areas along the reservoir shoreline.

Peak hour attendance at these facilities was estimated by the TVA Recreation Resources Branch and is shown in Tables 2.1.3-11 through 2.1.3-16 for various distances and direction. The attendance at the major facilities is distributed to various segments according to where specific activities are located within the total park.

The transient population on the site is very limited. The Sequoyah Energy Connection is less than one mile southwest of the plant and it accommodates visitor groups of up to about 75. This visitation is not reflected in Tables 2.1.3-13 through 2.1.3-19.

2.1.3.5 Population Center

The nearest population center (as defined in 10 CFR Part 100) is Chattanooga, Tennessee, located as described previously.

2.1.3.6 Public Facilities and Institutions

Schools are the only public institutions containing significant population concentrations within 10 miles of the site. Their names, locations, and the 1990, 1993, 1997, and projected enrollments are contained in Table 2.1.3-20. To project enrollments, TVA consulted with the Hamilton County and Bradley County school officials.

2.1.4 Uses of Adjacent Lands and Waters

Land use in the vicinity of the proposed plant site can be examined best by dividing the area into four parts (see Figure 2.1.4-1): (1) the area west of Chickamauga Reservoir and north of the plant; (2) the area west of Chickamauga Reservoir, north of the city of Chattanooga, and southwest of the plant; (3) the area east of Chickamauga Reservoir and southeast of Harrison Bay and the Volunteer Army Ammunition Plant (VAA Plant); and (4) the area east of Chickamauga Reservoir and northeast of Harrison Bay and the VAA Plant.

Area No. 1

With the exception of the community of Soddy-Daisy, the area west of Chickamauga Reservoir and north of the site is sparsely settled. Development consists of scattered dwellings with some associated small-scale farming. Public access areas, campgrounds, boat docks, and an occasional small residential subdivision have been developed along the reservoir shoreline in scattered locations. The Soddy, Possum, and Sale Creek embayments are especially popular with fishermen and family boaters.

U.S. Highway 27 parallels the reservoir approximately five miles to the west. Soddy-Daisy, with a 1985 population of 8,400, is located along this highway about six miles from the plant.

This area is projected to experience a number of changes by the year 2010. One that was recently completed is the upgrade of U.S. 27 into a major north-south highway connecting northern Hamilton County with downtown Chattanooga. It has replaced the old two lane road and reduced commuting time significantly. Much more residential development is forecast for this area because of that, but not to the point that population densities will be significant. Contributing to the projected development are two other proposals. First is the provision of sewer to part of the area, which would increase both the rate and density of growth. Second is a proposed east-west road crossing the lake just north of the Sale Creek embayment. It would connect Cleveland with highways in Sequatchie County. If built, it would stimulate development along its route and a major concentration of commercial and high-density residential at its

intersection with U.S. 27 if the proposed sewers are built. Another significant proposed land use is an industrial park between the nuclear plant and Hixson Pike. It too is dependent on the provision of sewers. It would likely house light manufacturing plants.

Area No. 2

The area west of Chickamauga Reservoir between the Chattanooga city limits and the site has experienced considerable residential growth in the last few years. The area is characterized by considerable vacant land interspersed with high quality residential subdivisions. Much of the new residential development is concentrated between the Hixson and Dallas Hills communities and along the reservoir shoreline. Public recreation facilities are dominated by the 280-acre Chester Frost County Park (formerly Hamilton County Park) receiving over 250,000 visits annually. North Chickamauga Creek in the 9-10 mile range has been designated as a "greenway" with the development of trails and day use facilities near the mouth of the creek underway. Residential development is expected to advance steadily in this general area in the future because of the improvement to U.S. 27 discussed in Area 1. In summary, this area is considered a growth area in Hamilton County. As the population projections indicate, increases are expected throughout the area. In the past the tendency has been to concentrate along the reservoir shoreline. This trend is expected to continue; but, as the shoreline becomes developed, growth is expected to take place in the form of infilling throughout the entire area utilizing the now vacant land.

Area No. 3

Until 1977, when explosives production ceased, the VAA Plant had been a significant barrier to growth in this area because of environmental problems. Since then, residential development has picked up in the area, especially in the vicinity of the lake. There is also substantial commercial and light industrial use along State Highways 58 and 153. This pattern of growth is expected to continue within the natural limitation of the area, which is primarily poor soil for septic tank drain fields. In addition, a significant portion of the VAA site is being marketed for use as an industrial park, which should also increase the development in this area. Sewers are projected for this area, which would increase the rate and density of residential development. The primary recreation feature is the Booker T. Washington State Park, which had 393,000 visits in 1987.

Area No. 4

As in Area No. 3, much of this area also has been affected in the past by the VAA Plant, with residential development picking up in recent years. However, the basic character of the area is rural, with the exception of the Harrison Bay State Park in the two- to five-mile range along the eastern shoreline. In addition to numerous farms, there are scattered private cottages and houses in the vicinity of the park. Public campsites are also located at Skull Island and Grasshopper Creek Park.

From 7 to 10 miles in the vicinity of the city of Cleveland, residential subdivisions have concentrated along existing roads. Also, Interstate 75 is causing readjustments in development through the area.

At present, Area No. 4 is not a growth area for Chattanooga and sewers are not projected for most of the area. Therefore, due to the hilly terrain and poor soils for drain fields, future residential development is expected to be very low density. However, industrial development at the VAA plant, as mentioned previously, may have an impact in this area.

Hamilton and Bradley Counties, Tennessee, fall within a 10-mile radius of the Sequoyah site, having a total land area of approximately 555,000 acres with 159,359 acres of this in farms or about 29 percent of the total land area. On the 1,367 farms in this area, 87,465 acres were found to be used as cropland. A breakdown of the farm oriented land use for each county is given in Table 2.1.4-1. Table 2.1.4-2 tabulates yield and associated land area for various harvested crops. As of 11-1-88, the number of dairy cows within a 5-mile radius of the plant site was 69. In general, the land adjacent to the plant site is suitable dairying land. A land use census is conducted annually by TVA to locate the nearest milk producing animals. In 1988 all animals were cows.

A 1980 U.S. Forest Service survey of Tennessee indicates that approximately 51 percent of the land area in Bradley and Hamilton counties is forested and 49 percent is non-forested. These two counties contain 96,600 and 202,710 acres of forest respectively. Growing stock volume in the counties is estimated to be 335.3 million cubic feet, with 51.8 percent softwood and 48.2 percent hardwoods. The general extent and type of forest cover is shown in Figure 2.1.4-2.

Chickamauga Reservoir is one of a series of TVA multipurpose reservoirs located on the mainstream of the Tennessee River. The primary project uses are for flood control, navigation and hydropower generation, although extensive secondary uses including industrial and public water supply, commercial and sport fishing, recreation, and disposal of treated wastewater have also developed.

Chickamauga Reservoir, which extends from Chickamauga Dam (TRM 471.0) to Watts Bar Dam (TRM 529.9), has been classified by the Tennessee Division of Water Pollution Control for the following uses: municipal water supply, industrial water supply, fish and aquatic life, recreation, irrigation, livestock watering and wildlife, and navigation. The reservoir receives extensive use for these purposes.

The historic water quality and aquatic ecology conditions of Chickamauga Reservoir were described in the final Environmental Statement for Sequoyah Nuclear Plant Units 1 and 2, TVA, February 13, 1974. On July 26, 1974 TVA submitted a Standard Form C Application to the Environmental Protection Agency (EPA) for a National Pollutant Discharge Elimination System permit (NPDES) for the nonradiological discharges from Sequoyah Nuclear Plant. On June 4, 1979, TVA received NPDES permit No. TN0026450 from the EPA for the nonradiological component of the discharges from Sequoyah Nuclear Plant. This permit is updated as required to maintain permits for nonradiological discharges from Sequoyah Nuclear Plant. The permit includes appropriate provisions for the implementation and reporting of instream preoperational and operational monitoring programs in Chickamauga Reservoir with respect to water quality and aquatic ecology. As required by the permit, copies of these reports are also submitted to NRC. The reports of instream monitoring programs submitted under the NPDES permit, both past and future, contain updating information on the water quality and aquatic ecology of Chickamauga Reservoir. A separate updating and reporting of the aquatic conditions of Chickamauga Reservoir outside of the established framework of the NPDES permit requirements is neither planned or warranted in the FSAR.

2.2 NEARBY INDUSTRIAL, TRANSPORTATION, AND MILITARY FACILITIES

There are no industrial or military facilities within five miles of the Sequoyah Nuclear Plant site which would potentially pose a hazard to the safe operation of the plant. A discussion of the highway network in the vicinity of the plant site is contained in Section 2.1. Facilities of interest beyond five miles include the Volunteer Army Ammunition (VAA) Plant and the Dallas Bay Sky Park. Also, Federal Airway V333 passes directly over the site, and Chickamauga Lake is a commercially navigable waterway. The Chattanooga Airport is located approximately 14.5 miles from the plant site. These are the only facilities of potential significance to the safe operation of the plant, and based on the evaluations set forth below, these activities will pose no hazard.

2.2.1 Location and Routes

Chickamauga Lake is a navigable waterway used by both commercial and recreational traffic. Through a series of locks and dams, commercial traffic can travel from Knoxville, upstream of the site to the mouth of the Tennessee River at the Ohio River.

The Dallas Bay Sky Park is a general aviation airport located about 5.5 miles WSW of the plant. The Chattanooga Airport is a full-service commercial airport located about 14.5 miles SSW of the plant.

The nearest boundary of the VAA Plant is about eight miles from the plant site. Figure 2.1.1-3 shows this relationship. The plant is in a stand-by mode and has not produced explosives since 1977. It is not expected to resume production unless there would be a national emergency. However, a small amount of munitions is stored on the site and shipped to and from the site by truck. There are no specific restrictions on the routes to be taken by trucks that would keep them away from the nuclear plant. Barges have never been used for shipping and they are not expected to be used in the future. Rail cars have been used in the past for explosives when the plant was in production but are not expected to be used in the future unless production resumes. (The nearest mainline railroad is about five and one-half miles west of the nuclear plant.) Also, the VAA plant currently contracts its facility to Raytheon Company, which utilizes the plant for final assembly of two air-to-ground missiles: The IR Maverick Missile and the SM-2 Standard Missile. The missiles are shipped to and from the site by truck. Trucks leaving the VAA follow Bonnie Oaks Drive to I-75 and proceed either North or South. West bound shipments exit onto I-24 West.

2.2.2 Description of Products

Up to 44 training operations per day take place at the Dallas Bay Sky Park with an average of about 25. Many of them involve low-altitude maneuvers in the general vicinity of the plant.

Air traffic on or near Federal Airway V333 on the most recent peak traffic day at the Chattanooga Airport was 42. This includes both IFR (Instrument Flight Rules) and VFR (Visual Flight Rules) flights. They ranged in altitude from 2,000 to 15,000 feet. The type of aircraft which utilize Federal Airway V333 include: Cessna 152; Cessna 425; BA-31; DC-9; MD-80; Boeing 727; K-10; F-28; C-130; SW-3; BE-100; BE-200; and BE-90.

The data were for an 18 hour period on July 21, 1992, and reflect the peak traffic for the area of responsibility of the airport, not necessarily V333. Traffic during the six undocumented hours is likely to be very small.

Air traffic at the Chattanooga Airport averages about 140 incoming flights per day. Under certain wind conditions, an estimated 35 - 40 percent will make an approach that takes them over or near the plant at an elevation of about 2500 feet above the ground.

The SM-2 Standard Missile contains 285 pounds net explosive weight and is transported 18 to a truck. The IR Maverick Missile contains 362 pounds net explosive weight and is shipped 36 to a truck. The small munitions are stored in two magazines each designed to store 500,000 pounds of TNT. Table 2.2.2-1b shows the type of munitions stored on site; the typical amount stored on site; and the typical amount transported by truck. There is no set schedule for the shipment of the munitions.

Table 2.2.2-1 shows the total amount of certain hazardous materials shipped past the Sequoyah Nuclear Plant from 1982 to 1992 on a yearly basis based on Corps of Engineers lock data. The product listed as gasoline on the table is actually RU250. In addition, data on chlorine shipments became available starting in 1990. Table 2.2.2-1a contains 1990 shipping data from a TVA survey of dock operators.

Based on 1992 shipping data, chlorine is shipped at a rate of about one 1,100 ton barge every ten days; RU250 (gasoline) is no longer shipped; residual fuel oil is shipped at a rate of one three-barge tow every three months with about 1,500 tons per barge; and asphalt is shipped at a rate of about three barges per month with two 1,500-ton barges and one 3,000-ton barge. Variations in total yearly shipments occur by adjusting any or all of the three variables--shipping frequency, number of barges per tow, and barge size.

2.2.3 Evaluations

2.2.3.1 Evaluation of Explosion Hazards from Nearby Transportation Routes

As indicated in Tables 2.2.3-1 and 2.2.3-2, certain hazardous materials are transported by river barge past the Sequoyah Nuclear Plant site. In addition, explosive materials are also transported over nearby railroad lines. Therefore, these materials were evaluated for their potential to damage the safety related structures of the plant. The materials include TNT, gasoline, liquid natural gas (LNG) and unspecified fertilizers.

Table 1736 of AMCH-385-224 requires that 500,000 lb of TNT (maximum transported by rail) be stored at least 5,400 feet from any unbarricaded, inhabited building and that 400,000 lb of TNT be stored at least 2,550 feet from such building. These distances are much less than the nearest railroad (29,000 feet) or highway (39,000 feet) to Sequoyah over which large amounts of explosives can be transported. Thus, there is no potential for damage to the Sequoyah plant due to the transport of TNT from or storage of TNT at the VAA Plant.

Table 2.2.3-3 indicates the amount of gasoline shipped past the Sequoyah site over the past 15 years. The gasoline supply for Knoxville is provided by pipeline. As of 1974 with the pipeline in

full operation no future gasoline barge shipments past the Sequoyah site are expected except in case of an emergency. The potential for damage to the Sequoyah plant from a gasoline barge explosion is considered to be negligible.

In response to concerns raised by the ACRS, the possibility of a barge explosion in the vicinity of the new ERCW pumping station has been reviewed. Our response is as follows:

(1) The ACRS identified liquid natural gas (LNG) as a substance to be considered in an exploding barge scenario. From our review of the barge shipments past Sequoyah for calendar year 1978, there were no shipments of LNG on the Tennessee River. It should be noted that barge shipments of LNG past Sequoyah are not likely since natural gas transportation is handled almost entirely by pipeline in this region. Therefore, we do not consider the potential for an exploding LNG barge near the new ERCW pumping station to be a credible event.

(2) As indicated in Table 2.2.3-2, there were, in calendar year 1978, shipments of unspecified fertilizers past the Sequoyah Nuclear Plant. Hence, the possibility of an accidental explosion must be considered.

In 1966, the U.S. Bureau of Mines issued a study entitled "Explosion Hazards of Ammonium Nitrate Under Fire Exposure," which examined the deflagration and detonation hazards associated with Ammonium Nitrate (AN). The study indicates:

(a) Ordinary fertilizer-grade AN requires strong overpressures to initiate detonation within the mixture.

(b) AN and AN-fuel mixtures were exposed to fire with no transition from deflagration to detonation being observed.

(c) A combination of fire and overpressure results in transition to detonation. However, in free-flowing beds of AN and AN-fuel mixtures, pressures as high as 8000 lb/in^2 did not generate detonation. Only in experiments where the AN was not allowed to flow freely was transition to detonation observed in the AN-fuel mixture at pressures above 1000 lb/in^2, but not with pure AN.

(d) It was found that hot AN (under fire exposure) readily detonated when impacted with a high velocity projectile or shock wave. Explosions in storage and shipments of AN have apparently resulted only when nearby explosions or structure collapse have occurred concurrent with fire in the AN.

(e) Gas detonations have been shown incapable of initiating detonation in AN mixtures. In general, fertilizers shipped on the Tennessee River employ diatomaceous earth and kaolin clay for anticaking dusts rather than using oil sealant, thus detonations are possible only in cargoes where fire and missiles or external detonation are present. Most bulk fertilizers with earth or clay mixtures will not burn without mixing a considerable amount of paper or flammable material into the fertilizer.

Based on the insensitivity to detonation exhibited by most common fertilizers, the unlikely sequence of events required for detonation must include: Barge collision, fire in the fertilizer cargo, and concurrent detonation or missile-inducing event. Therefore, given the low probability of a barge collision and the low percentage of fertilizer shipments on the Tennessee River, it is concluded that, because of the very low probabilities associated with the event, no hazard exists to the intake pumping station from the transportation of fertilizers by barge on the Tennessee River system.

2.2.3.2 Evaluation of Barge Impact with the ERCW Intake Structure

The collision of a tow with the ERCW intake pumping station is considered to be an unlikely event. The intake structure is protected by location from collision with river traffic heading downstream for water surfaces up to elevation 705, which is 22 feet above maximum normal pool level and 15 feet above a flood condition equivalent to one-half the probable maximum flood. The probability per year of a collision with a drifting barge heading downstream is conservatively estimated to be 4.4×10^{-8}. The probability of a collision involving a tow heading upstream has been determined to be 1.6×10^{-5}/year. These probabilities were calculated using the event tree techniques (Reference 1) as described below and are believed to be conservative.

Collision With River Traffic Heading Downstream

1. Probability of reaching or exceeding flood level 705. Because of the existence of an upstream protective dike with a top elevation of 700.0 as shown in Figure 2.1.2-1 the flood level has to be 705.0 or higher in order for a river vessel to go over the top of the dike and subsequently collide with the intake structure. The probability of a water surface reaching or exceeding flood level 705 is 4×10^{-6} in any given year.

2. Probability of random hit. The probability that a barge drifts, on a collision course, toward the intake structure depends on the relative sizes of river width and intake structure. Probability of random hit equals structure size divided by river width: $P=67/6000 = 1.1 \times 10^{-2}$. The width of the river at the plant site, based on a flood level of 705, was estimated conservatively from Figure 2.4.1-1. The length of the upstream exterior wall of the intake structure was used as the structure size in the computation.

3. Other considerations.

    a. Mechanics of river flow. The Sequoyah Nuclear Plant is located on the convex bank of the river. According to flow theory and actual observations made on various rivers (Reference 2), surface-drifting subjects will never be able to reach the vicinity of the intake structure. Water particles in a bend have a "transverse circulation"; particles near the surface move toward the concave bank and those at the bottom move toward the convex bank. Since the transverse circulation of water particles and the direction of the bend are related by the laws of fluid dynamics, the reversal of the direction of the transverse circulation is a condition almost impossible to exist.

    b. Correlation between flood occurrence and river vessel release. Occurrence of a flood does not necessarily result in the release of a river vessel, and for any given level the probability of release is always less than one.

c. Probability of river vessel arrival. Even if a certain flood level were reached and a river vessel were released, the river vessel might not be able to arrive at the immediate upstream station of the intake structure due to the fluctuation of the flood level and the irregularity of the bank formation.

If only the probability of reaching flood level 705 and the probability of random hit are accounted for, the collision probability is then the product of the probabilities of the two individual events, yielding a probability of 4.4×10^{-8} collisions/year.

This procedure is conservative because the consideration of river flow mechanics and chance of release and arrival of river vessel are not included in the computation. Therefore, river traffic-intake structure collision at the Sequoyah Nuclear Plant site is considered to be incredible.

Collision With River Traffic Heading Upstream

Tow operators on the Tennessee River have been required to be licensed by the U.S. Coast Guard since 1972. A requirement for this license is that they must abide by the Western Rivers Rules of the Road. These rules provide that only tows having radar may proceed during inclement weather while those not having radar must tie up. The U.S. Coast Guard has stated that the type of shoreline and mooring cells in the vicinity of Sequoyah Nuclear Plant afford excellent weather protection. The plant is located between Tennessee River Mile (TRM) 484 and 485; first class safety harbors are located near TRM 483 and 489. The Coast Guard has further stated that the present channel markings are more than sufficient for a prudent navigator. The pumping station is well outside the navigation channel (approximately 300 feet from the boundary) and a daymarker and light is located on the far side of the channel directly opposite the plant to guide upstream traffic away from the plant.

Sequoyah Nuclear Plant is located on the convex bank of a bend in the Tennessee River Channel. Upstream tows attempting to cut short the navigation of the bend would have a difficult angle of approach to the pumping station. As addressed in the discussion for traffic heading downstream, tows losing power in the bend and drifting will drift toward the shoreline opposite the intake structure.

The probability of 1.6×10^{-5} collisions/year was obtained using the following information. The calculation is believed to be conservative.

1. Data available for the years 1945-1979 was searched for barge groundings on the Chickamauga Reservoir. Of the 10 groundings found, 7 were not applicable because of grounding during inclement weather before 1972 or because of intentional grounding caused by loss of power. A range of 40.35 miles (40.35 x 5280 x 2 feet) of shoreline and a total of 19,674 tows during these years were involved. This yields a probability of grounding per tow per foot of shoreline on the reservoir of 3.6×10^{-10}.

2. The target length of the intake structure susceptibility was conservatively taken as 200 feet. (The intake structure is 118 feet by 67 feet.) The average number of tows heading upstream past the intake structure during 1974 to 1979 was approximately 225 per year. The number of tows on the Chickamauga Reservoir reached a peak in 1970, but has been

roughly uniform during 1974 to 1979 and is believed to be a good indication of the expected number of tows for the next several years. The probability is therefore calculated as 3.6 x 10^{-10} groundings per tow per foot of shoreline x 200 feet of shoreline x 225 tows per year = 1.6 x 10^{-5} collisions/year.

An evaluation of the navigation capabilities and requirements for navigation through this section of the river, mile 484 to 485, was conducted. This evaluation provides a strong qualitative rationale that the expected rate of occurrence of an upstream barge impact on the ERCW pumping station is very unlikely compared to the random probability of a tow grounding.

TVA is confident that the real expected rate of occurrence of barge impact on the ERCW is far less than the calculated value of 1.6 x 10^{-5} events per year. TVA's understanding of the inadequately documented events has led to the belief that the calculated random probability of hitting a portside bank (tow traveling upstream) at the Sequoyah river location is conservative. The rationale for this belief is discussed below.

Discussions with the U.S. Coast Guard revealed the following information about the potential for a barge tow to accidentally collide (direct impact or otherwise) with the ERCW pumping station.

The certified barge tug pilot primarily navigates in the traditional "river-pilot" manner, which is by (1) experience, (2) line of sight to landmarks, (3) U.S. Corps of Engineers chart (updated annually), and (4) the Coast Guard Western Rules of the Road. However, the modern (1981) river tug pilot is generally equipped with depth finders (sonar fathomometers), range finding radars, electronics to define water and wind vectors, 2-way radio, and electronic status indication of operational systems. The development and upgrade of modern navigational aids, as well as a more reliable propulsion system, ensures an increasingly accurate, effective navigation of the river by barge pilots.

In all weather, the position, without electronic aids, is known to less than 200 feet, and with navigational electronics, to less than 50 feet. On Chickamauga Reservoir, in the traverse by the Sequoyah Nuclear Plant, the position is very well defined because there are buoys every 0.2 mile on the port and starboard sides (a total of 14); there are five navigation lights; the river and riverbank topography is unusually distinctive; and there are distinctive landmarks (the Sequoyah cooling towers and power transmission lines). The radar equipped boat uses the transmission lines as the primary position locator. A river pilot going upstream by Sequoyah will choose to go on the starboard side because of courtesy (Western Rules of the Road) and because of the need to efficiently and safely navigate an "s" curve through this traverse.

The upstream barge is surprisingly maneuverable. A barge can make a 180° change in course without emergency measures in about twice the length of tow (i.e., within 400 to 800 feet). An upstream barge can make a 90° controlled turn in less than 0.2 mile under typical conditions, i.e., current (2-1/2 knots), wind (10 knots), and power (single screw). If a tug loses propulsion in upstream traverse, he still has effective steerage for 1/4-1/2 mile (approximately 3-6 minutes, worst case). The pilot can make emergency stops by slipping an anchor or a spud. An upstream barge can easily be piloted to hit a target area 90° to port or starboard within 25 feet under bad conditions and within 5 feet under good conditions. Therefore, a certified river pilot, even in extremis (defined as 'must take emergency measures to avoid trouble or to ground his

tow'), can and would avoid the ERCW. The ERCW is a significant structure, which is well marked and lighted as a navigation hazard. In extremis, a pilot will select the best course of action from an economic and safety standpoint. And, in a traverse by the Sequoyah ERCW, he will most likely attempt a grounding on an underwater shoal to his starboard side (the Denny Bluff Shoal).

The river barge pilot is a U.S. Coast Guard certified pilot, whose license is renewed annually and who has periodic physical and proficiency examinations. If a pilot is suspected of malfeasance, a suspension and relocation proceeding is conducted. No cases of malfeasance or of reported drunkenness have occurred on the north Tennessee River in the last five years.

2.2.3.3 Evaluation of Hazards from Air Traffic

Traffic along Federal Airway V333 is so slight and passes at such an altitude (4000 feet minimum) so as to pose no hazard.

2.2.3.4 Evaluation of the Accidental Release of Toxic Gases from Onsite Storage Facilities

Main control room habitability during a postulated hazardous chemical release at or near the plant has been evaluated (reference 3). This evaluation utilizes the approach outlined in Regulatory Guide 1.78 and concludes that the main control room habitability is not jeopardized by accidental release of chemicals stored on site. In addition, plant procedures maintain a list of these hazardous materials, their storage facilities, and quantities they are stored in.

2.2.3.5 Evaluation of the Accidental Release of Toxic Gases from Offsite Storage Facilities

There are no industrial or military facilities where large quantities of toxic chemicals could be stored within a 5-mile radius of the plant.

2.2.3.6 Evaluation of the Upstream Release of Corrosive Liquids or Oils on the ERCW Intake Structure

Protection of the ERCW intake structure from corrosive liquids or oils, released upstream of the plant site, is provided by the mechanics of river flow. The intake structure is located on the inside convex bank of the river bend downstream of a dike rising to an elevation of approximately 700 feet (MSL). The dike coupled with the mechanics of river flow protects the structure. According to flow theory and actual observations made on various rivers, water particles in a bend have a "transverse circulation"; particles near the surface move toward the concave bank and those at the bottom move toward the convex bank. Hence, for normal river levels, the released material would be swept around the intake structure. In the event of liquids or oils reaching the intake structure, no significant effect should occur. Pumps take suction approximately 50 feet below the minimum normal water level and approximately 13 feet below the level anticipated in the event of downstream dam failure. Any oils or fluids which did enter the pumps would be highly diluted and in such a state would have a minimum effect on system piping losses and heat exchanger capabilities.

2.2.3.7 Evaluation of the Potential for Damage to Equipment or Structures Important to Reactor Safety in the Event of the Collapse of Cooling Towers

As shown in Figure 2.1.2-1, the natural draft cooling towers are located a distance away from safety-related structures at least equal to the height of the towers above grade. Therefore, if the towers collapse, the function of the safety-related structures will not be impaired. Missiles resulting from flying debris will also not impair the safety-related structures as discussed in Chapter 3.

2.2.3.8 Evaluation of a Release on the Tennessee River of Toxic or Flammable Materials on Plant Safety Features and Control Room Habitability

The shipping on the Tennessee River consists mainly of fuel oils, wood products and minerals. Chemicals represent only a minor percentage of the barge shipping by the Sequoyah Nuclear Plant. A list of the commodities shipped passed the Sequoyah Nuclear Plant in 1972 is presented in Table 2.2.3-1. On the average, seven tows per week consisting of three barges passed the Sequoyah site. Of the dangerous cargo traffic, one tow per week consisting of two barges passed the Sequoyah site on the average.

The release of flammable or toxic materials on the river in the vicinity of the plant will have no effect on the plant safety features.

The ERCW intake pumping station is protected against fire by virtue of design. Pump suction is taken from the bottom of the channel. All pumps and essential cables and instruments are protected from fire by being enclosed within concrete walls. Even if fuel oil from a spill should reach the intake pumping station, the oil would not have significant effect on the water intake system or the systems it serves. Entry of oil in the intake structure is unlikely since oil will float on water. Any oil that did enter the pumps would be highly diluted and in such a state would have a minor effect on system piping losses and heat exchanger capabilities.

In the event of a release of dense smoke from combustion of flammable liquids in the direction of the control room, personnel in the MCR can manually initiate a CRI which will isolate the control room when a hazardous smoke concentration level is detected. (See sections 6.4 and 9.4.) The Control Room Air Cleanup System has high efficiency particulate filters and charcoal absorbers. A portion of the control room air recirculation flow is also passed through filters. Thus, the concentration of smoke will be maintained at a very low level. In addition, self-contained breathing apparatus will also be available.

2.2.3.9 Evaluation of Potential Fire and Smoke Hazard from Onsite Fuel Oil Storage Facilities

The onsite storage facilities for diesel fuel oil are described in detail in Sections 9.5.4.1 and 9.5.4.2. The maximum amount of fuel oil stored at the plant is (1) 68,000 gallons in each of four storage tanks within the diesel generator building, (2) Two 550-gallon "day" tanks are also located within each diesel generator room. (3) Two storage tanks with a capacity of 71,000 gallons each are located south-southeast of the diesel generator building and (4) two 2,900 gallon FLEX diesel generator Day Tanks are located in the Additional Diesel Generator Building. The storage sites are approximately 260 and 300 meters from the control building, respectively.

The oil storage tanks in the diesel generator building (DGB) are embedded in a concrete substructure of a Class I seismic building. The storage tanks and diesel generators are separated by thick concrete walls. Fire protection for the DGB is described in the fire protection report (see 9.5.1).

A postulated fire involving the oil storage facilities which are located south-southeast of the diesel generator building should have no consequences other than the effects of dense smoke. These tanks are separated from other facilities and are surrounded by a high dike.

Additional fuel oil storage tanks have been added to support Diverse and Flexible Coping Strategies (FLEX) operations. These include: (1) Two 185-gallon “day” tanks for the two 225-kVA diesel generators located on the Auxiliary Building roof (elevation 763.0), and (2) One 9,495-gallon fuel oil storage tank located in the yard south of the Auxiliary Building. Each diesel generator (including day tank) has fire suppression and detection. The fuel oil storage tank is a double wall UL2085 Fireguard tank and because it is located more than 50 feet from a critical building, fire detection and suppression are not required (NFPA 30). The Auxiliary Building roof and Control and Auxiliary Building walls which could be exposed to fire from either of these sources are all credited as 3-hour fire barriers.

An evaluation of the hazard to personnel in the control room from a release of dense smoke is given in Section 6.4.1.2.

2.2.4 Forest Fires

Further clearing has taken place since the time of plant construction. For the most part, the ground has been cleared for two thousand feet around the plant buildings. There are no wooded areas close enough to present a hazard from forest fires.

2.3 METEOROLOGY

2.3.1 Regional Meteorology

2.3.1.1 Data Sources

References used in describing the regional meteorology were the (1) general surface windflow patterns shown by the normal sea level pressure distribution (annual, February, July, and October) for North America and the North Atlantic Ocean--from the U.S. Atomic Energy Commission, ORO-99, A Meteorological Survey of the Oak Ridge Area, Weather Bureau, Oak Ridge, Tennessee, November 1953; (2) wind storm and thunderstorm occurrence--from (a) Local Climatological Data, "Annual Summary with Comparative Data," Chattanooga, Tennessee, U.S. Department of Commerce, NOAA, National Climatic Center, 1979, and (b) Severe Local Storm Occurrences, 1955-1967, ESSA Technical Memorandum WSTM FCST 12, U.S. Department of Commerce, Weather Bureau (now NWS), Silver Spring, Maryland, September l969; (3) tornado occurrence--from (a) "Tornado Occurrences in Tennessee, 1916-1964," John V. Vaiksnoras, State Climatologist, U.S. Department of Commerce, Weather Bureau, Nashville, Tennessee, May 5, 1965, (b) "Tornado Probabilities," H. C. S. Thom, Monthly Weather Review, Volume 91, Nos. 10-12, 1963, (c) discussion with John Vaiksnoras, State Climatologist for Tennessee, Nashville, Tennessee, August 3, 1972, (d) "Tornadoes of the United States," Snowden D. Flora, University of Alabama, November 1953, and (e) National Severe Storms Forecast Center tornado data, 1987 (4) air pollution potential--from Mixing Heights, Wind Speeds, and Potential for Urban Air Pollution Throughout the Contiguous United States, George C. Holzworth, Division of Meteorology, Environmental Protection Agency, Preliminary Document, May 10, 1971; and (5) precipitation--from (a) Precipitation in the Tennessee River Basin, TVA, Division of Water Control Planning, Hydraulic Data Branch, period of record 35 years (1935-1969), (b) Local Climatological Data, "Annual Summary with Comparative Data," Chattanooga, Tennessee, U.S. Department of Commerce, NOAA, National Climatic Center, 1979, (c) U.S. Army, Domestic Area Section, Glaze - Its Meteorology and Climatology, Geographical Distribution, and Economic Effects, Technical Report EP-105, Quartermaster Research and Engineering Center, Natick, Massachusetts, March 1959, and (d) Ostby, Frederick (Employee of U.S. Department of Commerce, NOAA, NWS, National Severe Storms Forecast Center, Kansas City, Missouri), telephone conversation with TVA meteorologist, Norris Nielsen, September 14, 1973.

2.3.1.2 General Climate

The Sequoyah site is in the eastern Tennessee portion of the Southern Appalachian region which is dominated much of the year by the Azores-Bermuda anticyclonic circulation shown in the annual normal sea level pressure distribution (Figure 2.3.1-1). [1] This circulation over the southeastern United States is most pronounced in the fall and is accompanied by extended periods of fair weather and widespread atmospheric stagnation. [2] In winter, the normal circulation pattern becomes diffuse as the eastward moving migratory high and low pressure systems, associated with the midlatitude westerly current, bring alternating cold and warm air masses into the area with resultant changes in wind direction, wind speed, atmospheric stability, precipitation, and other meteorological elements. In summer, the migratory systems are less frequent and less intense, and the area is under the dominance of the western edge of the Azores-Bermuda anticyclone with a warm moist air influx from the Atlantic Ocean and the Gulf of Mexico.

The terrain features of the region have some effect on the general climate. With the mountain ridge and valley terrain aligned northeast-southwest over eastern Tennessee, there is a definite bimodal upvalley-downvalley windflow in the lower 500 to 1000 feet during much of the year. The high Cumberland Plateau terrain, 1500 to 1800 feet above the valley elevation, tends to moderate many of the migratory storms which move from the west across the region. A detectable lake breeze circulation resulting from discontinuities in differential surface heating between land and water is not expected because of the relatively narrow width of the Tennessee River as it flows southwestward through the valley area.

2.3.1.3 Severe Weather

Wind storms may occur several times a year, particularly during winter, spring, and summer with winds exceeding 35 mph and on occasion exceeding 60 mph. The records show the highest wind speed recorded in Chattanooga was 82 mph in March 1947. [3] The highest hourly wind speed recorded at the Sequoyah meteorological facility during the first year of operation, April 2, 1971 -March 31, 1972, was 40 mph. High wind may accompany moderate-to-strong cold frontal passages about 20 to 30 times a year with the maximum frequency in March and April.

High wind may accompany thunderstorms, which occur on about 55 days a year with a maximum frequency in July [3]. The distribution of average monthly thunderstorm occurrences recorded during 1931-1979 at the Chattanooga National Weather Service Office is as follows:

Jan.	Feb.	Mar.	Apr.	May	June	July	Aug.	Sep.	Oct.	Nov.	Dec.	Annual
1	2	4	5	7	l0	11	9	4	1	1	1	56

Severe storm data for 1955-1967 [4] show l0 occurrences of hail 3/4 inch or greater in diameter, 20 occurrences of wind storms with speeds of 50 knots or greater, and 15 occurrences of tornadoes in the one degree latitude-longitude square containing the site. If these severe storm occurrences are assumed to be exclusive of one another, it can be assumed that about 45 severe thunderstorms occurred in the one degree square in this 13-year period. The annual occurrence for the square would be about 3.5. A smaller annual occurrence would be expected for the immediate site area, which is much smaller than the one degree square for which these statistics apply.

The probability of tornado occurrence is extremely low. Statistics show that during the 49-year period, 1916-1964, no tornadoes were reported in Hamilton County, where the Sequoyah site is located. [5] During the 1965-1986 period, three tornadoes were reported in the county. [18] During 1987-October 2002, seven tornadoes were reported in the county. [24] During 1955-1967, a total of 15 tornadoes was recorded for the one degree latitude-longitude square containing the site, for an annual occurrence of 1.15. [4] Using the principles of geometric probability described by H. C. S. Thom, [6] his frequency data for that 1-degree square, and a tornado path size of 0.284 mi^2, [7] the probability of a tornado striking any point in the plant site area is $4.4 \times 1O^{-5}$.

The National Severe Storms Forecast Center in Kansas City, Missouri calculated the tornado return probability for the Sequoyah site based on tornado occurrences within a 30 nautical mile (nm) radius during 1950-1986.[18] A circle of 30 nm radius has an area comparable to a one

degree latitude-longitude square. Based on the 29 tornado occurrences with path size estimates in the 37-year period, the return probability is 1.635×10^{-4} and the mean return interval is 6,115 years. The annual tornado occurrence in the 30nm radius circle was 0.84 (based on 31 tornadoes reported) during that period. During the subsequent period spanning 1987 through October 2002, 23 tornadoes were reported in the same circle. [24] Thus, for the period spanning 1950 through October 2002, 54 tornadoes occurred for an annual occurrence of 1.02. Given the typically small path size of these tornadoes, the return probability and return interval given above should still be representative.

Tornadoes in the eastern Tennessee area generally move northeasterly and cover an average surface path five miles long and one hundred yards wide. [7] Winds of 150 to 200 mph are common in the whirl and are estimated to occasionally reach 300 mph. [7,8]

Days of high air pollution potential, shown in Figure 2.3.1-2, have been depicted by G. C. Holzworth, who presents an expected frequency of high meteorological potential for air pollution. [9] Over a five-year period, his data show that there were about thirty days, or about six days annually, that such conditions could have affected the site area, with most of the days occurring in the fall.

The highest monthly average rainfall near the site area occurs during the winter and early spring months, with March usually having the greatest amount. [10] The maximum 24-hour rainfall reported near the plant site was 7.56 inches in August. High precipitation is also observed in July when air mass thunderstorm activity is common. Minimum precipitation occurs normally in October.

The occurrence of snow, freezing rain, and ice storms in the mid-winter period is not uncommon. During 1931-1995, the maximum total monthly snowfall recorded at Chattanooga was 20.0 inches in March 1993. [25] The average annual snowfall for this period was 4.4 inches. The best estimate of the 100-year recurrence snowfall from a single storm is 14.5 inches which fell during a period from December 4, 1886 through December 6, 1886. [19] The maximum amount on the ground at any one time was 19 inches. This March 1993 24-hour storm was the maximum that occurred in 118 years of record at Chattanooga, Tennessee. No greater single storm or monthly amounts were observed in the southeastern Tennessee area around the plant site through July 2002. [26] The record depth of snow is below the maximum that the safety-related structures can withstand. Assuming the 20-inch snowfall was the depth on top of above ground structures, this equates to a snow load of 14.6 pounds per square foot compared to the design snow load of 20 pounds per square foot. Design criteria for the roofs of safety-related structures is given in Section 3.8. From 1917-18 to 1924-25, there were about three observations of ice storms heavy enough to damage telephone and telegraph lines in the Sequoyah site area. [ll] At least three and perhaps as many as six glaze storms occurred in the general area of the site from 1925-26 to 1952-53. There were about four glaze storms with ice thickness 1/4-inch or more during the period 1928-29 to 1936-37. Also, from 1939 to 1948, freezing rain or drizzle of a trace (0.01 inch) or more occurred on about two days a year.

Hail storms of significant intensity (hailstones 3/4 inch or more in diameter) would likely never occur in the plant area. [7] The probability of occurrence of such a storm can be calculated using Thom's tornado probability equation. [6] With a mean hail path area of two mi.^{2} (1/2 mi. by 4 mi.) [12], an annual occurrence (of hail 3/4 inch or more in diameter) of 0.77 [4], and an area of 3887 mi.^{2} for the one degree latitude-longitude square containing the site [6], the probability is calculated to be 3.96×10^{-4}.

Lightning strike density in the vicinity of the plant has been computed to be an average of about 8 ground strikes per square kilometer per year. [27] These are defined as cloud to ground strokes of lightning.

2.3.2 Local Meteorology

2.3.2.1 Data Sources

Most of the data used in this meteorological description were collected at the onsite meteorological facility (Environmental Data Station) in the four-year period from January 1, 1972 through December 31, 1975. Location of this facility with respect to the Sequoyah Nuclear Plant is shown in Figure 2.3.2-1.

A one-year period (May 1, 1975 - April 30, 1976) of wind and temperature data was used for comparison of stability classifications based on hourly-average vertical temperature difference (WT) values with those based on end-of-hour WT values. This comparison was done to determine any effects on the stability class frequency distribution and the joint wind speed and wind direction frequency distributions by stability class resulting from the change in temperature recording procedure from an end-of-hour reading to an hourly-average value.

Because of the limited period of onsite data, long-term fog and snowfall trends as well as supplementary temperature information were obtained from data records for the National Weather Service Office at Lovell Field, Chattanooga, located 14.5 miles south-southwest of the site (Figure 2.3.2-2). Precipitation data were obtained from a 20-year record from the TVA rain gauge station 685, Friendship School, Tennessee, located about 2.5 miles north-northeast of the plant site.

2.3.2.2 Normal and Extreme Values of Meteorological Parameters

With the limited period of onsite data, it is not reasonable to discuss normal and extreme values of meteorological parameters measured onsite; instead, the data should point toward representative mean values of the local meteorological parameters. Therefore, normal and extreme values of parameters measured offsite should be more representative of long-term regional climate, although local site influences may not be reflected.

Wind Direction

Data from the 33-foot wind instruments at the permanent meteorological facility for the January 1972 - December 1975 period represent reasonably well the expected wind conditions in the plant site area. The annual and monthly patterns (Tables 2.3.2-1 through 2.3.2-13 and Figures 2.3.2-3 through 2.3.2-15) show the predominant directions from the northeast and southwest quadrants which reflect the orographic channeling effects of the northeast-southwest aligned valley-ridge terrain.

For most of the months, but especially for the cooler months of the year, there is a weak secondary maximum of wind frequency from the northwest quadrant. This is most likely associated with post cold frontal winds, which are most likely during the optimum seasons (winter and early spring) for frequent migratory low pressure systems.

Wind Direction Persistence

The wind direction persistence1 analysis (based on the 33-foot (10-meter) data) shown in Table 2.3.2-14, gives the persistence for periods two hours or more from the given wind directions. The greatest persistence was from the north-northeast, which included the maximum of 33

hours. Persistence of 24 hours or more occurred with winds from the southwest, north, and northeast. The analysis shows that the occurrence of persistence periods lasting three hours or more is about 59 percent. For 12 hours or more, the occurrence is about four percent.

Wind Speed

The seasonal and annual occurrences of wind speed at the 33-foot tower level for all wind directions are shown in Tables 2.3.2-1 through 2.3.2-13 and Figures 2.3.2-3 through 2.3.2-15. The preponderance of winds from the northeast within the 0.6 to 3.4 mph wind speed range is most likely attributable to the anticyclonic circulation that dominates the eastern Tennessee region in the late summer and fall. Also, the identification of wind speeds less than 3.5 mph with stable anticyclonic flow is reflected in the high frequency of occurrence of this range in late summer and early fall--a period during which stable anticyclonic conditions are most common. On the other hand, these low wind speeds occur least often in winter and early spring--a period frequented by the passage of migratory low pressure systems.

Wind speeds 7.5 mph and greater occurred most frequently with upvalley winds (from the southwest). These wind speeds occurred very infrequently with winds from the east-northeast, east, east-southeast, and southeast. The predominance of strong winds from the southwest may be attributable to the channeling of the southerly and southwesterly flow preceding the passage of cold fronts through the area. Winds greater than 7.5 mph were more frequent from November through April, with a maximum of about 32 percent in April; they occurred least often in July and August.

[1] Persistent wind is defined in this analysis as a continuous wind from one of the 22-1/2 degree sectors (e.g., north-northeast) except that the persistence is not considered to be interrupted if the wind departs from the sector for one hour and then returns, or if there are up to two hours of missing data followed by a continuation of the same directional persistence.

Temperature

A summary of the first year (April 2, 1971 - March 31, 1972) of onsite temperature data from the meteorological facility is shown in Table 2.3.2-15. The average annual temperature was 59.7°F with the range of monthly averages from 40.1°F in February to 75.5°F in August. The extreme maximum and minimum were 96.3°F and 2.9°F in June and January, respectively. Onsite temperature data compare reasonably well with the normal temperature records from the Chattanooga National Weather Service Office (Weather Bureau) shown in Table 2.3.2-16, although extremes of temperature from the one year of onsite data are somewhat conservative as compared to extremes for Chattanooga. [3] [25]

Atmospheric Water Vapor

The first year of onsite temperature and dew point data were used to compute mean and extreme values of absolute and relative humidity shown in Tables 2.3.2-17 and 2.3.2-18. The average annual absolute humidity was 9.7 g/m^3 with the range of monthly averages from 16.2 g/m^3 in June to 4.2 g/m^3 in February. The extreme maximum was 22.3 g/m^3 in June and the extreme minimum was 1 g/m^3 in February.

The average annual relative humidity was 66.5 percent with the range of monthly averages from 50.6 percent in April to 78.4 percent in October and December. The extreme maximum was 100 percent in March, June, September, November, and December, and the extreme minimum was 17 percent in April.

Precipitation

Precipitation patterns, based on a 20-year period (1948-1967) of data collection at the TVA rain gauge station 685, 2.5 miles north-northeast of the plant site, are shown in Table 2.3.2-19. [10] The data show that there was an average of 117 days annually with 0.01 inch or more of precipitation. The average monthly precipitation was 4.81 inches, with the maximum monthly average 6.76 inches occurring in March and the minimum monthly average 2.86 inches occurring in October. The extreme monthly maximum and minimum were 16.58 inches in November and 0.09 inch in October, respectively. This station was discontinued after 1972, but examination of records for 1968-1972 showed no changes in extremes. [28] Also, the extreme maximum and minimum values in Table 2.3.2-19 have not been exceeded at the Chattanooga airport station during the 1940-2002 period. [25]

Snowfall does not occur often in the Sequoyah site area. Chattanooga snowfall data in Table 2.3.2-20 are considered representative. [25] The average annual snowfall was 4.4 inches and occurred mostly in December through March. The maximum 24-hour snowfall reported at Chattanooga was 20.0 inches in March 1993; the next highest was 10.2 inches in January 1988.

Fog

No observations of the frequency and intensity of fogs have been made in the site area. However, Chattanooga National Weather Service records (Table 2.3.2-21) indicate that heavy fogs (visibility of 1/4 mile or less) occurred on an average of 36 days annually with a maximum average monthly frequency of six days in October and a minimum average monthly frequency of two days from February through July. [3]

Atmospheric Stability

At the present time, atmospheric stability is calculated from the difference between the hourly-average temperature values from two levels. Prior to January 8, 1975, the temperature difference was calculated by a high speed digital computer that was programmed to convert the difference between the ambient temperature sensor resistances at any two instrument levels to a temperature difference value (WT). Before January 8, 1975, both temperature and temperature difference data were obtained from end-of-hour readings.

Four years (January 1, 1972 - December 31, 1975) of onsite temperature difference data from the 33- and 150-foot (9- and 46-meter) tower levels of the permanent meteorological facility were categorized into seven atmospheric stability groups (Pasquill classes A through G). Table 2.3.2-22 shows that the Pasquill stability classes E, F, and G occurred about 72 percent of the time. The most stable class, G, occurred about seven percent of the time. The total occurrence of the least stable classes, A, B, and C, was about eight percent, while the neutral stability class, D, occurred about 20 percent of the time.

Joint percentage frequencies of wind direction and wind speed for the Pasquill stability classes A through G are summarized in Tables 2.3.2-23 through 2.3.2-29 and Figures 2.3.2-16 through 2.3.2-22. The most critical conditions, class G and wind speeds less than 3.5 mph (Table 2.3.2-29, Figure 2.3.2-22), occurred less than six percent of the time. Stability category G is most often associated with downvalley winds (from the north-northeast and northeast), with a secondary maximum associated upvalley winds (from the southwest and south-southwest). Annual frequencies for classes E and F (Tables 2.3.2-27 and 2.3.2-28) show respective frequencies of about 17 and 15 percent for wind speeds less than 3.5 mph.

Using the same type of instrumentation, the capability for calculating hourly average ΔT values (based on hourly-average temperature values) was established in January 1975. A special adjustment of the computer program developed for this purpose was made to also obtain instantaneous, end-of-hour ΔT values for comparison with the hourly-average values.

Table 2.3.2-30 provides the frequencies for hourly-average and end-of-hour stability classes (Pasquill A-G), and Tables 2.3.2-31 through 2.3.2-58 provide joint frequencies of wind direction and wind speed by stability class, each for hourly-average and end-of-hour ΔT values. Summaries based on hourly-average and end-of-hour ΔT values are presented for 33- to 150-foot ΔT and 33-foot wind direction and wind speed data, and for 33- to 300-foot ΔT and 300-foot wind direction and wind speed data. The same wind direction and wind speed data were used with the hourly-average and the end-of-hour ΔT data.

2.3.2.3 Potential Influence of the Plant and its Facilities on Local Meteorology

The presence and operation of the Sequoyah Nuclear Plant should have no noticeable effects on the local meteorology, with the exception of a slight increase in frequency, duration, and intensity of steam fogs forming at the river surface due to heated water releases through the diffusers. These fogs develop as a result of elevation of the dew point by the addition of moisture to the air from the water surface. Once this shallow fog moves on shore, the moisture source is cut off and the fog dissipates. Thus, the increased fogging should be confined within the boundaries of the Chickamauga Reservoir and should not affect long-term fog patterns in the surrounding area. This phenomenon has been observed frequently over the extended river and reservoir system within the Tennessee Valley Region.

Based on previous experience with natural-draft cooling tower operation at the TVA Paradise Steam Plant, no adverse impact on the local meteorology is expected from the operation of supplemental natural-draft cooling towers at the Sequoyah Plant. Some minor effects may include increased atmospheric moisture, decreased solar radiation, and increased concentrations of aerosols related to the drift. However, the significance of these effects would be very difficult or impossible to measure.

2.3.2.4 Topographical Description

The principal effect of the topography in the Sequoyah area on the diffusion of effluent releases is one of confinement to the downwind sectors of predominant wind. Figure 2.3.2-23, sheets 1-9, shows the topographic features within five miles and topographic cross sections in the 16 compass sectors. Annually, the majority of the releases of radioactive effluent would be

dispersed within the northeasterly and southwesterly quadrants from the plant as a result of the upvalley-downvalley low-level wind. Therefore, relative ground-level concentrations would be expected to be higher in these sectors, particularly during periods of low wind and stable conditions. Also, with the relatively flat and undulating valley floor, there should be minimal discontinuity of the general low-level wind pattern from terrain roughness or irregularity. Furthermore, differences in the ambient thermal or stability structure in the area from differential surface heating between land and water should not cause significant alterations to the wind and stability patterns in the plant area. On rare occasions, slight buildup of effluent concentration could occur in the Cumberland escarpment area, about 15 miles to the northwest, where some geographically induced impingement or entrapment of the effluent might be expected.

2.3.3 On-Site Meteorological Measurement Program

2.3.3.1 Siting and Description of Instruments

The Sequoyah meteorological facility consists of a 91-meter (300 foot) instrumented tower for wind and temperature measurements, a separate 10-meter (33 foot) tower for dewpoint measurements, a ground-based instrument for rainfall measurements, and an Environmental Data Station (EDS), which houses the data collection and recording equipment. A system of lightning and surge protection circuitry with proper grounding is included in the facility design. This facility is located approximately 0.74 miles (1.2 kilometers) southwest of the Reactor Building and about 50 feet (15 meters) above plant grade (Figure 2.3.2-1).

Rainfall is monitored from a rain gauge located approximately 55 feet from the tower. Data collected include: (1) wind speed and direction at 10, 46, and 91 meters (33, 150, and 300 feet), (2) temperature at 10, 46, and 91 meters; (3) dewpoint at 10 meters; and (4) rainfall at 1 meter (3 feet). More exact measurements heights for wind and temperature sensors are given in EDS Manual [Reference 20]. Elsewhere in this document, temperature and wind sensor heights are given as 10, 46, and 91 meters. Collection of onsite meteorological data at the Sequoyah Nuclear Plant commenced in April 1971 with measurements of wind speed and wind direction at 10 meter and 91 meters, temperature at 1, 10, 46, and 91 meters; and dewpoint and rainfall at 1 meter. Measurements of 46 meter wind speed/direction and 10 meter dewpoint began on August 6, 1976. Measurement of 1 meter dewpoint ended on January 9, 1979. Measurement of 1 meter temperature ended on January 10, 1979. The dewpoint sensor was moved to a separate tower on June 7, 1994.

Instrument Description

A description of the meteorological sensors follows. More detailed sensor specifications are included in the EDS manual. Replacement sensors, which may be of a different manufacturer or model, will satisfy Regulatory Guide 1.23 (Revision 1). [Reference 13]

SENSOR	HEIGHT (meters)	DESCRIPTION
Wind Direction and Wind Speed	10, 46, and 91	Ultrasonic Wind Sensor.

SENSOR	HEIGHT (meters)	DESCRIPTION
Temperature	10, 46, and 91	Platinum wire resistance temperature detector (RTD) with aspirated radiation shield.
Dewpoint	10	Capacitive Humidity Sensor.
Rainfall	1	Tipping bucket rain gauge.

2.3.3.2 Data Acquisition System

The data acquisition system is located at the EDS and consists of meteorological sensors, a computer (with peripherals), and various interface devices. These devices send meteorological data to the plant, to the Central Emergency Control Center (CECC), and to enable callup for data validation and archiving offsite.

System Accuracies

The meteorological data collection system is designed and replacement components are chosen to meet or exceed specifications for accuracy identified in NRC Regulatory Guide 1.23, Revision 1.

The meteorological data collection satisfies the R.G. 1.23 accuracy requirements. A detailed listing of error sources for each parameter is included in the EDS manual.

2.3.3.3 Data Recording and Display

The data acquisition is under control of the computer program. The output of each meteorological sensor is scanned periodically, scaled, and the data values are stored.

Meteorological sensor outputs (except rainfall) are measured every five seconds (720 per hour). Rainfall is measured continuously as it occurs. Software data processing routines within the computer accumulate output and perform data calculations to generate 15-minute and hourly averages of wind speed and temperature, 15-minute and hourly vector wind speed and direction, 15-minute and hourly total precipitation, hourly average of dewpoint, and hourly horizontal wind direction sigmas. Vector wind speed and direction are calculated along with arithmetic average wind speed.

Selected data each 15 minutes and all data each hour are stored for remote data access.

Data sent to the plant computer systems every minute includes 10, 46, and 91 meter values for wind speed, wind direction, and temperature.

Data sent to the Central Emergency Control Center (CECC) computer in Chattanooga every 15 minutes includes 91-, 46-, and 10-meter wind direction, wind speed, and temperature values. These data are available from the CECC computer to other TVA and State emergency centers in support of the Radiological Emergency Plan (REP), including the Technical Support Center at Sequoyah. Remote access of meteorological data by the NRC is available through the CECC computer.

Data are sent from the EDS to an offsite computer for validation, reporting, and archiving.

2.3.3.4 Equipment Servicing, Maintenance, and Calibration

The meteorological equipment at EDS is kept in proper operating condition by staff that are trained and qualified for necessary tasks.

Most equipment is calibrated or replaced at least every six months of service. The methods for maintaining a calibrated status for the components of the meteorological data collection system (sensors, recorders, electronics, DVM, data logger, etc.) include field checks, field calibration, and/or replacement by a laboratory calibrated component. More frequent calibration intervals for individual components may be conducted, on the basis of the operational history of the component type. Detailed procedures are used and are referenced in the EDS Manual.

2.3.3.5 Operational Meteorological Program

The operational phase of the meteorological program includes those procedures and responsibilities related to activities beginning with the initial fuel loading and continuing through the life of the plant. This phase of the meteorological data collection program will be continuous without major interruptions. The meteorological program has been developed to be consistent with guidance given in NRC Regulatory Guide 1.23 (Revision 1) and the reporting procedure in Regulatory Guide 1.21 (Revision 1). [Reference 14] The basic objective is to maintain data collection performance to assure at least 90 percent joint recoverability and availability of data needed for assessing the relative concentrations and doses resulting from accidental or routine releases.

The restoration of the data collection capability of the meteorological facility in the event of equipment failure or malfunction will be accomplished by replacement or repair of affected equipment. A stock of spare parts and equipment is maintained to minimize and shorten the periods of outages. Equipment malfunctions or outages are detected by maintenance personnel during routine or special checks. Equipment outages that affect the data transmitted to the plant can be detected by review of data displays in the reactor control room. Also, checks of data availability to the emergency centers are performed each work day. When an outage of one or more of the critical data items occurs, the appropriate maintenance personnel will be notified.

In the event that the onsite meteorological facility is rendered nonfunctional, or there is an outage of communications or data access systems; there is no fully representative offsite source of meteorological data for identification of atmospheric dispersion conditions. Therefore; TVA has prepared objective backup procedures to provide estimates for missing or garbled data. These procedures incorporate available onsite data (for a partial loss of data), offsite data, and conditional climatology. The CECC meteorologist will apply the appropriate backup procedures.

2.3.4 Short-Term (Accident) Diffusion Estimates

2.3.4.1 Objective

Two sets of atmospheric dilution factors (X/Q values) are currently used for accident releases modeled as ground level releases from the Sequoyah Nuclear Plant for specified time intervals and distances. The first set is based on one year (April 2, 1971 through March 31, 1972) of data from the Sequoyah permanent meteorological facility. Part of this set was used in the design accident dose calculations and is shown in Table 15A-2. The latest and most widely used set is based on four years (January 1972 through December 1975) of data (Tables 2.3.2-23 through 2.3.2-29). This data was used in Chapter 11.

2.3.4.2 Calculations

Two mathematical models were used in estimating atmospheric dilution factors during postulated reactor accidents - one for the 1-hour and 8-hour (0-8 hours) averaging periods and the other for the 16-hour (8-24 hours), 3-day (1-4 days), and 26-day (4-30 days) averaging periods. Calculations with the two models utilize hourly values of wind direction, wind speed, and atmospheric stability (Pasquill classes A through G).

Nomenclature

A = minimum cross-sectional area of the Reactor Building (m^2)

c = an empirical constant used in defining the magnitude of the building wake (dimensionless)

Q = source strength or effluent release rate (curies/sec)

u = mean horizontal wind speed at 10 meters (m/sec)

x = distance from effluent release point to point at which X/Q values are computed (m)

⦸ = 3.1416

σ_y = Pasquill horizontal crosswind plume standard deviation (m)

σ_z = Pasquill vertical plume standard deviation (m)

x = ground-level concentration (curies/m^3)

Model for the 1-Hour and 8-Hour Averaging Periods

Atmospheric dilution factors were calculated for the 1-hour and 8-hour averaging periods using a Gaussian centerline building wake diffusion equation discussed in NRC Regulatory Guide 1.4 (Revision 2) [15] and Slade [16]:

$$X / Q = \frac{1}{(\eta \, \sigma_Y \, \sigma_Z + cA)\bar{u}} \qquad (1)$$

where cA is a building wake factor.

Model for Averaging Periods Greater than 8 Hours

Atmospheric dilution factors were calculated for the 16-hour, 3-day, and 26-day averaging periods using a Gaussian sector average building wake diffusion equation presented in NRC Regulatory Guide 1.4 (Revision 2):

$$X / Q = \frac{2.032}{\sigma_Z \, x\bar{u}} \qquad (2)$$

For this model, it is assumed that sufficient time elapses to allow the plume to meander and uniformly spread across the 22-1/2-degree downwind sector.

Locations for Which Atmospheric Dilution Factors Were Calculated and Effluent Release Zones

Atmospheric dilution factors were calculated for two location categories: (1) exclusion area boundary, and (2) outer boundary of the Low Population Zone (LPZ). The effluent release zones for the Sequoyah Plant were defined for three locations (see Figure 2.1.2.-2): (1) Release Zone 1, the Auxiliary Building vent exhaust and the Shield Building vent exhaust; (2) Release Zone 2, the radioactive chemical hood exhaust; and (3) Release Zone 3, the condenser air ejector exhaust.

Atmospheric Dilution Factors for the Exclusion Area Boundary

Each release zone was considered individually in calculating atmospheric dilution factors at the exclusion area boundary. The distances from each effluent release zone to the intersections of the 16 compass-point directional sectors with the exclusion area boundary are shown in Table 2.3.4-1.

The hourly average wind speed and atmospheric stability were obtained for a given hour in the January 1972 - December 1975 data period. These data were used with equation (l) to calculate an atmospheric dilution factor corresponding to the exclusion area boundary distance for a particular release zone. This procedure was repeated for each release zone as frequently as there was valid hourly meteorological information available during the 48-month period. These calculations resulted in a list of hourly values for each of the three release zones which were tabulated into cumulative frequency distributions and are shown in Tables 2.3.4-2, 2.3.4-3, and 2.3.4-4 corresponding to Release Zones 1, 2, and 3, respectively. The 5th and 50th percentile and average values of the atmospheric dilution factors for each release zone were also computed and follow:

One-Hour Atmospheric Dilution Factors

At Exclusion Area Boundary (sec/m^3)

Release Zone	5th Percentile	50th Percentile	Average
1	0.859×10^{-3}	0.163×10^{-3}	0.269×10^{-3}
2	0.795×10^{-3}	0.145×10^{-3}	0.243×10^{-3}
3	0.892×10^{-3}	0.164×10^{-3}	0.279×10^{-3}

A more conservative approach consisted of using the above procedure except selecting the shortest distance from each release zone to the exclusion area boundary and calculating the atmospheric dilution factor for all directions using this fixed distance. The minimum distances as shown in Table 2.3.4-1 are 556 meters, 600 meters, and 509 meters for Release Zones 1, 2, and 3, respectively. The calculations resulted in a list of hourly values for each of the three release zones. These values were tabulated into cumulative frequency distributions as shown in Tables 2.3.4-5, 2.3.4-6, and 2.3.4-7, corresponding to Release Zones 1, 2, and 3, respectively. The 5th and 50th percentile and average atmospheric dilution factors follow:

One-Hour Atmospheric Dilution Factors

At Exclusion Area Boundary (sec/m^3)

Release Zone	5th Percentile	50th Percentile	Average
1	0.147×10^{-2}	0.234×10^{-3}	0.396×10^{-3}
2	0.130×10^{-2}	0.215×10^{-3}	0.365×10^{-3}
3	0.162×10^{-2}	0.258×10^{-3}	0.435×10^{-3}

Atmospheric Dilution Factors for Outer Boundary of the LPZ

Atmospheric dilution factors for the outer boundary of the LPZ were calculated by considering a single source or release zone that was assumed to be representative of the three actual release zones. Unlike the calculations for the actual exclusion area boundary in which distances changed with direction, the distance of 4828 meters was used for all calculations for the outer boundary of the LPZ. These values were calculated for averaging times of 1 hour, 8 hours, 16 hours, 3 days, and 26 days. All 1-hour average values were obtained by use of equation (1) and the hourly meteorological observations. The cumulative frequency distribution of these values is listed in Table 2.3.4-8. The 5th and 50th percentile and average values are also shown.

For a given sector, the 8-hour average atmospheric dilution factor was obtained by averaging the hourly values. For a given 8-hour period, sixteen 8-hour averages were obtained--one for each compass-point sector. The average value selected to represent the given 8-hour period was the maximum of the sixteen. There were 35,057 8-hour periods from January 1, 1972 through December 31, 1975 where consecutive 8-hour periods overlapped for seven hours. An atmospheric dilution factor was not calculated for an 8-hour period unless there were at least four hours of valid meteorological observations during the period. After the values were computed for the valid 8-hour periods, they were summarized into the cumulative frequency distribution shown in Table 2.3.4-9. The average and 5th and 50th percentile statistics were also computed.

All other averages (the 16-hour, 3-day, and 26-day averages) were treated in a fashion analogous to the 8-hour average except that equation (2) was used to calculate the atmospheric dilution factors. Tables 2.3.4-10, 2.3.4-11, and 2.3.4-12 summarize the cumulative frequency distributions of the values for the corresponding l6-hour, 3-day, and 26-day averaging periods, respectively. The 5th and 50th percentile and average values for each averaging period are included in the following table:

Averaging Time	Atmospheric Dilution Factor at Outer Boundary of LPZ (sec/m^3) 5th Percentile	50th Percentile	Average
1-hour	0.139×10^{-3}	0.142×10^{-4}	0.319×10^{-4}
8-hour	0.539×10^{-4}	0.980×10^{-5}	0.169×10^{-4}
16-hour	0.717×10^{-5}	0.236×10^{-5}	0.299×10^{-5}
3-day	0.434×10^{-5}	0.176×10^{-5}	0.201×10^{-5}
26-day	0.271×10^{-5}	0.153×10^{-5}	0.148×10^{-5}

Data from the one-year period (May 1, 1975 through April 30, 1976) were used to compare atmospheric dilution factors obtained from stability classes determined from end-of-hour

temperature measurements and those determined from hourly average temperature measurements. These data (Tables 2.3.2-31 through 2.3.2-44) include wind direction and wind speed at 33 feet (10 meters) above ground and temperature difference between the elevations of 33 and 150 feet (46 meters).

Table 2.3.4-13 compares atmospheric dilution factors based on (1) hourly-average ΔT data and (2) end-of-hour ΔT data. The values presented for comparison are fifth percentile values for 1-hour and 8-hour periods at the minimum exclusion area boundary distance of 556 meters and for 8-hour, 16-hour, 3-day, and 26-day periods at the LPZ distance of 4828 meters.

It is apparent from examination of the data tables that the differences between atmospheric dilution factors obtained from the data set containing hourly-average ΔT and those obtained from the data set containing end-of-hour ΔT are not significant. The joint frequencies of wind direction and wind speed by atmospheric stability class for 33- to 300-foot ΔT and 300-foot wind data show even closer agreement than those based on 33- to 150-foot ΔT and 33-foot wind data. Therefore, any calculations based on end-of-hour 33- to 300- foot ΔT, or even 150- to 300-foot ΔT, could be expected to be at least as representative of those based on hourly-average ΔT as those for 33- to 150-foot ΔT and 33-foot wind data presented in Table 2.3.4-13.

2.3.5 Long-Term (Routine) Diffusion Estimates

2.3.5.1 Objective

In this section, calculated average annual atmospheric dispersion factors (X/Q values) are reported at specified distances for routine releases from the Sequoyah Nuclear Plant. A dispersion equation is applied which accounts for initial dilution of gaseous effluents in the building wake. Joint frequency distributions of wind direction and speed by atmospheric stability class based on onsite meteorological data collected during the period of January 1972 through December 1975 are used in the calculations. Joint frequency distributions are presented in Tables 2.3.2-23 through 2.3.2-29.

2.3.5.2 Calculations

Average annual atmospheric dispersion factors are calculated for locations along 16 radial lines corresponding to the major compass points drawn from the center of the nuclear plant complex. Calculations in each of the 16 sectors are made for the site boundary and for the distances 1, 2, 3, 4, 5, 10, 15, 20, 30, 40, and 50 miles. Three effluent release zones are designated for calculating atmospheric dispersion factors at the site boundary (see Figure 2.1.2-2). These are as follows:

Release Zone 1 - Auxiliary Building vent exhaust and Shield Building vent exhaust.

Release Zone 2 - Radioactive chemical hood exhaust.

Release Zone 3 - Condenser air ejector exhaust.

In calculating the average annual atmospheric dispersion factors for the selected distances between 1 and 50 miles, it is assumed that gaseous effluents are released from a single point (the three release zones are not considered in these calculations). The distances to the unrestricted area boundary from this point are shown in Table 11.3.9-1.

Atmospheric dispersion calculations are based on a building wake model described by Davidson [16,17]. The average annual atmospheric dispersion factor at any point of interest x is given by:

$$\frac{X}{Q_o} = \left(\frac{2}{\pi}\right)^{1/2} \frac{1}{W} \underset{\substack{\text{wind}\\\text{speeds}}}{\Sigma i} \; \underset{\substack{\text{stability}\\\text{types}}}{\Sigma j} \; \frac{f_{ij}}{(\Sigma_z)_j \; U_i}, \; \text{SEC}/m^3$$

where

W = 2p x/16, the sector width at downwind distances x, m,

u_i = wind speed i, m/s,

f_{ij}= frequency with which wind speed u_i occurs in the sector of interest during atmospheric stability class j,

$$(\Sigma_z)_j = \left((\sigma_z)_j^2 + \frac{cA}{\pi} \right)^{1/2}$$

the vertical standard deviation of the plume (modified for the effect of building wake dilution) at the distance x for stability class j, m,

$(\sigma_z)_j$ = Pasquill vertical standard deviation of the plume at the distance x for stability class j, m,

c = parameter that relates the cross-sectional area of a building to the size of the turbulent wake caused by the building,

A = minimum Reactor Building cross-sectional area, m^2.

In the expression for (σ_z), c is assumed to be 0.5 and A is assumed to be 1,800 m^2. Table 2.3.4-14 lists average annual atmospheric dispersion factors for the Sequoyah site.

METEOROLOGICAL FACILITY located 1.2 km southwest of Sequoyah Nuclear Plant
WIND SPEED AND DIRECTION MEASURED AT THE 9.73 METER LEVEL

NOTE: Persistent wind is defined in this analysis as a wind blowing continuously from one of the named 22-1/2° sectors (i.e., north-northwest) except that it is not considered to be interrupted if it departs from that sector for one hour and then returns, or if there are up to two hours of missing data followed by a continued directional persistence.

	Annual	36

[a] Local Climatological Data, "Annual Summary With Comparative Data," Chattanooga, Tennessee, U.S. Department of Commerce, NOAA, National Climatic Center, Asheville, N.C., 1979.

[b] Heavy fog is defined as fog reducing the visibility to 1/4 mile or less.

[c] Period of record 49 years, through 1979. Rounding to whole days results in one-day difference between the sum of the monthly averages and the annual average.

Table 2.3.2-22

PERCENT OCCURRENCE OF ATMOSPHERIC STABILITY*

Sequoyah Nuclear Plant

January 1, 1972 - December 31, 1975

Pasquill Stability Class	Vertical Temperature Difference (Δ T)**	Percent Occurrence**
A	$\Delta T \leq -1.9^{\circ}C/100$ m	2.91
B	$-1.9 < \Delta T \leq -1.7^{\circ}C/100$ m	1.24
C	$-1.7 < \Delta T \leq -1.5^{\circ}C/100$ m	3.78
D	$-1.5 < \Delta T \leq -0.5^{\circ}C/100$ m	19.91
E	$-0.5 < \Delta T \leq 1.5^{\circ}C/100$ m	44.36
F	$1.5 < \Delta T \leq 4.0^{\circ}C/100$ m	20.79
G	$\Delta T > 4.0^{\circ}C/100$ m	6.93
Total		99.92

*Temperature instruments 9 and 46 meters above ground.

**Valid ΔT = 91.33 percent of total hours in period; percent occurrences are percentages of valid ΔT occurrences.

2.4 HYDROLOGIC ENGINEERING

2.4.1 Hydrologic Description

2.4.1.1 Site and Facilities

The location of key plant structures and their relationship to the original site topography are shown on Figure 2.1.2-1. The structures which have safety-related equipment and systems are indicated on this figure and are tabulated below, along with the elevation of major exterior accesses.

Structure	Access	Number of Accesses	Elevation
Intake pumping structure	(1) Stairwell entrance	1	705.0
	(2) Access hatches	6	705.0
	(3) Cable tunnel	1	690.0
Auxiliary and control buildings	(1) Railroad access opening	1	706.0
	(2) Doors to turbine building	2	706.0
	(3) Doors to turbine building	2	732.0
	(4) Doors to turbine building	2	685.0
	(5) Personnel lock to SB	1	690.0
	(6) General vent or intake	2	714
	(7) Doors to AEB and MSVV	4	714
Shield building	(1) Personnel lock (watertight)	1	691.0
	(2) Equipment hatch	1	730.0
	(3) Personnel lock	1	732.0
Diesel generator building	(1) Equipment access door	4	722.0
	(2) Personnel access door	1	722.0
	(3) Emergency exit	4	722.0
	(4) Emergency exit	1	740.5
ERCW intake pumping station	(1) Access door	1	725.0
	(2) Trash sluice	1	723.5
	(3) Deck drainage (sealed for flood)	1	720.0

Exterior accesses are also provided to each of the class IE electrical systems manholes and handholes at elevations varying from 700 to 724 feet MSL, depending upon the location of each structure.

The relationship of the plant site to the surrounding area can be seen in Figures 2.1.2-1 and 2.4.1-1. It can be seen from these figures that significant natural drainage features of the site have not been altered. Local surface runoff drains into the Tennessee River.

2.4.1.2 Hydrosphere

The Sequoyah Nuclear Plant (SQN) site comprises approximately 525 acres on a peninsula on the western shore of Chickamauga Lake at Tennessee River Mile (TRM) 484.5. As shown by Figure 2.4.1-1, the site is on high ground with the Tennessee River being the only potential source of flooding.

The Tennessee River above SQN site drains 20,650 square miles. The drainage area at Chickamauga Dam, 13.5 miles downstream, is 20,790 square miles. Three major tributaries--Hiwassee, Little Tennessee, and French Broad Rivers--rise to the east in the rugged Southern Appalachian Highlands. They flow northwestward through the Appalachian Divide which is essentially defined by the North Carolina-Tennessee border to join the Tennessee River which flows southwestward. The Tennessee River and its Clinch and Holston River tributaries flow southwest through the Valley and ridge physiographic province which, while not as rugged as the Southern Highlands, features a number of mountains including the Clinch and Powell Mountain chains. The drainage pattern is shown on Figure 2.1.1-1. About 20 percent of the watershed rises above elevation 3000 with a maximum elevation of 6,684 at Mt. Mitchell, North Carolina. The watershed is about 70 percent forested with much of the mountainous area being 100 percent forested.

The climate of the watershed is humid temperate. Mean annual precipitation for the Tennessee Valley is shown by Figure 2.4.1-2. Above Chickamauga Dam, annual rainfall averages 51 inches and varies from a low of 40 inches at sheltered locations in the mountains to high spots of 85 inches on the southern and eastern divide. Rainfall occurs relatively evenly throughout the year. See Section 2.3 for a discussion of rainfall.

Major flood-producing storms are of two general types; the cool-season, winter type, and the warm-season, hurricane type. Most floods at SQN, however, have been produced by winter-type storms in the months of January through early April.

Watershed snowfall is relatively light, averaging only about 14 inches annually above the plant. The maximum average annual snowfall of 63 inches occurs at Mt. Mitchell, the highest point east of the Mississippi River. The overall snowfall average above the 3,000-foot elevation, however, is only 22 inches annually. Individual snowfalls are normally light, with an average of 13 snowfalls per year. Snowmelt is not a factor in maximum flood determinations.

Chickamauga Dam, 13.5 miles downstream, affects water surface elevations at SQN. Normal full pool elevation is 683.0 feet. At this elevation the reservoir is 58.9 miles long on the Tennessee River and 32 miles long on the Hiwassee River, covering an area of 35,400 acres, with a volume of 628,000 acre-feet. The reservoir has an average width of nearly 1 mile, ranging from 700 feet to 1.7 miles. At SQN, the reservoir is about 3,000 feet wide with depths ranging between 12 feet and 50 feet at normal pool elevation.

The Tennessee River above Chattanooga, Tennessee, is one of the best regulated rivers in the United States. A prime purpose of the TVA water control system is flood control with particular emphasis on protection for Chattanooga, 20 miles downstream from SQN.

There are 20 major reservoirs in the TVA system upstream from the plant, 13 of which have substantial reserved flood detention capacity during the main flood season. Table 2.4.1-1 lists pertinent data for TVA's major dams prior to modifications made by the Dam Safety Program (see Table 2.4.1-5). In addition, there are six major dams owned by the Aluminum Company of America (ALCOA). The ALCOA reservoirs often contribute to flood reduction but were ignored in this analysis because they do not have dependable reserved flood detention capacity. The locations of these dams and the minor dams, Nolichucky and Walters (Waterville Lake), are shown on Figure 2.1.1-1. Table 2.4.1-2 lists pertinent data for the major and minor ALCOA dams and Walters Dam.

The flood detention capacity reserved in the TVA system varies seasonally, with the greatest amounts during the flood season. Figure 2.4.1-3, containing 14 sheets, shows tributary and main river reservoir seasonal operating guides for those reservoirs having major influence on SQN flood

flows. Table 2.4.1-3 shows the flood control reservations at the multiple-purpose projects above SQN at the beginning and end of the winter flood season and in the summer. Assured system detention capacity above the plant varies from 5.6 inches on January 1 to 4.5 inches on March 15, decreasing to 1.0 inch during the summer and fall. Actual detention capacity may exceed these amounts, depending upon inflows and power demands.

Flood control above SQN is provided largely by 11 tributary reservoirs. Tellico Dam is counted as a tributary reservoir because it is located on the Little Tennessee River, although, because of canal connection with Fort Loudoun Dam, it also functions as a main river dam. On March 15, near the end of the flood season, these provide a minimum of 4,436,000 acre-feet of detention capacity, equivalent to 5.8 inches on the 14,476 square-mile area they control. This is 90 percent of the total available above Chickamauga Reservoir. The two main river reservoirs, Fort Loudoun and Watts Bar, provide 490,000 acre-feet, equivalent to 1.5 inches of detention capacity on the remaining area above the plant.

Daily flow volumes at the plant, for all practical purposes, are represented by discharges from Chickamauga Dam with drainage area of 20,790 square miles, only 140 square miles more than at the plant. Momentary flows at the nuclear plant may vary considerably from daily averages, depending upon turbine operations at Watts Bar Dam upstream and Chickamauga Dam downstream. There may be periods of several hours when there are no releases from either or both Watts Bar and Chickamauga Dams. Rapid turbine shutdown at Chickamauga may sometimes cause periods of up-stream flow in Chickamauga Reservoir.

Based upon discharge records since closure of Chickamauga Dam in 1940, the average daily streamflow at the plant is 32,600 cfs. The maximum daily discharge was 223,200 cfs on May 8, 1984. Except for two special operations on March 30 and 31, 1968, when discharge was zero to control milfoil, the minimum daily discharge was 700 cfs on November 1, 1953. Flow data for water years 1951-1972 indicate an average rate of about 27,600 cfs during the summer months (May-October) and about 38,500 cfs during the winter months (November-April). Flow durations based upon Chickamauga Dam discharge records for the period 1951-1972 are tabulated below.

Average Daily Discharge, cfs	Percent of Time Equaled or Exceeded
5,000	99.6
10,000	97.7
15,000	93.3
20,000	84.0
25,000	69.3
30,000	46.8
35,000	31.7

Channel velocities at SQN average about 0.6 fps under normal winter conditions. Because of lower flows and higher reservoir elevations in the summer months, channel velocities average about 0.3 fps.

As listed on Table 2.4.1-4, there are 23 surface water users within the 98.6-mile reach of the Tennessee River between Dayton, TN and Stevenson, AL. These include fifteen industrial water supplies and eight public water supplies.

The industrial users exclusive of SQN withdraw about 497 million gallons per day from the Tennessee River. Most of this water is returned to the river after use with varying degrees of contamination.

The public surface water supply intake (Savannah Valley Utility District), originally located across Chickamauga Reservoir from the plant site at TRM 483.6, has been removed. Savannah Valley Utility District has been converted to a ground water supply. The nearest public downstream intake is the East Side Utility (formerly referred to as U.S. Army, Volunteer Army Ammunition Plant). This intake is located at TRM 473.0.

Groundwater resources in the immediate SQN site are described in Section 2.4.13.

2.4.1.3 TVA Dam Safety Program

Most of the dams upstream from SQN were designed and built before the hydrometerological approach to spillway design had gained its current level of acceptance. Spillway design capacity was generally less than would be provided today. The original FSAR analyses were based on the existing dam system before dam safety modifications were made and included failure of some upstream dams from overtopping.

In 1982, TVA officially began a safety review of its dams. The TVA Dam Safety Program was designed to be consistent with Federal Guidelines for Dam Safety and similar efforts by other Federal agencies. Technical studies and engineering analyses were conducted and physical modifications implemented to ensure the hydrologic and seismic integrity of the TVA dams and demonstrate that TVA's dams can be operated in accordance with Federal Emergency Management Agency (FEMA) guidelines. Table 2.4.1-5 provides the status of TVA Dam Safety hydrologic modifications as of 1998. These modifications enable these projects to safely pass the probable maximum flood. The remaining hydrologic modifications planned for Bear Creek Dam and Chickamauga Dam will not affect SQN in any manner which might invalidate the reanalysis described below.

In 1997-98, TVA reanalyzed the nuclear plant design basis flood events. The purpose of the reanalysis was to evaluate the effects of the hydrologic dam safety modifications on the flood elevations and response times in the SQN FSAR and to confirm the adequacy of the plant flood plans. The following methods and assumptions were applied to the reanalysis:

1. The computer programs and modeling methods were the same as previously used and documented in the FSAR.

2. Probable maximum precipitation, time distribution of precipitation, precipitation losses and reservoir operating procedures were unchanged from the original analysis.

3. The original stability analyses and postulated seismic dam failure assumptions were conservatively assumed to occur in the same manner and in combination with the same previously postulated rainfall events. No credit was taken for the 1988 post-tensioning of Fontana and Melton Hill Dams to prevent seismic failure. Nor was any credit taken for Dam Safety seismic evaluations of Norris, Cherokee, Douglas, Fort Loudon, Tellico, Hiwassee, Apalachia, and Blue Ridge Dams which demonstrated their structural integrity for a seismic event with a return period of approximately 10,000 years.

4. The planned modification of Chickamauga Dam (armoring the embankment to permit overtopping) was conservatively assumed to have been implemented for the purpose of calculating flood effects. Under present existing conditions, the Chickamauga embankment would be severely eroded in the overtopping PMF event and the maximum flood elevation at SQN would be lower than that with the planned modification.

2.4.2 Floods

2.4.2.1 Flood History (Historical)

The nearest location with extensive formal flood records is 20 miles downstream at Chattanooga, Tennessee, where continuous records are available since 1874. Knowledge about significant floods extends back to 1826, based upon newspaper and historical reports. Flood flows and stages at Chattanooga have been altered by TVA's reservoir system beginning with the closure of Norris Dam in 1936 and reaching essentially the present level of control in 1952 with closure of Boone Dam, the last major dam with reserved flood detention capacity constructed above Chattanooga. Tellico Dam provides additional reserved flood detention capacity; however, the percentage increase in total detention capacity above the Watts Bar site is small. Thus, for practical purposes, flood records for the period 1952 to date can be considered representative of prevailing conditions. Figure 2.4.2-1 shows the known flood experience at Chattanooga in diagram form. The maximum known flood under natural conditions occurred in 1867. This flood reached elevation 690.5 at SQN. The maximum flood under present-day regulation reached elevation 687.9 at the site on May 9, 1984.

The following table lists the highest floods at SQN:

Date	Elevation, Feet	Discharge, cfs
Before Regulation		
March 11, 1867	690.5	450,000
March 1, 1875	686.2	405,000
April 3, 1886	684.5	385,000
March 7, 1917	680.0	335,000
April 5, 1920	676.5	270,000
Since Present Regulation		
February 3, 1957	683.7	180,000
March 13, 1963	684.8	205,000
March 18, 1973	687.0	219,000
May 9, 1984	687.9	250,000

2.4.2.2 Flood Design Considerations

TVA has planned the SQN project to conform with regulatory position 2 of Regulatory Guide 1.59.

The types of events evaluated to determine the worst potential flood included (1) Probable Maximum Precipitation (PMP) on the total watershed and critical subwatersheds, including seasonal variations and potential consequent dam failures and (2) dam failures in a postulated Safe Shutdown Earthquake (SSE) or one-half SSE with guide specified concurrent flood conditions.

The computed maximum stillwater flood level in the reservoir at the plant site from any cause is elevation 719.6. Maximum level including wave height is 722.4. This elevation would result from the probable maximum precipitation critically centered on the watershed and a 45-mile-per-hour overwater wind, from the most critical direction coincident with the peak of the resulting flood.

Other rainfall floods will also exceed plant grade, elevation 705, and will necessitate plant shutdown. Flood warning criteria and forecasting techniques have been developed to assure that there will always be adequate time to shut the plant down and be ready for floodwaters above plant grade and are described in Subsections 2.4.10 and 2.4.14, and Appendix 2.4A.

Seismic and concurrent flood events could create flood levels which would exceed plant grade. The maximum elevation reached in such an event is elevation 707.9, 2.9 feet above plant grade and 11.7 feet below the controlling event probable maximum flood (PMF), excluding wind-wave considerations. In all such events there is adequate time for safe plant shutdown after the seismic event and before plant grade would be crossed. The emergency protective measures and warning criteria are described in Subsections 2.4.10 and 2.4.14, and Appendix 2.4A.

Most safety-related building accesses are located at elevation 706 or above. The accesses below elevation 706 are within the powerhouse and will not be exposed to floodwater until plant grade is exceeded. Therefore, the structures are protected from flooding prior to the end of the shutdown period.

Drainage to the Tennessee River has been provided to accommodate runoff from the probable maximum precipitation on the local area of the plant site.

Specific analysis of Tennessee River flood levels resulting from oceanfront surges and tsunamis is not required because of the inland location of the plant.

Snowmelt and ice jam considerations are also unnecessary because of the temperate zone location of the plant. Flood waves from landslides into upstream reservoirs required no specific analysis, in part because of the absence of major elevation relief in nearby upstream reservoirs and because the prevailing thin soils offer small slide volume potential compared to the available detention space in reservoirs.

All safety-related facilities, systems, and equipment are housed in structures which provide protection from flooding for all flood conditions up to plant grade at elevation 705.

For the condition where flooding exceeds plant grade, as described in Subsections 2.4.3 and 2.4.4, all equipment required to maintain the plant safely during the flood, and for 100 days after the beginning of the flood, is either designed to operate submerged, located above the maximum flood level, or otherwise protected.

Safety-related facilities, systems, and equipment located in the containment structure are protected from flooding by the shield building. All accesses and penetrations below the maximum flood level in the shield building are designed and constructed as essentially water tight elements.

The turbine, control, and auxiliary building will be allowed to flood.

Wind wave run-up during the PMF at the diesel generator building reaches elevation 721.8 which is 0.2 feet below the operating floor. Consequently, wind wave run-up will not impair the safety function of systems in the diesel generator building.

The accesses and penetrations below this elevation in the diesel generator building are designed and constructed to minimize leakage into the buildings. Redundant sump pumps are provided within the building to remove minor leakage. Protective measures are taken to ensure that all safety-related systems and equipment in the Emergency Raw Cooling Water (ERCW) pump station will remain functional when subjected to the maximum flood level.

Class IE electrical cables, located below the Probable Maximum Flood (PMF) plus wind-wave activity and required in a flood, are designed for submerged operation.

Structures housing safety-related facilities, systems, and equipment are protected from flooding during a local PMF by the slope of the plant yard. The yard is graded so that the surface runoff will be carried to Chickamauga Reservoir without exceeding the elevation of the external accesses given in Paragraph 2.4.1.1 except those at the intake pumping station whose pumps can operate submerged.

2.4.3 Probable Maximum Flood (PMF) on Streams and Rivers

The guidance of Appendix A of Regulatory Guide 1.59 was followed in determining the PMF. Plant surface drainage was evaluated and found capable of passing the local probable maximum storm without reaching or exceeding the critical floor elevation 706, as further described in 2.4.3.5.

Evaluation of seasonal and areal variations of probable maximum storms showed that the probable maximum Tennessee River flood level at the plant would be caused by a sequence of storms occurring in March centered in the mountains, east of the plant. The flood crest at the plant would be augmented by the failure of the west saddle dike at Watts Bar Dam upstream. The estimated maximum discharge is 1,236,000 cfs. The probable maximum elevation at the plant is 719.6, excluding any wind-wave effects, and excluding any lower flood level due to failure of Chickamauga Dam downstream.

2.4.3.1 Probable Maximum Precipitation

Probable maximum precipitation (PMP) for the Tennessee River watershed above SQN has been defined for TVA by the Hydrometeorological Branch of the National Weather Service in Hydrometeorological Report No. 41 Reference [1]. Two basic storm positions were evaluated. One would produce maximum rainfall over the total watershed. The other would produce maximum rains in the part of the basin downstream from major TVA tributary reservoirs, hereafter referred to as the 7,980-square-mile storm. Snowmelt is not a factor in generating maximum floods at the plant site.

Controlling PMP depths for 21,400-square-mile and 7,980-square-mile areas are tabulated below. These storms would occur in March. Depths for other months would be less.

Depth, Inches				
	72-Hour	Main Storm		
Sq. Miles	Antecedent Storm	6-Hour	24-Hour	72-Hour
21,400	6.7	5.03	11.18	16.78
7,980	8.1	7.02	14.04	20.36

Two possible isohyetal patterns producing the total area depths are presented in Report No. 41. The one critical to this study is the "downstream pattern" shown in Figure 2.4.3-1. The isohyetal pattern for the 7,980-square-mile storm is shown in Figure 2.4.3-2. The pattern is not orographically fixed and can be moved parallel to the long axis northeast and southwest along the Valley.

A 72-hour storm three days antecedent to the main storm was assumed to occur in all PMP situations with storm depths equivalent to 40 percent of the main storm.

Potential storm amounts differing by seasons were analyzed in sufficient number to make certain that the March storms would be controlling. Enough centerings were investigated to assure that a most critical position was used.

Storms producing PMP above upstream tributary dams, whose failure has the potential to create maximum flood levels, were evaluated in the original FSAR analysis. Dam safety modifications at upstream tributary dams have eliminated these potential failures and subsequent plant site flood levels.

A standard time distribution pattern was adopted for all storms based upon major observed storms transposable to the Tennessee Valley and in conformance with the usual practice of Federal agencies. The adopted distribution is shown on Figure 2.4.3-3.

The critical probable maximum storm was determined to be a total basin storm with downstream orographically fixed pattern (Figure 2.4.3-1) which would follow an antecedent storm commencing on March 15. Translation of the PMP from Report No. 41 to the basin results in an antecedent storm producing an average precipitation of 6.4 inches in three days, followed by a three-day dry period, and then by the main storm producing an average precipitation of 16.5 inches in three days. Figure 2.4.3-4 is an isohyetal map of the maximum three-day PMP. Basin rainfall depths are given in Table 2.4.3-1.

To evaluate the local plant drainage system for a PMP event, Hydrometeorological Report No. 56 was used to calculate a 1-hr storm totaling 16.21 inches. Three different temporal distributions were applied to the model, with peak intensity of 2.81 inches/5-min = 33.72 in/hr shifted between early, middle, and late occurrence. Depths for each 5-minute increment of the controlling late peak distribution were 0.68, 0.78, 0.87, 0.97, 0.97, 1.17, 1.26, 1.36, 1.55, 2.81, 2.04, and 1.75. Rainfall on plant building roofs was assumed to discharge to the ground surface.

2.4.3.2 <u>Precipitation Losses</u>

Precipitation losses in the probable maximum storm are estimated with multivariable relationships used in the day-to-day operation of the TVA system. These relationships, developed from a study of storm and flood records, relate the amount of precipitation excess (and hence the precipitation loss) to the week of the year, an antecedent precipitation index (API), and geographic location. The relationships are such that the loss subtraction from rainfall to compute precipitation excess is greatest at the start of the storm and decreases to no subtraction when the storm rainfall totals from 7 to 16 inches. Precipitation losses become zero in the late part of extreme storms.

For this probable maximum flood analysis, median moisture conditions as determined from past records were used to determine the API at the start of the storm sequence. The antecedent storm is so large, however, that the precipitation excess computed for the later main storm is not sensitive to variations in adopted initial moisture conditions. The precipitation loss in the critical probable maximum storm totals 4.13 inches, 2.30 inches in the antecedent storm amounting to 36 percent of the 3-day 6.44-inch rainfall, and 1.83 inches in the main storm amounting to 11 percent of the 3-day, 16.46 inch rainfall. Table 2.4.3-1 displays the API, rain, and precipitation excess for each of the 45 subwatersheds of the hydrologic model for the SQN probable maximum flood.

No precipitation loss was applied in the probable maximum storm on the local area used to test the adequacy of the site drainage system and roofs of safety-related structures. Runoff was made equal to rainfall.

2.4.3.3 Runoff Model

The runoff model used to determine Tennessee River flood hydrographs at SQN is divided into 45 unit areas. Unit hydrographs are used to compute flows from these areas. The unit area flows are combined with appropriate time sequencing or channel routing procedures to compute inflows into the most upstream reservoirs, which in turn are routed through the reservoirs, using standard techniques. Resulting outflows are combined with additional local inflows and carried downstream using appropriate time sequencing or routing procedures, including unsteady flow routing. Figure 2.4.3-5 shows unit areas of the watershed upstream from SQN.

The runoff model used in this updated FSAR differs from that used previously because of refinements made in some elements of the model during PMF studies for other nuclear plants and those made from information gained from the 1973 flood, the largest that has occurred during present reservoir conditions.

Changes are identified when appropriate in the text. They include both additional and revised unit hydrographs and additional and revised unsteady flow stream course models.

Unit hydrographs were developed for each unit area from maximum flood hydrographs either recorded at stream gauging stations or estimated from reservoir headwater elevation, inflow, and discharge data. The number of unit areas has been increased from 34 used previously to 45. The differences include:

1. Use of the model developed for the Phipps Bend study which combined the two unit areas for Watauga River (Sugar Grove and Watauga local) into one unit area and divided the Cherokee to Gate City unit area into two unit areas (Surgoinsville local and Cherokee local below Surgoinsville);

2. Use of the model developed for the Clinch River Breeder Reactor which increased the unit areas on the Clinch River from 3 to 11 and the Watts Bar local from 1 to 2;

3. Changes to add an unsteady flow model for the Fort Loudoun-Tellico Dam complex which included dividing the lower Little Tennessee River unit area into two unit areas (Fontana to Chilhowee and Chilhowee to Tellico), and the Fort Loudoun local unit area into three unit areas (French Broad River local, Holston River local and Fort Loudoun local); and

4. Combining the two unit areas above Ocoee No. 1 (Ocoee No. 1 and Ocoee No. 3) into one unit area (Ocoee No. 1 to Blue Ridge).

In addition, eight of the unit graphs have been revised. Figure 2.4.3-6, which contains 11 sheets, shows the unit hydrographs. Table 2.4.3-2 contains essential dimension data for each unit hydrograph and identification of those hydrographs which are new or revised.
Tributary reservoir routings, except for Tellico, were made using the Goodrich semigraphical method and flat pool storage conditions. Main river reservoir and Tellico routings were made using unsteady flow techniques. This differs from the previous submission in that:

1. An unsteady flow model has been added for the Fort Loudoun-Tellico complex, and

2. The Chickamauga unsteady flow model has been revised using the 1973 flood data and results from the HEC-2 backwater computer program.

In the original study, the failure wave hydrograph of the mouth of the Hiwassee River was approximated for the postulated failures of Hiwassee, Apalachia and Blue Ridge dams as described in section 2.4.4.2.1. In the 1998 reassessment, an unsteady flow model developed during the dam safety studies was used as an adjunct to route the Hiwassee, Apalachia and Blue Ridge failures in the one half SSE. The model was verified by comparing model elevations in a state of steady flow with elevations computed by the standard-step method. This was done for steady flows ranging from 25,000 cfs to 1,000,000 cfs.

Unsteady flow routings were computer-solved with a mathematical model based on the equations of unsteady flow, [3]. Boundary conditions prescribed were inflow hydrographs at the upstream boundary, local inflow, and headwater discharge relationships at the downstream boundary based upon normal operating rules, or based upon rated curves when geometry controlled.

The unsteady flow mathematical model for the 49.9-mile-long Fort Loudoun Reservoir was divided into twenty-four 2.08-mile reaches. The model was verified at three gauged points within Fort Loudoun Reservoir using 1963 and 1973 flood data. The unsteady flow model was extended upstream on the French Broad and Holston Rivers to Douglas and Cherokee Dams, respectively. The French Broad and Holston River unsteady flow models were verified at one gaged point each at mile 7.4 and 5.5, respectively, using 1963 and 1973 flood data.

The Little Tennessee River was modeled from Tellico Dam, mile 0.3, through Tellico Reservoir to Chilhowee Dam at mile 33.6, and upstream to Fontana Dam at mile 61.0. The model for Tellico Reservoir to Chilhowee Dam was tested for adequacy by comparing its results with steady-state profiles at 1,000,000 and 2,000,000 cfs computed by the standard-step method. Minor decreases in conveyance in the unsteady flow model yielded good agreement. The average conveyance correction found necessary in the reach below Chilhowee Dam to make the unsteady flow model agree with the standard-step method was also used in the river reach from Chilhowee to Fontana Dam.

The Fort Loudoun and Tellico unsteady flow models were joined by a canal unsteady flow model. The canal was modeled with five equally-spaced cross Sections at 525-foot intervals for the 2,100-foot-long canal.

The unsteady flow routing model for the 72.4-mile-long Watts Bar Reservoir was divided into thirty-four 2.13-mile reaches. The model was verified at two gauged points within the reservoir using 1963 flood data.

The unsteady flow mathematical model for the total 58.9-mile-long Chickamauga Reservoir was divided into twenty-eight 2.1-mile reaches providing twenty-nine equally-spaced grid points. The grid point at mile 483.62 is nearest to the plant, mile 484.5. The unsteady flow model was verified at four gauged points within Chickamauga Reservoir using 1973 flood data. This differs from the previous submission in that the 1973 flood was added for verification, replacing the 1963 flood. The 1973 flood occurred during preparation of the FSAR and therefore, was not available for verification. The 1973 flood is the largest which has occurred since closure of South Holston Dam in 1950. Comparisons between observed and computed stages in Chickamauga Reservoir are shown in Figure 2.4.3-7.

It is impossible to verify the models with actual data approaching the magnitude of the probable maximum flood. The best remaining alternative was to compare the model elevations in a state of steady flow with elevations computed by the standard step method. This was done for steady flows ranging up to 1,500,000 cfs. An example shown by the rating curve of Figure 2.4.3-8 shows the good agreement.

The watershed runoff model was verified by using it to reproduce the March 1963 and March 1973 floods; the largest recorded since closure of South Holston Dam. This differs from the previous submission in that the 1973 flood was added for verification, replacing the 1957 flood. Observed volumes of precipitation excess were used in verification. Comparisons between observed and computed outflows from Watts Bar and Chickamauga Dams for the 1973 and 1963 floods are shown in Figures 2.4.3-9 and 2.4.3-10, respectively.

From a study of the basic units of the predicting system and its response to alterations in various basic elements, it is concluded that the model serves adequately and conservatively to determine maximum flood levels.

2.4.3.4 Probable Maximum Flood Flow

The probable maximum flood discharge at SQN was determined to be 1,236,000 cfs. The hydrograph of this flood is shown in Figure 2.4.3-11. This flood would result from the total basin downstream orographically fixed storm pattern, Figure 2.4.3-4, more completely described in Section 2.4.3.1. The dam safety modification to Fort Loudon, Tellico, and Watts Bar Dams enable them to safely pass the PMF. The west saddle dike at Watts Bar Dam would be overtopped and breached. Chickamauga would be overtopped but was assumed not to fail as a failure would reduce the flood level at the site.

In the original FSAR analysis, the flood would overtop and breach the earth embarkments of Fort Loudon, Tellico, and Watts Bar Dams upstream.

A second candidate storm is the 7,980-square-mile storm centered at Bulls Gap, Tennessee, 50 miles northeast of Knoxville, shown in Figure 2.4.3-2. The flood from this storm would overtop and breach the west saddle dike at Watts Bar Dam. The flood from the 7,980-square-mile storm is the less critical storm and would produce a probable maximum discharge less than from the total basin storm.

The previous PMF evaluations considered candidate situations involving upstream tributary dams Douglas and Watauga. These two situations were shown at that time to be non-governing. Dam safety modifications have since eliminated the potential failures of these dams. Therefore, these two candidate situations have been eliminated.

Reservoir routings started at median observed elevations for the mid-March large area PMP storms. Median levels were reevaluated using operating experience for:

1. The total project period, or

2. The five-year period, 1972-1976, for those projects whose operating guides were changed in 1971.

Because of the wet years of 1972-1975 and the operating guide changes, median elevations were higher for 8 of the 13 tributary reservoirs where routing is involved.

Normal reservoir operating procedures were used in the antecedent storm. These used turbine and sluice discharge in the tributary reservoirs. Turbine discharges are not used in the main river reservoirs after large flood flows develop because head differentials are too small. Normal operating procedures were used in the principal storm, except that turbine discharge was not used in either the tributary or main river dams.

All gates were determined to be operable without failures during the flood. Gates on main river dams would be fully raised, thus requiring no additional operations by the last day of the storm, which is before the structures and access roads would be inundated.

Median initial reservoir elevations were used at the start of the storm sequence used to define the PMF to be consistent with statistical experience and to avoid unreasonable combinations of extreme events. As a result, 53 percent of the total reserved system flood detention capacity was occupied at the start of the main flood. This is considered to be amply conservative. The statement made in the PSAR and subsequent versions of the FSAR that 67 percent of the reserved system detention capacity was occupied at the start of the main storm was in error. The correct percentage was 33. The remaining reserved system detention capacity was 67 percent. This erroneous statement was first made in the PSAR and was copied in subsequent statements where the routings were the same. In the revised analysis submitted in Amendment 51, all reservoirs are higher or about the same elevation at the beginning of the main storm as a result of the revised starting levels explained in Section 2.4.3.4 of the FSAR. This conservative change results in 53 percent of the total reservoir system detention capacity being occupied at the start of the main flood rather than 33 percent in previous studies.

Neither the initial reservoir levels nor the operating rules would have significant effect on maximum flood discharges and elevations at the plant site because spillway capacities, and hence, uncontrolled conditions, were reached early in the flood.

The procedures used to determine if and when an overtopped earth embankment would fail and the procedures for computing the effect of such failures are described in 2.4.4.2 and 2.4.4.3.

In testing the adequacy of the yard drainage system, to safely pass the site PMP, all underground drains were assumed clogged and the surface drainage to be full.

2.4.3.5 Water Level Determinations

The elevation hydrograph of the controlling PMF, cresting at elevation 719.6, is shown on Figure 2.4.3-12. Computation of both the probable maximum discharge hydrograph (Figure 2.4.3-11) and the corresponding elevation hydrograph was accomplished concurrently using the unsteady flow techniques described in Section 2.4.3.3.

The less critical total area storm-producing PMP depths on the 7,980-square-mile watershed would produce crest elevation 718.9 at the plant site.

Maximum water levels at buildings expected to result from the local plant PMP were determined using a transient flow (unsteady flow) model with hydraulically connected storage areas. Much of the plant site is flat, particularly at the switchyards, and a single flow path is not well defined. A transient model with interconnected storage areas very roughly approximates a two-dimensional model using one-dimensional methods by providing multiple simultaneous outlet paths for the exterior areas adjacent to plant buildings.

The separate watershed subareas and flowpaths are shown on Figure 2.4.3-13a.

The western plant site was evaluated as six interconnected storage areas with four primary weir-flow outlets and one connected transient flow stream-course model. Runoff from the western plant site will flow: Northwest to a channel along the main plant tracks and then across the main access highway (Area 7); to the West through a parking lot (Areas 6A, 6C, and 6E connected to transient flow model); Southwest through the vehicle barrier system directly to Chickamauga Lake (Area 6E); or South through the vehicle barrier system to the Yard Drainage and other Ponds (Area 6C). The maximum water surface elevations in Areas 6A and 6BS are below critical floor elevation 706.

The eastern plant site was evaluated as three interconnected storage areas with three weir-flow outlets and two connected transient flow stream-course models. Runoff from the eastern plant site will flow: North around the West and East ends of the multipurpose building to the intake channel (Area 5 connected to two transient flow models); South to the Condenser Circulating Water Discharge Channel (Areas 4 and 6D); or Southwest into the western plant site (Area 6D into 6C). The maximum water surface elevations in Areas 4, 5, and 6D are below critical floor elevation 706.

Underground drains were assumed clogged throughout the storm. For fence sections, the Manning's n value was doubled to account for increased resistance to flow and the potential for debris blockage.

The only stream adjacent to SQN is the Tennessee River. There are no streams within the site. The 1 percent-chance floodplain of the Tennessee River at the site is delineated on Figure 2.4.3-14. Details of the analyses used in the computation of the 1-percent-chance flood flow and water elevation are described in a study made by TVA for the Federal Insurance Administration (FIA) and published in February 1979 [5].

The only structures located in the 1-percent-chance floodplain are transmission towers, the intake pumping station skimmer wall, and the ERCW pump station deck. The ERCW pumps are located on the pump station deck at elevation 720.5, well above the 1-percent-chance flood level. These structures are shown on Figure 2.4.3-14.

The structures that are located in the floodplain will not alter flood flows or elevations. The 20,650-square-mile drainage area is not altered and the reduction in flow area at the site is infinitesimal and at the fringe of the flooded area. The site will be well maintained and any debris generated from it will be minimal and will present no problem to downstream facilities.

2.4.3.6 Coincident Wind-Wave Activity

Some wind waves are likely when the probable maximum flood crests at SQN. The flood would be near its crest for a day beginning about 2-1/2 days after cessation of the probable maximum storm. The day of occurrence would most likely be in the month of March or possibly the first week in April.

A conservatively high velocity of 45 miles per hour over water was adopted to associate with the probable maximum flood crest. A 45-mile- per-hour overwater velocity exceeds maximum March one-hour velocities observed in severe March windstorms of record in a homogeneous region as reported by the Corps of Engineers [6].

That a 45-mile-per-hour overwater wind is conservatively high, is supported also by an analysis of March day maximum winds of record collected at Knoxville and Chattanooga, Tennessee. The records analyzed varied from 30 years at Chattanooga to 26 years at Knoxville, providing samples ranging from 930 to 806 March days. The recorded fastest mile wind on each March day was used

rather than hourly data because this information is readily available in National Weather Service publications. Relationships to convert fastest mile winds to winds of other durations were developed from Knoxville and Chattanooga wind data contained in USWB Form 1001 and the maximum storm information contained in Technical Bulletin No. 2 [6]. From the wind frequency analysis it was determined that the 45-mile-per-hour overwater wind for the critical minimum duration of 20 minutes had an 0.1 percent chance of occurrence on any given March day.

The probability that this wind might occur on the specific day that the probable maximum flood would crest is extremely remote. Even assuming that the flood was to crest once during the 40-year plant life, the probability of the wind occurring on that particular day is in the order of 1×10^{-6}.

TVA estimates that the probability of the flood and wind occurring in a given year on the same day to be in the order of 1×10^{-11} to 1×10^{-13}.

Computation of wind waves was made using the procedures of the Corps of Engineers [7]. The critical directions were from the north-northwest and northeast with effective fetches of 1.7 and 1.5 miles, respectively. For the 45-mile-per-hour wind, 99.6 percent of the waves approaching the plant would be less than 4.2- and 4.0-foot-high crest to trough for the 1.7- and 1.5-mile fetches as shown on Figures 2.4.3-15 and 2.4.3-16. Maximum water surfaces in the reservoir approaching the plant would be 2.8 and 2.7 feet above the maximum computed level or elevations 722.4 and 722.3, respectively.

The maximum water level attained due to the PMF plus wind-wave activity is elevation 723.8 at the ERCW pump station and the nuclear island structures (shield, auxiliary, and control building).

The wind waves approaching the Diesel Generator Building and cooling towers break before reaching the structures due to the shallow depth of water. The topography surrounding these structures is such that the wind waves will break on a steeper slope (4H:1V) than the slope immediately adjacent to the structures. This is shown by Figure 2.4.3-17.

The runup estimates are calculated on the basis that the incoming wind waves break before reaching the structure and then reform for a shallower water depth. This reformed wave then approaches the structure. The runups are lower than the maximum reservoir level due to the small wave height for the reformed wave, the shallow water, and the very shallow slope before reaching the structures.

Wind-wave runup coincident with the maximum flood level for the diesel generator building and cooling towers is elevation 721.8. The level inside structures that are allowed to flood is elevation 720.1. The flood elevations used as design bases are given in Section 2.4A.1.1.

Dynamic Effect of Waves

1. Nonbreaking Waves

   The dynamic effect of nonbreaking waves on the walls of safety- related structures was investigated using the Rainflow Method [8]. As a result of this investigation, concrete and reinforcing stresses were found to be within allowables.

2. Breaking Waves

   The dynamic effect of breaking waves on the walls of safety-related structures was investigated using a method developed by D. D. Gaillard and D. A. Molitar. The concrete and reinforcing stresses were found to be less than the allowable stresses using this method.

3. Broken Waves

   The dynamic effect of broken waves on the walls of safety-related structures was investigated using a method proposed by the U.S. Army Coastal Engineering Research Center [7]. This method of design yielded concrete and reinforcing stresses within allowable limits.

   All safety-related structures are designed to withstand the static and dynamic effects of the water and waves as stated in Section 2.4.2.2.

2.4.4 Potential Dam Failures (Seismically and Otherwise Induced)

There are 20 major dams above SQN. These were examined individually and in groups to determine if failure might result from a seismic event and if such failure or failures occurring concurrently with storm runoff would create critical flood levels at the plant. Two situations were examined: (1) a one-half Safe Shutdown Earthquake (SSE) as defined in Subsection 2.5.2, imposed concurrently with one-half the probable maximum flood and (2) a Safe Shutdown Earthquake (SSE) as defined in Subsection 2.5.2, imposed concurrently with a 25-year flood. Neither of these conditions would create levels greater than the hydrologic probable maximum flood at SQN, described previously in 2.4.3. Details of the dam failure analysis are discussed in Section 2.4.4.2, Dam Failure Permutations.

Failure of Chickamauga Dam, downstream, can affect cooling water supplies at the plant. Consequently for conservatism, an arbitrary failure was imposed. This resulting condition would not be critical to plant operation, as discussed in Section 2.4.11.6.

2.4.4.1 Reservoir Description

Characteristics of dams that influence river conditions at SQN are contained in Tables 2.4.1-1 and 2.4.1-2. Their location with respect to the plant is shown on Figure 2.1.1-1. Seismic safety criteria were not incorporated in the design of dams upstream from SQN, except Tellico and Norris. Those projects having a potential to influence plant flooding levels were examined, as described in Section 2.4.4.2.

Elevation-storage relationships and seasonally varying storage allocations in the major projects are shown on the 14 sheets of Figure 2.4.1-3.

2.4.4.2 Dam Failure Permutations

The plant site and upstream reservoirs are located in the Southern Appalachian Tectonic Province and, therefore, subject to moderate earthquake forces with possible attendant failure. All upstream dams, whose failure has the potential to cause flood problems at the plant, were investigated to determine if failure from seismic or hydrologic events would endanger plant safety. Potential failures from both seismic and hydrologic events and the resulting consequences are discussed in this section.

It should be clearly understood that these studies have been made solely to ensure the safety of SQN against failure by floods caused from excessive rainfall or by the assumed failure of dams due to seismic forces. To assure that safe shutdown of SQN is not impaired by flood waters, TVA has in these studies added conservative assumptions to conservative assumptions to be able to show that the plant can be safely controlled even in the event that all these unlikely events occur in just the proper sequence. TVA is of the strong opinion that the chances of the assumed events occurring approach zero probability.

By furnishing this information, TVA does not infer or concede that its dams are inadequate to withstand great floods and/or earthquakes that may be reasonably expected to occur in the TVA region under consideration. TVA has a program of inspection and maintenance carried out on a regular schedule to keep its dams safe. Instrumentation of the dams to help keep check on their behavior was installed in many of the dams during original construction. Other instrumentation has been added since and is still being added as the need may appear or as new techniques become available.

In short, TVA has confidence that its dams are safe against catastrophic destruction by any natural forces that could be expected to occur.

2.4.4.2.1 Seismic Failure Analysis

Seismic failure analysis consisted of the following:

1. Determination of the water level at the plant during one-half the PMF with full reservoirs if its crests were augmented by flood waves from the postulated failure of upstream dams during a one-half SSE.

2. Determination of the water level at the plant during a 25-year flood with full reservoirs if its crests were augmented by flood waves from the postulated failure of upstream dams during a Safe Shutdown Earthquake (SSE).

The one-half SSE identified in condition 1 is defined in FSAR Section 2.5.2.4 as having a peak horizontal acceleration value of 0.09 g at the rock foundation. The discussion in Section 2.5.2.4 shows the extreme conservatism contained in the analysis.

In the 1998 reanalysis all potentially critical seismic events involving dam failure upstream of the plant site were reevaluated. The six events included the postulated one-half SSE failure of (1) Norris, (2) Fontana, (3) Cherokee-Douglas, and (4) Fontana-Hiwassee-Apalachia-Blue Ridge during one-half the PMF; and the postulated SSE failure of (5) Norris-Cherokee-Douglas and (6) Norris-Douglas-Fort Loudoun-Tellico during a 25 year flood.

Seismic failure of upstream dams during nonflood periods pose no threat to the plant.

Summary

A summary of the results of the seismic analysis is given in Table 2.4.4-1. SQN and upstream dams are located as shown on Figure 2.1.1-1. The highest flood level at SQN from different seismic dam failure and flood combinations would be elevation 707.9 from simultaneous failure of Fontana Dam on the Little Tennessee River and Hiwassee, Blue Ridge, and Apalachia Dams on the Hiwassee River during a one-half safe shutdown earthquake coincident with one-half the PMF. This includes improvements resulting from modifications performed for the Dam Safety Program. Wind waves could raise the elevation to 709.6 in the reservoir. Runup could reach elevation 710.4 on a 4:1 slope to elevation 712.8 on a vertical wall in shallow (4.9 feet) water, and to elevation 710.4 on a vertical wall in deep water.

Only one other seismic dam failure combination with coincident floods could cause elevations above plant grade.

Plant safety would be assured by shutdown prior to these floods crossing plant grade, elevation 705, using the warning system described in Appendix 2.4A.

The effect of postulated seismic bridge failure and resulting failure of spillway gate anchors at Watts Bar and Fort Loudoun Dams would not create a safety hazard at SQN.

Procedures

Concrete Structures

The standard method of computing stability is used. The maximum base compressive stress, average base shear stress, the factor of safety against overturning, and the shear strength required for a shear-friction factor of safety of 1 are determined. To find the shear strength required to provide a safety factor of 1, a coefficient of friction of 0.65 is assigned at the elevation of the base under consideration.

As stated in Section 2.4.1.2, all of the original stability analyses and postulated dam failure assumptions in the 1998 reanalyses were conservatively assumed to occur in the same manner and in combination with the same postulated rainfall events.

The analyses for earthquake are based on the static analysis method as given by Hinds [10] with increased hydrodynamic pressures determined by the method developed by Bustamante and Flores [11]. These analyses include applying masonry inertia forces and increased water pressure to the structure resulting from the acceleration of the structure horizontally in the upstream direction and simultaneously in a downward direction. The masonry inertia forces are determined by a dynamic analysis of the structure which takes into account amplification of the accelerations above the foundation rock.

No reduction of hydrostatic or hydrodynamic forces due to the decrease of the unit weight of water from the downward acceleration of the reservoir bottom is included in this analysis.

Waves created at the free surface of the reservoir by an earthquake are considered of no importance. Based upon studies by Chopra [12] and Zienkiewicz [13], it is our judgment that before waves of any significant height have time to develop, the earthquake will be over. The duration of earthquake used in this analysis is in the range of 20 to 30 seconds.

Although accumulated silt on the reservoir bottom would dampen vertically traveling waves, the effect of silt on structures is not considered. There is only a small amount of silt now present, and the accumulation rate is slow, as measured by TVA for many years [14].

Embankment

Embankment analysis was made using the standard slip circle method, except for Chatuge and Nottely Dams where the Nemark method for the dynamic analysis of embankment slopes was used. The effect of the earthquake is taken into account by applying the appropriate static inertia force to the dam mass within the assumed slip circle.

In the analysis, the embankment design constants used, including the sheer strength of the materials in the dam and the foundation, are the same as those used in the original stability analysis.

Although detailed dynamic soil properties are not available, a value for seismic amplification through the soil has been assumed based on previous studies pertaining to TVA nuclear plants. These studies have indicated maximum amplification values slightly in excess of two for a rather wide range of shear wave velocity to soil height ratios. For these analyses, a straight-line variation is used with an acceleration at the top of the embankment being two times the top of rock acceleration.

Flood Routing

The runoff model described in Section 2.4.3.3, which includes unsteady flow models for critical reservoirs and river reaches, was used to reevaluate plant site flood levels resulting from the postulated SSE and one-half SSE dam failure combinations. The remaining events produced plant site flood levels sufficiently lower than the controlling events and were not evaluated.

Reservoir operating procedures used were those applicable to the season and flood inflows.

This section was revised with a major rearrangement to locate the controlling events evaluated in the 1998 analysis first and the non-controlling events, which were not re-calculated later. The non-controlling events are left in the SAR for history.

<u>One-half SSE Concurrent With One-Half the Probable Maximum Flood</u>

Previous evaluations have been made which determined flood levels at SQN for potentially critical events. Re-evaluations made later using the updated runoff model described in Section 2.4.3.3 and including the Dam Safety Program modifications did not determine flood levels for those events which were previously shown to clearly not be controlling. The 1998 analysis for determining the effects of the Dam Safety Program modifications determined that non-flood related seismic dam failure events clearly pose no threat to the plant. Flood levels were determined for six combined seismic/flood events. Only two of these controlling seismic/flood events would exceed plant grade. These two events consist of multiple dam failures on (1) Little Tennessee/Hiwassee, and (2) Clinch/Upper Tennessee rivers with flood levels at SQN of El. 707.9 and 706, respectively. The following is detailed descriptions of the potentially critical controlling events including reevaluated flood levels, followed by brief descriptions of the non-controlling failure events previously evaluated.

<u>Multiple Failures</u>

Although considered, as discussed in the following paragraphs, TVA believes that multiple dam failures are an extremely unlikely event. TVA's search of the literature reveals no record of failure of concrete dams from earthquake. The postulation of an SSE of 0.18 g acceleration is a very conservative upper limit in itself (as stated in Section 2.5.2). In addition, the SSE must be located in a very precise region to have the potential for multiple dam failures.

SSE - In order to fail three dams--Norris, Cherokee, and Douglas--the epicenter of a SSE must be confined to a relatively small area, the shape of a football, about 10 miles wide and 20 miles long. In order to fail four dams--Norris, Douglas, Fort Loudoun, and Tellico--the epicenter of an SSE must be confined to a triangular area with sides of approximately 1 mile in length. However, as an extreme upper limit the above two combinations of dams are postulated to fail as well as the combinations of (1) Fort Loudoun, Tellico, and Fontana; (2) Fontana and Douglas; and (3) Fontana and the six Hiwassee River dams. The 1998 re-analysis determined that only the first two combinations are controlling and need to be considered. Only the Norris-Cherokee-Douglas event would exceed plant grade elevation.

One-half SSE - Attenuation studies of the one-half SSE show that there are three combinations of simultaneous failures of more than one dam which need to be considered with respect to SQN safety which are discussed below. These are (1) Cherokee-Douglas, (2) Fontana-Hiwassee-Apalachia-Blue Ridge, and (3) Hiwassee-Apalachia-Blue Ridge-Ocoee No 1.-Nottely. The 1998 re-analysis determined that only the first two combinations are controlling and need to be considered. Only the Fontana-Hiwasse-Apalachia-Blue Ridge event would exceed plant grade.

The following descriptions are first for the controlling events for which flood levels were calculated for the 1998 reanalysis, followed by the non-controlling events which were not re-analyzed in 1998.

<u>One-half SSE Concurrent With One-Half the Probable Maximum Flood (Controlling Events)</u>

1. Norris Dam

Results of the Norris Dam stability analyses for a typical spillway block and a typical non-overflow section of maximum height are shown on Figure 2.4.4-8. Because only a small percentage of the spillway base is in compression, this structure is judged to fail. The high non-overflow section with a small percentage of the base in compression and with high compressive and shearing stresses is also judged to fail.

Figure 2.4.4-9 shows the likely condition of the dam after failure. Based on stability analyses, the non-overflow blocks remaining in place are judged to withstand the one-half SSE. Blocks 33-44 are judged to fail by overturning.

The location of the debris is not based on any calculated procedure of failure because it is believed that this is not possible. It is TVA's judgment, however, that the failure mode shown is one logical assumption; and, although there may be many other logical assumptions, the amount of channel obstruction would probably be about the same.

The discharge rating for this controlling, debris section was developed from a 1:150 scale hydraulic model at the TVA Engineering Laboratory and was verified closely by mathematical analysis.

In the hydrologic routing for this failure, Melton Hill Dam was postulated to fail when the flood wave reached headwater elevation 804, based on structural analysis. The headwater at Watts Bar Dam would reach elevation 758.1, 8.9 feet below top of dam. The west saddle dike at Watts Bar Dam would be overtopped and breached. A complete washout of the dike was assumed. The resulting water level at the nuclear plant site is 698.1, 6.9 feet below plant grade 705.

2. Fontana Dam

Fontana Dam was assumed to fail in the one-half SSE, although no stability analysis was made. Fontana is a high dam constructed with three longitudinal contraction joints in the higher blocks.

A structural defect in Fontana Dam was found in October of 1972 and consists of a longitudinal crack in three blocks in the curved portion at the left end of the dam (see Figure 2.4.4-16). Strengthening of these blocks by post-tensioning and grouting of the cracks was completed in October 1973 (see Figure 2.4.4-17). Only these three blocks are cracked, and there is no evidence that any other portion of the dam is weakened.

Studies and tests, undertaken with the concurrence of a board of private consulting engineers, indicate that this cracking was caused by a longitudinal thrust created by a combination of long-time concrete growth and expansion due to temperature rise in the summer months. This thrust tends to push the curved blocks upstream. The studies and tests will continue until there is established a basis for design of permanent measures to control the future behavior of the dam.

The strengthening work has reestablished the structural integrity of the cracked blocks. Although the joints are keyed and grouted, it is possible that the grouting was not fully effective. Consequently, there is some question as to how this structure will respond to the motion of a severe earthquake. To be conservative, therefore, it is assumed that Fontana Dam will not resist the one-half SSE without failure.

Figure 2.4.4-16 shows the part of Fontana Dam judged to remain in its original position after failure and the assumed location of the debris of the failed portion. The location of the debris after failure is one logical assumption based on a failure of the dam at the longitudinal contraction joints. There may be other logical assumptions, but the amount of channel obstruction would probably be about the same.

The higher blocks 9-27, containing either two or three longitudinal joints, are assumed to fail. Right abutment blocks 1-8 and left abutment blocks 28 and beyond were judged to be stable for the following reasons:

1. Their heights are less than one-half the maximum height of the dam.

2. None of these blocks have more than one longitudinal contraction joint, and some have no longitudinal joints.

3. The back slope of Fontana Dam is one on 0.76, which the original stability analysis shows is flatter than that required for stability for the normal static loadings.

Although not investigated, it was assumed that Nantahala Dam, upstream from Fontana and Santeetlah on a downstream tributary, and the three ALCOA dams, downstream on the Little Tennessee River, Cheoah, Calderwood, and Chilhowee, would fail along with Fontana in the one-half SSE. Instant vanishment was assumed. Tellico and Watts Bar Dam spillway gates would be operable during and after the one-half SSE. Failure of the bridge at Fort Loudoun Dam would render the spillway gates inoperable in the wide-open position.

The flood wave would overtop Tellico Dam and its saddle dikes. Transfer of water into Fort Loudoun would occur but would not be sufficient to overtop the dam or to prevent failure of Tellico Dam. Tellico was postulated to completely fail. Watts Bar headwater would reach elevation 761.3, 5.7 feet below top of dam. The Watts Bar west saddle dike would be overtopped and breached. A complete washout of the dike was assumed. The elevation at the plant site would be 702.8, 2.2 feet below plant grade.

3. Cherokee-Douglas

The simultaneous failure of Cherokee and Douglas Dams could occur when the one-half SSE is located midway between the dams which are just 15 miles apart.

Results of the Cherokee Dam stability analysis for a typical spillway block are shown in Figure 2.4.4-10. Based on this analysis, the spillway is judged stable at the foundation base elevation 900. Analyses made for other elevations above elevation 900, but not shown in Figure 2.4.4-10, indicate the resultant of forces falls outside the base at elevation 1010. The spillway is assumed to fail at that elevation.

The non-overflow dam is embedded in fill to elevation 981.5 and is considered stable below that elevation. However, stability analysis indicates failure will occur above the fill line.

The powerhouse intake is massive and backed up by the powerhouse. Therefore, it is judged able to withstand the one-half SSE without failure.

Results of the analysis for the highest portion of the south embankment are shown on Figure 2.4.4-11. The analysis was made using the same shear strengths of material as were used in the original analysis and shows a factor of safety of 0.85. Therefore, the south embankment is assumed to fail during the one-half SSE. Because the north embankment and saddle dams 1, 2, and 3 are generally about one-half or less as high as the south embankment, they are judged to be stable for the one-half SSE.

Figure 2.4.4-12 shows the assumed condition of the dam after failure. All debris from the failure of the concrete portion is assumed to be located downstream in the channel at elevations lower than the remaining portions of the dam, and therefore, will not obstruct flow.

Results of the Douglas Dam original stability analysis for a typical spillway block are shown in Figure 2.4.4-13. The upper part of the Douglas spillway is approximately 12 feet higher than Cherokee, but the amplification of the rock surface acceleration is the same. Therefore, based on the Cherokee analysis, it is judged that the Douglas spillway will fail at elevation 937, which corresponds to the assumed failure elevation of the Cherokee spillway.

The Douglas non-overflow dam is similar to that at Cherokee and is embedded in fill to elevation 927.5. It is considered stable below that elevation. However, based on the Cherokee analysis, it is assumed to fail above the fill line. The abutment non-overflow blocks 1-5 and 29-35, being short blocks, are considered able to resist the one-half SSE without failure.

The powerhouse intake is massive and backed up downstream by the powerhouse. Therefore, it is considered able to withstand the one-half SSE without failure.

Results of the original analysis of the saddle dam shown on Figure 2.4.4-14 indicate a factor of safety of one. Therefore, the saddle dam is considered to be stable for the one-half SSE.

Figure 2.4.4-15 shows the portions of the dam judged to fail and the portions judged to remain. All debris from the failed portions is assumed to be located downstream in the channel at elevations lower than the remaining portions of the dam and, therefore, will not obstruct flow.

These failures, in conjunction with one-half the probable maximum flood, would overtop Fort Loudon for only 6 hours, but would not fail the dam. At Watts Bar the west saddle dike would be overtopped and breached. A complete washout of the dike was assumed. Crest level at SQN would be elevation 701.1, 3.9 feet below plant.

4. Fontana, Hiwassee, Apalachia, and Blue Ridge Dams

Fontana, Hiwassee, Apalachia, and Blue Ridge Dams could fail when the one-half SSE is located within the football-shaped area shown in Figure 2.4.4-18.

This event produces maximum ground accelerations of 0.09 g at Fontana, 0.09 g at Hiwassee, 0.07 g at Apalachia, 0.08 g at Chatuge, 0.05 g at Nottely, 0.03 g at Ocoee No. 1, 0.04 g at Blue Ridge, 0.04 g at Fort Loudoun and Tellico, and 0.03 g at Watts Bar. Failure is postulated for Fontana and Hiwassee for an earthquake epicenter located anywhere within the football-shaped area shown on

Figure 2.4.4-18. Ground accelerations shown for the various dams are maximum that could occur for epicenters located at various points in the described area and would not occur simultaneously. Fort Loudoun, Tellico, and Watts Bar Dams and spillway gates would remain intact. The degree of Fontana failure and likely position of debris are judged to be comparable to that shown for single failure in Figure 2.4.4-16. Hiwassee, Apalachia, and Blue Ridge Dams were assumed to completely disappear. Chatuge was judged not to fail as the acceleration is less than for the one-half SSE centered at the dam.

Nottely Dam is a rockfill dam with large central impervious rolled fill core. The maximum attenuated ground acceleration at Nottely is only 0.054 g. A field exploration boring program and laboratory testing program of samples obtained in a field exploration was conducted. During the field exploration program, standard penetration tests blow counts were obtained on both the embankment and its foundation materials. Both static and dynamic (cyclic) triaxial shear tests were made. This information was used in the Newmark Method of Analysis. The "Newmark Method of Analysis" (Newmark, N. M., "Effects of Earthquake on Dams of Embankments," Geotechnique 15:140-141, 156, 1965) utilizing the information obtained from the testing program was used to determine the structural stability of Nottely Dam. We conclude Nottely Dam can easily resist the attenuated ground acceleration of 0.054 g with no detrimental damage.

Ocoee No. 1 Dam is a concrete gravity structure. The maximum attenuated ground acceleration is 0.03 g. The 0.03 g with the proper amplification was used to analyze the structural stability of structures at Ocoee No. 1. The method of analysis used was the same as described previously under "Procedures, Concrete Structures." The analysis shows low stresses with good factors of safety against sliding and overturning. We conclude the dam will not fail.

In the original analysis, the failure wave hydrograph was approximated for the Hiwassee River at its mouth for the failures of Hiwassee, Apalachia and Blue Ridge Dams. In the 1998 re-analysis an unsteady flow model described in Section 2.4.3.3 developed during the dam safety studies was used as an adjunct to route the Hiwassee, Apalachia and Blue Ridge failures.

In the simultaneous failure of Fontana, Hiwassee, Apalachia, and Blue Ridge Dams, the Fontana failure wave would overtop and fail the Tellico embankments. Transfer of water into Fort Loudoun would occur but would not be sufficient to overtop the dam or to prevent failure of Tellico. Tellico was postulated to completely fail. Watts Bar headwater would reach elevation 761.3, 5.7 feet below top of dam. The west saddle dike at Watts Bar would be overtopped. A complete washout of the dike down to ground elevation was assumed. This flood wave combined with that of Hiwassee, Blue Ridge, and Apalachia Dams would produce a maximum flood level at the plant site of 707.9, 2.9 feet above 705 plant grade. This is the highest flood resulting from any combination of seismic and concurrent flood events. The stage hydrograph at the plant site is shown on Figure 2.4.4-21.

<u>SSE Concurrent With 25-Year Flood (Controlling Events)</u>

5. Norris, Cherokee, and Douglas

Norris, Cherokee, and Douglas Dams were also postulated to fail simultaneously. Figure 2.4.4-29 shows the location of an SSE, and its attenuation, which produces 0.15 g at Norris, 0.09 g at Cherokee and Douglas, 0.08 g at Fort Loudoun and Tellico, 0.05 g at Fontana, and 0.03 g at Watts Bar. Fort Loudoun, Tellico, and Watts Bar have been judged not to fail for the one-half SSE (acceleration value of 0.09 g) (see following discussion of non-controlling events). The bridge at Fort Loudoun Dam, however, might fail under 0.08 g forces, falling on any open gates and on gate-hoisting machinery. Trunnion anchor bolts of open gates would fail and the gates would be washed downstream, leaving an open spillway. Closed gates could not be opened. The most conservative

assumption was used that at the time of the seismic event on the upstream tributary dams, the crest of the 25-year flood would likely have passed Fort Loudoun and flows would have been reduced to turbine capacity. Hence spillway gates would be closed. As stated before, it is believed that multiple dam failure is extremely remote, and it seems reasonable to exclude Fontana on the basis of being the most distant in the cluster of dams under consideration. For the postulated failures of Norris, Cherokee, and Douglas, the portions judged to remain and debris arrangements are as given in Figures 2.4.4-9, 2.4.4-12, and 2.4.4-15, respectively.

The SSE will produce the same postulated failures of Cherokee and Douglas Dams as were described for the one-half SSE.

For Norris under SSE conditions, blocks 31-45 (883 feet of length) are judged to fail. The resulting debris downstream would occupy a greater span of the valley cross section than would the debris from the one-half SSE but with the same top level, elevation 970. Figure 2.4.4-28 shows the part of the dam judged to fail and the location and height of the resulting debris. The discharge rating for this controlling debris section was developed from a 1:150 scale hydraulic model at the TVA Engineering Laboratory and was verified closely by mathematical analysis. The somewhat more extensive debris in SSE failure restricts discharge slightly compared to one-half SSE failure conditions.

The flood for the postulated failure combination would overtop and breach Fort Loudoun Dam. Although transfer of water into Tellico would occur, it would not be sufficient to overtop the dam. At Watts Bar Dam the headwater would reach 764.9, 2.1 feet below the top of the earth embankment of the main dam. However, the west saddle dike at Watts Bar Dam would be overtopped and breached. Resulting water surface at SQN would reach elevation 706. This is 1.0 foot higher than plant grade. This is the highest flood resulting from any combination of SSE seismic and flood events. The flood elevation Flow and stage hydrographs at the plant site is shown on Figure 2.4.4-30.

6. Norris, Douglas, Fort Loudoun, and Tellico

Norris, Douglas, Fort Loudoun, and Tellico Dams were postulated to fail simultaneously. Figure 2.4.4-31 shows the location of an SSE, and its attenuation, which produces 0.12 g at Norris, 0.08 g at Douglas, 0.12 g at Fort Loudoun and Tellico, 0.07 g at Cherokee, 0.06 g at Fontana, and 0.04 g at Watts Bar. Cherokee is judged not to fail at 0.07 g; Watts Bar has previously been judged not to fail at 0.09 g; and, for the same reasons as given above, it seems reasonable to exclude Fontana in this failure combination. For the postulated failures of Norris, Douglas, Fort Loudoun, and Tellico, the portions judged to remain and the debris arrangements are as given in Figures 2.4.4-9, 2.4.4-15, 2.4.4-26, and 2.4.4-27, respectively. For analysis purposes, Fort Loudoun and Tellico were postulated to fail completely as the portions judged to remain are relatively small.

The SSE will produce the same postulated failure of Douglas Dam as was described for the one-half SSE.

Results of the stability analysis for Fort Loudoun Dam are shown on Figure 2.4.4-24. Because the resultant of forces falls outside the base, a portion of the spillway is judged to fail. Based on previous modes of failure for Cherokee and Douglas, the spillway is judged to fail above elevation 750 as well as the bridge supported by the spillway piers.

The results of the slip circle analysis for the highest portion of the embankment are shown on Figure 2.4.4-25. Because the factor of safety is less than one, the embankment is assumed to fail.

No analysis was made for the powerhouse under SSE. However, an analysis was made for the one-half SSE with no water in the units, a condition believed to be extremely remote to occur during the one-half SSE. Because the stresses were low and a large percentage of the base was in compression, it is considered that the addition of water in the units would be a stabilizing factor, and the powerhouse is judged not to fail.

Figure 2.4.4-26 shows the condition of the dam after assumed failure. All debris from the failure of the concrete portions is assumed to be located in the channel below the failure elevations.

No structural analysis was made for Tellico Dam failure in the SSE. Because of the similarity to Fort Loudoun, the spillway and entire embankment are judged to fail in a manner similar to Fort Loudoun. Figure 2.4.4-27 shows after failure conditions with all debris assumed located in the channel below the failure elevation.

This postulated failure combination results in Watts Bar headwater elevation 758.9, 8.1 feet below above the top of the embankment of the main dam. The west saddle dike at Watts Bar Dam would be overtopped and breached. A complete washout of the dike was assumed. The resulting water level at SQN would be elevation 699.3, 5.7 feet below plant grade 705.

<u>One-half SSE Concurrent With One-Half the Probable Maximum Flood (Non-controlling Events-Historical)</u>

1. Watts Bar Dam

Stability analyses of Watts Bar Dam powerhouse and spillway sections result in the judgment that these structures will not fail. The analyses show low stresses with about 38 percent of the spillway base in compression and about 42 percent of the powerhouse base in compression. Results are given in Figure 2.4.4-1. Dynamic analysis of the concrete structures resulted in the determination that the base acceleration is amplified at levels above the base.

The slip circle analysis of the earth embankment section results in a factor of safety of 1.52, and the embankment is judged not to fail. Results are given in Figure 2.4.4-2.

Normally for the condition of peak discharge at the dam for one-half the PMF, the spillway gates would be in the wide open position (Figure 2.4.4-3). But, analysis of the bridge structure for forces resulting from a one-half SSE, including amplification of acceleration results in the determination that the bridge could fail as a result of shearing the anchor bolts. The downstream bridge girders could strike the spillway gates. The impact of the girders striking the gates could fail the bolts which anchor the gate trunnions to the pier anchorages allowing the gates to fall. The flow over the spillway crest would be the same as that prior to bridge and gate failure. Hence, bridge failure will cause no adverse effect on the flood.

A potentially severe condition is the bridge falling when most spillway gates would be closed. The gate hoisting machinery would be inoperable after being struck by the bridge. As a result, the flood would crest with the gates closed and the bridge deck and girders lying on top of the spillway piers. Analysis of the concrete portions of the dam for the headwater for this condition shows that they will not fail.

Flood levels at SQN for all the conditions described above is safely below plant grade elevation 705.

2. Fort Loudoun Dam

Stability analyses of Fort Loudoun Dam powerhouse and spillway sections result in the judgment that these structures will not fail. The analyses show low base stresses, with near two-thirds of the base in compression. Results are given in Figure 2.4.4-4.

Slip circle analysis of the earth embankment results in a factor of safety of 1.26, and the embankment is judged not to fail. Results are given in Figure 2.4.4-5.

The spillway gates and bridge are of the same design as those at Watts Bar Dam. Conditions of failure during a one-half SSE are the same, and no problems are likely. Coincident failure at Fort Loudoun and Watts Bar does not occur.

For the potentially critical case of Fort Loudoun bridge failure at the onset of the main portion of one-half the probable maximum flood flow into Fort Loudoun Reservoir, it was found that the Watts Bar inflows are much less than the condition resulting from simultaneous failure of Cherokee and Douglas.

3. Tellico Dam

No part of Tellico Dam is judged to fail. Results of the stability analyses for a typical non-overflow block and a typical spillway block are shown in Figure 2.4.4-6. The result of the stability analysis of the earth embankment is shown in Figure 2.4.4-7 and indicates a factor of safety of 1.28.

4. Cherokee Dam

No hydrologic results are given for the single failure of Cherokee Dam because the simultaneous failure of Cherokee and Douglas is more critical.

5. Douglas Dam

No hydrologic results are given for the single failure of Douglas Dam because the simultaneous failure of Cherokee and Douglas is more critical.

6. Hiwassee River Dams

Hiwassee Dam was assumed to fail in the one-half SSE. No hydrologic results are given for the single failure of Hiwassee Dam because its simultaneous failure with other dams is more critical.

7. Apalachia

Apalachia Dam was assumed to fail in the one-half SSE. No hydrologic results are given for the single failure of Apalachia Dam because its simultaneous failure with other dams is more critical.

8. Blue Ridge

Blue Ridge Dam was assumed to fail in the one-half SSE. No hydrologic results are given for the single failure of Blue Ridge Dam because its simultaneous failure with other dams is more critical.

9. Ocoee No. 1

Ocoee No. 1 Dam was assumed to fail in the one-half SSE. No hydrologic results are given for the single failure of Ocoee No. 1 Dam because its simultaneous failure with other dams is more critical.

10. Nottely

Nottely Dam was assumed to fail in the one-half SSE. No hydrologic results are given for the single failure of Nottely Dam because its simultaneous failure with other dams is more critical.

11. Chatuge

Chatuge Dam is a homogeneous, impervious rolled-fill dam. With the epicenter of the one-half SSE located at the dam, the maximum ground acceleration at Chatuge is 0.09 g. Ground accelerations of this magnitude should have no detrimental effects on a well-constructed compacted earthfill embankment. We know of no failures of compacted earth embankment slopes from earthquake motions. Failures to date have been associated with other liquefaction of hydraulic fill embankments of liquefaction of loose granular foundation materials. The rolled embankment materials in Chatuge are not sensitive to liquefaction. To verify these conclusion analysis using the "Newmark Method for the Dynamic Analysis of Embankment Slopes" (Newmark, N. M., "Effects of Earthquake on Dams of Embankments," Geotechnique 15:140-141, 156, 1965) was made to determine the structural stability of Chatuge. We conducted a field exploration boring program and laboratory testing program of samples obtained in the field exploration. During the field exploration program, standard penetration tests blow counts were obtained on both the embankment and its foundation materials. Both static and dynamic (cyclic) triaxial shear tests were made. This information was used in the Newmark Method of Analysis. We concluded from the Analysis that the Chatuge Dam can easily resist the ground acceleration of 0.09 g with no detrimental damage.

12. Hiwassee, Apalachia, Blue Ridge, Ocoee No. 1, and Nottely

Hiwassee, Apalachia, Blue Ridge, Ocoee No.1, and Nottely Dams could fail when the one-half SSE is critically located. All five dams were assumed to completely disappear in this event. Resulting crest level at SQN would be below plant grade 705.

<u>SSE Concurrent With 25-Year Flood (Non-controlling Events - Historical)</u>

1. Watts Bar Dam

A reevaluation was not made for Watts Bar Dam for SSE conditions. A previous evaluation had determined that even if the dam is arbitrarily removed instantaneously, the level at the nuclear plant site would be below plant grade.

2. Fort Loudoun Dam

No hydrologic routing for the single failure of Fort Loudoun, including the bridge structure, is made because its simultaneous failure with Tellico and Fontana, as well as with Tellico, Norris, and Douglas, are controlling.

3. Tellico Dam

No routing for the single failure of Tellico is made for the reasons given above for Fort Loudoun.

4. Norris Dam

This postulated single failure would result in peak headwater at Watts Bar below the top of the earth portions of the dam. Routing was not carried further because it was evident that flood levels at the plant site would be considerably lower than for the Norris failure in the one-half SSE combined with the one-half PMF.

5. Hiwassee River Dams Considered Separately

No structural analyses were made for Chatuge, Nottely, Blue Ridge, Ocoee No. 1, Hiwassee, and Apalachia in the SSE. Instead, all six dams were postulated to fail completely.

No routing for the failure of the six Hiwassee dams alone is made because their simultaneous failure with Fontana is considered as discussed earlier in this subparagraph.

6. Cherokee, Douglas, and Fontana Considered Separately

The SSE will produce the same postulated failures of Cherokee, Douglas, and Fontana Dams as were described for the one-half SSE. None of these failures need to be carried downstream, however, because elevations would be lower than the same failures in one-half the probable maximum flood.

7. Fort Loudoun, Tellico, and Fontana

An SSE centered between Fontana and the Fort Loudoun-Tellico complex was postulated to fail these three dams. The four ALCOA dams downstream from Fontana and Nantahala, an ALCOA dam, upstream were also postulated to fail completely in this event. Watts Bar Dam and spillway gates would remain intact, but failure of the roadway bridge was postulated which would render the spillway gates inoperable. At the time of seismic failure, discharges would be small in the 25-year flood. For conservatism, Watts Bar gates were assumed inoperable in the closed position after the SSE event. This event would result in a flood level at the nuclear plant site below 705 plant grade.

8. Douglas and Fontana

Douglas and Fontana were postulated to fail simultaneously. The location of an SSE required to fail both dams would produce 0.14 g at Douglas, 0.09 g at Fontana, 0.07 g at Cherokee, 0.05 g at Norris, 0.06 g at Fort Loudoun and Tellico, and 0.03 g at Watts Bar. For the postulated failures of Douglas and Fontana, the portions judged to remain and the debris arrangements are as given in Figures 2.4.4-15 and 2.4.4-16. Fort Loudoun, Tellico, and Watts Bar have previously been judged not to fail for the OBE (0.09 g). The bridge at Fort Loudoun Dam, however, might fail under 0.06 g forces, falling on gates and on gate hoisting machinery. Fort Loudoun gates were assumed inoperable in the closed position following the SSE event. Resulting water surface at SQN would be below plant grade.

9. Fontana and Hiwassee River Dams

Fontana and six Hiwassee River dams--Hiwassee, Apalachia, Chatuge, Nottely, Blue Ridge, and Ocoee No. 1--were postulated to fail simultaneously. For the postulated failure of Fontana, the portion judged to remain and the debris arrangements are as given in Figure 2.4.4-16. The six Hiwassee dams were assumed to fail completely. Fort Loudoun, Tellico, and Watts Bar are judged not to fail with all gates operable. The Fontana surge combined with that of the six Hiwassee River dams would reach an elevation at the plant site below the plant grade.

2.4.4.2.2 Hydrologic Failure Analysis

All upstream and downstream dams which could have significant influence on flood levels at SQN were examined for potential failure during all flood conditions, which would have the potential to produce maximum plant flood levels including the dam PMF at the individual upstream dams. Concrete sections were examined for overturning and horizontal shear and sliding. Spillway gates were examined for stability at potentially critical water levels and against failure from being struck by water borne objects. Locks and lock gates were examined for stability, and earth embankments were examined for erosion due to overtopping.

During the SQN PMF, the only failure would be the west saddle dike at Watts Bar. Chickamauga Dam would be overtopped but was conservatively assumed not to fail.

Concrete Section Analysis

For concrete dam sections, comparisons were made between the original design headwater and tailwater levels and those that would prevail in the PMF. If the overturning moments and horizontal forces were not increased by more than 20 percent, the structures were considered safe against failure. All upstream dams passed this test except Douglas, Fort Loudoun, and Watts Bar. Original designs showed the spillway sections of these dams to be most vulnerable. These spillway sections were examined in further detail and judged to be stable.

Spillway Gates

During peak PMF conditions the radial spillway gates of Fort Loudoun and Watts Bar Dams will be wide open with flow over the gates and under the gates. For this condition both the static and dynamic load stresses in the main structural members of the gate will be less than the yield stress by a factor of three. The stress in the trunnion pin is less than the allowable design stress by a factor greater than 10. The trunnion pin is prevented from dislodgment by a key into the gate anchorage assembly and fitting into a slot in the pin.

The gates were also investigated for the condition when rising headwater level first begins to exceed the bottom of the gates in the wide-open position. This condition produces the largest forces tending to rotate the radial gates upward. In the wide-open position the gates are dogged against steel gate stops anchored to the concrete piers. The stresses in the gate stop members are less than the yield stress of the material by a factor of 2.

It is concluded that the above-listed margins are sufficient to provide assurance also that the gates will not fail as a result of additional stresses which may result from possible vibrations of the gates acting as orifices.

Waterborne Objects

Consideration has been given to the effect of water borne objects striking the spillway gates and bents supporting the bridge across Watts Bar Dam at peak water level at the dam. The most severe potential for damage would be by a barge which has been torn loose from its moorings and floats into the dam.

Should the barge approach the spillway portion of the dam end on, one bridge bent could be failed by the barge and two spillway gates could be damaged and possibly swept away. The loss of one bridge bent will not collapse the bridge because the bridge girders are continuous members and the stress in

the girders will be less than the ultimate stress for this condition of one support being lost. Should two gates be swept away, the nappe of the water surface over the spillway weir would be such that the barge would be grounded on the tops of the concrete spillway weirs and provide a partial obstruction to flow comparable to unfailed spillway gates. Hence the loss of two gates from this cause will have little effect on the peak flow and elevation.

Should the barge approach the spillway portion broadside, two and possibly three bridge bents could be failed. For this condition, the bridge would collapse on the barge and the barge would be grounded on the tops of the spillway weirs. This would be probable because the approach velocity of the barge would be from 4-to-7 miles per hour and the bottom of the barge would be about six inches above the tops of the weirs. For this condition the barge would be grounded before striking the spillway gates because the gates are about 20 feet downstream from the leg of the upstream bridge bents.

Lock Gates

The lock gates at Fort Loudoun, Watts Bar, and Chickamauga were examined for possible failure with the conclusion that no potential for failure exists because the gates are designed for a differential hydrostatic head greater than that which exists during the probable maximum flood.

Embankment Breaching

In the 1998 reanalysis, the only embankment failure would be the west saddle dike at Watts Bar Dam. Chickamauga Dam, downstream of the plant, would be overtopped but was assumed not to fail. This is conservative as failure of Chickamauga Dam would slightly lower flood elevations at the plant.

The adopted relationship to compute the rate of erosion in an earth dam failure is that developed and used by the Bureau of Reclamation in connection with its safety of dams program [16]. The expression relates the volume of eroded fill material to the volume of water flowing through the breach. The equation is:

$$\frac{Q_{soil}}{Q_{water}} = Ke^{-x}$$

where

Q_{soil} = Volume of soil eroded in each time period

Q_{water} = Volume of water discharged each time period

K = Constant of proportionality, 1 for the soil and discharge relationships in this study

e = Base of natural logarithm system

$$X = \frac{b}{H} \tan \phi_d$$

Where

b = Base length of overflow channel at any given time
H = Hydraulic head at any given time
ϕ_d = Developed angle of friction of soil material. A conservative value of 13 degrees was adopted for materials in the dams investigated.

Solving the equation, which was computerized, involves a trial and error procedure over short depth and time increments. In the program, depth changes of 0.1 foot or less are used to keep time increments to less than one second during rapid failure and up to about 350 seconds prior to breaching.

The solution of an earth embankment breach begins by solving the erosion equation using a headwater elevation hydrograph assuming no failure. Erosion is postulated to occur across the entire earth section and to start at the downstream edge when headwater elevations reached a selected depth above the dam top elevation. Subsequently, when erosion reaches the upstream edge of the embankment, breaching and rapid lowering of the embankment begins. Thereafter, computations include headwater adjustments for increased reservoir outflow resulting from the breach.

Watts Bar West Saddle Dike Embankment Failure

Figure 2.4.4-37 is a general plan of Watts Bar showing elevations and sections. Figure 2.4.4-38 is a topographic map of the general vicinity of Watts Bar Dam. Figure 2.4.4-39 is a general plan and section of the west saddle dike.

The west saddle dike was examined and found subject to failure from overtopping. This failure was assumed to be a complete washout and add to the discharge from Watts Bar Dam.

Some verification for the breaching computational procedures illustrated above was obtained by comparison with actual failures reported in the literature and in informal discussion with hydrologic engineers. These reports show that overtopped earth embankments do not necessarily fail. Earth embankments have sustained overtopping of several feet for several hours before failure occurred. An extreme example is Oros earth dam in Brazil [17] which was overtopped to a depth of approximately 2.6 feet along a 2,000-foot length for 12 hours before breaching began. Once an earth embankment is breached, failure tends to progress rapidly, however. How rapidly depends upon the material and headwater depths during failure. Complete failures computed in this and other studies have varied from about one-half to six hours after initial breaching. This is consistent with actual failures.

Chickamauga Embankment Failure

In the original analysis, the failure of earth embankments at Chickamauga Dam, 13.5 miles downstream from SQN, reduced reduce flood levels at the plant by 0.9 feet. Future embankment improvements are planned for Chickamauga Dam, which if implemented, would prevent failure. Therefore, although overtopped in the PMF, the dam was assumed not to fail in determining flood elevations at the plant. This assumption is conservative.

2.4.4.3 Unsteady Flow Analysis of Potential Dam Failures

Unsteady flow routing techniques were used to evaluate plant site flood levels wherever their inherent accuracy was needed. For PMF determinations unsteady flow models described in Section 2.4.3.3 were used. For routing floods from postulated seismically induced dam failures of tributary dams, additional unsteady flow models were used as adjuncts to those described in Section 2.4.3.3.

Unsteady flow techniques were applied in Norris Reservoir. The Norris Reservoir model was developed in sufficient detail to define the manner in which the reservoir would supply and sustain outflow following postulated dam failure. The model was verified by comparing its routed headwater level in the one-half PMF with those using storage-routing techniques. Headwater level agreed within a foot, and the model was considered adequate for the purpose.

Unsteady flow techniques were also applied in Cherokee, Douglas, and Fontana Reservoirs. The reservoir models were developed in sufficient detail to define the manner in which the reservoirs would supply and sustain outflow following postulated dam failure.

2.4.4.4 Water Level at Plant Site

Maximum water level at the plant from different postulated combinations of seismic dam failures coincident with floods would be elevation 707.9, excluding wind wave effects. It would result from the one-half SSE failure of Fontana, Hiwassee, Apalachia, and Blue Ridge Dams coincident with one-half the probable maximum flood. March wind with one percent exceedance probability over the 1.4-mile effective fetch from the critical north-northwest direction is 26 miles per hour over land. This would cause reservoir waves to reach elevation 709.6. Runup could reach elevation 710.4 on a smooth 4:1 slope, elevation 712.8 on a vertical wall in shallow (4.9 feet) water, and elevation 710.4 on a vertical wall in deep water.

2.4.5 Probable Maximum Surge and Seiche Flooding (HISTORICAL INFORMATION)

Chickamauga Lake level during nonflood conditions could be no higher than elevation 685.44, top of gates, and is not likely to exceed elevation 682.5, normal summer level, for any significant time. No conceivable hurricane or cyclonic-type winds could produce the over 20 feet of wave height required to reach plant grade elevation 705.

2.4.6 Probable Maximum Tsunami Flooding (HISTORICAL INFORMATION)

Because of its inland location, SQN is not endangered by tsunami flooding.

2.4.7 Ice Flooding and Landslides (HISTORICAL INFORMATION)

Because of the location in a temperate climate, significant amounts of ice do not form on the Tennessee Valley rivers and lakes. SQN is in no danger from ice flooding.

Flood waves from landslides into upstream reservoirs pose no danger because of the absence of major elevation relief in nearby upstream reservoirs and because the prevailing thin soils offer small slide volume potential compared to the available detention space in reservoirs.

2.4.8 Cooling Water Canals and Reservoirs (HISTORICAL INFORMATION)

2.4.8.1 Canals

The intake channel, as shown in Figure 2.1.2-1, referenced in paragraph 2.4.1.1, is designed for a flow of 2,250 cfs. At minimum pool (elevation 675), as shown in Figure 2.4.8-1, this flow is maintained at a velocity of 2.7 fps.

The protection of the intake channel slopes from wind-wave activity is afforded by the placement of riprap, shown in Figure 2.4.8-1, in accordance with TVA Design Standards, from elevation 665 to elevation 690. The riprap is designed for a wind velocity of 45 mph.

2.4.8.2 Reservoirs (HISTORICAL INFORMATION)

Chickamauga Reservoir provides the cooling water for SQN. This reservoir and the extensive TVA system of upstream reservoirs, which regulate inflows, are described in Table 2.4.1-1. The location in an area of ample runoff and the extensive reservoir system assures sufficient cooling waterflow for the plant.

2.4.9 Channel Diversions (HISTORICAL INFORMATION)

Channel diversion is not a potential problem for the plant. There are now no channel diversions upstream of SQN that would cause diverting or rerouting of the source of plant cooling water, and none are anticipated in the future. The floodplain is such that large floods do not produce major channel meanders or cutoffs. Carbon 14 dating of material at the high terrace levels shows that the Tennessee River has essentially maintained its present alignment for over 35,000 years. The topography is such that only an unimaginable catastrophic event could result in flow diversion above the plant.

2.4.10 Flooding Protection Requirements

Assurance that safety-related facilities are capable of surviving all possible flood conditions is provided by the discussions given in Paragraph 2.4.2.2, Section 3.4, Section 3.8, and Appendix 2.4A.

The plant is designed to be shutdown and remain in a safe shutdown condition for any rainfall flood exceeding plant grade, up to the "design basis flood" discussed in Subsection 2.4.3, and for lower, seismic-caused floods discussed in Subsection 2.4.4. Any rainfall flood exceeding plant grade will be predicted at least 27 hours in advance by TVA's Reservoir Operations. Warning of seismic failure of key upstream dams will be available at the plant at least 27 hours before a resulting flood surge would reach plant grade. Hence, there is adequate time to prepare the plant for any flood.

See Appendix 2.4A for a detailed presentation of the flood protection plan.

2.4.11 Low Water Considerations

Because of its location on Chickamauga Reservoir, maintaining minimum water levels at SQN is not a problem. The high rainfall and runoff of the watershed and the regulation afforded by upstream dams assure minimum flows for plant cooling.

2.4.11.1 Low Flow in Rivers and Streams

The targeted minimum water level at SQN is elevation 675, which corresponds to the lower bound of the winter operating zone for Chickamauga Reservoir. On rare occasions, the water level may be slightly lower (.1 or .2 tenths of a foot) for a brief period of time (hours) due to hydropower peaking operations at Chickamauga and Watts Bar Dams during the winter season. A minimum elevation of 675 must be maintained in order to provide the prescribed commercial navigation depth in Chickamauga Reservoir.

The “Preferred Alternative” Reservoir Operating Policy was designed to provide increased recreation opportunities while avoiding or reducing adverse impacts on other operating objectives and resource areas. Under the Preferred Alternative, TVA will no longer target specific summer pool elevations at 10 tributary storage reservoirs. Instead, TVA tends to manage the flow of water through the system to meet operating objectives. TVA will use weekly average system flow requirements to limit the drawdown of 10 tributary reservoirs (Blue Ridge, Chatuge, Cherokee, Douglas, Fontana, Nottely, Hiawassee, Norris, South Holston, and Watauga) June 1 through Labor Day to increase recreation opportunities. For four main stem reservoirs (Chickamauga, Guntersville, Wheeler, and Pickwick), summer operating zones will be maintained through Labor Day. For Watts Bar Reservoir, the summer operating zone will be maintained through November 1.

Weekly average system minimum flow requirements from June 1 through Labor Day, measured at Chickamauga Dam, are determined by the total volume of water in storage at the 10 tributary reservoirs compared to the seasonal total tributary system minimum operating guide (SMOG). If the

volume of water in storage is above the SMOG, the weekly average system minimum flow requirement will be increased each week from 14,000 cfs (cubic feet per second) the first week of June to 25,000 cfs the last week of July.

Beginning August 1 and continuing through Labor Day, the weekly average flow requirement will be 29,000 cfs. If the volume of water in storage is below the SMOG curve, 13,000 cfs weekly average minimum flows will be released from Chickamauga Dam between June 1 and July 31, and 25,000 cfs weekly average minimum flows will be released from August 1 through Labor Day.

Within these weekly averages, TVA has the flexibility to schedule daily and hourly flows to best meet all operating objectives, including water supply for TVA's thermal power generating plants. Flows may be higher than these stated minimums if additional releases are required at tributary or main river reservoirs to maintain allocated flood storage space or during critical power situations to maintain the integrity and reliability of the TVA power supply system.

In the assumed event of complete dam failure of the south embankment of Chickamauga Dam resulting in a breach width of 400 feet, with the Chickamauga pool at elevation 681, the water surface at SQN will begin to drop within one hour and will fall to elevation 641 about 60 hours after failure. TVA will begin providing steady releases of at least 14,000 cfs at Watts Bar within 12 hours of Chickamauga Dam failure to assure that the water level recession at SQN does not drop below elevation 641. The estimated minimum river flow requirement for the ERCW system is only 45 cfs.

Reference: Programmatic Environmental Impact Statement, TVA Reservoir Operations Study, Record of Decision, May 2004.

2.4.11.2 Low Water Resulting From Surges, Seiches, or Tsunamis

Because of its inland location on a relatively small, narrow lake, low water levels resulting from surges, seiches, or tsunamis are not a potential problem.

2.4.11.3 Historical Low Water

From the beginning of stream gauge records at Chattanooga in 1874 until the closure of Chickamauga Dam in January 1940, the lowest daily flow in the Tennessee River at SQN was 3,200 cfs on September 7 and 13, 1925. The next lowest daily flow of 4,600 cfs occurred in 1881 and also in 1883.

Since January 1942, low flows at the site have been regulated by TVA reservoirs, particularly by Watts Bar and Chickamauga Dams. Under normal operating conditions, there may be periods of several hours daily when there are no releases from either or both dams, but average daily flows at the site have been less than 5,000 cfs only 0.65 percent of the time and have been less than 10,000 cfs, 5.19 percent of the time.

On March 30 and 31, 1968, during special operations for the control of watermilfoil, there were no releases from either Watts Bar or Chickamauga Dams during the two-day period. The previous minimum daily flow was 700 cfs on November 1, 1953. TVA no longer conducts special operations for the control of water milfoil on Chickamauga Reservoir.

Since January 1940, water levels at the plant have been controlled by Chickamauga Reservoir. Since then, the minimum level at the dam was 673.3 on January 21, 1942. TVA no longer routinely conducts pre-flood drawdowns below elevation 675 at Chickamauga Reservoir and the minimum elevation in the past 20 years (1987 - 2006) was 674.97 at Chickamauga head water.

2.4.11.4 Future Control

Future added controls which could alter low flow conditions at the plant are not anticipated because no sites that would have a significant influence remain to be developed.

2.4.11.5 Plant Requirements

2.4.11.5.1 Two-Unit Operation

The safety related water supply systems requiring river water are: the essential raw cooling water (ERCW) (Subsection 9.2.2), and that portion of the high-pressure fire-protection system (HPFP) (Subsection 2.4A.4.1) supplying emergency feedwater to the steam generators. The fire/flood mode pumps are submersible pumps located in the CCW intake pumping station. The CCW intake pumping station sump is at elevation 648. The entrances to the suction pipes for the fire/flood mode pumps are at elevation 651 feet 0 inches which is 32 feet and 24 feet, respectively, below the maximum normal water elevation of 683.0 and the normal minimum elevation of 675.0 for the reservoir. Abnormal reservoir level is 670 feet with a technical specification limit of 674 ft. For flow requirements of the HPFP during engineering safety feature operation (Reference 22). The ERCW pump sump in this independent station is at elevation 625.0, which is 58.0' below maximum normal water elevation, 50.0' below minimum normal water elevation, and 16' below the 641' minimum possible elevation of the river.

Since the ERCW pumping station has direct communication with the river for all water levels and is above probable maximum flood, the ERCW system for two-unit plant operation always operates in an open cooling cycle.

2.4.11.6 Heat Sink Dependability Requirements

The ultimate heat sink, its design bases and its operation, under all normal and credible accident conditions is described in detail in Subsection 9.2.5. As discussed in Subsection 9.2.5, the sink was modified by a new essential raw cooling water (ERCW) pumping station before unit 2 began operation. The design basis and operation of the ERCW system, both with the original ERCW intake station and with the new ERCW intake station, is presented in Subsection 9.2.2. As described in these sections, the new ERCW station is designed to guarantee a continued adequate supply of essential cooling water for all plant design basis conditions. This position is further assured since additional river water may be provided from TVA's upstream multiple-purpose reservoirs, as previously discussed during Low Flow in Rivers and Streams.

2.4.11.6.1 Loss of Downstream Dam

The loss of downstream dam will not result in any adverse effects on the availability of water to the ERCW system or these portions of the original HPFP supplying emergency feedwater to the steam generator. Loss of downstream dam reduces ERCW flow about 7% to the component cooling and containment spray heat exchangers. ERCW flow does not decrease below that assumed in the analysis (analyzed as 670' to 639') until more than two hours after the peak containment temperature and pressure occurs. (See Section 6.2.1.3.4.)

2.4.11.6.2 Adequacy of Minimum Flow

The cooling requirements for plant safety-related features are provided by the ERCW system. The required ERCW flow rates under the most demanding modes of operation (including loss of downstream dam) as given in Subsection 9.2.2 are contained in TVA calculations and flow diagrams.

Two other safety-related functions may require water from the ultimate heat sink; these are fire protection water (refer to Subparagraph 2.4.11.6.3) and emergency steam generator feedwater (refer to Subsection 10.4.7). These two functions have smaller flow requirements than the ERCW systems. Consequently, the relative abundance of the river flow, even under the worst conditions, assures the availability of an adequate water supply for all safety-related plant cooling water requirements.

River operations methodology for maintaining UHS temperatures are discussed in “Monitoring and Moderating Sequoyah Ultimate Heat Sink,” Reference 21.

2.4.11.6.3 Fire-Protection Water

Refer to the Fire Protection Report discussed in Section 9.5.1.

2.4.12 Environmental Acceptance of Effluents

The ability of surface waters near SQN, located on the right bank near Tennessee River Mile (TRM) 484.5, to dilute and disperse radioactive liquid effluents accidentally released from the plant is discussed herein. Routine radioactive liquid releases are discussed in Section 11.2.

The Tennessee River is the sole surface water pathway between SQN and surface water users along the river. Liquid effluent from SQN flows into the river from a diffuser pond through a system of diffuser pipes located at TRM 483.65. An accidental, radioactive liquid effluent release from SQN would enter the Tennessee River after it reached the diffuser pond and entered the diffuser pipes. The contents of the diffuser pond enter the diffuser pipes and mix with the river flow upon discharge. The diffusers are designed to provide rapid mixing of the discharged effluent with the river flow. The flow through the diffusers is driven by the elevation head difference between the diffuser pond and the river [1](McCold 1979). Descriptions of the diffusers and SQN operating modes are given in Paragraph 10.4.5.2. Flow is discharged into the diffuser pond via the blowdown line, ERCW System (Subsection 9.2.2) and CCW System (Subsection 10.4.5). A layout of SQN is given in Figures 2.1.2-1 and 2.1.2-2. Two pipes comprise the diffuser system and are set alongside each other on the river bottom. They extend from the right bank of the river into the main channel. The main channel begins near the right bank of the river and is approximately 900 feet wide at SQN [1] (McCold, 1979). Each diffuser pipe has a 350-foot section through which flow is discharged into the river. The downstream diffuser leg discharges across a section 0 to 350 feet from the right bank of the main channel. The upstream diffuser leg starts at the end of the downstream diffuser leg and discharges across a section 350 to 700 feet from the right bank of the main channel. The two diffusers therefore provide mixing across nearly the entire main channel width.

The river flow near SQN is governed by hydro power operations of Watts Bar Dam upstream (TRM 529.9) and Chickamauga Dam downstream (TRM 471.0). The backwater of Chickamauga Dam extends to Watts Bar Dam. Peaking hydro power operations of the dams cause short periods of zero (i.e., stagnant) and reverse (i.e., upstream) flow near the plant. Effluent released from the diffusers during these zero and reverse flow periods will not concentrate near the plant or affect any water intake upstream. The maximum flow-reversal during 1978-1981 were not long enough to cause discharge from the diffusers to extend upstream to the SQN intake [2] (El-Ashry, 1983), which is the nearest intake and located at the right bank near TRM 484.7. Moreover, the warm buoyant discharge from the diffusers will tend toward the water surface as it mixes the river flow and away from the cooler, denser water found near the intake opening below the skimmer wall. The intake opening extends the first 10 feet above the riverbed elevation of about 631 feet mean sea level (MSL). The minimum flow depth at the intake is approximately 45 feet [3] (Ungate and Howerton, 1979). There are no other surface water users between the diffusers and this intake.

Subsection 2.4.13 discusses groundwater movement at SQN. Effluent released through the diffusers will have no impact on SQN groundwater sources along the banks of the river. Paragraph 2.2.3.8 discusses the effect on plant safety features from flammable or toxic materials released in the river near SQN.

The predominant transport and effect of a diffuser release is along the main channel and in the downstream direction. The nearest downstream surface water intake is located along the left bank at TRM 473.0 (Table 2.4.1-4).

A mathematical analysis is used to estimate the downstream transport and dilution of a contaminant released in the Tennessee River during an accidental spill at SQN. Only the main channel flow area without the adjacent overbank regions is considered in the analysis. The mathematical analysis of a potential spill scenario can involve: (1) a slug release, which can be modeled as an instantaneous release; (2) a continuous release, which can be modeled as a steady-state release; (3) a bank release, which can be modeled as a vertical line source; and (4) a diffuser release, which can be modeled either as a vertical line or plane source, depending on the width of the diffuser with respect to the channel width.

The following assumptions are used in the mathematical analyses to compute the minimum dilution expected downstream from SQN and, in particular, at the nearest water intake.

1. Mixing calculations are based on unstratified steady flow in the reservoir. River flow, Q, is assumed to be 27,474 cubic feet per second (cfs), which is equalled or exceeded in the reservoir approximately 50 percent of the time (Paragraph 2.4.1.2). Because various combinations of the upstream and downstream hydro power dam operations can create upstream flows past SQN, a minimum flow is not well defined. Larger (smaller) flows will decrease (increase) the travel time to the nearest intake but cause less than an order of magnitude change in the calculated dilution.

2. Because the SQN diffusers and the nearest downstream water intake are on opposite banks of the river, and the diffusers extend across most of the main channel width, an analysis using a diffuser release (rather than a bank release) is selected to yield a lesser (i.e., more conservative) dilution at the intake. Thus, the accidental spill is modeled as a vertical plane source across the width of the main channel.

3. The contaminant concentration profile from a slug release is assumed to be Gaussian (i.e., normal) in the longitudinal direction.

4. The contaminant is conservative, i.e., it does not degrade through radioactive decay, chemical or biological processes, nor is it removed from the reservoir by adsorption to sediments or by volatilization.

5. The transport of the contaminant is described using the motion of the river flow, i.e., the contaminant is neutrally buoyant and does not rise or sink due to gravity.

The main channel and dynamic, flow-dependent processes of the reservoir reach between SQN and the first downstream water intake are modeled as a channel of constant rectangular cross section with the following constant geometric, hydraulic and dispersion characteristics.

Longitudinal distance, x = 10.6 miles

Average water surface elevation = 678.5 feet MSL (Figure 2.4.1-3 (1))

Average width, W = 1175 feet

Average depth, H = 50 feet

Average velocity, U (= Q/(W H)) = 0.468 feet per second (fps)

Average travel time (for approximate peak contaminant), t (= x/U) = 1.4 days

Manning coefficient n (surface roughness) = 0.03

Longitudinal dispersion parameter, alpha = 200

where: alpha = E_x / (H u)

E_x = constant longitudinal dispersion coefficient (square feet per second)

u = shear velocity (fps) = $\sqrt{gRS}$

g = acceleration due to gravity = 32.174 ft/s^2

R = hydraulic radius (ft)

S = slope of the energy line (ft/ft)

The average width and depth were estimated from measurements of 9 cross sections in the reach [4] (TVA) [5] (TVA). For wide channels (i.e., large width-to-depth ratio), the hydraulic radius can be approximated as the average depth. The value of alpha = 200 is on the conservative (i.e., low) side [6] (Fischer, et al., 1979). The value of the Manning coefficient n is representative for natural rivers [7] (Chow, 1959).

The equation used to describe the maximum downstream activity (or concentration), C, at a point of interest due to an instantaneous plane source release of volume V is [8] (Guide 1.113):

$$\frac{C}{C_o} = \frac{V}{W H \sqrt{4 \pi E_x t}} \qquad (2.4.12\text{-}1)$$

where:

C_o = initial activity (or concentration) in the plant of the released contaminant

π = 3.14156

Any consistent set of units can be used on each side of Equation 2.4.12-1 (e.g., C and C_o in mCi/ml; V in cf; W and H in ft; E_x in ft^2/s; t in s).

The term, C/C_o, is the relative (i.e., dimensionless) activity (or concentration) and its reciprocal is the dimensionsless dilution factor. Equation 2.4.12-1 simplifies to C/C_o = 8.3E-10 * V (V expressed in cubic feet (cf)) when the parameters are substituted and the Manning equation [7] (Chow, 1959) is used in the definition of the shear velocity, u. In the substitution, u = 0.028 ft/s and E_x = 282.1 ft^2/s.

The equation used to describe the maximum downstream concentration at a point of interest due to a continuous plane source release rate, Q_s, where $Q_s << Q$, is [8] (Guide 1.113):

$$\frac{C}{C_o} = \frac{Q_s}{Q} \qquad (2.4.12\text{-}2)$$

Any consistent set of units can be used on each side of Equation 2.4.12-2 (e.g., C and C_o in mCi/ml; Q_s and Q in cfs).

Equation 2.4.12-2 simplifies to $C/C_o = 3.64E\text{-}05 * Q_s$ (Q_s expressed in cfs) for Q = 27,474 cfs.

Examples of quantities and concentrations of potential contaminant releases and the use of Equations 2.4.12-1 and 2.4.12-2 follow. Because C_o is defined as the in-plant activity (or concentration) and not that of the diffuser release, an estimate of the dilution of liquid waste occurring in the diffuser pond and diffuser pipes is not needed. This is because the flow available for dilution in the plant (e.g., CCW and ERCW) is taken from and returned to the river. Only effluent extraneous to the river flow requires consideration in the analyses to calculate the dilution. More information on the possible means which liquid waste from the plant enters the diffuser pond is contained in Subsection 10.4.5.

The largest outdoor tanks whose contents flow into the diffuser pond are the two condensate storage tanks (Paragraph 11.2.3.1), which each have an overflow capacity of 398,000 gallons. Liquid waste that reaches the diffuser pond enters the Tennessee River through the diffuser system. The diffuser pond is approximately 2000 feet long and 500 feet wide with a depth that, although it depends on the Chickamauga Reservoir elevation, averages about 10 feet [9] (McIntosh, et al., 1982). The design flow residence time of the pond is approximately one hour (i.e., diffuser design flow is 2,480 cfs at maximum plant capacity [3] [Ungate and Howerton, 1979]).

For example, assume an instantaneous plane source release into the Tennessee River of the contents of one condensate storage drain tank. Assume the full 398,000 gallon (53,210 cf) volume contains Iodine-131 (I-131) at an activity of 1.5E-06 mCi/gm (Table 10.4.1-1). From Equation 2.4.12-1, the activity, C, at the first downstream water intake would be 6.6E-11 mCi/gm, which is within the acceptable limit [10] (CFR) for soluble I-131.

For a continuous plane source release, assume the contents of the 398,000 gallon (53,210 cf) floor drain tank leak out steadily over a 24-hour period. The effective release rate is 0.6 cfs at an activity of 1.5E-06 mCi/gm. The expected activity at the first downstream water intake would be 3.4E-11 mCi/gm using Equation 2.4.12-2 and is within the acceptable limit [10] (CFR) for soluble I-131.

2.4.13 <u>Groundwater</u> (HISTORICAL INFORMATION)

2.4.13.1 <u>Description and Onsite Use</u>

The peninsula on which SQN is located is underlain by the Conasauga Shale, a poor water-bearing formation. About 2,000 feet northwest of the plant site, the trace of the Kingston Fault separates this outcrop area of the Conasauga Shale from a wide belt of Knox Dolomite. The Knox is the major water bearing formation of eastern Tennessee.

Groundwater in the Conasauga Shale occurs in small openings along fractures and bedding planes; these rapidly decrease in size with depth, and few openings exist below a depth of 300 feet. Groundwater in the Knox Dolomite occurs in solutionally enlarged openings formed along fractures and bedding planes and also in locally thick cherty clay overburden.

There is no groundwater use at SQN.

2.4.13.2 <u>Sources</u>

The source of groundwater at SQN is recharged by local, onsite precipitation. Discharge occurs by movement mainly along strike of bedrock, to the northeast and southwest, into Chickamauga Lake. Rises in the level of Chickamauga Lake result in corresponding rises in the water table and recharge along the periphery of the lake, extending inland for short distances. Lateral extent of this effect varies with local slope of the water table, but probably nowhere exceeds 500 feet. Lowering levels of Chickamauga Lake results in corresponding declines in the water table along the lake periphery, and short-term increase in groundwater discharge.

When SQN was initially evaluated in the early 1970s, it was in a rural area, and only a few houses within a two-mile radius of the plant site were supplied by individual wells in the Knox Dolomite (see Table 2.4.13-1, Figure 2.4.13-1). Because the average domestic use probably does

not exceed 500 gallons per day per house, groundwater withdrawal within a two-mile radius of the plant site was less than 50,000 gallons per day. Such a small volume withdrawal over the area would have essentially no effect on areal groundwater levels and gradients. Although development of the area has increased, public supplies are available and overall groundwater use is not expected to increase.

Public and industrial groundwater supplies within a 20 mile radius of the site in 1985 are listed in Table 2.4.13-2. The area groundwater gradient is towards Chickamauga Lake, under water table conditions, and at a gradient of less than 120 feet per mile. The water table system is shallow, the surface of which conforms in general to the topography of the land surface. Depth to water ranges from less than 10 feet in topographically low areas to more than 75 feet in higher areas underlain by Knox Dolomite. Figure 2.4.13-2 is a generalized water-table map of SQN, based on water level data from five onsite observation wells, and in private wells adjacent to the site in April 1973, and also based on surface resistivity measurements of depth to water table made in 1972.

Because permeability across strike in the Conasauga Shale is extremely low, and nearly all water movement is in a southwest-northeast direction, along strike, the Conasauga-Knox Dolomite Contact is a hydraulic barrier, across which only a very small volume of water could migrate in the event large groundwater withdrawals were made from the adjacent Knox.

Although some water can cross this boundary, the permeability normal to strike of the Conasauga is too low to allow development of an areally extensive cone of depression.

Groundwater recharge occurs to the Conasauga Shale at the plant site. Recharge water moves no more than 3,000 feet before being discharged to Chickamauga Lake.

2.4.13.3 <u>Accident Effects</u>

Design features in SQN further protect groundwater from contamination.

Category I structures in the SQN facility are designed to assure that all system components perform their designed function, including maintenance of integrity during earthquake.

Buildings in which radioactive liquids could be released due to the equipment failure, overflow, or spillage are designed to retain such liquids even if subject to an earthquake equivalent to the safe shutdown earthquake. Outdoor tanks that contain radioactive liquids are designed so that if they overflow, the overflow liquid is redirected to the building where the liquid is collected in the radwaste system. Two outdoor tanks that contain low concentrations of radioactivity at times overflow to yard drains which discharge into the diffuser pond. Overflow liquid is discharged near the discharge diffuser.

The capacity for dispersion and dilution of contaminants by the groundwater system of the Conasauga Shale is low. Dispersion would occur slowly because water movement is limited to small openings along fractures and bedding planes in the shale. Clay minerals of the Conasauga Shale do, however, have a relatively high exchange capacity, and some of the radioactive ions would be absorbed by these minerals. Any ions moving through the groundwater system eventually would be discharged to Chickamauga Lake.

The Conasauga Shale is heterogeneous and anisotropic vertically and horizontally. Water-bearing characteristics change abruptly within short distances. Standard aquifer analyses cannot be applied, and meaningful values for permeability, time of travel, or dilution factors cannot be obtained.

Bedrock porosity is estimated to be less than 3 percent based on examination of results of exploratory core drilling. It is known from experience elsewhere in this region that water movement in the Conasauga Shale occurs almost entirely parallel to strike. Subsurface movement of a liquid radwaste release at the plant site would be about 1,000 feet to the northeast or about 2,000 feet to the southwest before discharge to Chickamauga Lake.

Time of travel can only be estimated as being a few weeks for first arrival, a few months for peak concentration arrival, and perhaps two or more years for total discharge. The computed mean time of travel of groundwater from SQN to Chickamauga Lake is 303 days.

No radwaste discharge would reach a groundwater user. At the nearest point, the reservation boundary lies 2,200 feet northwest of the plant site, across strike. Groundwater movement will not occur from the plant site in this direction across this distance.

During initial licensing, the radionuclide concentrations were determined for both groundwater and surface water movement to the nearest potable water intake (Savannah Valley Utility District, which is no longer in service) and found to be of no concern (see Safety Evaluation Report, March 1979, Section 2.4.4 Groundwater).

2.4.13.4 Monitoring or Safeguard Requirements

SQN is on a peninsula of low-permeability rock; the groundwater system of the site is essentially hydraulically isolated and potential hazard to groundwater users of the area is minimal. The environmental radiological monitoring program is addressed in Section 11.6.

Monitor wells 1, 2, 3, and 4 were sampled and analyzed for radioactivity during the period from 1976 through 1978. Well 5 was not monitored because of insufficient flow. An additional well (Well 6) was drilled in late 1978 downgradient from the plant and a pump sampler installed.

Wells 1, 2, 4, and 5 are each 150 feet deep, Well 6 is 250 feet deep, and Wells L6 and L7 are 75-80 feet deep. All of the wells are cased in the residuum and open bore in the Conasauga Shale.

2.4.13.5 Conclusions

SQN was designed to provide protection of groundwater resources by preventing the escape of the leaks of radionuclides. Site soils and underlying geology provide further protection in that they retard the movement of water and attenuate any contaminants that would be released. All groundwater movement is toward Chickamauga Lake. The Knox Dolomite is essentially hydraulically separated from the Conasauga Shale; therefore, offsite pumping, including future development, should have little effect upon the groundwater table in the Conasauga Shale at the plant.

Even though the potential for accidental contamination of the groundwater system is extremely low, the radiological monitoring program will provide ample lead times to mitigate any offsite contamination.

As a consequence of the geohydrologic conditions that remain unchanged from evaluations conducted in the 1970s, the information in Chapter 2.4.13 Groundwater is historical and should not be subject to updating revisions.

2.4.14 Technical Requirements and Emergency Operation Requirements

Emergency flood protection plans, designed to minimize impact of floods above plant grade on safety-related facilities, are described in Appendix 2.4A. Procedures for predicting rainfall floods, arrangements to warn of upstream dam failure floods, and lead times available and types of action to be taken to meet related safety requirements for both sources of flooding are described therein. The Technical Requirements Manual specify the action to be taken to minimize the consequences of floods.

TABLE 2.4.1-5

DAM SAFETY MODIFICATION STATUS (HYDROLOGIC)

DAM	*DAM MODIFICATION	Year Completed
Main River Dams		
Fort Loudon-Tellico	Fort Loudon Dam embarkment was raised 3.25 with a concrete wall to elevation 833.25. A 2000-foot uncontorolled spillway with crest at elevation 817 was added at Tellico Dam.	1989
Watts Bar	Embankment of main dam was raised 10 feet with earthfill/concrete wall to elevation 767. West Saddle Dike was not modified. Top of saddle dike remains at elevation 757.	1997
Nickajack	South embankment was raised 5 feet with earthfill/concrete wall to elevation 657. A 1900-foot roller-compacted concrete overflow dam with top at elevation 634 was added below the north embankment.	1992
Guntersville	Embankments were raised 7.5 feet with earthfill and concrete walls to elevation 617.5.	1996

TABLE 2.4.1-5
Sheet 2 of 2

DAM SAFETY MODIFICATION STATUS (HYDROLOGIC)

DAM	*DAM MODIFICATION	Year Completed
Tributary Dams		
Little Bear Creek	Embankment was raised 4.5 feet.	1998
Beech	Embankment was raised 4.5 feet with earthfill to elevation 475.5.	1992
Blue Ridge	Three (3) additional spillway bays were added in 1982. Embankment was raised 7 feet with earthfill/concrete wall to elevation 1713, and a 320-foot uncontrolled spillway with crest at elevation 1691 was added in 1995.	1995
Boone	Embankment was raised 8.5 feet with earthfill to elevation 1408.5.	1984
Cedar Creek	Embankment was raised 5.5 feet with concrete wall to elevation 605.	1997
Chatuge	Embankment was raised 6.5 feet with earthfill to elevation 1946.5.	1986
Cherokee	A portion (600 feet) of the non-overflow dam was raised 7.75 feet to elevation 1089.75.	1982
Douglas	A portion of the non-overflow dam was raised 13.5 feet to elevation 1022.5, and eight saddle dams were raised 6.5 feet with earthfill to elevation 1023.5.	1988
Nottely	Embankment was raised 13.5 feet with rockfill to elevation 1807.5	1988
Upper Bear Creek	Embankment was raised 4 feet with concrete wall to elevation 817.	1997
Watauga	Embankment was raised 10 feet with rockfill to elevation 2012.	1983
Fontana	Dam post-tensioned.	1988
Melton Hill	Dam post-tensioned.	1988

* These dam safety modifications enable these projects to safely pass the probable maximum flood (PMF).
Note: Plans are to armor the embankment at Chickamauga and Bear Creek Dams to permit overtopping.

Definition of Symbols

Q_p = Peak discharge in cfs
C_p = Snyder coefficient
T_p = Time in hours from beginning of precipitation excess to peak of unit hydrograph
W_{50} = Width in hours at 50 percent of peak discharge
W_{75} = Width in hours at 75 percent of peak discharge
T_B = Base length in hours of unit hydrograph
a = Revised
b = New

Table 2.4.4-1

FLOODS FROM POSTULATED SEISMIC FAILURES OF UPSTREAM DAMS
Plant Grade is Elevation 705

One-Half SSE Failures With One-Half Probable Maximum Flood	Elevation
1. Norris [a, b]	698.1
2. Fontana [b, c, d, e]	702.8
3. Cherokee-Douglas [b, f]	701.1
4. Fontana-Hiwassee-Apalachia-Blue Ridge [b, e]	707.9
SSE Failures With 25-Year Flood	
5. Norris-Cherokee-Douglas [g, h]	706.0
6. Douglas-Fort Loudoun-Tellico [b]	699.3

a. Melton Hill fails from failure wave.

b. Watts Bar West Saddle Dike fails from failure wave.

c. Includes failure of five Alcoa dams - Nantahala upstream, Santeetlah on a downstream tributary; and Cheoah, Calderwood and Chilhowee downstream.

d. Fort Loudoun gates fail in open position.

e. Tellico fails from failure wave.

f. Failure wave overtops but does not fail Fort Loudoun.

g. Fort Loudoun gates blocked in closed position from failure of bridge. Failure wave would overtop and breach Watts Bar West Saddle Dike.

h. Failure wave overtops and fails Fort Loudoun.

FIGURE 2.4.1-3
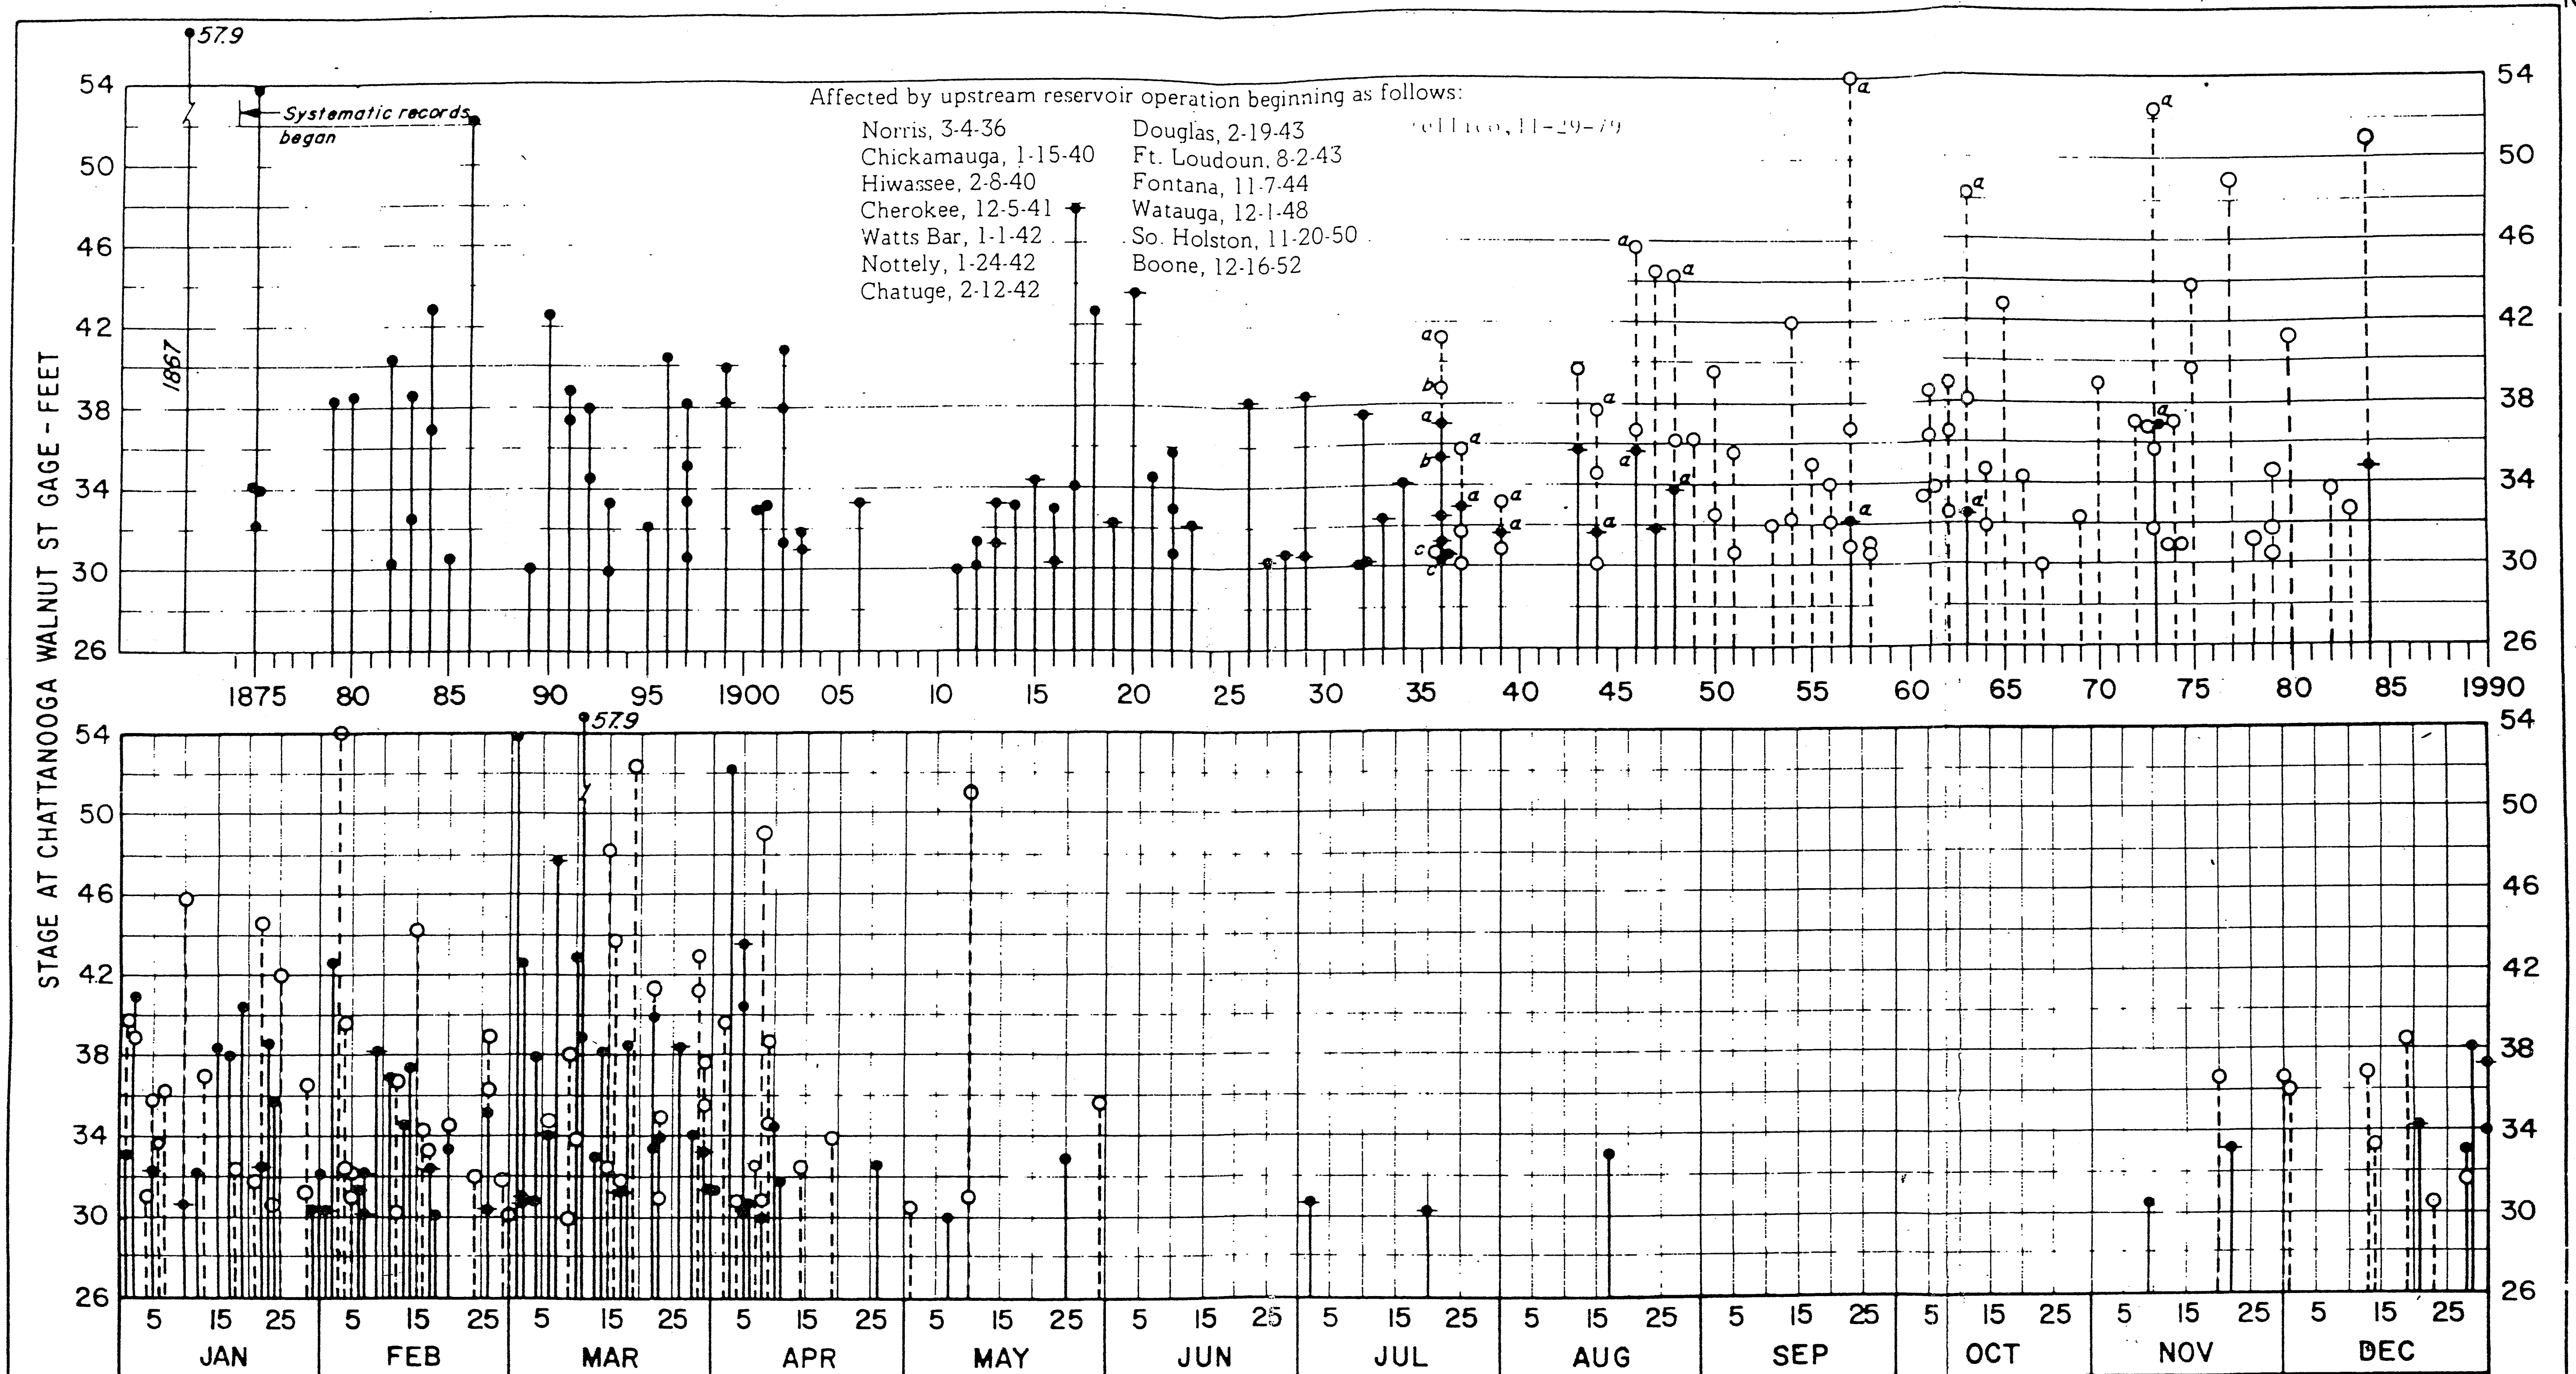
SHEET 14 OF 1

Revised by Amend. 7



Gage zero = 621.12 (1929 genl. adj)
USWB flood stage = 30 feet
Drainage area = 21,400 sq mi

NOTES:

The stages shown for the 1867 flood and the highest flood in 1875 are from well authenticated flood marks. All other stages, except in 1874 and 1875, are reported (◆) or estimated (●) crests from observations at the same datum and location, Walnut Street. The stage readings in 1874 and 1875 were based on a different datum, but the estimated crests were corrected to be comparable to later records. Stages since October 22, 1913 are not comparable with earlier ones because of the backwater effect of Hales Bar Dam, 35 miles downstream. A change in Hales Bar Spillway in 1948, the closure of Nickajack Dam in December 1967, and subsequent removal of Hales Bar Dam further affected Chattanooga stages, making later stages incomparable to earlier periods.

Since March 4, 1936, when upstream regulation began, both computed natural (O) and reported crests are shown on the yearly chart. These natural crests are based on conditions when TVA was established, and hence are comparable to stages from 1913 to 1948. Only natural crests since March 1936 are shown on the seasonal diagram.

Complete to Oct. 1, 1985

Note A:
The powerhouse and spillway structures are well keyed into the rock foundation. The rock formations are severely folded with the dip generally in a dnstr direction varying from 10° to 40°. Any failure would require cross bed shear of the rock. Rock of this type has cross bed shear strength much in excess of that reqd for a Factor of Safety of 1.

NOTES:
1. OBE earthquake inertia forces assumed as 0.09 g horizontally and 0.06 g vertically at the base and amplified up the structure.
2. Spillway gates were assumed open for this analysis.

* Shear, s, that is reqd for Q=1 is calculated from shear-friction formula, $Q = \frac{0.65\,\Sigma V + SA}{\Sigma H}$. A is assumed to be entire base area.

APPENDIX 2.4A

FLOOD PROTECTION PLAN

TABLE OF CONTENTS

LIST OF TABLES

LIST OF FIGURES

APPENDIX 2.4A
FLOOD PROTECTION PLAN

2.4A.1 Introduction

This appendix describes the methods by which the Sequoyah Nuclear Plant will be made capable of tolerating floods above plant grade without jeopardizing public safety. Since flooding of this magnitude, as explained in section 2.4, is most unlikely, extreme steps are considered acceptable including actions that create or allow extensive economic damage to the plant. The actions described herein will be implemented for floods ranging from slightly below plant grade, to allow for wave runup, to the Design Basis Flood (DBF).

2.4A.1.1 Design Basis Flood

The DBF is the calculated upper limit flood that includes the probable maximum flood (PMF) plus the wave runup caused by a 45-mile-per-hour overwater wind; this is discussed in subsection 2.4.3.6. The table below gives representative levels of the DBF at different plant locations.

Design Bases Flood (DBF) Levels

Probable maximum flood (still reservoir)	719.6
DBF runup on vertical external, unprotected walls	723.8
DBF surge level within flooded structures	720.1

The lower flood elevations listed above are actual DBF elevations and are not normally used for the purpose of design but are typically used in plant procedures including procedures which direct plant actions in response to postulated DBF. For purposes of designing the flood protection for systems, structures, and components, the following higher elevations should be used thus ensuring additional margin has been included in the development of design analysis.

Design Analysis Flood Levels

Maximum still reservoir	723.5
Runup on vertical external, unprotected walls	729.5
Surge level within flooded structures	724.0

See FSAR References 2.4A.10-1 and 2.4A.10-2.

In addition to level considerations, plant flood preparations will cope with the "fastest rising" flood which is the calculated flood that can exceed plant grade with the shortest prediction notice. Reservoir levels for large floods in the Tennessee Valley can be predicted well in advance.

A minimum of 27 hours, divided into two stages, is provided for safe plant shutdown by use of this prediction capability. Stage I, a minimum of 10 hours long, will commence upon a prediction that flood-producing conditions might develop. Stage II, a minimum of 17 hours long,

will commence on a confirmed estimate that conditions will provide a flood. This two-stage scheme is designed to prevent excessive economic loss in case a potential flood does not fully develop.

2.4A.1.2 Combinations of Events

Because floods above plant grade, earthquakes, tornadoes, or design basis accidents, including a loss-of-coolant accident (LOCA), are individually very unlikely, a combination of a flood plus any of these events or the occurrence of one of these during the flood recovery time or of the flood during the recovery time after one of these events is considered incredible.

Surges from seismic failure of upstream dams, however, can exceed plant grade, but to lower DBF levels, when imposed coincident with wind and certain floods. A minimum 27 hours of warning is assured so that ample time is available to prepare the plant for flooding.

2.4A.1.3 Post Flood Period

Because of the improbability of a flood above plant grade, no detailed procedures will be established for return of the plant to normal operation unless and until a flood actually occurs. If flood mode operation (subsection 2.4A.2) should ever become necessary, it will be possible to maintain this mode of operation for a sufficient period of time (100 days) so that appropriate recovery steps can be formulated and taken. The actual flood waters are expected to recede below plant grade within 1 to 6 days.

2.4A.1.4 Localized Floods

Localized plant site flooding due to the probable maximum storm (subsection 2.4.3) will not enter vital structures or endanger the plant. Plant shutdown will be forced by water ponding on the switchyard and around buildings, but this shutdown will not differ from a loss of offsite power situation as described in Chapter 15. The other steps described in this appendix are not applicable to this case.

2.4A.2 Plant Operation During Floods Above Grade

"Flood mode" operation is defined as the set of conditions described below by means of which the plant will be safely maintained during the time when flood waters exceed plant grade (elevation 705) and during the subsequent period until recovery (subsection 2.4A.7) is accomplished.

2.4A.2.1 Flooding of Structures

Only the Reactor Building, the Diesel Generator Building (DGB), and the Essential Raw Cooling Water Intake Station will be maintained essentially water tight during the flood mode. Walls and penetrations are designed to withstand all static and dynamic forces imposed by the DBF.

The Reactor Buildings protect SSCs contained within that are required for Flood Mode operations. All penetrations below the Design Analysis Flood level of elevation 724’ have been sealed with seals, which are tested to withstand hydrostatic forces generated by the Design Basis Flood. Analysis demonstrates the acceptability of minor leakage through the seals into the annulus.

The lowest floor of the DGB is at elevation 722 with its doors on the uphill side facing away from the main body of flood water. This elevation is lower than the previous DBF elevation of 722.6. The 1998 reanalysis determined the still water elevation to be 719.6, with wind wave runup at the DGB to elevation 721.8. Therefore, flood levels do not exceed floor elevation of 722. The entrances into

safety-related areas and all mechanical and electrical penetrations into safety-related areas are sealed to prevent major leakage into the building for water up to the PMF, including wave runup. Due to the 1998 reanalysis this only applies to below grade features. Redundant sump pumps are provided within the building to remove minor leakage.

The Essential Raw Cooling Water (ERCW) intake station is designed to remain fully functional for floods up to the PMF, including wind-wave runup. The deck elevation (elevation 720) is below the PMF plus wind wave runup, but it is protected from flooding by the outside walls. The traveling screen wells extend above the deck elevation up to the design basis surge level. The wall penetration for water drainage from the deck in nonflood conditions is below the DBF elevation, but it is designed for sealing in event of a flood. All other exterior penetrations of the station below the PMF are permanently sealed. Redundant sump pumps are provided on the deck and in the interior rooms to remove rainfall on the deck and water seepage.

All other structures, including the service, turbine, auxiliary, and control buildings, will be allowed to flood as the water exceeds their grade level entrances. All equipment, including power cables, that is located in these structures and required for operation in the flood mode is either above the DBF or designed for submerged operation.

2.4A.2.2 Fuel Cooling

Spent Fuel Pit

Fuel in the spent fuel pit will be cooled by the normal Spent Fuel Pit Cooling (SFPC) System. The pumps are located on a platform at elevation 721 which is above the surge level of 720.1. During the flood mode of operation, heat will be removed from the heat exchangers by ERCW instead of component cooling water.

As a backup to spent fuel cooling, water from the Fire Protection (FP) System can be dumped into the spent fuel pool, and steam removed by the area ventilation system.

Reactors

Residual core heat will be removed from the fuel in the reactors by natural circulation in the Reactor Coolant (RC) system. Heat removal from the steam generators will be accomplished by adding river water from the FP System (subsection 9.5.1) and relieving steam to the atmosphere through the power relief valves. Primary system pressure will be maintained at less than 500 lb/in^{2}g by operation of the pressurizer relief valves and heaters. This low pressure will lessen leakage from the system. Secondary side pressure will be maintained at or below 90 psig by operation of the steam line relief valves.

An analysis has been performed to ensure that the limiting atmospheric relief capacity would be sufficient to remove steam generated by decay heat. At times beyond approximately 10 hours following shutdown of the plant two relief valves have sufficient capacity to remove the steam generated by decay heat. Since a minimum of 27 hours flood warning is available it is concluded that the plant could be safely shutdown and decay heat removed by operation of only two relief valves. Reference FSAR 2.4A.10-1.

The main steam power operated relief valves will be adjusted to maintain the steam pressure at or below 90 psig. If this control system malfunctions, then the controls in the main control room can be utilized to operate the valves in an open-closed manner. Also, a manual loading station and the relief valve handwheel provide additional backup control for each relief valve. The secondary side steam pressure can be maintained for an indefinite time by the means outlined above.

The cooling water flow paths conform to the single failure criteria as defined in FSAR Section 3.1.1. In particular, all active components of the secondary side feedwater supply and ERCW supply are redundant and can therefore tolerate a single failure in the short or long term. A passive failure, consistent with the 50 gpm loss rate specified in FSAR Section 3.1.1, can be tolerated for an indefinite period without interrupting the required performance in either supply.

If one or both reactors are open to the containment atmosphere as during the refueling operations, then the decay heat of any fuel in the open unit(s) and spent fuel pit will be removed in the following manner. The refueling cavity will be filled with borated water (approximately 2000 ppm boron concentration) from the refueling water storage tank. The SFPC System pump will take suction from the spent fuel pit and will discharge to the SFPC System heat exchangers. The SFPC System heat exchanger output flow will be directed by a piping connection to the Residual Heat Removal (RHR) System heat exchanger bypass line. The tie-in locations in the SFPC System and the RHR System are shown in Figures 9.1.3-1 and 5.5.7-1, respectively. This connection will be made using prefabricated, in- position piping which is normally disconnected. During flood mode preparations, the piping will be connected using prefabricated spool pieces.

Prior to flooding, valve number 78-513 (refer to Figure 9.1.3-1) and valves FCV 74-33, and 74-35 (refer to Figure 5.5.7-1) will be closed; valves HCV 74-36, 74-37, FCV 74-16, 74-28, 63-93, and 63-94 (refer to Figure 5.5.7-1 and 6.3.1-1) will be opened or verified open. This arrangement will permit flow through the RHR heat exchangers and the four normal cold leg injection paths to the reactor vessel. The water will then flow downward through the annulus, upward through the core (thus cooling the fuel), then exit the vessel directly into the refueling cavity. This results in a water level differential between the spent fuel pit and the refueling cavity with sufficient water head to assure the required return flow through the 20-inch diameter fuel transfer tube thereby completing the path to the spent fuel pit.

Except for a portion of the RHR System piping, the only RHR System components utilized below flood elevation are the RHR System heat exchangers. Inundation of these passive components will not degrade their performance for flood mode operation. After alignment, all valves in this cooling circuit located below the maximum flood elevation will be disconnected from their power source to assure that they remain in a safe position.

The modified cooling circuit for open reactor cooling will be assured of two operable SFPC System pumps (a third pump is available as a backup) as well as two SFPC System heat exchangers. Also, the large RHR System heat exchangers are supplied with essential raw cooling water during the open reactor mode of fuel cooling; these heat exchangers provide an additional heat sink not available for normal spent fuel cooling.

Fuel coolant temperature calculations, assuming conservative heat loads and the most limiting, single active failure in the SFPC System, indicate that the coolant temperatures are acceptable.

The temperatures can be maintained at a value appreciably less than the fuel pit temperature calculated for the nonflood spent fuel cooling case when assuming the loss of one equipment train.

As further assurance, the open reactor cooling circuit was aligned and tested, during pre-operational testing, to confirm flow adequacy. Normal operation of the RHR System and SFPC System heat exchangers will confirm the heat removal capabilities of the heat exchangers.

High spent fuel pit temperature will cause an annunciation in the MCR, thus indicating equipment malfunction. Additionally, that portion of the cooling system above flood water will be frequently inspected to confirm continued proper operation.

For either mode of reactor cooling, leakage from the Reactor Coolant System will be collected, to the extent possible, in the reactor coolant drain tank; nonrecoverable leakage will be made up from supplies of clean water stored in the four cold leg accumulators, the pressurizer relief tank, the cask decontamination tank, and the demineralized water tank. If these sources prove insufficient, the FP System can be connected to the Auxiliary Charging System (subsection 9.3.5) as a backup. Whatever the source, makeup water will be filtered, demineralized, tested, and borated, as necessary, to the normal refueling concentration, and pumped by the Auxiliary Charging System into the reactor (see Figures 2.4A-2 and 2.4A-3).

Power

Electric power will be supplied by the onsite diesel generators starting at the beginning of Stage II or when offsite power is lost, whichever occurs first (subsection 2.4A.5.3).

Cooling of Plant Loads

Plant cooling requirements, with the exception of the FP System which must supply feedwater to the steam generators, will be met by the ERCW System (refer to subsection 9.2.2).

Plant Water Supply

The plant water supply is thoroughly discussed in subsection 9.2.2. The following is a summary description of the water supply provided for use during flooded plant conditions. The ERCW station is designed to remain fully functional for all floods up to and including the DBF. The CCW intake forebay will provide a water supply for the fire/flood mode pumps. If the flood approaches DBF proportions, there is a remote possibility that Chickamauga Dam will fail. Such an event would leave the Sequoyah Plant CCW intake forebay isolated from the river as flood water recedes below EL 665. Should this event occur, the CCW forebay has the capacity of retained water to supply two steam generators in each unit and provide spent fuel pit with evaporation makeup flow until CCW forebay inventory makeup is established. The ERCW station is designed to be operable for all plant conditions and includes provisions for makeup to the forebay. Reference FSAR 2.4A.10-1.

2.4A.3 Warning Plan

Plant grade elevation 705 can be exceeded by both rainfall floods and seismic-caused dam failure floods. A warning plan is needed to assure plant safety from these floods.

2.4A.3.1 Rainfall Floods

Protection of the Sequoyah Plant from the low probability rainfall floods that might exceed plant grade depends on a flood warning issued by TVA's River Operations as described in Section 2.4A.8. With TVA's extensive climate monitoring and flood predicting systems and flood control facilities, floods in the Sequoyah area can be reliably predicted well in advance. The Sequoyah Nuclear Plant flood warning plan will provide a minimum preparation time of 27 hours including a 3 hour margin for operation in the flood mode. Four additional, preceding hours will provide time to gather data and produce the warning. The warning plan will be divided into two stages--the first a minimum of 10 hours long and the second of 17 hours--so that unnecessary economic penalty can be avoided while adequate time is ensured for preparing for operation in the flood mode.

The first stage, Stage I, of shutdown will begin when there is sufficient rainfall on the ground in the upstream watershed to yield a projected plant site water level of 697 in the winter months (October 1 through April 15) and 703 in the summer (April 16 through September 30). This assures that the additional time required is available when shutdown is initiated. The water level of 703 (two feet below plant grade) will allow margin so that waves due to high winds cannot disrupt the flood mode preparation. Stage I will allow preparation steps causing some damage to be sustained but will withhold major economic damage until the Stage II warning assures a forthcoming flood above grade.

The plant preparation status will be held at Stage I until either Stage II begins or TVA's River Operations determines that flood waters will not exceed elevation 703 at the plant. The Stage II warning will be issued only when enough rain has fallen to predict that elevation 703 is likely to be exceeded.

2.4A.3.2 Seismic Dam Failure Floods

Protection of the Sequoyah plant from flood waves generated by seismically caused dam failures which exceed plant grade depends on TVA’s River Operation organization to identify when a critical combination of dam failures and floods exist. There are nine upstream dams whose failure, in combination coincident with certain storm conditions, would cause a flood to exceed plant grade. These dams are Norris, Cherokee, Douglas, Fort Loudoun, Fontana, Hiwassee, Apalachia, Blue Ridge, and Tellico.

2.4A.4 Preparation for Flood Mode

At the time the initial flood warning is issued, the plant may be operating in any normal mode. This means that either or both units may be at power or either unit may be in any stage of refueling.

2.4A.4.1 Reactors Initially Operating at Power

If both reactors are operating at power, Stage I and then, if necessary, Stage II procedures will be initiated. Stage I procedures will consist of a controlled reactor shutdown and other easily revokable steps such as moving supplies necessary to the flood protection plan above the DBF level and making temporary connections and load adjustments on the onsite power supply. Stage II procedures will be the less easily revokable and more damaging steps necessary to have the plant in the flood mode when the flood exceeds plant grade. The fire/flood mode pumps may supply auxiliary feedwater for reactor cooling (Reference 3). Other essential plant cooling loads will be transferred from the component cooling water to the ERCW System (subsection 9.2.2). Radioactive Waste System (Chapter 11) and CVCS tanks, which are susceptible to flotation will be secured by either filling the tanks during flood preparations or by opening the tanks to allow floodwaters to enter, tanks which are adequately anchored to prevent floatation are exempt from these requirements. Some power and communication lines running beneath the DBF and not designed for submerged operation will require disconnection. Batteries beneath the DBF will be disconnected.

2.4A.4.2 Reactor Initially Refueling

If time permits, fuel will be removed from the unit(s) undergoing refueling and placed in the spent fuel pit; otherwise fuel cooling will be accomplished as described in subsection 2.4A.2.2. If the refueling canal is not already flooded, the mode of cooling described in subsection 2.4A.2.2 requires that the canal be flooded with borated water from the refueling water storage tank. If the flood warning occurs after the reactor vessel head has been removed or at a time when it could be removed before the flood exceeds plant grade, the flood mode reactor cooling water will flow directly from the vessel into the refueling cavity. If the warning time available does not permit this, then the upper head injection piping will be disconnected above the vessel head to allow the discharge of water through the four upper head injection standpipes. Additionally, it is required that the prefabricated piping be installed to connect the RHR and SFPC Systems, and that ERCW be directed to the secondary side of the RHR System and SFPC System heat exchangers.

2.4A.4.3 Plant Preparation Time

All steps needed to prepare the plant for flood mode operation can be accomplished within 24 hours of receipt of the initial warning that a flood above plant grade is possible. An additional 3 hours are available for contingency margin before wave runup from the rising flood might enter the buildings. Site grading and building design prevent any flooding before the end of the 27 hour preflood period.

2.4A.5 Equipment

Both normal plant components and specialized flood-oriented supplements will be utilized in coping with floods. All such equipment required in the flood mode is either located above the DBF or is within a nonflooded structure or is designed for submerged operation. Systems and components needed only in the preflood period are protected only during that period.

2.4A.5.1 Equipment Qualification

To ensure capable performance in this highly unlikely but rigorous, limiting design case, only high quality components will be utilized. Active components are redundant or their functions diversely supplied. Since no rapidly changing events are associated with the flood, repairability offers reinforcement for both active and passive components during the long period of flood mode operation. Equipment potentially requiring maintenance will be accessible throughout its use, including components in the Diesel Generator Building.

2.4A.5.2 Temporary Modification and Setup

Normal plant components used in flood mode operation and in preparation for flood mode operation may require modification from their normal plant operating configuration. Such modification, since it is for a limiting design condition and since extensive economic damage is acceptable, will be permitted to damage existing facilities for their normal plant functions. However, most alterations will be only temporary and nondestructive in nature. For example, the switchover of plant cooling loads from the component cooling water to the ERCW System will be done through valves and a prefabricated spool piece, causing little system disturbance or damage.

Equipment especially provided for the flood design case includes both permanently installed components and more portable apparatus that will be emplaced and connected into other systems during the preflood period.

Detailed procedures to be used under flood mode operation have been developed and are incorporated in the plant's Abnormal Operating Instructions.

2.4A.5.3 Electric Power

Because there is a possibility that high winds may destroy powerlines and disconnect the plant from offsite power at any time during the preflood transition period, only onsite power will be used once Stage II of the preparation period begins. While most equipment requiring alternating current electric power is a part of the permanent emergency onsite power system, other components will be temporarily connected, when the time comes, by prefabricated jumper cables.

All loads that are normally supplied by onsite power but are not required for the flood will be switched out of the system during the preflood period. Those loads used during the preflood period but not during flood mode operation will be disconnected when they are no longer needed. During the preparation period, all power cables running beneath the DBF level, except those especially designed for submerged operation, will be disconnected from the onsite power system. Similarly, direct current electric power will be disconnected from unused loads and potentially flooded lines. Charging will be maintained for each battery by the onsite alternating current power system as long as it is required. Batteries that are beneath the DBF will be disconnected during the preflood period when they are no longer needed.

2.4A.5.4 Instrument Control, Communication and Ventilation Systems

All instrument, control, and communication lines that will be required for operation in the flood mode are either above the DBF or within a nonflooded structure or are designed for submerged operation. Unneeded cables that run below the DBF will be disconnected to prevent short circuits.

Redundant means of communications are provided between the central control area (the main and auxiliary control rooms) and all other vital areas that might require operator attention, such as the Diesel Generator Building.

Instrumentation is provided to monitor all vital plant parameters such as the reactor coolant temperature and pressure and steam generator pressure and level. Control of the pressurizer heaters and relief valves and steam generator feedwater flow and atmospheric relief valves will ensure continued natural circulation core cooling during the flood mode. All other important plant functions will be either monitored and controlled from the main control area or, in some cases where time margins permit, from other points in the plant that are in close communication with the main control area. Ventilation, when necessary, and limited heating or air-conditioning will be maintained for all points throughout the plant where operators might be required to go or where required by equipment heat loads.

2.4A.6 Supplies

All equipment and most supplies required for the flood are on hand in the plant at all times. Some supplies will require replenishment before the end of the period in which the plant is in the flood mode. In such cases supplies on hand will be sufficient to last through the short time (subsection 2.4A.1.3) that flood waters will be above plant grade and until replenishment can be supplied. For instance, there is sufficient diesel generator fuel available at the plant to last for 3 or 4 weeks; this will allow sufficient margin for the flood to recede and for transportation routes to be reestablished.

2.4A.7 Plant Recovery

The plant is designed to continue safely in the flood mode for 100 days even though the water is not expected to remain above plant grade for more than 1 to 6 days. After recession of the flood, damage will be assessed and detailed recovery plans developed. Arrangements will then be made for reestablishment of offsite power and removal of spent fuel.

The 100-day period provides more than adequate time for the development of procedures for any maintenance, inspection, or installation of replacements for the recovery of the plant or for a continuation of flood mode operations in excess of 100 days. A decision based on economics will be made on whether or not to regain the plant for power production. In either case, detailed plans will be formulated after the flood, when damage can be accurately assessed.

2.4A.8 Basis For Flood Protection Plan In Rainfall Floods

Summary

Large Tennessee River floods can exceed plant grade elevation 705 at Sequoyah Nuclear Plant. Plant safety in such an event requires shutdown procedures which may take 24 hours to

implement. TVA flood forecast procedures will provide at least 27 hours of warning before river levels reach elevation 703. Use of elevation 703, 2 feet below plant grade, provides enough freeboard to prevent waves from 45-mile-per-hour, overwater winds from endangering plant safety during the final hours of shutdown activity. For conservatism the fetches calculated for the PMF (Figures 2.4.3-15 and 2.4.3-16) were used to calculate maximum wind wave additive to the reservoir surface at elevation 703 feet msl. The maximum wind additive to the reservoir surface would be 2.8 feet and would not endanger plant safety during the final hours of shutdown. This is due to the long shallow approach and the waves breaking at the perimeter road (elevation 705 feet msl). After the waves break there is not sufficient depth or distance between the perimeter road and the safety-related facilities for new waves to be generated. Forecast will be based upon rainfall already reported to be on the ground.

Different target river level criteria are needed for winter use and for summer use to allow for seasonally varied reservoir levels and rainfall potential.

To be certain of 27 hours for preflood preparation, warnings of floods with the prospect of reaching elevation 703 must be issued early; consequently, some of the warnings may later prove to have been unnecessary. For this reason preflood preparations are divided into two stages. Stage I steps, requiring 10 hours, would be easily revokable and cause minimum damage. The estimated probability is less than 0.0026 that a Stage I warning will be issued during the 40-year life of the plant.

Additional rain and streamflow information obtained during Stage I activity will determine if the more damaging steps of Stage II need to be taken with the assurance that at least 17 hours will be available before elevation 703 is reached. The estimated probability is less than 0.0010 that shutdown will need to continue into Stage II during plant life.

Flood forecasting to assure adequate warning time for safe plant shutdown during floods will be by River Operations of River System Operations.

<u>TVA Forecast System</u> (HISTORICAL INFORMATION)

TVA has in constant use an extensive, effective system to forecast flow and elevation as needed in the Tennessee River Basin. This permits efficient operation of the reservoir system and provides warning of when water levels will exceed critical elevations at selected, sensitive locations.

Elements of the present (2001) forecast system above Sequoyah Nuclear Plant include the following:

1. One hundred sixty (160) rain gages measure rainfall, with an average density of 165 square miles per rain gage. Of these gages 112 are owned by TVA, 35 are owned by the National Weather Service (NWS), 7 are owned by the United States Geological Service (USGS), 2 are owned by the United States Corps of Engineers (USACE), and 4 are owned by Alcoa. Most of these gages are tipping buckets collector type and the transmission of the data is either by satellite or telephone. At some of the gages located at hydroplants, the data is manually read.

Information normally is received daily from the gages at 6 a.m. and at least every 6 hours during flood periods. Close interval rainfall reports can be obtained from a majority of the gages if needed.

2. Streamflow data are received for 35 gages from 16 TVA gages amd 19 USGS gages. These gages trasmit their data either by satellite or telephone or both. Discharge data are received from 26 hydroplants. Of these plants, 25 also transmit headwater elevation data, and 13 transmit tailwater elevation data. Therefore, steamflow data are available from 61 locations. Streamflow data are received daily at 8 a.m. and at least every 2 hours if needed during flood operations.

3. Weather forecasts including quantitative precipitation forecasts are received four times daily and at other times when changes are expected.

4. Computer programs which translate rainfall into streamflow based on current runoff conditions and which permit a forecast of flows and elevations based upon both observed and predicted rainfall. Two separate computers are utilized and are designed to provide backup for each other. One computer is used primarily for data collection, with the other used for executing forecasting programs for reservoir operations. The time interval between receiving input data and producing a forecast is less than 4 hours. Forecasts normally cover at least a 8-day period.

As effective as the forecast system already is, it is constantly being improved as new technology provides better methods to interrogate the watershed during floods and as the watershed mathematical model and computer system are improved. Also, in the future, improved quantitative precipitation forecasts may provide a more reliable early alert of impending major storm conditions and thus provide greater flood warning time.

The TVA forecast center is manned 24 hours a day. Normal operation produces two forecasts daily, one by 12 noon based on data collected at 6 a.m. Central time, and the second by 4 a.m. based on data collected at midnight Central Time. When serious flood situations demand, forecasts are produced every 4 hours.

Basic Analysis

To develop a forecast procedure to assure safe shutdown of Sequoyah Nuclear Plant for flooding, 17 hypothetical PMP storms, including their antecedent storms, were analyzed. They enveloped potentially critical seasonal variations and time distributions of rainfall. To be certain that fastest rising flood conditions were included, the effects of varied time distribution of rainfall were tested by alternatively placing the maximum daily PMP on the first, the middle, and the last day of the 3-day main storm. In each day the maximum 6-hour depth was placed during the second interval except when the maximum daily rain was placed on the last day. Then the maximum 6-hour amount was placed in the last 6 hours.

The procedures used to compute flood flows and elevations are described in subsections 2.4.3.1, 2.4.3.2, and 2.4.3.3. Some flood events were analyzed using earlier versions of the watershed model described in subsection 2.4.3.3. Those events which established important elements of the warning system or those where the present model might produce significant differences in warning times have been reevaluated. Events reevaluated have been noted either in tables or figures where appropriate.

The warning system is based on those storm situations which resulted in the shortest time interval between watershed rainfall and elevation 703, thus assuring that this elevation could be predicted at least 27 hours in advance.

Hydrologic Basis for Warning System

A minimum of 27 hours has been allowed for preparation of the plant for operation in the flood mode. An additional 4 hours for communication and forecasting computations are provided to translate rain on the ground to river elevations at the plant. Hence the warning plan must provide 31 hours from arrival of rain on the ground until critical elevation 703 could be reached. The 27 hours allowed for shutdown at the plant are utilized for a minimum of 10 hours of Stage I preparation and an additional 17 hours for Stage II preparation. This 27 hour allocation includes a 3-hour margin.

Although river elevation 703, 2 feet below plant grade to allow for wind waves, is critical during final stages of plant shutdown for flooding, lower forecast target levels are used in most situations to assure that the 27 hours preflood transition interval will always be available. The target river levels differ with season.

During the October 1 through April 15 "winter" season, Stage I shutdown procedures will be started as soon as target river elevation 697 has been forecast. Shutdown will be carried to completion if and when target river elevation 703 has been forecast. Corresponding target river elevation for the April 16 through September 30 "summer" season is 703. The one target river elevation in the summer season permits waiting to initiate shutdown procedures until enough rain is on the ground to forecast reaching critical elevation 703; shutdown would then be initiated and carried to completion.

Inasmuch as the hydrologic procedures and target river elevations have been designed to provide adequate shutdown time in the fastest rising flood, longer times will be available in other floods. In such cases there will be a waiting period after the Stage I 10-hour shutdown activity during which activities shall be in abeyance until it is predicted from recorded rainfall that Stage II shutdown should be implemented or it is determined from weather conditions that plant operation can be resumed.

Resumption of plant operation following Stage I shutdown activities will be allowable only after flood levels and weather conditions have returned to a condition in which 27 hours of warning will again be available.

River Scheduling of River Operations prepares at least an 8-day water level forecast seven days per week for Tennessee River locations. During prospective flooding conditions forecasts can be prepared 4 times a day so that warnings for Sequoyah will assure that 27 hours always will be available to shut down the plant and prepare it for flooding.

Hydrologic Basis for Target Stages

Figure 2.4A.-4, in four parts, shows how target forecast flood elevations at the Sequoyah plant have been determined to assure adequate warning times. The floods shown are the fastest

rising floods at the site which are produced by the 21,400-square-mile PMP with downstream centering described in subsection 2.4.3.1. The storms are the main PMP amounts and have been preceded 3 days earlier by a 3-day storm having 40 percent of the main storm rainfall. This has caused soil moisture to be high and reservoirs to be well above seasonal levels when the main storm begins.

Figure 2.4A.-4 (A, B, and C) shows the winter PMP which could produce the fastest rising flood which would cross plant grade and variations caused by changed time distribution. The fastest rising flood occurs during a PMP when the 6-hour increments increase throughout the storm with the maximum 6 hours occurring in the last period. Figure 2.4A-4 (B) shows the essential elements of this storm which provides the basis for the warning scheme. In this flood 9.2 inches of rain would have fallen 31 hours (27 + 4) prior to the flood crossing elevation 703 and would produce elevation 697 at the plant. Hence, any time rain on the ground results in a predicted plant stage of 697 a Stage I shutdown warning will be issued. Examination of Figure 2.4A.-4 (A and C) shows that following this procedure in these noncritical floods would result in a lapsed time of 42 and 44 hours between when 9.2 inches had fallen and the flood would cross critical elevation 703.

An additional 2.2 inches of rain must fall promptly for a total of 11.4 inches of rain to cause the flood to cross critical elevation 703. In the fastest rising flood, Figure 2.4A.-4 (B), this rain would have fallen in the next 5 hours. A Stage II warning would be issued within the next 4 hours. Thus, the Stage II warning would be issued 5 hours after issuance of a Stage I warning and 22 hours before the flood would cross critical flood elevation 703. In the slower rising floods, Figure 2.4A.-4 (A and C), the time between issuance of a Stage I warning and when the 11.4 inches of rain required to put the flood to elevation 703 would have occurred is 6 and 10 hours respectively. This would result in issuance of a Stage II warning not less than 4 hours later or 32 and 30 hours respectively before the flood would reach elevation 703.

The summer flood shown by Figure 2.4A.-4 (D), with the maximum 1-day rain on the last day provides controlling conditions when reservoirs are at summer levels. At a time 31 hours (27 + 4) before the flood reaches elevation 703, 11 inches of rain would have fallen. This 11 inches of rain, under these runoff conditions, would produce critical elevation 703, so this level becomes both the Stage I and Stage II target.

The above criteria all relate to forecasts which use rain on the ground. In actual practice quantitative rain forecasts, which are already a part of daily operations, would be used to provide advance alerts that need for shutdown may be imminent. Only rain on the ground, however, is included in the procedure for firm warning use.

Because the above analyses have used fastest possible rising floods at the plant, all other floods will allow longer warning times than required for all physical plant shutdown activity.

In summary, the predicted target levels which will assure adequate shutdown times are:

Season	Forecast Flood Elevations at Sequoyah For Stage I Shutdown	For Stage II Shutdown
Winter (October 1-April 15)	697	703
Summer (April 16-September 30)	703	703

Communications Reliability (HISTORICAL INFORMATION)

Communication between projects in the TVA power system is via (a) TVA owned microwave network, (b) Fiber-Optic System, and (c) by commercial telephone. In emergencies, additional communication links are provided by Transmission Power Supply radio network. The four networks provide a high level of dependability against emergencies.

The hydrologic network for the watershed above Sequoyah that would be available in flood emergencies if commecial telephone communications is lost include 138 rainfall gages (24 at power installations and 114 satellite and file transfer gages) and 47 streamflow gages (26 at hydroplants, 20 satellite gages, and 1 file transfer gage). River Scheduling is linked to the TVA power system by all four communication networks. The data from the satellite gages are received via a data collection platform-satellite computer system located in the River Scheduling's office. These are so distributed over the watershed that reasonable flood forecasting can be done from this data while the balance of data is being secured from the remaining hydrologic network stations.

The preferred, complete coverage of the watershed, employ 160 rainfall and 61 streamflow locations above the Sequoyah plant. Involved in the communications link to these locations are routine radio, radio satellite, and commercial telephone system networks. In an emergency, available radio communications would be called upon to assist.

The various networks proved to be capable in the large floods of 1957, 1963, 1973, 1984, 1994, and 1998 of providing the rain and streamflow data needed for reliable forecasts.

2.4A.9 Basis for Flood Protection Plan in Seismic-Caused Dam Failures

Floods resulting from combined seismic and flood events can exceed plant grade, thus requiring emergency measures. The 1998 reanalysis showed that only two combinations of seismic dam failures coincident with a flood would result in floods above plant grade: (1) failure of Fontana, Hiwassee, Apalachia, and Blue Ridge Dams in the one-half SSE concurrent with a 1/2 PMF, (2) SSE failure of Norris, Cherokee, and Douglas concurrent with a 25 year flood. As shown in Table 2.4.4-1 all other potentially critical candidates would create flood levels below plant grade elevation 705.

Dam failure during non-flood periods would not present a problem at the plant. The reanalysis showed that failure in a non-flood period and at summer flood guide levels in the most critical dam failure combination (SSE failure of Norris, Cherokee and Douglas) would produce a maximum elevation of 703.6 at the plant, 1.4 feet below plant grade. All other combinations in non-flood periods would produce elevations much lower.

The time from seismic occurrence to arrival of failure surge at the plant is adequate to permit safe plant shutdown in readiness for flooding. Table 2.4A-2 lists the time between the postulated seismic event and when the flood wave would exceed plant grade elevation 705 and elevation 703. Use of elevation 703 provides a margin for possible wind wave effects.

The warning plan for safe plant shutdown is based on the fact that a combination of critically centered large earthquake and rain produced flood conditions must coincide before the flood wave from seismically caused dam failures will cross plant grade. In flood situations, an extreme earthquake must be precisely located to fail three or more major dams before a flood threat to the site would exist.

The combination producing the shortest time interval between seismic event and plant grade crossing is a one-half SSE located so as to fail Fontana, Hiwassee, Apalachia, and Blue Ridge Dams during the one-half PMF. The time between the seismic event and the resulting flood wave crossing plant grade elevation 705 is 40 hours. The time to elevation 703, which allows a margin for wind wave considerations, is 35 hours. The event producing the next shortest time interval to elevation 703 involves the SSE failure of Norris, Cherokee, and Douglas during the 25-year flood resulting in a time interval of 63 hours.

The warning system utilizes TVA's flood forecast system to identify when flood conditions will be such that seismic failure of critical dams could cause a flood wave to exceed elevation 703 at the plant site.

Two levels of warning will be provided: (1) an early warning will be issued to SQN whenever a dam failure has occurred or is imminent for any single critical dam; or it appears from rain and flood forecasts that a critical situation may develop and (2) a flood warning or alert to begin preparation for plant shutdown when a critical situation exists that will result in the flood level to exceeding plant grade. A Stage I flood warning is declared once failure of critical dams has been confirmed and flood conditions are such that the flood surge will exceed plant grade. It shall be issued at least 27 hours before the flood level exceeds elevation 703 at the site. A Stage II flood warning will be issued at least 17 hours before the flood level exceeds elevation 703 at the site. Communication will be established and maintained during these two levels of warning to assure the 27 hour flood preparation period. Any prolonged interruption of communication or failure to confirm that a critical case has not occurred will result in the initiation of flood preparation at the plant site. The flood preparation shall continue until completion, unless communication is re-established and the site is notified that a critical case has not occurred.

Communications between the plant, dams, power system control center, and River Operations at Knoxville, Tennessee, are provided by microwave networks, fiber-optic network, radio networks, and commercial telephone service.

2.5 GEOLOGY AND SEISMOLOGY

2.5.1 Basic Geologic and Seismic Data

2.5.1.1 Site Location and Scope of Exploration

The Sequoyah plant site lies in Hamilton County, Tennessee, on a peninsula extending from the right shore into Chickamauga Lake between river miles 484 and 485 (Figure 2.5.1-1).

The site first was explored in 1953. Twenty-nine holes were drilled into rock while 17 were fishtailed to the top of sound rock.

From September 1968 to February 1969 additional holes were drilled to fill in a 100-foot grid in the control and auxiliary building area, and in the reactor areas, with holes drilled at the intake structure and other locations in the general plant area. In addition to obtaining information on the foundation conditions, the holes in the reactor areas were used for dynamic seismic investigations.

During September and October 1969 a third drilling program was carried out to further investigate the reactor, control and auxiliary areas on a 50-foot spacing, and to examine the condition of the Kingston fault northwest of the plant site. For further details see ref. 84.

2.5.1.2 Physiography

The Sequoyah site is located in the Appalachian Valley subregion of the Valley and Ridge Province of the Appalachian Highlands (Figure 2.5.1-1). Physiographically, this subregion is characterized by long narrow ridges and somewhat broader intervening valleys having a northeast-southwest trend. The ridges are roughly parallel and fairly evenly topped. They are developed in areas underlain by resistant sandstones and the more siliceous limestones and dolomites. The valleys have been excavated in the areas underlain by easily weathered shales and the more soluble limestone formations.

In the vicinity of the Sequoyah site, the Tennessee River, prior to the impoundment of Chickamauga Lake, had entrenched its course to elevation 640. The small tributary Valley floors slope from the river up to around elevation 800, while the crests of the intervening ridges range between 900 and 1000 feet in elevation.

2.5.1.3 Geologic History

The Sequoyah area lies near the western border of what was the active part of the Appalachian geosyncline during most of the Paleozoic era. During this time, the area was below sea level and more than 20,000 feet of sedimentary rocks were deposited. At the end of the Paleozoic era, some 250,000,000 years ago, the area was uplifted and subjected to compressive forces acting from the southeast. Folds developed which were compressed tightly, overturned to the northwest, and finally broken by thrust faults along their axial planes. The resultant structure, there- fore, is characterized by a series of overlapping linear fault blocks which dip to the southeast. Since this period of uplift, the area apparently has been above sea level and has been subjected to numerous cycles of erosion. This erosion accentuated the underlying geologic structure by differential weathering of the more resistant and less resistant strata resulting in the development of parallel ridges and valleys which are characteristic of the region.

2.5.1.4 Stratigraphy

Conasauga Formation

The bedrock at the site is the Conasauga formation of Middle Cambrian age. In this region, the Conasauga is composed of interbedded limestone and shale in varying proportions. The shale, where fresh and unweathered, is dark gray, banded, and somewhat fissile in character. The limestone is predominantly light gray, medium grained to coarse crystalline to oolitic, with many shaly partings. A statistical analysis of the cores obtained from the site area indicates a ratio of 56 percent shale to 44 percent limestone. Farther to the southeast, higher in the geologic section, the amount of limestone increases in exposures along the shore of the lake.

2.5.1.5 Structure

The controlling features of the geologic structure at the Sequoyah plant site are the Kingston Thrust fault and a major overturned anticline which resulted from the movement along the fault. This fault lies about a mile northwest of the plant site (Figure 2.5.1-2) and can be traced for 75 miles northeastward and 70 miles southwestward. The fault dips to the southeast, under the plant site, and along it steeply dipping beds of the Knox dolomite have been thrust over gently dipping strata of the Chickamauga limestone. The distance from the plant site, about one mile, and the dip of the fault, 30 degrees or more, will carry the plane of the fault at least 2000 feet below the surface at the plant site.

The major overturned anticline results in the Conasauga formation at the plant site resting upon the underlying Knox dolomite which normally overlies it (Figure 2.5.1-3). As a result of the ancient structural movement of the fault and major fold, the Conasauga formation at the plant site is highly folded, complexly contorted, and cut by many very small subsidiary faults and shears. The general strike of these beds are N 30 degrees E and the overall dip is to the southeast, but the many small tightly folded, steeply pitching anticlines and synclines result in many local variations to the normal trend.

In some of the drill cores, small faults and shears were noted intersecting the bedding at various angles. These dislocations are the result of shearing along the limbs of the minor folds which developed contemporaneously with the major movement along the Kingston fault.

The Kingston fault is only one of the several lengthy thrust faults which characterize the geologic structure of the Appalachian Valley, a part of the "Valley and Ridge" physiographic province. A study of any one of these faults involves a consideration of the major structural features of the Valley as a whole.

Structurally, the Appalachian Valley in eastern Tennessee is characterized very largely by a series of overlapping linear fault blocks of northeast-southwest strike and southeast dips.

Most studies have attributed the deformation in the Southern Appalachians to the Appalachian orogeny at the end of the Paleozoic era. It has been assumed that the major tectonic structures have been inactive since the cessation of the orogenic movement. The duration of this orogenic epoch cannot be determined precisely in the Southern Appalachians since the Pennsylvanian strata are the youngest rocks known to have been affected. That some deformation continued after the major faults had attained their present development is attested by folded and faulted thrust sheets. These late structures may represent the final phase of the orogeny.

The only undeformed materials occurring in the Valley as mappable units are the unconsolidated materials: alluvial deposits, including the high level terrace deposits as well as the recent floodplain alluvium, and the residuum that nearly everywhere mantles bedrock. The alluvium along the Tennessee River and its tributaries ranges in age from less than a decade at the top up to several tens of thousand years at the base. The higher terrace deposits are much older than the lower terraces. The high level terraces have been considered as Pleistocene (King, 1949, page 89) or even older.

The residuum which blankets the bedrock in the Appalachian Valley ranges in thickness from a feather's edge up to a maximum of a hundred feet or more. The age range within a thick accumulation of residuum has not been determined, but the oldest part of the residuum may be of Paleocene or even later Upper Cretaceous age. In several areas of the Valley, masses of bauxite occur in association with brown iron ores and lignite in the thick residuum over limestones and dolomites. The bauxite and the associated materials accumulated in the sinks or sink-like depressions. Bridge (1950, page 194) considers these deposits to be late Paleocene. The following quotation is from Rodgers: "The age of the residuum is even less definite. Weathering is going on and presumably some residuum is being formed now, yet some residuum was apparently already present when the bauxite-bearing clay bodies formed in their sinkholes." Thus it has probably been forming virtually throughout Cenozoic time, though perhaps at a greater rate at certain times, such as those of little stream erosion, than at others. Several lines of evidence suggest a time of particularly intensive chemical decay and activity during or after the formation of the "Valley Flood Peneplain" in the Appalachian Valley, perhaps in the earlier Cenozoic (King and others, 1944, pages 24-25, 59; Rogers, 1948, pages 15, 40; King, 1949, pages 82-83; Bridge, 1950).

As indicated above, the age of the various unconsolidated materials in the Appalachian Valley of eastern Tennessee can be at best only estimated in very general terms. The bedrock and its structures are concealed very largely by these materials. The lack of any evidence of faulting, creep, or renewed movement in the unconsolidated materials even along the major tectonic faults indicates that there has been no movement along these faults for a very long time. This is true of the Kingston fault and all of the other numerous faults in the area.

No formal trenching or age dating was attempted at the Sequoyah plant. The evidence previously cited is related to general observations and the field mapping experience of dozens of geologists for the past 100 years. None of the reports published by geologists working in east Tennessee mention any evidence of actual observations of displacement of surface features which relate to fault movement in historic time. More positive evidence comes from a branch of the Kingston fault called the Missionary Ridge Fault.

The Missionary Ridge fault is a branch, or subsidiary, fault of the Kingston fault (Rodgers 1953, page 130-131, Plate 15, Figure 10). It runs northwest from the Kingston fault and has a total length of approximately 25 miles extending southwestward from the point where it diverges from the Kingston fault, 3 miles southwest of the Sequoyah site, and dying out in northwest Georgia (Hardeman, 1966; Butts and Gildersleeve, 1948). Along most of its length Cambro-Ordovician Knox dolomite and limestone are thrust over Middle and Upper Ordovician Chickamauga limestone. Near its southern terminus Knox is thrust over the Silurian Red Mountain formation.

The Missionary Ridge fault crosses the Tennessee River just upstream from Chickamauga Dam. In 1848 a railroad tunnel was driven through Missionary Ridge in Chattanooga and in the process the tunnel crossed the Missionary Ridge fault. The lining of this tunnel was inspected in 1974 and no cracking of the lining, offset along joints, or other signs of structural defects were found that would indicate any evidence or movement along the Missionary Ridge fault in the last 125 years. Three other vehicular tunnels through Missionary Ridge were also inspected and no structural indications of possible fault movement were found.

TVA has drilled through some of the major faults in eastern Tennessee. Diamond core borings at Chickamauga Dam (1935-1936) went through the Missionary Ridge fault and the cores through the fault zone came out unbroken. The fault was not simply "healed" or recemented with secondary deposits of calcite or dolomite, but was a very tight contact along which apparently pulverized material had recrystallized.

The recrystallization and solidification of the material along the fault plane indicated that this material had not been disturbed by renewed movements for an unknown, but apparently very long, period. Until recently, no indication of how long a period since the last movement was available. In studies for the Clinch River Breeder Reactor Plant, Law Engineering obtained similar material from the Copper Creek fault, one of the same family of faults as the Kingston and Missionary Ridge faults in east Tennessee, and obtained radiometric dates of 280 to 290 million years, ± 10 million years. The results of these tests indicate that the last movements on these faults occurred during the late Paleozoic.

Core borings have been made through at least one other major thrust fault in eastern Tennessee. It was reported to be "solid" similar to that through the Missionary Ridge fault.

Although light earthquakes occasionally occur in the Valley of eastern Tennessee, there has not been a single instance in which the surface was deformed. The shocks are of "normal" focus, 15 to 20 km, but even at such shallow depths, the hypocenters are in the crystalline basement rock well below the sedimentary rocks.

As previously stated, a study of any one of our major thrust faults involves a consideration of all the other similar faults. Many of the geologists who have spent years doing geologic work in eastern Tennessee believe that the several named faults are merely branches of a single nearly flat sole fault developed in some relatively incompetent formation just above the crystalline basement. Some, if not all, of the thrust sheets flatten out with depth, and some of them are cut through by erosion.

It was not until early 1974 that definitive evidence was released to support the "thin-skinned" hypothesis. At that time Geophysical Services Incorporated published an advertising brochure describing reflection seismic data they had available for sale. The example of a reflection profile used in their brochure was made along U.S. Highway 70 from near Kingston, Tennessee, to the vicinity of Knoxville, Tennessee. This profile essentially at right angles to the regional strike is reproduced in Figure 2.5.1-4.

The vertical scale of this profile is represented in seconds. This indicates the double travel time necessary for the shock wave to descend to the reflector and return to the surface. Assuming a

wave velocity of 20,000 ft/s, the times indicated equate to depths in thousands of feet. The "thin-skinned" tectonic structure of the upper strata, above the 1.5 second (15,000 foot) line, is clearly indicated. The depth of approximately 15,000 feet to basement strata in this area is confirmed by gravity and magnetic data (Watkins, 1964).

The significance of the confirmation of "thin-skinned" tectonics in the area in relation to the geologic and seismic considerations of the Sequoyah plant lies in the fact that data now exist to show the separation of faults cropping out at the surface from geologic structures in the basement at a depth of approximately 15,000 feet or 4.5 km. This means that earthquakes with hypocenters at depths of five or more kilometers cannot be associated with faults cropping out at the surface even though the epicenter (surface projection of the hypocenter) falls on or near the trace of the fault.

The evidence available from all of the geologic studies that have been made suggests that all of the Appalachian Valley faults, including the Kingston fault, are inactive. In the voluminous literature on the geologic structure of the Southern Appalachians, there is no mention of the possibility that any of the faults may still be potentially active.

2.5.1.6 Groundwater

See Section 2.4.13.

2.5.1.7 Physical Character of the Rocks

Unconfined compressive strength determinations were made on seven core samples from the Sequoyah site. The results of these tests gave compressive strengths varying from 16,794 lb/in^2 and 11,936 lb/in^2 for limestone and 5758 lb/in^2 for shale. Seismic methods were used to determine the dynamic moduli of the foundation. The results of this work are explained below.

Seismic measurements were made in boreholes located in the two proposed reactor foundations. The purpose of these measurements was to determine the dynamic modulus of elasticity, E, for these foundations so that an earthquake design criteria could be established. Laboratory velocity measurements of core samples were not made because the varying changes in rock types would not give valid results.

The bedrock in which the seismic measurements were made is the Conasauga formation of middle Cambrian age. It is composed of inter-bedded lime- stone and shale in varying proportions. The shale, when unweathered, is dark gray to green, and somewhat fissile in character. In its weathered state it is very soft and in some cases has some of the characteristics of clay. The limestone is predominantly light gray, medium to coarse crystalline, oolitic, with many shaly partings and calcite healed fractures. The rock is badly contorted with dips ranging from 5 degrees to 90 degrees.

Results of the Dynamic Testing Program

Tables 2.5.1-1 and 2.5.1-2 give the results of the seismic studies that were made for each of the two reactor foundations. The average density of the rock is approximately 170 lb/ft^3. Density values from representative core samples were established at 170 lb/ft^3 and 169 lb/ft^3.

Tables 2.5.1-1 and 2.5.1-2 give the up-hole and cross-hole velocity measurements by which the E was calculated from formulae shown on Table 2.5.1-3. The difference in the values is thought to be attributed primarily to the changes in dip and rock type for each borehole. The average up-hole modulus for both reactor foundations is 4.2 x 10E6 and for the cross-hole modulus it is 4.4 x 10E6 lb/in^2.

2.5.1.8 Foundation Conditions

As shown on Figures 2.5.1-5 through 2.5.1-8, bedrock was mantled by a varying thickness of residual material derived from the weathering of the underlying shale and limestone. As would be expected in a foundation composed of alternating strata of different composition and competency, the configuration of the bedrock surface was irregular. The strike of the rock strata is approximately parallel to the centerline of the reactors. Preliminary excavation down to 18 inches above design grade resulted in a series of alternating ridges of harder limestone separated by troughs underlain by the softer shale trending across the plant area. The last 18 inches were removed by careful and controlled means so as to limit breakage below the design grade to a minimum. Once foundation grade was reached, the area was carefully cleaned and then inspected jointly by engineers and geologists to determine what, if any, additional material needed to be removed because of weathering or shattering by blasting.

After the final excavation was approved, the area was covered either by a coating of thick grout or a fill pour of concrete to prevent breakdown of the shale interbeds due to prolonged exposure.

Observation of rock exposed in the foundation areas, examination of cores, and investigations of the walls of exploratory holes with a borehole television camera all indicated that solution cavities or caves are not a major problem in the foundation. Verified cavities generally were limited to the upper few feet or rock where solution developed in limestone beds near the overburden-rock interface. Practically all of this zone was above design grade and was removed. Inspection of other areas of nonrecovery of core at greater depths by the borehole television equipment proved that so-called cavities as reported by the drillers were in fact interbeds of shale that had been ground between overlying and underlying harder limestone strata. In the walls of the holes the camera showed solid shale in these nonrecovery areas. Large solution cavities are not to be expected in formations such as the Conasauga which are made up of interbedded limestone and shale. The insolubility of the shale precludes the development of large openings.

Inspection of the walls of the exploratory holes with television disclosed thin, less than 0.05 foot, near-horizontal openings in some of the limestone beds. At the corresponding position, the drill cores showed unweathered breaks. These open partings are interpreted as "relief joints" developed by unloading either from erosion or excavation. The majority were found in the upper few feet of rock, but some were observed as deep as 131 feet below the rock surface.

A consolidation grouting program was carried on from February 18, 1970 through June 15, 1970 in the foundation areas for the Reactor, Auxiliary, and Control Buildings at the Sequoyah Nuclear Plant. The extent of the area treated is shown on Figures 2.5.1-9 and 2.5.1-10.

The purpose of this program was twofold. The first was to consolidate near-surface fractures predominantly caused by blasting and excavation. The second was to treat any localized open joints, bedding planes, fractures, or isolated small cavities that pre-construction exploratory drilling indicated might be present to a depth of 45 feet below the design foundation grade.

In the excavated area the contact between the residual material and essentially unweathered rock occurs at an average elevation of 680. The highest design level for the plant foundation grade under the Class I structures is at elevation 665. As a result, the preliminary excavation averaged a minimum of 15 feet in rock. Over most of the area the rock was suitable for foundation purposes at elevation 665.

In two areas, however, additional rock had to be excavated to remove localized pockets of deeper weathering. These zones were confined in two synclinal areas which crossed the excavation parallel with the north- south baseline. The axis of one lies approximately 70 feet plant east of the baseline and the axis of the other is approximately 140 feet plant west of the baseline. These trough-like synclines had channeled ground- water movement toward and along their axes with the result that weathering had progressed deeper in these areas. Generally, less than 10 feet of additional rock had to be removed from the synclinal zones to obtain a satisfactory foundation; however, in the vicinity of W 140; S 220, on the south side of the Auxiliary Building, as much as 30 feet of weathered rock was removed. The limits of the synclinal areas are reflected on Figure 2.5.1-10 as zones of appreciable grout take. Elsewhere in the foundation area grout takes were minimal.

This treatment program was approached in the same manner as a consolidation grouting program under a major dam. Grout crews with experience in grouting dam foundations were used, and the onsite technical direction of the program was performed by a member of the Geologic Branch who had previously supervised grouting operations at major dams. All grouting was done in strict accordance with TVA specification G-26, Pressure Grouting of Rock Foundations with Portland Cement. While the grouting was in progress, the program was reviewed in the field at least weekly by a senior member of the Geologic Branch.

Prior to the start of any grouting, it was proposed to excavate the foundation area to be treated to a depth of two feet below required design grade. In practice, due to the irregularities of the rock foundation, this overexcavation varied from a minimum of 18 inches to a maximum of nearly 30 feet. As each section of the foundation was prepared, it was inspected and approved by a joint team consisting of representatives of the Division of Construction, the Division of Engineering Design, and the Geologic Branch. When the area was released by the inspection team, fill concrete was poured up to the design foundation grade. This fill pour acted as a grout cap, protected the shale strata in the bedrock from any tendency to slake or ravel due to prolonged exposure, and provided a good working surface for the grouting operations.

The data contained in columns 3 and 5 of Table 2.5.1-4 indicate the tightness of the foundation. As shown in column 3, in the primary holes--those drilled over the entire area on a 20-foot grid--only 11 percent of the 10-foot-deep holes and 23 percent of the 45-foot-deep holes accepted any grout. This confirms the assumption made from the evaluation of the exploratory drilling, that grout takes would be confined to localized areas. Further confirmation is supplied by the relatively low percentage of holes with grout takes in the subsequent series of split

spaced holes. Normally, it would be expected that a high percentage of the split-spaced holes, especially the secondary holes, would accept grout because they were drilled in areas shown by the primary holes to require further treatment. Although these percentages were higher than for the primary holes, they never exceeded 50 percent and usually were less than 40 percent.

A layout of the investigative programs for the other category I structures is presented as Figure 2.5.1-11.

Sections of Category I structures supported on soil, piles, or caissons are provided on Figures 2.5.1-12,-12a, and -12b. The ERCW piping and conduit support slab which is founded on piles to rock is shown in section on FSAR Figure 3.8.4-9. The sections show general details of excavation and backfill limits for the Category I structures as well as the type of foundation. The classifications of borrow materials are discussed in Subsection 2.5.1.11.

The Sequoyah foundation was completed prior to the time Atomic Energy Commission (AEC) began requesting commitments to produce geologic maps of the foundation. Therefore, detailed data such as were presented for the Watts Bar Nuclear Plant are not available.

There are available several hundred photographs of the rock foundation. TVA has submitted by letter a series of photographs which give the best representation of the overall foundation. In addition to the photographs, quality assurance forms were included which indicate approval of rock conditions prior to all concrete subpours in the Reactor, Auxiliary, and Control Building areas. Rock inspections were made by a senior geologist and by senior design engineers who initiated the forms.

2.5.1.9 Physical Characteristics of Soils

2.5.1.9.1 Static Physical Characteristics of Soils

A soils exploration program was conducted at the plant site to determine the static physical characteristics of the soils. Standard penetration split-spoon borings and undisturbed borings were made. Figure 2.5.1-13 shows the location of all borings made at the site for in situ soil sampling and testing. Graphic logs of all borings are kept on file by TVA.

2.5.1.9.2 Dynamic Characteristics of Soils

In situ soil dynamic studies were made at the plant site to obtain data for computation of elastic moduli for earthquake design criteria. The areas investigated at the site were the Diesel Generator Building, the Low Level Radwaste Storage Facilities, the ERCW pipeline, the Additional Diesel Generator Building, and the Primary Water Storage Tank.

1. Diesel Generator Building

   Down-hole seismic surveys and a seismic refraction survey were performed. The results are tabulated on Table 2.5.1-9.

2. Low Level Radwaste Storage Facilities

   Both compressional and shear wave velocities were obtained through a series of cross-hole and down-hole measurements. The results are tabulated on Table 2.5.1-10 and 2.5.1-11.

3. Essential Raw Cooling Water Pipeline

   Down-hole seismic surveys were made. The results are tabulated on Table 2.5.1-12.

4. Additional Diesel Generator Building

   Cross-hole and down-hole seismic surveys were performed. The results are tabulated on Table 2.5.1-13.

5. Primary Refueling Water Tanks

   Seismic refraction surveys were made. The results are tabulated on Table 2.5.1-14.

2.5.1.10 Detailed Safety-Related Criteria and Computed Factors of Safety For the Materials Underlying the Foundations for Category I Structures

1. Category I Rock-Supported Structures

   The allowable rock-bearing pressure for sustained loading was determined based on the strength and stratigraphy of the foundation rock. The result using the physical characteristics of the foundation rock as described in section 2.5.1.7, and the geologic characteristics given in section 2.5.1.4 provided a reasonable bearing pressure. The allowable rock-bearing capacity is less than the ultimate bearing capacity by a factor of 2.5.

   Table 2.5.1-5 lists the structures which are constructed with a base slab directly on rock. The table shows the allowable static and dynamic bearing pressures.

2. Category I Structures Supported by H-Piles or Caissons to Rock

   There are four Category I structures founded on piles or caissons. The structures are the East Steam Valve Room, the Waste Packaging Area, the Condensate Demineralizer Waste Evaporator Building, and the ERCW piping and conduit support slab in the ERCW pumping station access dike.The East Steam Valve Rooms were backfitted with caissons into rock after experiencing some settlement.

   The Waste Packaging Area, the Condensate Demineralizer Waste Evaporator Building, and the ERCW piping and conduit support slab in the ERCW pumping station access dike are all supported on H-piles founded on rock.

3. Category I Soil-Supported Structures

   The allowable soil-bearing capacity for sustained loading is determined using the general shear failure formula, developed by Terzaghi and modified by Meyerhof.

The allowable bearing pressure for sustained loads is less than the ultimate bearing by at least a factor of three.

For dynamic loading the soil-bearing pressure is permitted to exceed the allowable for sustained loading. In no instance is the ratio of the ultimate soil-bearing pressure to the allowable soil pressure less than two.

Table 2.5.1-6 contains a summary of the allowable soil-bearing capacities and factors of safety for the soil-supported Category I structures.

4. Category I Embankments

See Subsection 2.5.6.

2.5.1.11 Compaction Criteria for Engineering Backfill

2.5.1.11.1 Earthfill

Prior to and during construction, borrow investigations were made. These investigations were made on an as needed basis.

The borrow samples were tested by the central materials laboratory according to ASTM D-698 to develop compaction control curves. The compaction curves were divided into subclasses, and these compaction curves are shown on Figures 2.5.1-14 and -15. These curves were used by the project laboratory to control compaction of earthfill at the site.

At Sequoyah Nuclear Plant, Type A backfill was placed around all Category I structures. This material, which was selected earth placed in not more than 6-inch layers, has a minimum required compaction of 95 percent of the maximum dry density at optimum moisture content.

The limits of excavation and the backfill around the Category I structures are shown in Figures 2.5.1-12,-12a, and -12b. Tables 2.5.1-7 and 2.5.1-8 are a summary of field control tests on Type A backfill.

2.5.1.11.2 Granular Fill

Crushed Stone Fill

A free draining granular fill material, consisting of crushed stone or sand and gravel, was placed below or next to Category I structures. This material was obtained commercially from off-site sources.

The granular fill was suitable for compaction to a dense, stable mass and consisted of sound, durable particles which are graded within the following limits:

	Percent by Weight	
Passing	Minimum	Maximum
1-1/4-inch sieve		100
1-inch sieve	95	100

Passing	Percent by Weight Minimum	Maximum
3/4-inch sieve	70	100
3/8-inch sieve	50	85
No. 4 sieve	33	65
No. 10 sieve	20	45
No. 40 sieve	8	25
No. 200 sieve	0	10

The material was free of disintegrated stone, soft friable particles, shale, salt, alkali, organic matter, or an adherent coating and reasonably free of thin, flat, or elongated pieces.

The granular fill material was used; for structural support, to replace earthfill as a backfill material around piping or conduits during wet weather, and to provide a working base above wet soil. The material, when used for structural support, or replacement for earthfill, was compacted to a required relative density as determined by ASTM D 2049. When used for structural support, such as for the refueling water storage tank (Figure 2.5.1-12b), an average relative density of 85 percent or greater with a minimum relative density of 80 was required. When used as a replacement for earthfill, a relative density between 70 and 85 percent was required.

Limestone Sand Fill

A granular fill material that meets the gradation requirements of ASTM C 33 was used as backfill material around the ERCW piping along the piping alignment from the intake Pumping Station to the ERCW Pumping Station access dike. The gradation limits for the material are:

Passing	Percent by Weight Minimum	Maximum
3/8" sieve	100	
No. 4 sieve	95	100
No. 8 sieve	80	100
No. 16 sieve	50	85
No. 30 sieve	25	60
No. 50 sieve	10	30
No. 100 sieve	2	10

The granular fill was compacted to an average relative density of 75 percent or greater, with a minimum relative density of 70 percent as determined by ASTM D 2049.

2.5.1.11.3 Crushed Rock

A crushed rock material that meets the gradation requirements shown below was used to

construct the core of the ERCW access dike and the material was also used for remedial treatment in local areas. The gradation limits for the material are:

Passing	Percent by Weight Minimum	Maximum
3-inch sieve	95	100
2-inch sieve	25	55
1-1/2-inch sieve	0	15
1-inch sieve	0	2

The material consisted of sound durable particles; free of soft friable particles, shale, salt, organic matter, or an adherent coating (other than dust); and reasonably free of thin, flat or elongated pieces.

ERCW Access Dike

The ERCW Access Dike as shown on Figure 3.8.4-9 connects the ERCW Pumping Station Access Cells with the shore. The dike core was placed by end dumping the rockfill material between the shore and the access cells up to elevation 676.75 (1.75 feet above normal minimum reservoir level). Compaction was obtained using a vibratory roller. Above elevation 676.75, between the access cells and the shore, the rockfill material was placed in lifts and compacted using the same vibrating roller.

Remedial Treatment

The rockfill material was used in several locations at the site to improve the soil. This was generally done where moisture caused the soil to be unsatisfactory as a base for earthfill placement. The material was used in a limited area at the refueling water tank pipe tunnel.

The material was placed in approximate 6-inch loose layers and rolled into the soil. If the required stiffness for the placement of earthfill was achieved, lifts of earth- fill or crushed stone fill were placed. If the required stiffness was not achieved, then additional lifts of the material were placed and rolled to obtain the desired stiffness. If shearing or pumping accurred in placement of the first lift, additional lifts of the material were placed as necessary.

2.5.2 Vibratory Ground Motion

The lithologic, stratigraphic, and structural conditions at the site and in the surrounding area and the geologic history of the region have been discussed previously in Paragraphs 2.5.1.3, 2.5.1.4, and 2.5.1.5, and will not be repeated here. The static and dynamic engineering properties of the materials underlying the site are described in Paragraphs 2.5.1.7 through 2.5.1.9.

2.5.2.1 Regional Tectonics

The fact that Pennsylvanian strata were involved in the deformation of the Valley and Ridge province in the Southern Appalachian area has in the past been taken as conclusive evidence that the structural features of the Appalachian system were formed near the end of the Paleozoic

Era. This has been termed the "Appalachian Revolution." This late Paleozoic orogeny, however, may have been only one of many movements, and in fact may have been a relatively mild concluding phase.

The orogenic and tectonic history of the southern Appalachian geosyncline is composite. The lower part, up to about the middle of the Ordovician, is a thick mass of carbonates with sandstone at the base. These deposits indicate a time of crustal quiescence, with slow sinking of the area of deposition, and low marginal lands. The succeeding clastics, laid down in Middle Ordovician and later times, express a radical change in the environment of the geosyncline. The source of the sediments was now from the southeast and was probably orogenic in origin.

In the southern Appalachians, the first orogenic movement indicated by the sediments of the geosyncline took place in Middle Ordovician time. This is somewhat earlier than the late Ordovician and early Silurian Taconian movements of the northern Appalachians, but may be considered a phase of the Taconian orogeny. To the southeast is a thick mass of shales and sandstones of Middle Ordovician Age, succeeded by red sandstones and siltstones, probably also Middle Ordovician. Farther northwest, all the Middle Ordovician is limestone, but the Upper Ordovician includes shales and red beds. These beds are topped by cleanly washed, quartzose Silurian sandstones, a post-orogenic deposit.

Orogenic movements at about this time in the metamorphic and plutonic belt on the southeast are suggested by radioactive determinations which indicate that some of the pegmatites of that area are of Ordovician Age.

Acadian, or late Devonian and early Mississippian, orogeny of the northern Appalachians seems to be poorly represented in the southern Appalachians. Slight early Mississippian movements, possibly a late phase of the Acadian orogeny, are expressed by clastic rocks of early Mississippian Age. However, Middle Paleozoic time in the southern Appalachians seems to have been mainly one of quiescence and readjustment, following the Ordovician orogeny.

The next period of orogeny suggested by the sediments of the Valley and Ridge province probably took place in late Mississippian and early Pennsylvanian time, or at about the same time as the Wichita orogeny west of the Mississippi Embayment. Deposits of late Mississippian and early Pennsylvanian age thicken markedly southwestward along the Valley and Ridge province and reach their climax in the southeastern belts of outcrop in Alabama. If these thick late Mississippian and early Pennsylvanian deposits are related to orogeny, that orogeny must have occurred in the region southeast of the present belts of outcrop, for the deposits lie with apparent conformity on the beds beneath and share with them the strong folding and faulting of the Valley and Ridge province. No Paleozoic deposits younger than the Pottsville are present southwest of West Virginia and Kentucky. There may have been Arbuckle movements of late Pennsylvanian and early Permian age, and there may have been also Appalachian movements of late Permian age.

Since the end of the Paleozoic the southern Appalachian mountain system has stood as a positive area and has undergone profound erosion. The present topography is the result of differential weathering of strata of varying resistance. The more durable units underlie the higher areas and the valleys are cut in softer formations. This differential erosion in the Valley and

Ridge Province has accentuated the long northeast-southwest trending series of fault belts that developed in the Paleozoic and have remained quiescent since. The Valley and Ridge Province from Roanoke, Virginia, southwestward is characterized by a series of overlapping linear fault blocks of northeast-southwest strike and southeast dip. Along the southeast margin of the province the Lower Cambrian and Pre-Cambrian strata have moved northwestward along the Great Smoky fault as much as 20 to 30 mi. as evidenced by exposures of Upper Cambrian and Ordovician strata in windows eroded through the thrust plate far southeast of the present mountain front. While this was happening, the less competent strata to the northwest were shingled into a series of imbricate thrust plates. The soles of these plates are normally incompetent shales in or below the Middle Cambrian Rome formation. On the present surface as many as 10 of these sheets can be defined across the Valley and Ridge Province in Tennessee. Most geologists familiar with the area now believe that there are two to four "master thrusts," such as the Pulaski, Saltville, and Pine Mountain, and others are subsidiary branches off the major faults. It is also believed that these faults do not extend into the basement but are a series of decollements developed in some relatively incompetent formation above the crystalline basement.

There is no geologic evidence indicating that any of these faults could be considered to be "active" faults; that is, still undergoing movement. On the contrary, all geologic evidence points to the fact that they have not moved since the close of the Paleozoic era. Drainage patterns are controlled by the relative competency or incompetency of the strata crossed by the streams and do not indicate offsets where crossing faults.

There is no evidence of creep, faulting, or renewed movement in the unconsolidated residual or alluvial deposits overlying the fault traces nor any observable offset of Plio-Pleistocene high level alluvial terraces.

In exploration for various sites in the TVA area, some of these major fault planes have been intersected by exploratory drill holes. As an example, during the exploration for Chickamauga Dam near Chattanooga, Tennessee, cores across the Missionary Ridge fault were recovered unbroken. The fault was not simply "healed" or recemented with secondary deposits of calcite or dolomite, but was a very tight contact along which apparently pulverized material had recrystallized. In another instance at the Tellico Project near Knoxville, Tennessee, the Knoxville fault was cored in 10 holes and again the core across the fault was recovered unbroken although the stratigraphic displacement is in the neighborhood of 10,000 feet and the lateral displacement can be measured in miles. The evidence available from all of the geologic studies that have been made indicates that all of the thrusts in the Valley and Ridge Province are inactive. In the voluminous literature on the geologic structure of the southern Appalachians, there is no mention of the possibility that any of the faults may still be potentially active.

Although light earthquakes occasionally occur in the region, there has not been a single instance where the surface has been deformed. These shocks are all of "normal" focus, 15-20 km deep, but even at these relatively shallow depths the hypocenters are well into the crystalline basement rocks far below the 5 km maximum thickness of the sedimentary cover. For this reason, any map showing epicenters of earthquakes in this area plotted in relation to fault traces gives an erroneous impression, for any such map drawn to a reasonable scale will show some epicenters falling near or on some of the relatively closely spaced thrust faults to which they are in no way related.

2.5.2.2 Site Area Tectonics

In recognition of the fact that sites in the southern Appalachians cannot reasonably be tied to any one "tectonic structure," NRC (formally AEC) in the preliminary evaluation of the Sequoyah Nuclear Plant defined a "Southern Appalachian Tectonic Province." This province is bounded on the east by the western margin of the Piedmont Province; on the west by the western limits of the Cumberland Plateau; on the south by the overlap of the Gulf Coastal Plain Province; and on the north by the re-entrant in the Valley and Ridge Province near Roanoke, Virginia. The limits of the province are shown on Figure 2.5.2-1. Under this concept accelerations at the site will be determined by assuming that the largest historic earthquake known in the province occurred adjacent to the site. For the Sequoyah site, this earthquake would be the May 31, 1897 quake in Giles County, Virginia, which had a reported epicentral intensity of MM VIII.

In the specific site area there is no physical evidence of disturbance of surficial materials during prior earthquakes. Minor dislocations and shears in the substrata are directly related to movements along the major thrust faults which moved in the Paleozoic and have been "fossilized" since that time. The majority of these are healed and recemented although they do serve as loci for near-surface development of solution and cavities in the limestone strata.

2.5.2.3 Seismic History

The evaluation of the earthquake hazard at the Sequoyah site involves a consideration of the known seismic history of a large surrounding area. By plotting the epicenters of hundreds of earthquake shocks, the areas of continuing seismic activity become apparent. The more active areas are described in the following summary.

1. Mississippi Valley, especially the New Madrid region of Arkansas, Kentucky, Missouri, and Tennessee. This region has been active seismically since the appearance of the white man and very probably long before that. A few great earthquakes and thousands of light to moderately strong shocks have been centered in the Mississippi Valley. Light to moderate shocks are still occurring at an average frequency of a few per year. The New Madrid region is more than 250 miles northwest of the Sequoyah site.

2. The Lower Wabash Valley of Illinois and Indiana. This area has been the center of several moderately strong earthquakes, some of which were felt as far south as Nashville, Tennessee. It is about 260 miles northwest of the Sequoyah site.

3. Charleston area, South Carolina. One of the country's greatest earthquakes was centered in the Charleston area. Earlier, many light to moderate shocks had been centered in the area long before the great earthquake, and the activity has continued to the present time. Charleston is more than 300 miles east of the Sequoyah site.

4. The Appalachian Mountains of eastern Tennessee and western North Carolina. The mountain belt of eastern Tennessee and western North Carolina is a region of continuing minor activity. Light to moderate shocks occur at an average frequency of one or two per year. The activity is not uniform, as periods of several shocks per year are followed by longer periods of no perceptible shocks. This region is centered more than 50 miles to the east of the Sequoyah site.

In addition to these areas, shocks of light to moderate intensity have occurred at numerous other localities in the southeastern states at various distances from the Sequoyah site. At many of these localities, only a few light to moderate shocks from widely scattered epicenters are known. A few such shocks have occurred to the north and east of Huntsville, Alabama. Numerous light shocks have occurred in Knoxville and its environs.

An annotated list of the earthquakes which have either affected the Sequoyah area or were centered somewhere near the area is presented below. In each case, the maximum intensity, or that applicable to the Sequoyah area, is assessed in terms of the modified Mercalli scale.

1811, December 16:	36.6° N - 89.6° W
1812, January 23:	36.6° N - 89.6° W
1812, February 7:	36.6° N - 89.6° W

These were the strongest shocks of the great series of earthquakes of 1811-1812 centered in the Mississippi Valley and known collectively as the New Madrid earthquake. This series consisted of thousands of individual shocks, many of which were strong. The three strongest shocks had an intensity of XII in their epicentral areas, and were felt over an area of about 2,000,000 square miles. Topographic changes were effected over an area of 3000 to 5000 square miles in the Mississippi Valley. The three great shocks and many of the other strong shocks were felt in the Sequoyah area, where some of them may have attained intensities as high as VI or VII (Figure 2.5.2-2).

<u>1843, January 4</u>: 35.2° N - 90° W. A severe earthquake centered in the Mississippi Valley was felt over some 400,000 square miles in a 12-state area. Chimneys were thrown down in Memphis, Nashville, and St. Louis. Although the intensity was perhaps as high as in the epicentral area, it is not known to have attained damaging intensities in Alabama. This shock was perceptibly felt over the entire Tennessee Valley and may have had an intensity as high as V or VI in the Sequoyah area.

<u>1861, August 31</u>: A strong earthquake, thought to have been centered in Virginia, was felt from Washington, D.C., southward to Wilmington, North Carolina, and westward to Knoxville, Cincinnati, and Louisville. At Knoxville it was described as a "heavy shock" which "alarmed the encamped military very much." It may have affected the Sequoyah area at an intensity of III or IV.

<u>1886, August 31</u>: 32.9° N - 80.0° W. The great Charleston, South Carolina, earthquake was felt over the entire eastern U.S. Its maximum intensity in the epicentral area was X, but in eastern Tennessee it was perhaps between VI and VII, as shown on Figure 2.5.2-3.

<u>1886, September 1</u>: A shock reported at Chattanooga was believed to be an aftershock of the Charleston earthquake, many of which were felt in Tennessee.

<u>1892, December 2</u>: A very perceptible earthquake shock was felt in Chattanooga from Hill City (now north Chattanooga) to Missionary Ridge. According to contemporary reports, the motion was from north to south. Doors in houses flew open, piles of lumber were upset, coal at chutes rolled down, and water vibrated. These effects were reportedly limited to an area of 6.25 square miles, but a larger area probably was affected.

<u>1895, October 31</u>: 37.0° N - 89.4° W. A strong earthquake centered at Charleston, Missouri, affected an area of 1,000,000 square miles in 23 states. It threw down chimneys and damaged buildings at various places in the Mississippi Valley, including Memphis, Tennessee. The earthquake was felt over the entire Tennessee Valley, but it was of low intensity in eastern Tennessee.

<u>1897, May 31</u>: 37.3° N - 80.7° W. A strong earthquake centered in Giles County, Virginia, was felt over an area of more than 250,000 square miles. It was felt throughout eastern Tennessee as far west as Tullahoma, but did not attain damaging intensities outside the epicentral area.

<u>1902, May 29</u>: A "strong shock" (intensity V) shook houses and awakened sleepers in Chattanooga.

<u>1902, October 18</u>: 35.0° N - 85.3° W. A moderate shock affected some 1,500 square miles in Georgia and Tennessee. It was felt from Dalton to Chattanooga. The maximum intensity was IV-V, but it is not known to have been felt as far to the northeast as the Sequoyah plant site.

<u>1904, March 4</u>: 35.7° N - 83.5° W. The epicenter of this earthquake was between Maryville and Sevierville, but the disturbance was felt along the mountain front over a distance of 90 to 100 miles. The shock affected an area of about 5,000 square miles, but the intensity was nowhere above V and over much of the felt area it was much lower.

<u>1913, April 17</u>: 35.3° N - 84.2° W. This moderately strong earthquake was felt over an area of about 3,500 square miles in eastern Tennessee, western North Carolina, northern Georgia, and northwestern South Carolina. The intensity was higher (V-VI) along the major axis of the affected area between Ducktown and Kiser. As shown by the map (Figure 2.5.2-4), the earthquake was not felt in the Sequoyah area, but it was felt some miles away.

<u>1913, May 2</u>: A light shock of several seconds duration was felt near Madisonville, Tennessee. This shock, intensity III, was centered nearly 50 miles from the plant site.

<u>1914, January 23</u>: 35.60 N - 84.50 W. A sharp local shock (V) was felt at Niota and Sweetwater, some 35 miles from the plant site.

<u>1916, February 21</u>: 35.50 N - 82.50 W. The strong earthquake, intensity VII, was centered in the mountains of western North Carolina. It affected an area of 500,000 square miles in the Carolinas, Georgia, Tennessee, Alabama, Kentucky, and Virginia. It was felt over nearly all of Tennessee, but was most severe in the mountains of eastern Tennessee. Chimneys were damaged at Sevierville and plaster was shaken from walls at Bristol, Morristown, and Knoxville. At Memphis, there was considerable motion in the higher stories of buildings. The earthquake affected the Sequoyah area at intensities between III and IV (Figure 2.5.2-5).

<u>1916, October 18</u>: 33.50 N - 86.20 W. A strong earthquake centered near Easonville, Alabama, was felt over an area of 100,000 square miles in a seven-state area. About two-thirds of Tennessee was affected by this earthquake, but there was no damage in the state. The

disturbance was felt strongly at Chattanooga, Nashville, Waynesboro, Carthage, Sparta, McMinville, Lewisburg, and other points in central Tennessee. A light shock was noticed in Knoxville and Clinton. At the Sequoyah plant site, the intensity was not more than IV (Figure 2.5.2-6).

1918, June 21: 36.10 N - 84.10 W. Centered near Lenoir City, this moderate shock (IV-V) affected an area of 3000 square miles. It is not known to have affected the Sequoyah area.

1920, December 24: 36.00 N - 85.00 W. A moderately strong shock was felt at a number of localities in eastern Tennessee including Rockwood, Glen Alice, Spring City, Harriman, Decatur, and Crossville. Many sleepers were awakened and the entire village of Glen Alice was aroused. This earthquake, with a maximum intensity of V, was centered about 45 miles from the Sequoyah plant site and is not known to have affected the site area.

1921, December 15: An earthquake of "considerable intensity" was felt along the western portion of the Appalachian Valley from Kingston and Rockwood to Decatur and Dayton and as far eastward as Athens. The maximum intensity was V, but the shock is not known to have been felt any nearer to Sequoyah than Dayton.

1924, October 20: 35.0° N - 82.6° W. A strong earthquake (V-VI) centered in Pickens County, South Carolina, was felt over 56,000 square miles in the Carolinas, Georgia, Tennessee, Virginia, and Florida. Although buildings were strongly shaken in the epicentral area, there was little damage. The intensity in eastern Tennessee was nowhere greater than III. At the Sequoyah plant site, the intensity was less than II (Figure 2.5.2-7).

1927, October 8: A moderately strong earthquake was felt in all parts of Chattanooga and suburban areas, including north Chattanooga, East Ridge, Lookout Mountain, Signal Mountain, St. Elmo, and Red Bank. The shock was felt in small and large buildings. Lights trembled and loose objects were disturbed. Other mild shocks were reported within a few hours following this shock. The shock is not known to have been felt in the Sequoyah area.

1928, November 2: 35.8° N - 82.8° W. A strong earthquake centered in the mountains of Madison County, North Carolina, was felt over an area of 40,000 square miles in a six-State area. The maximum intensity was VII, but in Tennessee the intensity diminished from VI along the state line to extinction somewhere in central Tennessee. At the Sequoyah plant site, the intensity was less than III (Figure 2.5.2-8).

1930, August 30: 35.9° N - 84.4° W. This earthquake was felt at Kingston, Lenoir City, Lawnville, Oliver Springs, and other points west and southwest of Knoxville. The maximum intensity was V. This shock is not known to have affected the Sequoyah site area perceptibly.

1938, March 31: An earthquake centered in the mountains in the Little Tennessee Basin was widely felt in Tennessee and North Carolina. In Tennessee it was felt at Copperhill, Parksville, Knoxville, and Sweetwater where the intensities ranged from III to I. The shock is not known to have affected any part of Tennessee west of Sweetwater.

1940, October 19: An earthquake which shook houses and rattled loose objects awoke thousands of sleepers in Chattanooga. It affected some 1,100 square miles in Tennessee and Georgia. It was felt as far north as Charleston and Birchwood but at very low intensities (Figure 2.5.2-9).

1941, September 8: An earthquake was felt throughout Chattanooga and as far west as Jasper. It was especially strong in the Lookout Mountain area where walls vibrated, loose objects rattled, and glassware was broken. This earthquake is not known to have been felt upstream from Chattanooga.

1945, June 13: This shock, centered near Cleveland, Tennessee, where the intensity was V, was felt over an area of 4,000 square miles in southeastern Tennessee and northwestern Georgia. It was felt north-eastward to Knoxville, southwestward to Chattanooga, and southeastward to Blue Ridge, Georgia. The felt area of this shock was never mapped, but the shock may have affected the Sequoyah area at an intensity of III or less.

1946, April 6: Another light shock was felt at Cleveland, Tennessee. This shock was not reported felt outside of the city.

1947, December 27: A light earthquake (IV) felt in Chattanooga, Tennessee; and Fort Oglethorpe, Rossville, Ringgold, and Boynton, Georgia, affected an area of 300 miles. It was centered east of the Missionary Ridge fault, where houses shook, loose objects rattled and piano wires popped. The shock is not known to have been felt any nearer to Sequoyah than Chattanooga.

1954, January 22: A light earthquake was felt over much of McMinn County from Athens to Etowah and Englewood. It is not known to have been felt outside of the county.

1957, June 23: 35° 54' N - 84° 14' W. A light local earthquake was felt in western Knox County and nearby sections of Anderson and Loudon Counties. At Dixie Lee Junction and in neighboring communities, people were awakened by the "jumping" of houses and the rattling of loose objects.

1959, June 12: 35° 21' N - 84° 20' W. A light earthquake was felt over an area of 900 square miles in eastern Tennessee and western North Carolina. It was most strongly felt at Tellico Plains and Mount Vernon where an intensity of IV was attained.

1960, April 15: 35.8° N - 83.9° W. A shock of intensity V, centered near Knoxville, Tennessee, was felt over a 1,300 square mile area. It was not reported as felt in the Sequoyah area.

1966, August 24: 35.9° N - 83.9° W. This shock of intensity IV, centered near Knoxville, Tennessee, was not felt in the Sequoyah area.

1968, November 9: 38.0° N - 88.5° W. This earthquake, centered in southern Illinois, with an epicentral intensity of VII was felt over a 400,000 square mile area in 23 states, including Tennessee, and in Canada. In the Sequoyah area it had an approximate intensity between II and III.

1969, July 13: 36.1° N - 83.7° W. The epicenter of this intensity IV shock was located northeast of Knoxville, Tennessee. This shock was not felt in the Sequoyah area (Figure 2.5.2-10).

1969, November 20: 37.4° N - 81.0° W. This intensity V shock, with its epicenter in southern West Virginia, was not reported felt in the Sequoyah area.

1971, July 12: 35.9° N - 84.3°. A light local tremor (MM III-IV) was felt at 10:00 p.m. in the Knoxville-Oak Ridge area. It was not felt in the Sequoyah area.

A list of all seismic events to 1982 and within a 200-miles radius of the plant site is presented as Table 2.5.2-1.

The seismic history of the southeastern U.S. has been known for only about a century and a half, but so far as can be determined from the records the Sequoyah site is as stable seismically as any area in the State. Great distant earthquakes have affected the area with intensities equal to or greater than the maximum intensities of the several shocks centered within 50 or 60 miles of the site. Of the 40 earthquakes identified in the foregoing annotated list, only 12 are positively known to have been felt at Sequoyah. Of these, four were centered in the Mississippi Valley, one at Charleston, South Carolina, one in Alabama, one in Illinois, and five at various centers in east Tennessee, Virginia, and western North Carolina. In addition to these, it is probable that a few other shocks might have affected the area at very low intensities.

On Figure 2.5.2-1, epicenters of all historic quakes within 120 miles of the Sequoyah site and all epicenters of historic quakes with MM intensities of V or greater up to and beyond 250 miles from the site are plotted.

2.5.2.4 Site Seismic Evaluation

The known seismic history of the southeastern United States suggests that the earthquake hazard is negligible at the Sequoyah site. There are no active faults in the vicinity of the site and there is no physical evidence of any seismic activity at the site. There have been several shocks in the general area including two shocks of intensity MM V centered within 15 and 20 miles of the site. However, the nearest known epicenter of damaging intensity (MM VII) is 100 miles northeast of the site. The maximum intensity to have been felt at the site in the recorded history of the area is probably MM V and certainly no more than MM VI. On the basis of present knowledge, the maximum historic felt intensity was derived from major earthquakes centered at distant points, especially in the Mississippi Valley. There is continuing seismic activity in the Mississippi Valley and the possibility of another great earthquake in the New Madrid region cannot be discounted. An earthquake of intensity MM X to MM XII at New Madrid might be felt at Sequoyah with an intensity of MM V or MM VI.

There is no known correlation between earthquakes observed in the region and any surficial tectonic structures. The site lies in the Southern Appalachian tectonic province as defined during the preliminary evaluation of the Sequoyah Nuclear Plant site. This province is bounded on the east by the western edge of the Piedmont Province; on the west by the western limits of the Cumberland Plateau; on the south by the overlap of the Gulf Coastal Plain Province; and on The north by the re-entrant in the Valley and Ridge Province near Roanoke, Virginia (Figure 2.5.2-1).

The maximum historic quake reported in this province was assigned an intensity of MM VIII although there is reason to believe it should have been rated as MM VII. It occurred in Giles County, Virginia, in 1897. Although this earthquake occurred 285 miles northeast of the site, this intensity is assumed to occur at the site for the purpose of defining the Safe Shutdown Earthquake (SSE). The maximum acceleration for an intensity of this level is estimated to be 0.14 g. This peak acceleration has been estimated from empirical relationships which are based almost exclusively on data obtained on overburden and hence provide some margin of conservatism for a rock site (seismic site studies indicate a shear wave velocity of 7,000 ft/s).

Initially, it was felt the Housner spectrum for maximum top of rock acceleration of 0.14 g for the SSE best represented the historic seismic threat at the site, i.e., large shocks at long distances. This information was submitted to TVA's consultant (Weston Geophysical Research, Incorporated) for their review. TVA's consultant agreed that the maximum ground acceleration values were conservative but felt the Housner spectra did not give sufficient weight to the effect of close earthquakes. TVA's consultant recommended a spectrum reflecting more energy in the 5 to 10 Hz frequency range, and his recommendations were accepted by TVA. Another consultant was contracted to produce such a spectrum and a set of four artificial earthquake records whose average response would approximate this spectrum.

During the course of the Sequoyah PSAR review, a special meeting was called on November 13, 1969 to discuss earthquake design criteria. AEC structural and geological-seismological consultants for Sequoyah were present. At this meeting, AEC's geological-seismological consultants took the position that maximum top of rock accelerations should be 0.18 g for the SSE. AEC's structural consultants stated that 0.18 g coupled with a Housner spectrum would be considered satisfactory as a minimum design basis. TVA stated that it would use the arithmetically averaged response spectra generated by four artificial records previously mentioned after the high frequency end had been raised to coincide with the 0.18 g Housner spectra. The structural consultants agreed that if TVA wished to use these records, which give more conservative results, this would certainly be acceptable to them.

Accordingly, the plant is designed so that all structures, systems, and components important to safety will remain functional when subjected to an SSE having maximum horizontal acceleration of 0.18 g and maximum vertical ground acceleration of 0.12 g.

10 CFR Part 100, Appendix A, 1971, allowed the utilities to independently select the g-level for the Operating Basis Earthquake (OBE). Accordingly, TVA selected 0.00g as the OBE. The regulations required, however, the establishment of a "1/2 SSE" which was based on a g-level of 1/2 of the SSE. The 1/2 SSE for Sequoyah was therefore 0.09g (i.e., 1/2 of the 0.18g maximum horizontal ground acceleration).

The seismic design basis for Sequoyah Nuclear Plant is the 0.18 g modified Housner spectrum discussed above. However, in the course of their review for the operating license, NRC requested additional information concerning the seismic design basis. This culminated in the development of a site specific response spectrum. This spectrum represents the 84th percentile of 13 actual earthquake recordings and has a peak acceleration of 0.22 g. This site specific spectrum was used for evaluation of present designs and not as a design basis. The development of the site specific spectrum is presented in the following reports.

1. Justification of the Seismic Design Criteria Used for the Sequoyah, Watts Bar, and Bellefonte Nuclear Plants - Phase I, TVA, April 1978.

2. Justification of the Seismic Design Criteria Used for the Sequoyah, Watts Bar, and Bellefonte Nuclear Plants - Phase II, TVA, August 1978.

3. Prediction of strong motions for Eastern North America on the Basis of Magnitude, Weston Geophysical Report for TVA, August 1978.

4. Earthquake Ground Motion Study in the Vicinity of the Sequoyah Nuclear Power Plant, Weston Geophysical Report for TVA, February 1979.

5. Justification of the Seismic Design Criteria Used for the Sequoyah, Watts Bar, and Bellefonte Nuclear Plants - Phase II - Responses to NRC Questions 1 to 6, TVA, June 1979.

Therefore, as a result of the development of the site specific response spectrum in 1979, an SSE of 0.22g has been considered. 10 CFR Part 100, Appendix A, 1973, regulations no longer require a 1/2 SSE; however, applicants are required to select an OBE equal to at least 1/2 of the SSE unless supporting data are presented to clearly justify otherwise. TVA presented such data (reports 2 and 5, above) and justified an OBE of 0.09g, less than 1/2 of the present site specific SSE of 0.22g and the same as the 1/2 SSE used in early seismic analyses.

Figures 2.5.2-11 through 2.5.2-14 illustrate the relationship between the minimum design response spectra and the actual site seismic design response spectra for the SSE for all damping ratios used in the design of rock-supported structures.

2.5.3 Surface Faulting

The lithologic, stratigraphic, and structural conditions at the site and in the surrounding area and the geologic history of the region have been discussed previously in Paragraphs 2.5.1.3, 2.5.1.4, and 2.5.1.5, and will not be repeated here.

2.5.4 Stability of Surface Materials

2.5.4.1 Subsidence

Most major Category I structures are founded on bedrock and no subsidence is to be expected. In most instances the weight of rock removed in foundation excavation equals or exceeds the weight imposed by the structure. Sufficient exploratory drilling has been done to assure there are no karstic solution zones underlying the plant that would allow collapse. Any small solution areas below foundation grade have been grouted in the routine course of construction.

No mining or extensive groundwater withdrawal, either of which might allow subsidence, occurs in the area.

Loads imposed by the plant structures are not of sufficient magnitude to develop compaction subsidence in material having compressive strengths ranging from 5,000 to 15,000 lb/in^2. No regional warping is known in the southern Appalachian area of sufficient magnitude to impose unequal stresses on the plant structures.

2.5.4.2 Zone of Deformed or Weak Material

Sufficient exploration was done prior to final location of the individual structures to insure that weak or deformed zones are not present in the foundation areas. Any minor defects that were disclosed during excavation were treated appropriately as a standard construction procedure.

2.5.4.3 Bedrock Stresses

No specific investigations of residual stress accumulations in the foundation strata were made. Experience at numerous previous major construction projects in the region has shown that this is not a consideration. Such stress effects as "popping," rock bursts, and foundation "heaving" were not observed during foundation evacuation.

2.5.5 Stability of Subsurface Materials

2.5.5.1 Excavations and Backfill

Excavations and backfill are described in Paragraph 2.5.1.11.

2.5.5.2 Liquefaction Potential

The liquefaction potential of all slopes and soil deposits were evaluated by using empirical rules based on observed performance and by comparing the soil conditions and earthquake characteristics at the site with similar sites that have liquefied.

The empirical rules used are based on the Japanese experience during the Niigata earthquake. It was observed that the following general conditions could cause liquefaction:

1. The percentage of silt and clay-size particles should be less than 10 percent.
2. The particle diameter at 60 percent passing should be between 0.2 mm and 1.0 mm.
3. The uniformity coefficient should be between 2 and 5.
4. The blow count from Standard Penetration Tests should be less than 15.

Using these rules there were no soils which indicated potential liquefaction. A comparison of the soil conditions and the earthquake characteristics at the site with similar sites that have liquefied indicated that there were no potentially liquefiable soils at the site.

2.5.5.3 Static Analysis

2.5.5.3.1 Settlement Analysis

Soil supported Category I structures were investigated to determine the amount of settlement each would undergo. Settlement calculations were made for the Diesel Generator Building and the Low Level Radwaste Storage Facility.

Diesel Generator Building

The Diesel Generator Building (DGB) had a net increase in load on the soil.

The settlement calculations contain several conservative assumptions which make the estimated value of settlement an upper bound. As a result of these conservative assumptions, the settlement actually experienced is less than estimated.

A time-settlement rate was not determined for the original calculations, as we were committed to waiting for settlement to stabilize. We determined that settlement had stabilized sufficiently in the first two years (see Figure 2.5.5-1).

Low Level Radwaste Storage Facility

The Low Level Radwaste Storage (LLRW) Facility is located in an area that underwent significant changes during the construction of the plant. Initially, the area served as a borrow source, and material was excavated to approximately the final grade for the LLRW facility. The area was then used for a yard storage area and later as a storage area for spoil material. Prior to its use for the LLRW facility, the spoil material and some additional in situ material were removed to reach final grade. The maximum net increase in soil pressure due to the LLRW facility above the original overburden load was 0.32 tons/ft2. The resultant theoretical settlement due to the imposed load was less than the allowable settlement. A settlement monitoring program for the LLRW facility has been established and is described in section 2.5.5.3.2.

2.5.5.3.2 Settlement Monitoring

Settlement monitoring programs were developed for the Diesel Generator Building, the East Steam Valve Rooms, the Low Level Radwaste Storage Facility, and the ERCW Support Slab and Pumping Station. Settlement programs were not developed for the Waste Packing Area and the Condensate Demineralizer Waste Evaporator Building. The details of each program or the reasons for not developing a settlement program are given below.

Diesel Generator Building - This soil supported structure was monitored for settlement. It has a uniform bearing pressure of 1400 lb/ft2. Settlement monuments were placed at each corner of the structure. Readings were started in January 1973 and read monthly until January 1974 and then quarterly until January 1975. No readings were then made until April 1979.

Based on available data and our past experience, there are no adverse trends being exhibited; settlements are not significant; and there has been no adverse structural performance. Settlement readings will no longer be reported for this structure.

The construction period for the DGB extended from June 1972 to September 1973. The base slab and the first lift of the exterior walls were constructed before the settlement markers were placed and the first settlement readings were taken. The electrical conduit connections were made between November 1974 and January 1975. The piping connections were made after July 1978.

East Steam Valve Room - This structure was originally supported on soil but due to excessive settlement was underpinned with caissons. The caissons were completed between February and

August 1976. Negligible settlement has occurred since the caissons were installed. Because of this excellent performance, a continued settlement monitoring program is not warranted.

The electrical conduit connections were made between May 1978 and the present. The piping connections were made between September 1977 and October 1978. All of these were installed after the caissons were in place.

ERCW Support Slab and Pump Station - The ERCW support slab is supported on piles driven to rock. The ERCW pumping station is supported on rock. A settlement monitoring program was developed for both of these features. The survey markers were read monthly from June 1979 to March 1980, semiannually from March 1980 to September 1981, and annually from September 1981 to September 1984. Negligible settlement was found during the monitoring program. The settlement monitoring program was discontinued in September 1984 after 5 years of monitoring.

Waste Packaging Area and Condensate Demineralizer Waste Evaporator Building - These structures are supported on piles driven to rock. No settlement monitoring program was developed for these structures. Since the piles are driven to rock, there is no need to monitor settlement.

The supporting piles were driven to rock before placement of the foundation mat. For the Waste Packaging Area, the piles were completed in October 1975, and the electrical conduit connections were made between January 1977 and December 1978. There is no Category I piping for this building. For the Condensate Demineralizer Waste Evaporator Building, the piles were completed in June 1977. The piping connections were made in August 1978.

Low Level Radwaste Storage Facility

Each storage module has four individual compartments with each compartment being composed of five unit cells. The storage modules are designed for a total settlement of 9 inches, a differential settlement of 4 inches over an individual storage compartment, and a differential settlement of 4 inches between individual compartments. Settlement monitoring points are established on each corner of each compartment of each module and settlements are recorded annually until settlement has essentially ceased.

2.5.6 Slope Stability

2.5.6.1 Slope Characteristics

2.5.6.1.1 Slopes at Diesel Generator Building and Cooling Towers

The Diesel Generator Building and Cooling Towers are located on a gently sloping hillside southeast of the main plant area. A cross section of the hillside is shown in Figure 2.5.6-1.

The soil properties are obtained as described in Paragraph 2.5.1.9.

The R-test strengths of the soil are used in the seismic pseudo-static stability analyses. The soil properties used in the seismic pseudostatic stability analyses are shown in Figure 2.5.6-1.

2.5.6.1.2 Condenser Cooling Water Pumping Station Intake Channel Slopes

The intake channel shown in Figure 2.1.2-1 is located on the north side of the main plant area. The side slopes of both the approach channel and the forebay area are cut on a 3.5 horizontal to 1 vertical slope. Typical cross sections of the approach channel and forebay slopes are shown in Figure 2.4.8-1.

The side slopes in the forebay area are Category I slopes and are constructed to remain stable for the most critical design conditions. Enough water is retained in the forebay for plant shutdown using a closed mode of operation and therefore the approach channel slopes are not designed as Category I slopes.

The soil properties used in the seismic pseudostatic stability analysis of the side slopes are shown in Figure 2.5.6-2. See paragraph 2.5.1.9 for additional information on the soil properties.

2.5.6.1.3 Dike Slopes at the ERCW Pumping Station

The dike leading to the ERCW pumping station on Chickamauga Reservoir shown in Figure 2.1.2-1 is located northeast of the main plant across the embayment from the condenser cooling water supply pumping station. The dike has Category I slopes and is designed to remain stable for the most critical design conditions.

2.5.6.2 Design Criteria and Analysis

2.5.6.2.1 Design Criteria and Analysis of Slopes at Diesel Generator Building and Cooling Towers

The seismic stability analysis of the hillside is performed assuming circular failure arcs using the Modified Swedish Method with Slices and a Newmark analysis. Horizontal and vertical seismic accelerations are used in the analyses. The accelerations for the Safe Shutdown Earthquake in the soil deposit and on these soil-supported structures are obtained as discussed in Paragraphs 3.7.1.6 and 3.7.2.1.

The worst location for failure is a section which includes the Diesel Generator Building since it is the heaviest structure and has the largest seismic forces acting on it. The water table in the soil deposit is conservative assumed at elevation 705.0. The factor of safety during a Safe Shutdown Earthquake must be greater than 1.0.

Several circular failure arcs are considered to determine the location of the critical arc. The critical failure arc is shown in Figure 2.5.6-1. A Newmark analysis is performed for this critical failure arc. The Newmark analysis shows that the Design Basis Earthquake will not induce sliding along this failure arc. From these analyses it is concluded that the hillside will be stable during a Safe Shutdown Earthquake.

2.5.6.2.2 Design Criteria and Analysis of (Condenser Cooling Water Pumping Station) Intake Channel Slopes

The side slopes of the forebay portion of the intake channel are designed and constructed such that they remain stable for the most critical design condition, the occurrence of a Safe Shutdown Earthquake coincident with a sudden drawdown of the reservoir water level.

The stability analyses of the slopes were performed assuming circular failure planes using the Modified Swedish Method with Slices. Horizontal and vertical seismic coefficients were used in the analyses. The accelerations for the Safe Shutdown Earthquake in the soil deposit were obtained as discussed in Paragraph 3.7.1.6.

Several circular failure planes were considered and the minimum factor of safety was found to be 1.31. This failure plane is shown in Figure 2.5.6-2.

In addition a level ledge with a 15-foot-minimum width extends from the toe of the slide slopes to the edge of the forebay. This precludes the spillage of material into the forebay from a localized slippage of the slope.

2.5.6.2.3 Design Criteria and Analyses of Dike Slopes at the ERCW Pumping Station

The Category I slopes of the dike leading to the ERCW pumping station are designed such that they remain stable for the most critical design condition; the occurrence of a Safe Shutdown Earthquake coincident with normal reservoir level. The dike is also designed to remain stable during the PMF and subsequent drawdown.

The stability analysis of the slopes were performed using wedge analysis techniques. Pseudo-static analyses were used in all the seismic evaluations. Horizontal seismic coefficients were used in these analyses. The accelerations in the dike from the Safe Shutdown Earthquake were obtained as discussed in paragraph 3.7.1.6. The minimum factor of safety was determined to be 1.22.

Calculations were also performed to approximate the deformations which might be expected to occur as a result of stresses caused by a seismic event. This calculation considered the effect of vertical acceleration. The resulting deformations were shown to have no significant effect on the buried ERCW pipes.

2.5.6.3 Compaction Specifications

See Paragraph 2.5.1.11.

Note: A valid shear velocity measurement could not be established for seven stations.

Table 2.5.1-3

EQUATION FOR DYNAMIC MODULUS OF ELASTICITY

$$E = \frac{(V_p)^2 (1+\sigma)(1-2\sigma)}{144\, g\, (1-\sigma)}\ \gamma$$

Where

E = Dynamic modulus of elasticity (psi)

V_p = Compressional wave velocity (ft/sec)

σ = Poisson's Ratio

g = Gravitational constant of 32.2 ft/sec

γ = Unit Weight (lbs/ft^3)

EQUATION FOR POISSON'S RATIO

$$\sigma = \frac{\frac{1}{2}\left(\frac{V_p^2}{V_s^2}\right) - 1}{\left(\frac{V_p^2}{V_s^2}\right) - 1}$$

Where

σ = Poisson's Ratio

V_p = Compressional wave velocity (ft/sec)

V_s = Shear wave velocity (ft/sec)

661	80	4950						
656	85	4950						
652	89	5657						

Note:

1. Shear Wave velocities could not be obtained below elevation due to the difference in borehole depths.
2. The average compressional and shear wave velocities are calculated by averaging the measured velocities for the 25.4-, 19.8- and 14.6-foot distances.
3. The average compressional wave velocities below elevation 691 are calculated by averaging the measured velocities for the 19.8- and 14.6-foot distances. Hole C was blocked below this elevation, therefore no data could be obtained.
4. The density is a representative value determined from laboratory testing of soil samples taken near the array.

Calculation Reference CEB810515025

2.6 CONCLUSIONS

The various significant characteristics of the Sequoyah Nuclear Plant site which have, to varying degrees, influenced plant design and operating plans, are shown in Table 2.6-1. The foregoing discussions have shown how these various site characteristics have influenced the plant design and how this design has taken into consideration the site related aspects of the NRC Regulatory Guides, based on the material in Sections 2.1 through 2.5 and the following considerations, it is concluded that the Sequoyah Nuclear Plant site meets the Reactor Siting Criteria of 10 CFR Part 100:

l. The site, consisting of approximately 525 acres, provides a minimum exclusion distance of approximately 1824 feet.

2. There are no residences on the site.

3. The population density and use characteristics of the environs are compatible with the location of a nuclear plant. The low population zone and population center distances are approximately 3 and 7.5 miles, respectively.

4. The geological, seismological, hydrological, and meteorological characteristics of the site and environs are considered suitable for its intended uses and have been considered in the plant design and operating plans.

5. As analyzed in Chapter 15, the radiation doses to the public at the exclusion distance and low population zone distance, under postulated hypothetical accident conditions, are well within the reference values of 10 CFR Part 100.

Table 2.6-1
SEQUOYAH NUCLEAR PLANT SITE CHARACTERISTICS

1.	Site location	Approximately 7.5 miles northeast of Chattanooga, TN at TN River Mile (TRM) 484.5
2.	Site area	525 acres
3.	Exclusion distance	1824 feet
4.	Low population zone distance	three miles
5.	Population center distance	7.5 miles
6.	Elevation of plant grade	705 feet MSL
7.	Tennessee River normal maximum pool elevation	682.5 feet MSL
8.	Design basis flood	726.8 feet MSL
9.	Population density, 0-10 mile, 1970 census	102.32 persons/sq. mile
10.	Distance from diffuser discharge to the nearest downstream drinking water intake	10.7 miles
11.	Tectonic province of site	Southern Appalachian
12.	Maximum historical earthquake	MM VIII
13.	Safe Shutdown Earthquake (SSE) peak accelerations	0.18 g horizontal 0.12 g vertical
14.	Depth of soil overburden	Ranges from 3.2 to 45 feet
15.	Bedrock at site	Interbedded limestone and shale
16.	Tornado probability	4.4×10^{-5}
17.	Average annual air temperature	59.7°F
18.	Average annual precipitation	58 inches
19.	Chickamauga Reservoir surface temperature	Maximum 30°C Minimum 2°C
20.	Intake location	TRM 484.8
21.	Diffuser location	TRM 483.7

3.0 DESIGN CRITERIA STRUCTURES, COMPONENTS, EQUIPMENT AND SYSTEMS

3.1 CONFORMANCE WITH NRC GENERAL DESIGN CRITERIA

3.1.1 Single Failure Criteria

Each of the Engineered Safety Features is designed to tolerate a single failure during the period of recovery following an incident without loss of its protection functions. This period of recovery consists of two segments; the short-term period and the long-term period.

During the short-term period, the single failure is limited to a failure of an active component to complete its function as required. Should the single failure occur during the long-term period rather than the short term, the Engineered Safety-Related System is designed to tolerate an active failure or a passive failure without loss of its protective function.

The following definitions are applicable to terms that pertain to the single failure criterion:

Period of Recovery. The time necessary to bring the plant to safe shutdown and regain access to faulted equipment. The recovery period is the sum of the short-term and long-term periods defined below. Note that safe shutdown is used here in lieu of cold shutdown. SQN is a hot standby plant, not a cold shutdown plant. (Reference: NUREG 0011 & supplement 1; and NUREG 1232, Volume 2, pg. 2-7).

Incident. Any natural or accidental event of infrequent occurrence and its related consequences which affect the plant operation and require the use of engineered safeguards systems. Such events, which are analyzed independently and are not assumed to occur simultaneously, include the loss-of-coolant accident, steam line ruptures, steam generator tube ruptures, etc. A loss of offsite power may be an isolated occurrence or may be concurrent with any event requiring engineered safeguards systems use.

Short Term. The time immediately following the incident during which automatic actions are performed, system responses are checked, type of incident is identified and preparations for long-term recovery operation are made. The short term is the first 24 hours following initiation of engineered safeguards system operations.

Long Term. The remainder of the recovery period following the short term. In comparison with the short term where the main concern is to remain within Nuclear Regulatory Commission specified site criteria, the long-term period of operation involves bringing the plant to safe shutdown conditions where faulted equipment can be accessed and repaired. Note that safe shutdown is used here in lieu of cold shutdown. SQN is a hot standby plant, not a cold shutdown plant. (Reference: NUREG 0011 & supplement 1; and NUREG 1232 volume 2, pg. 2-7).

Active Failure. The failure of a powered component such as a piece of mechanical equipment, component of the electrical supply system or instrumentation and control equipment to act on command to perform its design function. Examples include the failure of a motor-operated valve to move to its correct position, the failure of an electrical breaker or relay to respond, the failure of a pump, fan or diesel generator to start, etc.

Equipment moving spuriously from the proper safeguards position without signal, such as a motor-operated valve inadvertently shutting at the moment it is required, is not considered credible.

Passive Failure. The structural failure of a static component which limits the components effectiveness in carrying out its design function. When applied to a fluid system, this means a break in the pressure boundary resulting in abnormal leakage not exceeding 50 gal/min for 30 minutes. Such leak rates are consistent with limited cracks in pipes, sprung flanges, valve packing leaks or pump seal failures.

3.1.2 Overall Requirements

The Sequoyah Nuclear Plant was designed to meet the intent of the Proposed General Design Criteria for Nuclear Power Plant Construction Permits published in July, 1967. The Sequoyah construction permit was issued in May, 1970. This FSAR, however, addresses the NRC General Design Criteria (GDC) published as Appendix A to 10 CFR 50 in July 1971.

Each criterion is followed by a discussion of the design features and procedures which meet the intent of the criteria. Any exception to the 1971 GDC resulting from the earlier commitments is identified in the discussion of the corresponding criterion. References to other sections of the FSAR are given for system design details.

Criterion 1 - Quality Standards and Records

Structures, systems, and components important to safety shall be designed, fabricated, erected, and tested to quality standards commensurate with the importance of the safety functions to be performed. Where generally recognized codes and standards are used, they shall be identified and evaluated to determine their applicability, adequacy, and sufficiency and shall be supplemented or modified as necessary to assure a quality product in keeping with the required safety function. A Quality Assurance Program shall be established and implemented in order to provide adequate assurance that these structures, systems, and components will satisfactorily perform their safety functions. Appropriate records of the design, fabrication, erection and testing of structures, systems, and components important to safety shall be maintained by or under the control of the nuclear power unit licensee throughout the life of the unit.

Compliance

Discussions related to the applicable codes, design criteria and standards used in the design of particular systems are contained in the appropriate FSAR sections and in Tables 3.2.1-1, 3.2.1-2, 3.2.1-3, 3.2.2-1 and 3.2.2-2.

The Quality Assurance Program conforms to the requirements of 10 CFR 50 Appendix B, "Quality Assurance Criteria for Nuclear Power Plant." Details of the program are given in Chapter 17 and the TVA Nuclear Quality Assurance Plan.

Criterion 2 - Design Bases for Protection Against Natural Phenomena.

Structures, systems, and components important to safety shall be designed to withstand the effects of natural phenomena such as earthquakes, tornadoes, hurricanes, floods, tsunami, and

seiches without loss of capability to perform their safety function. The design bases for these structures, systems, and components shall reflect:

1. Appropriate consideration of the most severe of the natural phenomena that have been historically reported for the site and surrounding area, with sufficient margin for the limited accuracy, quantity, and period of time in which the historical data have been accumulated,

2. Appropriate combinations of the effects of normal and accident conditions with the effects of the natural phenomena, and

3. The importance of the safety functions to be performed.

Compliance

The structures, systems, and components important to safety are designed to either withstand the effects of natural phenomena without loss of capability to perform their safety functions, or to fail in the safest condition. Those structures, systems, and components vital to the shutdown capability of the reactor are designed to withstand the maximum probable natural phenomenon expected at the site, determined from recorded data for the site vicinity, with appropriate margin to account for uncertainties in historical data. Appropriate combinations of normal, accident, and natural phenomena structural loadings are considered in the plant design.

The nature and magnitudes of the natural phenomena considered in the design of this plant are discussed in subsections 2.3, 2.4, and 2.5. Subsections 3.2 through 3.11 discuss the design of the plant in relationship to natural events. Seismic and safety classifications, as well as other pertinent standards and information, are given in the sections listed above and those sections discuss individual structures and components.

Criterion 3 - Fire Protection.

Structures, systems, and components important to safety shall be designed and located to minimize, consistent with other safety requirements, the probability and effect of fires and explosions. Noncombustible and heat-resistant materials shall be used wherever practical throughout the unit, particularly in locations such as the containment and control room. Fire detection and fighting systems of appropriate capacity and capability shall be provided and designed to minimize the adverse effects of fires on structures, systems, and components important to safety. Fire-fighting systems shall be designed to assure that their rupture or inadvertent operation does not significantly impair the safety capability of these structures, systems, and components.

Compliance

The plant is designed to minimize the probability of fires and explosions, and in the event of such occurrences to minimize the potential effects of such events to plant safety-related equipment and personnel. Prime consideration is given to these requirements throughout the design process by providing for the duplication and physical separation of components in plant design and the use of materials classified as noncombustible and/or fire resistant wherever practical in all areas of the plant. Equipment and facilities for fire protection, including detection, alarm, and

extinguishment are provided to protect both plant equipment and personnel from fire, explosion, and the resultant release of toxic vapors. Fire-fighting systems are designed to assure that their rupture or inadvertent operation will not impair systems important to safety. All portions of the Fire Protection Systems necessary to protect safety-related equipment in Class I structures are designed to seismic requirements.

All systems are designed and installed in accordance with the applicable requirements as described in the Fire Protection Report (see 9.5.1). The Fire Protection System is designed such that a failure of any component of the system or inadvertent operation:

1. Will not cause a nuclear accident or significant release of radioactivity to the environment.

2. Will not impair the ability of equipment to safely shut down and isolate the reactor or limit the release of radioactivity to the environment in the event of a postulated accident.

The Fire Protection Systems for the Sequoyah Nuclear Plant are discussed in the Fire Protection Report.

Criterion 4 - Environmental and Missile Design Bases.

Structures, systems, and components important to safety are designed to accommodate the effects of and to be compatible with the environmental conditions associated with normal operation, maintenance, testing, and postulated accidents, including LOCA. These structures, systems and components shall be appropriately protected against dynamic effects, including the effects of missiles, pipe whipping, and discharging fluids, that may result from equipment failures and from events and conditions outside the nuclear power unit.

Compliance

Structures, systems, and components important to safety are designed to accommodate the effects of and to be compatible with the environmental conditions associated with normal operation, maintenance, testing, and postulated accidents. The associated environmental parameters are identified and incorporated in the design requirements and specifications.
Particular care is given to the extreme environmental conditions associated with major incidents such as a loss of coolant. Required equipment and instrumentation are identified, environmental conditions such as temperature, pressure, humidity, irradiation, etc., are calculated, and the effects of the latter on the former are evaluated either analytically or experimentally. The dynamic effects associated with an accident are carefully identified and assurance is given that the structures and systems (including engineered safeguards) assumed undamaged in the total assessment of the accident consequences are suitably protected.

Emergency core cooling components are austenitic stainless steel or equivalent corrosion-resistant material and hence are compatible with the containment atmosphere over the full range of exposure during the postaccident conditions.

Where vital components cannot be located away from potential missiles, protective walls and slabs, local missile shielding, and restraining devices are provided to protect the containment and engineered safety feature components within the containment against damage from missiles generated by the equipment failures associated with the DBA.

The environmental design of safety-related items is discussed in subsection 3.8 on the design of structures, subsections 6.2.2 and 6.2.3 on containment heat removal and air purification and subsection 9.4 on ventilation systems. Safety-related systems and components use the input from these sections for design as discussed in subsection 3.11. The missile and environmental protection given each system is discussed with the individual system in Chapters 3 through 11.

Criterion 5 - Sharing of Structures, Systems, and Components.

Structures, systems, and components important to safety shall not be shared between nuclear power units unless it is shown that such sharing will not significantly impair their ability to perform their safety functions, including, in the event of an accident in one unit, an orderly shutdown and cooldown of the remaining units.

Compliance

The two units share several structures and systems, many of which have no safety function. The structures important to safety are the Auxiliary/Control Building (subsection 3.8), Diesel Generator Building (subsection 3.8), CCW Pumping Station (subsection 3.8), the ERCW pumping station (subsection 3.8), and a few miscellaneous structures. Shared safety-related systems include the ERCW (subsection 9.2), component cooling water (subsection 9.2), fire protection (subsection 9.5), fuel handling/storage and cooling (subsection 9.1), fuel oil storage (subsection 9.5), preferred and emergency electric power (subsections 8.2 and 8.3, respectively), chemical and volume control (subsection 9.3), condensate (subsection 9.2), radioactive waste (Chapter 11), Gas Treatment System (subsection 6.2), and Control and Auxiliary Building Ventilation Systems (subsections 6.4 and 9.4). The Vital Direct-Current Power System is shared to the extent that a few loads (e.g., the vital inverters) in one nuclear unit are energized by the direct-current power channels assigned primarily to power loads of the other unit. In no case does the sharing inhibit the safe shutdown of one unit while the other unit is experiencing an accident. All shared systems are sized for all credible initial combinations of normal and accident states for the two units, with appropriate isolation to prevent an accident condition in one unit from carrying into the other.

Criterion 10 - Reactor Design.

The reactor core and associated coolant, control, and protection systems shall be designed with appropriate margin to assure that specified acceptable fuel design limits are not exceeded during any condition of normal operation, including the effects of anticipated operational occurrences.

Compliance

The reactor core with its related coolant, control, and protection systems is designed to function throughout its design lifetime without exceeding acceptable fuel damage limits. The Reactor Trip System is designed to actuate a reactor trip, when necessary, for any anticipated combination of plant conditions, to ensure that fuel design limits are not exceeded. The core design, together with reliable process and decay heat removal systems, provides for this capability under all expected conditions of normal operation with appropriate margins for uncertainties and anticipated transient situations, including the effects of the loss of reactor coolant flow, trip of the turbine-generator, loss of normal feedwater, and loss of power.

Chapter 4 discusses the design bases and design evaluation of reactor components. Chapter 5 discusses the Reactor Coolant System. The details of the Reactor Trip and Engineered Safety Features Actuation Systems design and logic are discussed in Chapter 7. This information supports the accident analyses presented in Chapter 15.

Criterion 11 - Reactor Inherent Protection.

The reactor core and associated coolant systems shall be designed so that in the power operating range the net effect of the prompt inherent nuclear feedback characteristics tends to compensate for a rapid increase in reactivity.

Compliance

A negative reactivity coefficient is a basic feature of core nuclear design as discussed in Chapter 4.

Criterion 12 - Suppression of Reactor Power Oscillations.

The reactor core and associated coolant, or, control and protection systems shall be designed to assure that power oscillations which can result in conditions exceeding specified acceptable fuel design limits are not possible or can be reliably and readily detected and suppressed.

Compliance

Power oscillations of the fundamental mode are inherently eliminated by the negative Doppler and nonpositive moderator temperature coefficient of reactivity.

Oscillations, due to xenon spatial effects, in the radial, diametral and azimuthal overtone modes are heavily damped due to the inherent design and due to the negative Doppler and nonpositive moderator temperature coefficients of reactivity.

Oscillations, due to xenon spatial effects, in the axial first overtone mode may occur. Assurance that fuel design limits are not exceeded by xenon axial oscillations is provided as a result of reactor trip functions using the measured axial power imbalance as an input.

Oscillations, due to xenon spatial effects, in axial modes higher than the first overtone, are heavily damped due to the inherent design and due to the negative Doppler coefficient of reactivity.

The stability of the core against xenon-induced power oscillations and the functional requirements of instrumentation for monitoring and measuring core power distribution are discussed in subsection 4.3, Nuclear Design. Details of the instrumentation design and logic are discussed in Chapter 7.

Criterion 13 - Instrumentation and Control.

Instrumentation and control shall be provided to monitor variables and systems over their anticipated ranges for normal operation for anticipated operational occurrences, and for accident conditions as appropriate to assure adequate safety, including those variables and systems that

can affect the fission process, the integrity of the reactor core, the reactor coolant pressure boundary, and the containment and its associated systems. Appropriate controls shall be provided to maintain these variables and systems within prescribed operating ranges.

Compliance

Instrumentation and controls are provided to monitor and control neutron flux, control rod position, temperatures, pressures, flows, and levels as necessary to assure that adequate plant safety can be maintained. Instrumentation is provided in the Reactor Coolant System, Steam and Power Conversion System, the Containment, Engineered Safety Features Systems, Radiological Waste Systems, and other auxiliaries. Parameters that must be provided for operator use under normal operating and accident conditions are indicated in the control room in proximity with the controls for maintaining the indicated parameter in the proper range.

The quantity and types of process instrumentation provided ensures safe and orderly operation of all systems over the full design range of the plant. These systems are described in Chapters 5, 6, 7, 8, 9, 10, 11, and 12.

Criterion 14 - Reactor Coolant Pressure Boundary.

The reactor coolant pressure boundary shall be designed, fabricated, erected, and tested so as to have an extremely low probability of abnormal leakage or rapidly propagating failure and of gross rupture.

Compliance

The reactor coolant pressure boundary is designed to accommodate the system pressures and temperatures attained under all expected modes of plant operation, including all anticipated transients, and to maintain the stresses within applicable stress limits. In addition to the loads imposed on the piping under operating conditions, consideration is also given to abnormal loadings such as pipe rupture and seismic loadings as discussed in subsections 3.6 and 3.7. The piping is protected from overpressure by means of pressure relieving devices as required by applicable codes.

Reactor coolant pressure boundary materials selection and fabrication techniques ensure a low probability of gross rupture or significant leakage. The materials of construction are protected from corrosion which might otherwise reduce its structural integrity during its service lifetime, by control of coolant chemistry. Also, there are provisions for inspections, testing, and surveillance of critical areas to assess the structural and leaktight integrity (subsection 5.2). For the reactor vessel, a material surveillance program conforming to applicable codes is provided (subsection 5.4). Means are provided to detect significant uncontrolled leakage with indication in the main control room (subsection 5.2).

Criterion 15 - Reactor Coolant (RC) System Design.

The RC System and associated auxiliary, control, and protection systems shall be designed with sufficient margin to assure that the design conditions of the reactor coolant pressure boundary are not exceeded during any condition of normal operation, including anticipated operational occurrences.

Compliance

Transient analyses are included in RC System design which conclude that design conditions are not exceeded during normal operation. Protection and control set points are based on these transient analyses.

Additionally, reactor coolant pressure boundary components achieve a large margin of safety by the use of proven ASME materials and design codes, use of proven fabrication techniques, nondestructive shop testing and integrated hydrostatic testing of assembled components.

The effect of radiation embrittlement is considered in reactor vessel design, and surveillance samples will be used to monitor adherence to expected conditions throughout plant life.

Multiple safety and relief valves are provided for the Reactor Coolant System. These valves and their set points meet ASME criteria for overpressure protection. The ASME criteria are satisfactory based on a long history of industry use. Chapter 5 discusses RC System design.

Criterion 16 - Containment Design.

Reactor containment and associated systems shall be provided to establish an essentially leaktight barrier against the uncontrolled release of radioactivity to the environment and to assure that the containment design conditions important to safety are not exceeded for as long as postulated accident conditions require.

Compliance

The reactor containment (subsection 6.2) is a freestanding, continuous steel membrane structure. The ice condenser inside containment (subsection 6.2) assists in limiting containment pressure to a value less than design pressure both during and after a LOCA. A concrete shield building, surrounding the steel vessel, allows for collection of any containment leakage which is subsequently processed by the Emergency Gas Treatment System (subsection 6.2) before release to the environment. A containment spray system (subsection 6.2), which supplements the ice condenser in limiting pressure, also provides long-term cooling following a LOCA. The design pressure is not exceeded in any pressure transients which result from combining the effects of heat sources with minimal operation of the Engineered Safety Features.

The Containment System is designed to provide for protection of the public from the consequences of a LOCA based on a postulated break of the reactor coolant piping up to and including a double-ended break of the largest reactor coolant pipe. Periodic leak rate measurements ensure that the containment barrier is maintained within regulatory limits.

Criterion 17 - Electric Power Systems.

An onsite electric power system and an offsite electric power system shall be provided to permit functioning of structures, systems, and components important to safety. The safety function for each system (assuming the other system is not functioning) shall be to provide sufficient capacity and capability to assure that (1) specified acceptable fuel design limits and design conditions of the reactor coolant pressure boundary are not exceeded as a result of anticipated operational occurrences and (2) the core is cooled and containment integrity and other vital functions are maintained in the event of postulated accidents.

The onsite electric power sources, including the batteries, and the onsite electric distribution system, shall have sufficient independence, redundancy, and testability to perform their safety functions assuming a single failure. Electric power from the transmission network to the onsite Electric Distribution System shall be supplied by two physically independent circuits (not necessarily on separate rights of way) designed and located so as to minimize to the extent practical the likelihood of their simultaneous failure under operating and postulated accident and environmental conditions. A switchyard common to both circuits is acceptable. Each of these circuits shall be designed to be available in sufficient time following a loss of all onsite alternating current power supplies and the other offsite electric power circuit, to assure that specified acceptable fuel design limits and design conditions of the reactor coolant pressure boundary are not exceeded. One of these circuits shall be designed to be available within a few seconds following a LOCA to assure that core cooling, containment integrity, and other vital safety functions are maintained.

Provisions shall be included to minimize the probability of losing electric power from any of the remaining sources as a result of, or coincident with, the loss of power generated by the nuclear power unit, the loss of power from the transmission network, or the loss of power from the onsite electric power sources.

Compliance

The capacity and capability of either the onsite or offsite electric power system is sufficient to assure that (1) specified fuel design limits and design conditions of the reactor coolant pressure boundary are not exceeded as a result of anticipated operational occurrences and (2) the core is cooled and containment integrity and other vital functions are maintained in the event of postulated accidents.

Onsite Electrical Power System

The Onsite Electrical Power System serves both nuclear power units and certain common plant equipment. It consists of two independent diesel generator systems, two redundant Class IE electric power distribution trains, and four redundant vital instrument and control power channels, each provided with a battery, battery charger, and inverter for each unit. Each redundant onsite power supply, train, and channel has the capability and capacity to supply the required safety loads assuming the failure of its redundant counterpart.

Offsite Electrical Power System

The offsite electrical power source consists of two physically independent circuits which are normally energized. One of these circuits is immediately available (within a few seconds) following a LOCA. The offsite sources are discussed in Section 8.2. Power is normally provided via the Unit Station Service Transformers, but may be provided via the Common Station Service Transformers.

For a detailed description and analysis of the Electric Power System refer to Chapter 8 of the FSAR.

Criterion 18 - Inspection and Testing of Electric Power Systems.

Electric Power Systems important to safety shall be designed to permit appropriate periodic inspection and testing of important areas and features, such as wiring, insulation, connections,

and switchboards, to assess the continuity of the systems and the condition of their components. The systems shall be designed with a capability to test periodically (1) the operability and functional performance of the components of the systems, such as onsite power sources, relays, switches, and buses, and (2) the operability of the systems as a whole and, under conditions as close to design as practical, the full operation sequence that brings the systems into operation, including operation of applicable portions of the protection system, and the transfer of power among the nuclear power unit, the offsite power system and the onsite power system.

Compliance

Inspection

In addition to continuous surveillance by visual and audible alarms for any abnormal condition, the onsite power system is designed to permit inspection and checking of wiring, insulation, connections, and switchboards to the extent that personnel safety is not jeopardized, equipment not damaged, and the plant not exposed to accidental tripping.

On-Line Testing

The onsite power system is designed with provision for periodic testing during normal operation with the unit on line, to the extent that the plant is not exposed to accidental tripping and the reliability of the safety system not degraded. These features include provisions for automatic starting and loading of onsite diesels, and starting and loading of individual or groups of engineered safeguards to their respective buses. The system is also designed to permit testing of larger integrated segments of the system during planned cooldown of the Reactor Coolant System.

Off-Line Testing

The onsite power system is designed with facilities for a complete test of the operability of the system from initiation of protection system, starting and loading of diesels, transfer of power sources, and, as close to the design as practical, the full operational sequence of the safety related systems.

Inspection and testing of electrical power systems is further described in subsections 8.3.1.1 and 8.3.2.1 of the FSAR.

Criterion 19 - Control Room.

A control room shall be provided from which actions can be taken to operate the nuclear power unit safely under normal conditions and to maintain it in a safe condition under accident conditions, including LOCA. Adequate radiation protection shall be provided to permit access and occupancy of the control room under accident conditions without personnel receiving radiation exposures in excess of 5-rem whole body, or its equivalent to any part of the body, for the duration of the accident.

Equipment at appropriate locations outside the control room shall be provided (1) with a design capability for prompt hot shutdown of the reactor, including necessary instrumentation and controls to maintain the unit in a safe condition during hot shutdown, and (2) with a potential capability for subsequent cold shutdown of the reactor through the use of suitable procedures.

Compliance

The plant is provided with a separate enclosure designated as the control building. Within the control building are located the main control room, auxiliary instrument room, computer room, battery and dc equipment rooms , switchyard relay room, plant communications room and service facilities (office space, kitchen, toilet facilities, and mechanical equipment room for heating, ventilation, and air-conditioning equipment).

The Main Control Room is provided with unit control panels for each of the two units, the switchyard, dc distribution, operation of the Diesel Generator System, and for those systems shared by the two units. The unit control panels contain those instruments and controls necessary for operation of the unit functions such as the reactor and its auxiliary system, turbine generator, and the steam and power conversion systems. Selection of loading from the various plant electrical distribution boards such as the unit boards, common boards, and shutdown boards, can be accomplished from the unit control panels.

The control room is designed and equipped to minimize the possibility of events such as fire, high radiation levels, excessive temperature, etc., which might preclude occupancy. The main control room is continuously occupied by qualified operating personnel under all operating and accident conditions except in the case of events such as fire or smoke which could necessitate its evacuation. In the unlikely event that control room occupancy becomes impossible, provisions have been made to bring the reactor units to, and maintain them in, a hot standby condition from locations external to the main control room.

Sufficient shielding, distance, and containment integrity are provided to assure that under postulated accident conditions control room personnel shall not be subjected to radiation doses which would exceed 5 rem to the whole body, or its equivalent to any part of the body, including doses received during both ingress and egress. Control room ventilation is provided by a system having a large percentage of recirculated air. After an accident, makeup air will automatically be routed through a system of HEPA and charcoal filters.

The design of the control room for occupancy during accidents is discussed in subsection 6.4, Habitability Systems. The heating, ventilation, and air-conditioning of the control building is discussed in subsection 9.4. Radiation doses to control room personnel following a LOCA are evaluated in subsection 15.5.3.

Criterion 20 - Protection System Functions.

The Protection System shall be designed (1) to initiate automatically the operation of appropriate systems including the reactivity control systems, to assure that specified acceptable fuel design limits are not exceeded as a result of anticipated operational occurrences and (2) to sense accident conditions and to initiate the operation of systems and components important to safety.

Compliance

A fully automatic protection system (with appropriate redundant channels) is provided to cope with transients where insufficient time is available for manual corrective action. The design basis for all protection systems is in accord with IEEE Standard 279-1971. The Reactor Protection System automatically initiates a reactor trip when any monitored variable or combination of variables exceeds its normal operating range.

Setpoints are chosen to provide an envelope of safe operating conditions with adequate margin for uncertainties to ensure that fuel design limits are not exceeded.

Reactor trip is initiated by removing power to the rod drive mechanisms of all the full length rod cluster control assemblies. This will allow the assemblies to free fall into the core, rapidly reducing the reactor power output.

The Engineered Safety Features Actuation System automatically initiates emergency core cooling, and other safeguards functions, by sensing accident conditions using redundant process channels measuring diverse parameters. Manual actuation of safeguards is relied upon where ample time is available for operator action. The Engineered Safety Features Actuation System also provides a reactor trip on manual or automatic safety injection (S) signal generation.

The response and adequacy of the protection systems is analyzed for all conditions specified by the ANSI N18.2 standard, through Condition IV.

Criterion 21 - Protection System Reliability and Testability.

The Protection System shall be designed for high functional reliability and inservice testability commensurate with the safety functions to be performed. Redundancy and independence designed into the Protection System shall be sufficient to assure that (1) no single failure results in loss of the protection function and (2) removal from service of any component or channel does not result in loss of the required minimum redundancy unless the acceptable reliability of operation of the Protection System can be otherwise demonstrated. The Protection System shall be designed to permit periodic testing of its functioning when the reactor is in operation, including a capability to test channels independently to determine failures and losses of redundancy that may have occurred.

Compliance

The Protection System is designed for high functional reliability and inservice testability. The design employs redundant logic trains and measurement and equipment diversity.

The Protection System is designed in accordance with IEEE Standard 279-1971. All safety actuation circuitry is provided with a capability for testing with the reactor at power. The Protection Systems, including the engineered safety features test cabinet comply with Regulatory Guide 1.22 on periodic testing of Protection System actuation functions. Under the present design, there are protective functions which are not tested at power. The functions can be tested under shutdown plant conditions, so that they do not interrupt power operation as allowed by Regulatory Guide 1.22.

In those cases where equipment cannot be tested at power, it is only the device function which is not tested. The logic associated with the devices has the capability for testing at power. Such testing will disclose failures or reduction in redundancy which may have occurred. Removal from service of any single channel or component does not result in loss of minimum required redundancy. For example, a two-of-three function becomes a one-of-two function when one channel is removed. (Note that this is not true for the logic trains which are effectively a one-out-of-two logic.)

Semiautomatic testers are built into each of the two logic trains in a protection system. These testers have the capability of testing the major part of the protection systems very rapidly while the reactor is at power. Between tests, the testers continuously monitor a number of internal protection system points including the associated power supplies and fuses. Outputs of the monitors are logically processed to provide alarms for failures in one train and automatic reactor trip for failures in both trains. A self-testing provision is designed into each tester. Additional details can be found in subsections 7.2 and 7.3.

The Process Protection System performs automatic surveillance testing of the digital process protection racks via a portable Man Machine Interface (MMI) test cart as described in subsection 7.2.

Criterion 22 - Protection System Independence.

The Protection System shall be designed to assure that the effects of natural phenomena, and of normal operating, maintenance, testing, and postulated accident conditions on redundant channels do not result in loss of the protection function, or shall be demonstrated to be acceptable on some other defined basis. Design techniques, such as function diversity or diversity in component design and principles of operation, shall be used to the extent practical to prevent loss of the protection function.

Compliance

Design of Protection Systems includes consideration of natural phenomena, normal maintenance, testing and accident conditions such that the protection functions are always available.

Sufficient redundancy and independence are designed into the Protection System to assure that no single failure, or removal from service, of any component or channel of a system results in the loss of the protection function. The minimum redundancy is exceeded in each protection function which is active with the reactor at power. Functional diversity and consequential location diversity are designed into the system. The protective systems are discussed in detail in subsections 7.2 and 7.3.

Criterion 23 - Protection System Failure Modes.

The Protection System shall be designed to fail into a safe state or into a state demonstrated to be acceptable on some other defined basis if conditions such as disconnection of the system, loss of energy (e.g., electric power, instrument air), or postulated adverse environments (e.g., extreme heat or cold, fire, pressure, steam, water, and radiation) are experienced.

Compliance

The Protection System is designed with due consideration of the most probable failure modes of the components under various perturbations of the environment and energy sources. Each reactor trip channel is designed on the de-energize-to-trip principle so loss of power, disconnection, open channel faults, and the majority of internal channel short-circuit faults cause the channel to go into its tripped mode. The Protection System is discussed in subsections 7.2 and 7.3.

Criterion 24 - Separation of Protection and Control Systems.

The Protection System shall be separated from control systems to the extent that failure of any single control system component or channel, or failure or removal from service of any single protection system component or channel which is common to the control and protection systems leaves intact a system satisfying all reliability, redundancy, and independence requirements of the Protection System. Interconnection of the protection and control systems shall be limited so as to assure that safety is not significantly impaired.

Compliance

The Protection System is separate and distinct from Control Systems. Control Systems may be dependent on the Protection System in that control signals are derived from Protection System measurements where applicable. These signals are transferred to the Control System by isolation devices which are classified as protection components. The adequacy of system isolation has been verified by testing under conditions of postulated credible faults. The failure or removal of any signal control instrumentation and protection circuitry leaves intact a system which satisfies the requirements of the Protection System. Protection Systems are discussed in subsections 7.2 and 7.3. Control Systems are discussed in subsections 7.4, 7.5, and 7.7.

Criterion 25 - Protection System Requirements for Reactivity Control Malfunctions

The Protection System shall be designed to assure that specified acceptable fuel design limits are not exceeded for any single malfunction of the Reactivity Control Systems, such as accidental withdrawal (not ejection or dropout) of control rods.

Compliance

Reactor shutdown by full-length rod insertion is completely independent of the normal control function since the trip breakers interrupt power to the rod mechanisms regardless of existing control signals. The Protection System is designed to limit reactivity transients so that fuel design limits are not exceeded.

The analysis presented in Chapter 15 shows that for postulated dilution during refueling, startup or manual or automatic operation at power, the operator has ample time to determine the cause of dilution, terminate the source of dilution and initiate reboration before the shutdown margin is lost. The Rod Control System is discussed in subsections 4.2 and 7.7. The CVCS Makeup System is discussed in subsection 9.3.4. Analyses of the effects of possible malfunctions are discussed in Chapter 15. The analyses show that acceptable fuel damage limits are not exceeded even in the event of a single malfunction of either system.

Criterion 26 - Reactivity Control System Redundancy and Capability.

Two independent reactivity control systems of different design principles shall be provided. One of the systems shall use control rods, preferably including a positive means for inserting the rods, and shall be capable of reliably controlling reactivity changes to assure that under conditions of normal operation, including anticipated operational occurrences, and with appropriate margin for malfunctions such as stuck rods, specified acceptable fuel design limits are not exceeded. The second reactivity control system shall be capable of reliably controlling the rate of reactivity changes resulting from planned, normal power changes (including xenon burnout) to assure acceptable fuel design limits are not exceeded. One of the systems shall be capable of holding the reactor core subcritical under cold conditions.

Compliance

Two Reactivity Control Systems are provided. These are rod cluster control assemblies (RCCA) and chemical shim (boration). The RCCA are inserted into the core by the force of gravity.

During operation the shutdown rod banks are fully withdrawn. The full-length Control Rod System maintains a programmed average reactor temperature compensating for reactivity effects associated with scheduled and transient load changes. The shutdown rod banks along with the full-length control banks are designed to shut down the reactor with adequate margin under conditions of normal operation and anticipated operational occurrences thereby ensuring that specified fuel design limits are not exceeded. The most restrictive period in core life is assumed in all analyses and the most reactive rod cluster is assumed to stick in out of core position.

The boron chemical shim will maintain the reactor in the cold shutdown state independent of the position of the control rods and can compensate for all xenon burnout transients.

Details of the construction of the RCCA are included in subsection 4.2, with the operation discussed in subsection 7.7. The means of controlling the boric acid concentration is described in subsection 9.3. Performance analyses under accident conditions are included in Chapter 15.

Criterion 27 - Combined Reactivity Control Systems Capability.

The Reactivity Control Systems shall be designed to have a combined capability, in conjunction with poison addition by the Emergency Core Cooling System (ECCS), of reliably controlling reactivity changes to assure that under postulated accident conditions and with appropriate margin for stuck rods the capability to cool the core is maintained.

Compliance

Sufficient capability is provided to control reactivity for any anticipated cooldown transient, i.e., accidental opening of a steam bypass or relief valve or safety valve stuck open. This capability is achieved by a combination of RCCA and automatic boron addition via the ECCS with the most reactive control rod assumed to be fully withdrawn. Manually controlled boric acid addition is used to supplement the RCCA in maintaining the shutdown margin for the long-term conditions of xenon decay and plant cooldown.

Criterion 28 - Reactivity Limits.

The Reactivity Control Systems shall be designed with appropriate limits on the potential amount and rate of reactivity increase to assure that the effects of postulated reactivity accidents can neither (1) result in damage to the reactor coolant pressure boundary greater than limited local yielding nor (2) sufficiently disturb the core, its support structures or other reactor pressure vessel internals to impair significantly the capability to cool the core. These postulated reactivity accidents shall include consideration of rod ejection (unless prevented by positive means), rod dropout, steam line rupture, changes in reactor coolant temperature and pressure, and cold water addition.

Compliance

The maximum reactivity worth the control rods and the maximum rates of reactivity insertion employing control rods and boron removal are limited to values that prevent rupture of the RC System boundary or disruptions of the core or vessel internals to a degree that could impair the effectiveness of emergency core cooling.

The appropriate reactivity insertion rate for the withdrawal of RCCA and the dilution of the boric acid in the RC Systems are controlled by the Technical Specifications for the facility. The specification includes or references appropriate graphs that show the permissible mutual withdrawal limits and overlap of functions of the several RCCA banks as a function of power. These data on reactivity insertion rates, dilution and withdrawal limits are also discussed in subsection 4.3. The capability of the Chemical and Volume Control System to avoid an inadvertent excessive rate of boron dilution is discussed in Chapter 9. The relationship of the reactivity insertion rates to plant safety is discussed in Chapter 15.

Assurance of core cooling capability following accidents, such as rod ejection, steam line break, etc., is given by keeping the reactor coolant pressure boundary stresses within faulted condition limits as specified by applicable ASME codes. Structural deformations are checked also and limited to values that do not jeopardize the operation of needed safety features.

Criterion 29 - Protection Against Anticipated Operational Occurrences.

The Protection and Reactivity Control Systems shall be designed to assure an extremely high probability of accomplishing their safety functions in the event of anticipated operational occurrences.

Compliance

The Protection and Reactivity Control Systems are designed to ensure an extremely high probability of fulfilling their intended functions. The design principles of diversity and redundancy coupled with a rigorous Quality Assurance Program and analyses support this probability as does operating experience in plants using the same basic design. Subsections 4.2.3, 7.2, and 7.7 describe design bases and system design.

Criterion 30 - Quality of Reactor Coolant Pressure Boundary.

Components which are part of the reactor coolant pressure boundary shall be designed, fabricated, erected, and tested to the highest quality standards practical. Means shall be

provided for detecting and, to the extent practical, identifying the location of the source of reactor coolant leakage.

Compliance

All RC System components are designed, fabricated, inspected, and tested in conformance with Tables 3.2.2-1 and 3.2.2-2.

Detecting and locating, to the extent practical, leakage from the RCS pressure boundary is provided by diverse systems. Subsection 5.2.7 describes the reactor coolant pressure boundary leakage detection system.

Criterion 31 - Fracture Prevention of Reactor Coolant Pressure Boundary.

The reactor coolant pressure boundary shall be designed with sufficient margin to assure that when stressed under operating, maintenance, testing, and postulated accident conditions (1) the boundary behaves in a nonbrittle manner and (2) the probability of rapidly propagating fracture is minimized. The design shall reflect consideration of service temperatures and other conditions of the boundary material under operating, maintenance, testing, and postulated accident conditions and the uncertainties in determining (1) material properties, (2) the effects of irradiation on material properties, (3) residual, steady-state and transient stresses, and (4) size of flaws.

Compliance

Close control is maintained over material selection and fabrication for the RC System to assure that the boundary behaves in a nonbrittle manner. The RC System materials which are exposed to the coolant are corrosion resistant stainless steel or Inconel. The reference temperature RT_{NDT} of the reactor vessel material samples is established by Charpy V-Notch and dropweight tests. These tests also ensure that materials with proper toughness properties and margins are used.

As part of the reactor vessel specification certain requirements which are not specified by the applicable ASME codes are performed, as follows:

1. A complete independent review of the supplier stress analysis, Stress Report 30616-1130 Revision 1, Parts 1 and 2, has been conducted by Westinghouse on the reactor vessel. Independent stress analysis was conducted in selected areas to ascertain that the design conditions imposed by the Westinghouse specification have been adequately accounted for.

2. The reactor vessel receives a complete stress analysis, including analysis for cyclic pressure and temperature operation. The ASME Nuclear Power Plant Component Code, Section III, Class 1 rules to which these components are designed generally exempt them from cyclic analysis by code Paragraph NB-3222.4(d).

3. Reactor Vessel Out-of-Roundness Requirements - To ensure uniform coolant flow, the Westinghouse out-of-roundness requirements on the cylindrical region in the area of the thermal shield are above code. ASME Code, Section III, Class 1 out-of-roundness requirements are stated in Paragraph NB-4221.1 of the Code. This referenced paragraph

states that the difference in inches between the maximum and minimum inside diameters at any cross section shall not exceed the smaller of (D + 50)/200 and D/100, where D is the nominal inside diameter in inches at the cross section under consideration. Westinghouse requires the out-of-roundness to be less than 0.5 percent of the diameter in the cylindrical section of the vessel in the region of the thermal shield.

Special requirements are imposed by Westinghouse on the quality control procedure for both the basic materials of construction, and on various subassemblies and final assembly for the reactor coolant loop components. These requirements supplement the rules for quality assurance spelled out in the applicable design codes. Examples of the special quality assurance requirements for the reactor vessel that are beyond code requirements are contained in Section 5.4.4.

The fabrication and quality control techniques used in the fabrication of the RC System are equivalent to those for the reactor vessel. The inspections of reactor coolant pressure boundary are governed by requirements of Section 5.2.8.

The permissible pressure - temperature relationships for selected heatup and cooldown rates are calculated in accordance with the ASME Code as described in Section 5.2.4.3. The change in RT_{NDT} due to irradiation during plant life is calculated using conservative methods and verified periodically by surveillance program irradiated material test data.

Criterion 32 - Inspection of Reactor Coolant Pressure Boundary.

Components which are part of the reactor coolant pressure boundary shall be designed to permit (1) periodic examination and testing of important areas and features to assess their structural and leak-tight integrity, and (2) an appropriate material surveillance program for the reactor pressure vessel.

Compliance

The design of the reactor coolant pressure boundary provides the capability for accessibility during service life to the entire internal surface of the reactor vessel, certain external zones of the vessel including the nozzle to reactor coolant piping welds and the top and bottom heads, and external surfaces of the reactor coolant piping except for the area of pipe within the primary shielding concrete. The examination capability complements the Leakage Detection Systems in assessing the pressure boundary component's integrity. The reactor coolant pressure boundary is periodically inspected under the provisions of ASME B&PV Code, Section XI. Inservice Inspection is discussed in subsection 5.2.8.

Monitoring of the RT_{NDT} properties of the reactor vessel core region forgings, weldments and associated heat treated zones are performed in accordance with ASTM E 185, Recommended Practice for Surveillance Testing on Structural Materials in Nuclear Reactors. Samples of reactor vessel plate materials are retained and catalogued in case future engineering development shows the need for further testing.

The material properties surveillance program includes not only the conventional tensile and impact tests, but also fracture mechanics specimens. The observed shifts in RT_{NDT} of the core region materials with irradiation will be used to confirm the calculated limits to startup and shutdown transients.

To define permissible operating conditions below RT_{NDT}, a pressure range is established which is bounded by a lower limit for pump operation and an upper limit which satisfies reactor vessel stress criteria. To allow for thermal stresses during heatup or cooldown of the reactor vessel, an equivalent pressure limit is defined to compensate for thermal stress as a function of rate of change of coolant temperature. Since the normal operating temperature of the reactor vessel is well above the maximum expected RT_{NDT} brittle fracture during normal operation is not considered to be a credible mode of failure. Additional details can be found in subsection 5.2.

Criterion 33 - Reactor Coolant Makeup.

A system to supply reactor coolant makeup for protection against small breaks in the reactor coolant pressure boundary shall be provided. The system safety function shall be to assure that specified acceptable fuel design limits are not exceeded as a result of reactor coolant loss due to leakage from the reactor coolant pressure boundary and rupture of small piping or other small components which are part of the boundary. The system shall be designed to assure that for onsite electric power system operation (assuming offsite power is not available) and for offsite power electric power system operation (assuming onsite power is not available) the system safety function can be accomplished using the piping, pumps, and valves used to maintain coolant inventory during normal reactor operation.

Compliance

The Chemical and Volume Control System includes charging pumps and multiple makeup paths that serve the safety function of maintaining reactor coolant inventory during normal operations and in the event of small reactor coolant leakages. The charging pumps can maintain reactor coolant pressure sufficiently high to allow orderly reactor shutdown for small tubing or pipe breaks. Chapter 5 discusses the RC System, subsection 9.3.4 discusses the Chemical and Volume Control system and Chapter 15 analyzes charging pump performance and fuel damage in event of postulated accidents.

Criterion 34 - Residual Heat Removal.

A system to remove residual heat shall be provided. The system safety function shall be to transfer fission product decay heat and other residual heat from the reactor core at a rate such that specified acceptable fuel design limits and the design limits and the design conditions of the reactor coolant pressure boundary are not exceeded.

Suitable redundancy in components and features, and suitable interconnections, leak detection, and isolation capabilities shall be provided to assure that for onsite electric power system operation (assuming offsite power is not available) and for offsite electric power system operation (assuming onsite power is not available) the system safety function can be accomplished, assuming a single failure.

Compliance

The Residual Heat Removal (RHR) and Auxiliary Feedwater (AFW) Systems are provided to remove the reactor core residual heat. The RHR and AFW Systems include redundant trains with sufficient heat removal capability. The systems are provided electric power by onsite and offsite supplies. The systems accommodate the single-failure criterion.

The RHR and AFW Systems are described in subsections 5.5.7 and 10.4.7, respectively.

Criterion 35 - Emergency Core Cooling.

A system to provide abundant emergency core cooling shall be provided. The system safety function shall be to transfer heat from the reactor core following any loss of reactor coolant at a rate such that (1) fuel and clad damage that could interfere with continued effective core cooling is prevented and (2) clad metal-water reaction is limited to negligible amounts.

Suitable redundancy in components and features, and suitable interconnections, leak detection, isolation, and containment capabilities shall be provided to assure that for onsite electric power system operation (assuming offsite power is not available) and for offsite electric power system operation (assuming onsite power is not available) the system safety function can be accomplished, assuming a single failure.

Compliance

The ECCS design and safety analysis is in accordance with the NRC's (AEC) Interim Acceptance Criterion for Emergency Core Cooling System for Light-Water Power Reactors of June 1971.

By combining the use of passive accumulators, centrifugal charging pumps, safety injection pumps and residual heat removal pumps, emergency core cooling is provided even if there should be a failure of any component in any system. The ECCS employs a passive system of accumulators which do not require any external signals or source of power for their operation to cope with the short-term cooling requirements of large reactor coolant pipe breaks. Two independent and redundant pumping systems are provided for smaller break protection and to cool the core after the accumulators have discharged following a large break. These systems are arranged so that the single failure of any active component does not prevent meeting the short-term cooling requirements.

The primary function of the ECCS is to deliver borated cooling water to the reactor core in the event of a LOCA. This limits the fuel-clad temperature and thereby ensures that the core will remain intact and in place and fuel damage will not exceed that stipulated as a basis in the safety analysis (Chapter 15). This protection is afforded for:

1. All pipe break sizes up to and including the hypothetical circumferential rupture of a reactor coolant loop.

2. A loss of coolant associated with a rod ejection accident.

The ECCS is described in subsection 6.3. The LOCA, including an evaluation of consequences, is discussed in Chapter 15.

Criterion 36 - Examination of Emergency Core Cooling System.

The ECCS shall be designed to permit appropriate periodic examination of important components, such as spray rings in the reactor pressure vessel, water injection nozzles, and piping, to assure the integrity and capability of the system.

Compliance

Design provisions facilitate access to the critical parts of the reactor vessel internals, injection nozzles, pipes and valves for nondestructive examination.

The majority of components outside the containment are accessible for leaktightness inspection during operation of the reactor.

Details of the examination for the reactor vessel internals are included in subsection 5.4. Inspection of the ECCS is discussed in subsection 6.3. Inservice Inspection is discussed in subsection 5.2.8.

Criterion 37 - Testing of Emergency Core Cooling System.

The ECCS shall be designed to permit appropriate periodic pressure and functional testing to assure (1) the structural and leaktight integrity of its components, (2) the operability and performance of the system as a whole and under conditions as close to design as practical, the performance of the full operational sequence that brings the system into operation, including operation of applicable portions of the Protection System, the transfer between normal and emergency power sources, and the operation of the Associated Cooling Water System.

Compliance

The design provides for periodic inspection/testing of both active and passive components of the ECCS.

Proof tests of the components are performed in the manufacturer's shop. Preoperational system hydrostatic and performance tests demonstrate structural and leaktight integrity of components and proper functioning of the system. Thereafter, periodic tests demonstrate that components are functioning properly.

An active component of the ECCS may be individually actuated on the normal power source during plant operation to demonstrate operability when actuation does not interfere with plant operation. Components are actuated on the emergency power source during preoperational tests and subsequently during plant shutdown per technical specifications.

The design provides for capability to test initially, to the extent practical, the full operational sequence up to the design conditions including transfer to emergency power sources to demonstrate the readiness and capability of the system.

Details of the ECCS are found in subsection 6.3. Performance under accident conditions is evaluated in Chapter 15. Periodic testing is discussed in subsection 6.3.4. Inservice Inspection is discussed in subsection 5.2.8.

Criterion 38 - Containment Heat Removal.

A system to remove heat from the reactor containment shall be provided. The system safety function shall be to reduce rapidly, consistent with the functioning of other associated systems, the containment pressure and temperature following any LOCA and maintain them at acceptably low levels.

Suitable redundancy in components and features, and suitable interconnections, leak detection, isolation, and containment capabilitites shall be provided to assure that for onsite electric power system operation (assuming offsite power is not available) and for offsite electric power system operation (assuming onsite power is not available) the system safety function can be accomplished, assuming a single failure.

Compliance

Systems are provided to effect postaccident containment heat removal. The systems are classified as Engineered Safety Features (ESF) and as such incorporate a large degree of diversity and redundancy as well as being provided with multiple power supplies.

Containment heat removal is provided by the ice condenser and containment spray. The ice condenser is a passive system consisting of energy absorbing ice on which steam is condensed during and immediately after a LOCA. The condensation of steam on the ice limits the pressure and temperature to values less than containment design.

The Air Return System is used to circulate air and steam through the upper compartment, lower compartment, and ice condenser after the initial blowdown. This maintains proper mixing of the containment air and steam with the heat removal media, spray and ice, for the necessary heat removal.

The Containment Spray (CS) System sprays water into the upper compartment containment atmosphere in the event of a LOCA, thereby removing containment heat. The recirculation mode allows for long-term heat removal by means of two spray systems, each of which contains redundant spray headers. The CS System consists of two completely separate trains consisting of pumps, heat exchangers, valves, and headers. The CS System is initiated automatically upon containment high-high pressure and is manually aligned for operation in the recirculation mode. The Residual Heat Removal (RHR) System contains two spray headers which are supplied from separate trains of the RHR System by manual diversion of a portion of the low-pressure Safety Injection System flow during recirculation mode.

The loss of a single active component was assumed in the design of these systems. Emergency Power System arrangements assure the proper function of the Air Return Fan System and the CS System and the RHR System sprays upon loss of offsite power.

The ESF Systems are discussed in Chapter 6; the Electric Power Systems in Chapter 8; and the Protection Systems in Chapter 7.

Criterion 39 - Inspection of Containment Heat Removal System.

The Containment Heat Removal System shall be designed to permit appropriate periodic inspection of important components, such as the torus, pumps, spray nozzles, and piping to assure the integrity and capability of the system.

Compliance

The ice condenser design includes provisions for visual inspections of the ice bed flow channels, doors, and cooling equipment. The Air Return Fan System provides for visual inspection of the

fans and the associated backflow dampers and for duct systems that are not embedded in concrete. The CS System and the RHR System sprays are designed such that active and passive components can be readily inspected to demonstrate system readiness. Pressure contained systems can be inspected for leaks from pump seals, valve packing, flange joints, and relief valves. The piping systems are inspected as required by the inservice inspection program.

System design details are given in Chapter 6.

Criterion 40 - Testing of Containment Heat Removal System.

The Containment Heat Removal System shall be designed to permit appropriate periodic pressure and functional testing to assure (1) the structural and leaktight integrity of its components, (2) the operability and performance of the active components of the system, and (3) the operability of the system as a whole, and, under conditions as close to the design as practical, the performance of the full operational sequence that brings the system into operation of applicable portions of the protection system, the transfer between normal and emergency power sources, and the operation of the associated cooling water system.

Compliance

The Containment Heat Removal Systems described in Chapter 6 are designed to permit periodic testing so that proper operation can be assured. In some cases whole systems can be operated for test purposes. In others, individual components are operated for functional tests so that plant operations are not disrupted.

The ice condenser contains no active components required to function during an accident condition. Samples of the ice are taken periodically and tested for boron concentration. The lower inlet door opening force is periodically measured. The position of the lower inlet doors is monitored at all times. Top deck door and intermediate deck doors are tested for operability.

Active components of the CS System and the RHR System are tested in place after installation. These spray systems receive initial flow tests to assure proper dynamic functioning. Further testing of the active components is conducted after component maintenance. Air test lines are provided to assure that spray nozzles are not obstructed. Testing of transfer between normal and emergency power supplies is also conducted. Air return fans and their associated backflow dampers are tested for operability in accordance with the Technical Specifications.

Criterion 41 - Containment Atmosphere Cleanup.

Systems to control fission products, hydrogen, oxygen, and other substances which may be released into the reactor containment shall be provided as necessary to reduce, consistent with the functioning of other associated systems, the concentration and quality of fission products released to the environment following postulated accidents, and to control the concentration of hydrogen or oxygen and other substances in the containment atmosphere following postulated accidents to assure that containment integrity is maintained.

Each system shall have suitable redundancy in components and features, and suitable interconnections, leak detection, isolation, and containment capabilities to assure that for onsite

electric power system operation (assuming offsite power is not available) and for offsite electric power system operation (assuming onsite power is not available) its safety function can be accomplished, assuming a single failure.

Compliance

The Shield Building, surrounding the primary containment, serves as a secondary containment. The Emergency Gas Treatment (EGT) System (subsection 6.2) maintains this secondary containment at a negative pressure during the postaccident period. The EGT System also collects and processes the secondary containment atmosphere. After processing, the portion of this processed air necessary to assure a negative pressure is exhausted through the plant vent. The remainder is recirculated and distributed in the secondary containment.

The Auxiliary Building also serves as a secondary containment to collect containment leakage and equipment leakage during the recirculation of containment sump water. The Auxiliary Building General Ventilation System (subsection 9.4.2) is isolated by an Auxiliary Building Isolation signal. The Auxiliary Building Gas Treatment System (subsection 9.4.2) then maintains the building at a negative pressure and processes any in-leakage prior to release to the environment.

Distribution of the atmosphere within the containment is provided by the Air Return Fan System (subsection 6.6). The system also takes a suction in each compartment to prevent stagnation and excessive accumulation of hydrogen.

Criterion 42 - Inspection of Containment Atmosphere Cleanup Systems.

The Containment Atmosphere Cleanup Systems shall be designed to permit appropriate periodic inspection of important components, such as filter frames, ducts, and piping to assure the integrity and capability of the systems.

Compliance

The EGT System (subsection 6.2) filtration train and fans are located in the Auxiliary Building and are designed to facilitate inspections. The dampers that control recirculation and exhaust of the EGT System effluent are located inside the Shield Building annulus and is accessible for inspection.

The entire Auxiliary Building Gas Treatment System (subsection 9.4.2) is located in the Auxiliary Building and is designed to facilitate inspection. The electric hydrogen recombiners (subsection 6.2) are located inside the upper containment and are accessible for inspection.

Criterion 43 - Testing of Containment Atmosphere Cleanup Systems.

The Containment Atmosphere Cleanup Systems shall be designed to permit appropriate periodic pressure and functional testing to assure (1) the structural and leaktight integrity of its components, (2) the operability and performance of the active components of the systems such as fans, filters, dampers, pumps, and valves, and (3) the operability of the systems as a whole and, under conditions as close to design as practical, the performance of the full operational

sequence that brings the systems into operation, including operation of applicable portions of the protection systems, the transfer between normal and emergency power sources, and the operation of associated systems.

Compliance

The EGT System (subsection 6.2) is designed to permit testing to assure pressure and leaktightness of the filtration trains; functional testing to assure operability of the fans, dampers, and instrumentation; and performance testing to assure overall operability of the system and to demonstrate the proper alignment of the system to the accident unit.

The Auxiliary Building Gas Treatment System (subsection 9.4.2) is designed to allow testing to assure the pressure and leaktightness of the filtration trains; to assure the operability of the fans and dampers; and to assure the operability of the system as a whole. The system design permits testing of the actuation signals, the isolation of the normal ventilation system, and the proper alignment of dampers.

Criterion 44 - Cooling Water.

A system to transfer heat from structures, systems, and components important to safety, to an ultimate heat sink shall be provided. The system safety function shall be to transfer the combined heat load of these structures, systems, and components under normal operating and accident conditions.

Suitable redundancy in components and features, and suitable interconnections, leak detection, and isolation capabilities shall be provided to assure that for onsite electric power system operation (assuming offsite power is not available) and for offsite electric power system operation (assuming onsite power is not available) the system safety function can be accomplished, assuming a single failure.

Compliance

A Seismic Category I Component Cooling System (CCS) (subsection 9.2) is provided to transfer heat from the RC System, and selected reactor support equipment to a Seismic Category I Essential Raw Cooling Water (ERCW) System (subsection 9.2). The containment spray system heat exchangers are cooled directly by ERCW.

The CCS consists of two independent engineered safety subsystems, each of which is capable of serving all necessary loads under normal or accident conditions, powered by either offsite sources or onsite emergency power sources.

In addition to serving as the heat sink for the CCS, the ERCW System is also used as heat sink for the containment and engineered safety equipment through use of compartment and space

coolers and selected seal jackets on ESF pumps. The ERCW System consists of two independent loops, each of which is capable of providing all necessary heat sink requirements. The ERCW System transfers heat to the ultimate heat sink (subsection 9.2) and is powered by either offsite sources or onsite emergency power sources.

Criterion 45 - Inspection of Cooling Water System.

The Cooling Water System shall be designed to permit appropriate periodic inspection of important components, such as heat exchangers and piping, to assure the integrity and capability of the system.

Compliance

The Component Cooling Water System (subsection 9.2) and ERCW System (subsection 9.2) components can be visually inspected on a periodic basis. Those components that cannot be inspected with the unit in operation can be inspected during shutdown.

The CCS and ERCW pumps are arranged such that any pump may be isolated for inspection and maintenance.

Criterion 46 - Testing of Cooling Water System.

The Cooling Water System shall be designed to permit appropriate periodic pressure and functional testing to assure (1) the structural and leaktight integrity of its components, (2) the operability and the performance of the active components of the system, and (3) the operability of the system as a whole and under conditions as close to design as practical, the performance of the full operational sequence that brings the system into operation for reactor shutdown and for LOCA, including operation of applicable portions of the protection system and the transfer between normal and emergency power sources.

Compliance

The CCS & ERCW Systems are normally pressurized during plant operations. The systems/ components are subject to tests per the ASME Section XI ISI/IST programs The emergency functions of the systems are periodically tested out to the final actuated device.

For additional details refer to Electric Power (Chapter 8), Component Cooling Water (subsection 9.2), ERCW (subsection 9.2), and Instrumentation and Controls (Chapter 7).

Criterion 50 - Containment Design Basis.

The reactor containment structure, including access openings, penetrations, and the Containment Heat Removal System shall be designed so that the containment structure and its internal compartments can accommodate, without exceeding the design leakage rate and, with sufficient margin, the calculated pressure and temperature conditions resulting from any LOCA. This margin shall reflect consideration of (1) the effects of potential energy sources which have not been included in the determination of the peak conditions, such as energy in steam generators and energy from metal-water and other chemical reactions that may result from degraded

emergency core cooling functioning, (2) the limited experience and experimental data available for defining accident phenomena and containment responses, and (3) the conservatism of the calculational model and input parameters.

Compliance

The containment structure, including access openings and penetrations, is designed with sufficient conservatism to accommodate, without exceeding the design leakage rate, the transient peak pressure and temperature associated with a postulated reactor coolant piping break up to and including a double-ended rupture of the largest reactor coolant pipe.

The containment design consists of a freestanding steel containment vessel and a separate outer reinforced concrete reactor building. The ice condenser concept is used for energy absorption during a LOCA. The annular space between the containment vessel and the reactor building forms a double barrier to fission products and is maintained at less than atmospheric pressure. The ice condenser, which is located inside the steel containment and consists of a suitable quantity of borated ice in a cold storage compartment, provides rapid energy absorption to maintain the containment vessel design pressure at a low level and to reduce the peak duration, thus reducing the potential for escape of fission products from the primary containment vessel.

The functional design of the containment is based upon the following assumptions and conditions:

1. A design basis blowdown energy and mass release.

2. Secondary energy released by safety injection.

3. Carryover energy from zirconium-water reaction.

4. A decay heat from the reactor at rated power.

5. The single failure criterion is accommodated.

The internal pressure used for design of the containment is greater than the peak pressure occurring as the result of the complete blowdown of the reactor coolant through any rupture of the RC System up and including the hypothetical double-ended severance of the largest reactor coolant pipe. This pressure is not exceeded during any subsequent long-term pressure transient.

Refer to subsection 6.2 for further design details.

Criterion 51 - Fracture Prevention of Containment Pressure Boundary.

The reactor containment pressure boundary shall be designed with sufficient margin to assure that under operating, maintenance, testing, and postulated accident conditions (1) its ferritic materials behave in a nonbrittle manner and (2) the probability of rapidly propagating fracture is minimized. The design shall reflect consideration of service temperatures and other conditions of the containment boundary material during operation, maintenance, testing, and postulated accident conditions, and the uncertainties in determining (1) material properties, (2) residual, steady state, and transient stresses, and (3) size of flaws.

Compliance

The containment vessel and its penetration sleeves meet the material, design, and technical process requirements of ASME Boiler and Pressure Vessel Code, Section III, Class B. Charpy V-notch impact tests were made of the containment vessel material (ASTM A 516, Grade 60) 5/8 inch and greater, weld deposit, and the base metal weld heat effected zone employing a test temperature at least 30°F below minimum service temperature in accordance with ASME Code, Paragraph N-330. This test determines whether the material properties are above the ductile to brittle transition temperature with allowable values for energy absorption given in Tables N-421 and N-422. It is the basis to ensure that the material used will not behave in a brittle manner and that rapidly propagating fracture is minimized.

The containment boundary design considered uncertainties in material properties, residual, steady-state and transient stresses, and material flaws along with conservative allowable stress levels for all stressed elements of the containment boundary. All material was examined for flaws that would adversely affect the performance of the material in its intended purpose. See subsection 6.2, Containment Functional Design, for further details.

Criterion 52 - Capability for Containment Leakage Rate Testing.

The reactor containment and other equipment which may be subjected to containment test conditions shall be designed so that periodic integrated leakage rate testing can be conducted at containment design pressure.

Compliance

The reactor containment design permits overpressure strength testing during construction and permits preoperational integrated leakage rate testing at containment design pressure and at reduced pressure, in accordance to Appendix J, 10 CFR 50. The reactor containment and other equipment which may be subjected to containment test conditions are designed so that periodic integrated leakage rate testing can be conducted at containment design pressure. All equipment which may be subjected to the test pressure will either be vented to the containment, be removed from the containment during the test, or be designed to withstand the containment design pressure without damage.

The preoperational integrated leak tests at peak pressure and at reduced pressure verify that the containment, including the isolation valves and the resilient penetration seals, leaks less than the allowable value of 0.25 weight percent per day at peak pressure.

Details concerning the conduct of periodic integrated leakage rate tests are in subsection 6.2.1.4.

Criterion 53 - Provisions for Containment Testing and Inspection.

The reactor containment shall be designed to permit (1) appropriate periodic inspection of all important areas, such as penetrations, (2) an appropriate surveillance program, and (3) periodic testing at containment design pressure of the leaktightness of penetrations which have resilient seals and expansion bellows.

Compliance

The reactor containment and the Containment Isolation (CI) System (subsection 6.2) are designed so that:

1. Integrated leak tests can be run during plant lifetime (see compliance to Criterion 52).

2. Visual inspections can be made of all important areas, such as penetrations.

3. An appropriate surveillance program can be maintained (see subsection 6.2).

4. Periodic testing at containment design pressure of the leaktightness of isolation valves and penetrations which have resilient seals and expansion bellows is possible. In testing locally the resilient seals and expansion bellows leakages, the guidelines for Type B tests in Appendix J of 10 CFR 50 will be followed.

5. The operability of the CI System can be demonstrated periodically.

Criterion 54 - Piping Systems Penetrating Containment.

Piping systems penetrating primary reactor containment shall be provided with leak detection, isolation, and containment capabilities having redundance, reliability, and performance capabilities which reflect the importance to safety of isolating these piping systems. Such piping systems shall be designed with a capability to test periodically the operability of the isolation valves and associated apparatus and to determine if valve leakage is within acceptable limits.

Compliance

Containment isolation features are classified as Seismic Category I. These components require quality assurance measures which enhance reliability. The containment isolation design provides for a double barrier at the containment penetration in those fluid systems that are not required to function following a DBE.

All piping systems penetrating the containment, insofar as practical, have been provided with test vents and test connections or have other provisions to allow periodic leak testing as required. See subsection 6.2.4 for containment isolation details.

Criterion 55 - Reactor Coolant Pressure Boundary Penetrating Containment.

Each line that is part of the reactor coolant pressure boundary and that penetrates primary reactor containment shall be provided with containment isolation valves as follows, unless it can be demonstrated that the containment isolation provisions for a specific class of lines, such as instrument lines, are acceptable on some other defined basis:

1. One locked closed isolation valve inside and one locked closed isolation valve outside containment; or

2. One automatic isolation valve inside and one locked closed isolation valve outside containment; or

3. One locked closed isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment; or

4. One automatic isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment.

Isolation valves outside containment shall be located as close to containment as practical and upon loss of actuating power, automatic isolation valves shall be designed to take the position that provides greater safety.

Other appropriate requirements to minimize the probability or consequences of accidental rupture of these lines or of lines connected to them shall be provided as necessary to assure adequate safety. Determination of the appropriateness of these requirements, such as higher quality in design, fabrication, and testing, additional provisions for inservice inspection, protection against more severe natural phenomena, and additional isolation valves and containment, shall include consideration of the population density, use characteristics, and physical characteristics of the site environs.

Compliance

The reactor coolant pressure boundary (RCPB) is located entirely within the containment structure. Sampling lines are provided with remotely operated valves for isolation in the event of a failure. With the exception of the post accident sampling system (PASS) valves, these valves also close automatically on a containment isolation signal. RCS PASS valves are normally closed and require a control room permit signal to enable manipulation of these valves. Instrumentation lines that connect to the RCPB are provided with sealed systems if they penetrate containment. Other systems that connect to the RCPB are provided with appropriate isolation valves and/or flow restrictors prior to penetrating primary containment or with the appropriate combination of locked/automatic valves.

Additional information on lines penetrating primary containment can be found in subsection 6.2.4.

Criterion 56 - Primary Containment Isolation.

Each line that connects directly to the containment atmosphere and penetrates primary reactor containment shall be provided with containment isolation valves as follows, unless it can be demonstrated that the containment isolation provisions for a specific class of lines, such as instrument lines, are acceptable on some other defined basis:

1. One locked closed isolation valve inside and one locked closed isolation valve outside containment; or

2. One automatic isolation valve inside and one locked closed isolation valve outside containment; or

3. One locked closed isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment; or

4. One automatic isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment.

Isolation valves outside containment shall be located as close to the containment as practical and upon loss of actuating power, automatic isolation valves shall be designed to take the position that provides greater safety.

Compliance

At least two barriers are provided in penetrations that connect directly to the containment atmosphere or closed systems which are assumed vulnerable to accident forces unless an approved exception has been granted.

Refer to subsection 6.2.4 for information on exceptions and additional details.

Criterion 57 - Closed System Isolation Valves.

Each line that penetrates primary reactor containment and is neither part of the reactor coolant pressure boundary nor connected directly to the containment atmosphere shall have at least one containment isolation valve which shall be either automatic, or locked closed, or capable of remote manual operation. This valve shall be outside containment and located as close to the containment as practical. A simple check valve may not be used as the automatic isolation valve.

Compliance

Those lines that penetrate the containment, do not communicate with either the reactor coolant pressure boundary or the containment atmosphere, and are not affected by LOCA forces are defined as closed systems. All lines penetrating the containment are designed to meet NRC General Design Criterion 57, Closed System Isolation Valves, with approved exceptions. Refer to subsection 6.2.4 for additional information and exceptions.

Criterion 60 - Control of Releases of Radioactive Materials to the Environment.

The nuclear power unit design shall include means to control suitably the release of radioactive materials in gaseous and liquid effluents and to handle radioactive solid wastes produced during normal reactor operation, including anticipated operational occurrences. Sufficient holdup capacity shall be provided for retention of gaseous and liquid effluents containing radioactive materials, particularly where unfavorable site environmental conditions can be expected to impose unusual operational limitations upon the release of such effluents to the environment.

Compliance

Liquid, gaseous, and solid radioactive waste processing equipment is provided. The principles of filtration, demineralization, evaporation, solidification, storage for decay and sampling are utilized as described in subsections 11.2, 11.3, and 11.5. Process monitoring is provided to control this equipment and regulate releases to the environment as described in subsection 11.4.

Criterion 61 - Fuel Storage and Handling and Radioactivity Control.

The fuel storage and handling, radioactive waste, and other systems which may contain radioactivity shall be designed to assure adequate safety under normal and postulated accident conditions. These systems shall be designed (1) with a capability to permit appropriate periodic inspection and testing of components important to safety, (2) with suitable shielding for radiation protection, (3) with appropriate containment, confinement, and filtering systems, (4) with a residual heat removal capability having reliability and testability that reflects the importance to safety of decay heat and other residual heat removal, and (5) to prevent significant reduction in fuel storage coolant inventory under accident conditions.

Compliance

The Spent Fuel Pool Cooling and Cleanup System, Fuel Handling System, Radioactive Waste Processing Systems, and other systems that contain radioactivity are designed to assure adequate safety under normal and postulated accident conditions.

1. Components are designed and located such that appropriate periodic examination testing may be performed.

2. Areas of the plant are designed with suitable shielding for radiation protection based on anticipated radiation dose rates and occupancy as discussed in subsection 12.1.

3. Individual components which contain significant radioactivity are located in confined areas which are adequately ventilated through appropriate filtering systems when necessary.

4. The spent fuel cooling systems provide cooling to remove residual heat from the fuel stored in the spent fuel pool. The system is designed for testability to permit continued heat removal.

5. The spent fuel pool is designed such that no postulated accident could cause excessive loss of coolant inventory.

Radioactive waste treatment systems are located in the Auxiliary Building which contains or confines leakage under normal and accident conditions.

The Auxiliary Building Gas Treatment System includes filtration which minimizes radioactive material release associated with a postulated spent fuel handling accident.

Fuel storage and handling is discussed in subsection 9.1, and radioactive waste management in Chapter 11.

Criterion 62 - Prevention of Criticality in Fuel Storage and Handling.

Criticality in the fuel storage and handling system shall be prevented by physical systems or processes, preferably by use of geometrically safe configurations.

Compliance

The center-to-center distance between the adjacent spent fuel assemblies, together with the use of fixed boral neutron absorber panels in the storage racks and burnup credit administrative controls on fuel assembly placement, is sufficient to ensure subcriticality, even if unborated water is used to fill the spent fuel storage pool.

The design of the spent fuel storage rack modules in the spent fuel pool is such that it is impossible to insert the spent fuel assemblies in other than prescribed locations, e.g., outside of a storage cell adjacent to a rack module. Credit for borated water is permitted for inadvertent misplacement of an assembly e.g., loading of a fresh fuel assembly in a storage cell designated for exposed fuel in accordance with 10 CFR 50.68(b). Although it would be possible to place a fuel assembly outside of and adjacent to the rack module in the cask loading area of the cask pit adjacent to the spent fuel pool, subcriticality even in the absence of boron would be insured because storage in that area is administratively restricted to exposed fuel.

Layout of the fuel handling area is such that the spent fuel casks will never be required to traverse the spent fuel storage pool during removal of the spent fuel assemblies.

The restraints and interlocks provided for safe handling and storage of new or spent fuel are discussed in subsection 9.1.

Criterion 63 - Monitoring Fuel and Waste Storage.

Appropriate systems shall be provided in fuel storage and radioactive waste systems and associated handling areas (1) to detect conditions that may result in loss of residual heat removal capability and excessive radiation levels and (2) to initiate appropriate safety actions.

Compliance

Failure in the Spent Fuel Pool Cooling and Cleanup System and high radiation in the spent fuel storage and radioactive waste areas will produce both local and control room alarms. The operator can then take appropriate action to alleviate the situation.

Subsection 11.4 discusses the process and effluent radiological monitoring system.

Criterion 64 - Monitoring Radioactivity Releases.

Means shall be provided for monitoring the reactor containment atmosphere, spaces containing components for recirculation of LOCA fluids, effluent discharge paths, and the plant environs for radioactivity that may be released from normal operations, including anticipated operational occurrences, and from postulated accidents.

Compliance

The facility contains means for monitoring the containment atmosphere and all other important areas during both normal and accident conditions to detect and measure radioactivity which could be released under any conditions. The monitoring system includes indication and alarms to warn of high activity.

Subsections 11.4 and 12.1.4 discuss the process and effluent and area radiological monitoring systems; subsection 11.6 describes the offsite monitoring program.

3.2 CLASSIFICATION OF STRUCTURES, SYSTEMS, AND COMPONENTS

3.2.1 Seismic Qualifications

The Sequoyah Nuclear Plant structures, systems, and components important to safety have been designed to remain functional in the event of a Safe Shutdown Earthquake (SSE). These structures, systems, and components, designated as Category I, are those necessary to assure:

1. The integrity of the reactor coolant pressure boundary.

2. The capability to shut down the reactor and maintain it in a safe shutdown condition.

3. The capability to prevent or mitigate the consequences of accidents which could result in potential offsite exposures comparable to the guideline exposures of 10 CFR Part 100.

Moreover, those safety-related structures, systems, and components necessary to assure the above requirements, have been designed such that primary stress limits are well within the material yield limits for the loading effects of vibratory motion of at least 50 percent of the SSE.

Those components which are not essential to safe shutdown and isolation of the reactor but whose failure could jeopardize, to an unacceptable extent, the achievement of a primary safety function are considered Category I (L) safety related. Where portions of mechanical systems are Category I and the remaining portions not seismically classified, the systems have been seismically qualified through the first seismic restraint beyond the defined boundary such as a valve.

Category I and I (L) safety-related structures, portions of mechanical systems (excluding piping), and electrical systems and components are listed in Tables 3.2.1-1, 3.2.1-2, and 3.2.1-3, respectively. These structures, systems, and components are classified to the extent practical in accordance with NRC Regulatory Guide 1.29 R2 "Seismic Design Classification" and are designed to remain functional as required to safely shutdown and maintain the reactor in a safe condition after a SSE event. Exceptions are documented and justified in individual system design criteria documents.

3.2.2 System Quality Group Classification (Fluid Components)

Fluid system components for the Sequoyah Nuclear Plant that are important to nuclear safety have been classified by TVA as Class A, B, C, or D. (Some exceptions to these classes do exist but have been evaluated as acceptable.) For other non-piping component TVA classifications important to nuclear safety see subparagraph 3.2.2.5, Table 3.2.1-2, Table 3.2.2-1, and Table 3.2.2-3. The importance, as established by class assignment, has been considered in the design, material selection, manufacture or fabrication, assembly, erection, construction, and operational aspects.

3.2.2.1 Class A

Class A applies to reactor coolant pressure boundary components whose failure could cause a loss of reactor coolant which would not permit an orderly reactor shutdown and cooldown, assuming that makeup is only provided by the normal makeup system. Branch piping that is

larger than 3/8-inch inside diameter and that does not have a 3/8-inch or smaller orifice is included in Class A out to and including the second valve that is either normally closed or capable of automatic closure. Branch piping 3/8-inch inside diameter or smaller, or protected by a 3/8-inch diameter or smaller orifice, is exempt from Class A. The 3/4-inch branch piping for the pressurizer steam space instrumentation nozzles is exempt for Class A since the mass flow rate of saturated steam from the pressurizer is less than normal makeup flow.

3.2.2.2 Class B

Safety Class B applies to those components of safety systems necessary to fulfill a system safety function. The classification is specifically applicable to containment and to components of those safety systems, or portions thereof, through which reactor coolant water flows directly from the Reactor Coolant System or the containment sump.

The following are examples of Class B:

1. Residual Heat Removal (RHR) System.
2. Portion of Containment Spray System which may recirculate reactor coolant.
3. Extensions of containment.
4. Chemical and Volume Control System, including the portions of letdown and makeup lines.
5. Safety Injection System outside the limits of the reactor coolant pressure boundary which may recirculate reactor coolant.
6. Main Steam System from steam generator outlet through the anchor including power relief valves, safety valves, and isolation valves.
7. Feedwater System from the steam generator inlet back through the isolation valves and anchor.
8. Portions of the Reactor Coolant Pressure Boundary not covered under Class A.
9. Auxiliary feedwater from the main feedwater piping through first check valve outside containment.
10. All instrument sensing lines from systems covered by TVA Classes A and B from root valve through local panel shutoff valve.
11. All sampling or radiation monitoring lines from systems covered by TVA Classes A and B from root valve through first valve in sampling or radiation lines, or through second containment isolation valve if sample or radiation lines are extensions of containment.
12. Containment penetrations (between and including inboard and outboard isolation valves).
13. Air Return Fan System boundary between upper and lower compartments at the divider barrier.

3.2.2.3 Class C

Class C applies to components of those safety systems that are important to safe operation and shutdown of the reactor but that do not recirculate reactor coolant.

The following are examples of Class C:

1. Suction piping from refueling water storage tank to Emergency Core Cooling System.

2. Portions of the AFW System upstream of the first check valve outside of containment through the check valve in each pump suction line.

3. Portions of ERCW System that cool safety systems.

4. Accumulator discharge piping to accumulator isolation valve.

5. The portions of the Component Cooling System that cool safety systems or supply cooling to equipment essential for plant operation.

6. The portions of CVCS that supply boric acid to the Makeup System.

7. The portions of the Containment Spray System not covered under Class B.

8. Spent Fuel Pool Cooling and Cleanup System and components of fluid systems required for spent fuel cooling. (Embedded pipe welds are Class C.)

9. Auxiliary Control Air System not covered by Class B.

10. All instrument sensing lines from systems covered by TVA Classes C and D from root valve through local panel shutoff valve; also from local panel sensing line shutoff valve to, but not including, pressure boundary instruments and through the drain valves.

11. All sampling or radiation monitoring lines from systems covered by TVA Classes C and D from root valve through first valve in sampling or radiation lines, or up to the containment isolation valve if sample or radiation lines are extensions of containment.

3.2.2.4 Class D

Class D applies to components when their failure would result in release of radioactive gases to the environment and they are not included in safety classes A, B, or C.

The following are examples of safety Class D:

1. CVC System portions not covered by Classes B or C.

2. Portions of Waste Disposal System.

3.2.2.5 Relationship of Applicable Codes to Safety Classification for Mechanical Components

The applicable codes used for design and fabrication of mechanical system components (other than piping) for the various safety classes are summarized in Table 3.2.2-1. For each of these components, the applicable safety classification, design and fabrication code, and quality assurance requirement are included in Table 3.2.1-2.

Piping design and fabrication code requirements for the primary reactor coolant loops and auxiliary piping (Class A) are discussed in Chapter 5, Section 5.5.3. The applicable codes used for design and fabrication of other piping, and the erection, inspection, and testing of piping systems for the various safety classes, are summarized in Table 3.2.2-2.

Regulatory Guide 1.26, Quality Group Classifications and Standards for Water, Steam, and Radioactive-Waste-Containing Components of Nuclear Power Plants, is utilized to determine the applicability of the requirements of Tables 3.2.2-1 and 3.2.2-2 to certain exempt components within TVA Class B, C, and D boundaries. Regulatory Guide 1.26 does not cover systems such as instrument and service air, the diesel engines and their generators and auxiliary support systems, diesel fuel, emergency and normal ventilation, fuel handling and radioactive waste management systems. These systems are designed, fabricated, erected and tested to quality standards commensurate with the safety function to be performed. In general, fluid system components in the above systems are qualified in an equivalent manner to the requirements of Tables 3.2.2-1 and 3.2.2-2 for similar components. These equivalent standards are determined on a case-by-case basis.

In certain cases, TVA Class A, B, C, and D components cannot be purchased in full compliance with the requirements of Tables 3.2.2-1 and 3.2.2-2. In these cases, commercial quality components must be dedicated, or verified acceptable, for TVA Class A, B, C, or D service. This dedication process will be accomplished in accordance with applicable QA program documents.

ASME Section XI Code Class boundary equivalencies are shown on color-coded flow and instrumentation diagrams. (The color-coded diagram drawing number is suffixed by "-ISI".) The bases for these boundaries are documented in plant procedures. The ASME Section XI Code Class boundaries were developed by reviewing the safety function of each component on the applicable flow and instrumentation diagrams in accordance with American National Standard (ANS) N18.2, NRC Regulatory Guide 1.26, and 10 CFR 50.2 (for reactor coolant pressure boundary). Differences between the design boundaries (identified by TVA Classes on the flow diagrams) and the ASME Section XI boundaries (identified by the color-coded ISI boundary diagrams) are primarily due to the use of both the ANS N18.2-August 1970 draft and ANS N18.2-1973 for design safety classifications and the use of Regulatory Guide 1.26 for the original ASME Section XI boundaries. Additional details on the Section XI boundary bases and the corresponding classification criteria are located in plant procedures.

3.2.2.6 Nonnuclear Safety Class (NNS)

Components that are used in the Containment, Auxiliary, and Diesel Generator Buildings, whose failure will not result in a release of radioactive products and will not jeopardize safe shutdown of the reactor, have been assigned classifications that range from Class E through Class V. Since

these components complement safety-related components during normal operation and are in close proximity to them, they are designed to code requirements that will assure the integrity of the systems such that the minimum capability of safety components will not be compromised. These components are designated as either Seismic Category I(L)A - Pressure boundary retention or Seismic Category I(L)B - position retention. The applicable codes, along with the seismic considerations used for the design of the components covered by these classifications, are shown in Table 3.2.2-3.

CATEGORY I STRUCTURES

1. Reactor Building (includes Shield Building and all interior concrete structures)
2. Steel Containment Vessel
3. Auxiliary Building
4. Additional Equipment Building
5. Control Building
6. East Steam Valve Rooms
7. Condenser Cooling Water Intake Pumping Structure
8. Diesel Generator Building
9. Underground Concrete Encased Electrical Conduit Banks, Manholes, and Handholes for Class 1E Circuits
10. Essential Raw Cooling Water Intake Pumping Structure, Access Cells, and Pile Supported ERCW Piping Support Slab
11. Refueling Water Storage Tank and Foundation
12. Piping Tunnels Containing Classes A, B, C, or D Piping or Tubing
13. Condensate Demineralizer Waste Evaporator Building
14. Waste Packaging Area of the Auxiliary Building
15. Additional Diesel Generator Building (Refer to Note)

Note:
The Additional Diesel Generator Building (ADGB) was designed and constructed as a Category I structure. Modifications were performed to install Flexible Mitigation Strategies (FLEX) Response equipment to mitigate Beyond-Design-Basis External Events described in SQN-DC-V-48.0; FSAR Reference 3.13.2.1. The ADGB contains unisolable sections of safety-related ERCW piping. Blind flanges were installed where the piping immediately emerges through the base slab floor and a missile protection structure was installed over the blind flanges. The Category I qualification applies to portions of the building structure required to support and protect the ERCW piping which consists of the base slab floor and the missile protection structure.

(Notes)
SUMMARY OF CRITERIA - MECHANICAL SYSTEM COMPONENTS (EXCLUDING PIPING)

Notes:

(1) T = Tennessee Valley Authority
W = Westinghouse
W-CE = Westinghouse, Combustion Engineering Nuclear Power LLC (CENP)

(2) A = TVA Safety Class A
B = TVA Safety Class B
C = TVA Safety Class C
D = TVA Safety Class D
G = TVA Safety Class G
I = Seismic Class I, part of structure

(3) III-A = ASME Boiler and Pressure Vessel Code - Section III, Class A
III-B = ASME Boiler and Pressure Vessel Code - Section III, Class B
III-C = ASME Boiler and Pressure Vessel Code - Section III, Class C
IIIa9 = ASME Boiler and Pressure Vessel Code - Section III, Article 9 "Protection Against Overpressure"
VIII = ASME Boiler and Pressure Vessel Code - Section VIII
P&V-I = Draft ASME Code for Pumps and Valves for Nuclear Power, Class I, dated 1968
P&V-II = Draft ASME Code for Pumps and Valves for Nuclear Power, Class II, dated 1968, and March 1970 Addenda
P&V-III = Draft ASME Code for Pumps and Valves for Nuclear Power, Class III, dated 1968, and March 1970 Addenda
D100 = American Waterworks Association, Standard for Steel Tanks, Standpipes, Reservoirs, and Elevated Tanks for Water Storage, AWWA, D100
API-620 = American Petroleum Institute Recommended Rules for Design and Construction of Large Welded Low Pressure Storage Tanks
B31.1 = ANSI B31.1.0 (1967)
D = Designed in accordance with
ACI = American Concrete Institute
AACC = AACC CS8T - American Association for Contamination Control - Standard for High Efficiency Gas - Phase Adsorber Cells (July 1972)
MIL-F = MIL-F-51068C - Military Specification - Filter, Particulate, High Efficiency, Fire Resistant (1970)
UL-900 = UL-900-1971 - Underwriters Laboratory - Standard for Safety for Air Filter Units (1971)
AMCA = AMCA Publication 99 - Air Moving and Conditioning Association, Inc., AMCA Standards Handbook (1967)
NFPA = National Fire Protection Association
III-2 = ASME Boiler and Pressure Vessel Code - Section III, Class 2
III-3 = ASME Boiler and Pressure Vessel Code - Section III, Class 3
B58.1 = ANSI B58.1, Vertical Turbine Pumps

Table 3.2.1-2 (Sheet 10)
(Notes)
SUMMARY OF CRITERIA - MECHANICAL SYSTEM COMPONENTS (EXCLUDING PIPING)

Notes (continued)

HI = Standards of Hydraulic Institute

See Section 3.2.2.5 for further clarification of the applicability of these standards.

(4) Safety-related quality assurance required:
X = Yes, - = No

(5) C = Containment
AB = Auxiliary Building
DB = Diesel Generator Building
SB = Service Building
O = Outdoors above ground
B = Buried in ground
CB = Control Building
TB = Turbine Building

(6) X = Source of radiation
- = No source of radiation
P = Possible source of radiation

(7) I = Seismic Category I
I(L) = Seismic Category I(L)

(8) AMCA Class III and performance tested in accordance with AMCA Standard Air Moving Devices

(9) Performance test required

(10) Those components of the Heating, Ventilating, and Air Conditioning System (HVAC), which are not covered directly by the TVA piping classifications of subsection 3.2.2, have been designed and constructed to standards and specifications which are equivalent to ANS Safety Class 2b. Safety Class 2b (TVA Class Q) Main Control Room air flow delivery components (around flexible ducting, triangular fiberglass ducting, and air bars) and the suspended ceiling which supports them are qualified to Seismic Category I(L) requirements, analyzed to ensure that the components will remain in place, the physical configuration will be maintained such that flow will not be impeded, and the ducting pressure boundary will not be lost. See Section 3.7.3.16. The air flow delivery components are constructed of standard commercial grade materials. Limited QA requirements ensure they are maintained as qualified.

(11) This equipment is not required for two unit operation.

(12) This equipment meets the intent of TVA Class C for this application.

(13) Class G vessels are required as a minimum to be designed, manufactured, and inspected in accordance with ASME B&PV Code Section VIII, Division 1. This component was designed, manufactured, and inspected in accordance with stricter requirements of ASME B&PV Code Section III, Class C for safety-related vessels.

Table 3.2.1-2 (Sheet 11)
(Notes)
SUMMARY OF CRITERIA - MECHANICAL SYSTEM COMPONENTS (EXCLUDING PIPING)

Notes (continued)

(14) Field fabricated reservoirs shall meet requirements of American Waterworks Association, Standard for Steel Tanks, Standpipes, Reservoirs, and Elevated Tanks for Water Storage AWWA-DIOU or welded steel tanks for oil storage API-650.

(15) Class G components are required to be qualified, as a minimum, to Seismic Category I(L), per TVA Design Criteria SQN-DC-V-3.0. This component, however, was actually qualified to Seismic Category I.

(16) Various: Piping B31.1
Vessels III-3
Pumps and Valves P&V-I

(17) Design changes to the CDWE to make it capable of processing radwaste originally intended to be processed through the waste and auxiliary waste evaporators were done per ANSI B31.1 (1967).

(18) Charcoal filters AHCC, HEPA filters MIL-F, Prefilters UL900. Prefilters are not installed in Control Room Emergency Cleanup System but are installed in the Control Room AHUS.

* Denotes equipment which will be inundated during maximum flood.

Table 3.2.1-3 (Sheet 1)

ELECTRICAL POWER SYSTEM EQUIPMENT DESIGNED TO OPERATE DURING

AND AFTER A "SAFE SHUTDOWN EARTHQUAKE"

Equipment	Number Per Unit / Number In Plant	Qualified in Conformance with IEEE 344-1971[(1)]
6.9-kV Auxiliary Power System		
6.9-kV shutdown boards	2/4	Yes (2)
(Unit 1) 1A-A, 1B-B (Unit 2) 2A-A, 2B-B		
6.9-kV shutdown logic relay panels	2/4	Yes
(Unit 1) 1A-A, 1B-B (Unit 2) 2A-A, 2B-B		
6.9-kV/480-V shutdown board transformers	6/12	Yes
1500 kVA (Unit 1) 1A1-A, 1A-A, 1A2-A, 1B1-B, 1B-B, 1B2-B (Unit 2) 2A1-A, 2A-A, 2A2-A, 2B1-B, 2B-B, 2B2-B		
6.9 kV/480-V pressurizer heater backup group transformers (500 kVA)	2/4	Yes (5)

(1) Those equipment items procured prior to publication of IEEE 344-1971 were purchased under specifications which TVA believes conform to the intent of that document.

(2) The 6.9-kV shutdown boards are qualified under Section 3.2.2.4.3 of IEEE 344-1971. The test unit withstood higher accelerations than shown on the frequency response spectrum for resonance at 1 percent damping. The test table input was eight times the rigid response floor acceleration, and actual damping is 5 percent.

Table 3.2.1-3 (Sheet 5)
(Continued)

(3) The 500-kVA transformers were shown analytically to have lower stress under seismic loading conditions than the 1500-kVA transformers which were tested. The 500-kVA transformers are similar in design and construction to the 1500-kVA transformers.

(4) The sine beat test was used with 5 cycles per beat instead of 10. A rationale for this test modification was furnished by the vendor and approved by TVA.

(5) This equipment qualified in conformance with IEEE 344-1975.

(6) Replacement penetrations have been qualified in conformance with IEEE 344-1975.

Table 3.2.2-1

SUMMARY OF CODES AND STANDARDS FOR REQUIREMENTS FOR SEQUOYAH MECHANICAL SYSTEM COMPONENTS EXCLUDING PIPING*

Code Classifications

Component	Group A**	Group B**	Group C**	Group D**
Pressure Vessels	ASME Boiler and Pressure Vessel Code, Section III, Class A, 1968 Edition	ASME Boiler and Pressure Vessel Code, Section III, Class C, 1968 Edition	ASME Boiler and Pressure Vessel Code, Section VIII, Division 1	ASME Boiler and Pressure Vessel Code, Section VIII, Division 1 or Equivalent
0-15 Psig Storage Tanks	-	ASME Boiler and Pressure Vessel Code, Section III, Class C, 1968 Edition	ASME Boiler and Pressure Vessel Code, Section VIII, Division 1	ASME Boiler and Pressure Vessel Code, Section VIII, Division 1
Atmospheric Storage Tanks	-	Storage Tank Codes API-650, AWWA D100, or ANSI B96.1	Storage Tank Codes API-650, AWWA D100, or ANSI B96.1	Storage Tank Codes API-650, AWWA D100, or ANSI B96.1
Pumps	Draft ASME Code for Pumps and Valves Class I	Draft ASME Code for Pumps and Valves Class II	Draft ASME Code for Pumps and Valves Class III	Draft ASME Code for Pumps and Valves Class III or Equivalent
Valves	MSS-SP-66, ANSI B16.5 and Draft ASME Code for Pumps and Valves Class I	MSS-SP-66, ANSI B16.5 and Draft ASME Code for Pumps and Valves Class II	MSS-SP-66, ANSI B16.5 and Draft ASME Code for Pumps and Valves Class III	MSS-SP-66, ANSI B16.5

* - Refer to Table 3.2.2-2 for Codes and Standards Summary for Piping. See Section 3.2.2.5 for further clarification of the applicability of this table.

** - Listed Codes apply generally for component procurements up through April 2, 1973. After this date, component procurements generally followed the code requirements, in effect on the procurement date, listed below (vessels, tanks, pumps, and valves):

Class A - ASME Section III, Division 1, Class 1; Class B - ASME Section III, Division 1, Class 2; and Class C/D - ASME Section III, Division 1, Class 3.

Specific Code applicability for each component is included in Table 3.2.1-2.

Table 3.2.2-2 (Sheet 1)

SUMMARY OF CODES AND STANDARDS REQUIREMENTS
FOR SEQUOYAH PIPING (1)

Safety Class ANS N18.2	TVA Class	Seismic Category	Design (2)	Material Procurement (3)	Field Fabrication Erection, NDE and Tests
1	A	I	B31.1.0(4)	B31.7 C1 I/ ASME III C1 1(5)	B31.7 C1 I(6) (7)
2a	B	I	B31.1.0(4)	B31.7 C1 II/ ASME III C1 2(5)	B31.7 C1 II (6) (8)
2b	C	I	B31.1.0(4)	B31.7 C1 III/ ASME III C1 3(5)	B31.7 C1 III (6)
3	D	I	B31.1.0(4)	B31.7 C1 III/ ASME III C1 3(5)	B31.7 C1 III (6)

General Notes:

Reference to B31.1.0 means USAS B31.1.0-1967, addenda, and applicable Code Cases, with the NDE and acceptance standards of B31.1 Nuclear Code Cases N7, N9, and N10. Addenda b-1971 provides for use of later codes by agreement.

Reference to B31.7 means USAS B31.7-1969 including Addenda a, b, and c. Portions of B31.7 were used in lieu of B31.1.0 and Nuclear Code Cases N7, N9, and N10 (procurement and construction).

Reference to ASME III means ASME Section III, Class 1, 2, and 3 as applicable; Edition and Addenda in effect on the procurement date.

Specific Notes:

(1) Refer to Table 3.2.2-1 for Codes and Standards Summary for Components Excluding Piping. Refer to Chapter 5, Section 5.5.3, for design and fabrication code requirements for reactor coolant loops and pressurizer surge line piping.

(2) Design includes activities such as initial material selection and sizing based on pressure/temperature considerations, use of allowable stress values in the sizing calculations, and analysis of piping to verify acceptable design basis.

Table 3.2.2-2 (Sheet 2)
(Continued)

SUMMARY OF CODES AND STANDARDS REQUIREMENTS FOR SEQUOYAH PIPING

(3) Procurement includes activities such as material examination based on product form, documentation and certification, and vendor fabrication, inspection, and testing as required by contract.

(4) Analysis was performed using B31.1.0, supplemented by use of the provisions of Class 2, NC-3600, ASME Section III, 1971 Edition up to and including Winter 1972 Addenda.

(5) B31.7 prior to April 2, 1973: ASME Section III after April 2, 1973 (except that already existing contracts were in general not revised to require ASME procurement).

(6) B31.7 Code Case 115 accepts the ASME Code Section III as meeting B31.7 requirements. This Code Case was used for Sequoyah piping after its issue.

(7) A statistically significant reverification sampling of TVA Class A piping installation was performed in late 1986 to confirm pressure boundary material identification and control practices during construction. This reverification confirmed a 92 percent rate of correct and verified material installation for piping items sampled. Of the remaining 8 percent, 1 1/2 percent of the items were confirmed to be lower TVA class material (Class B), and 6 1/2 percent were found to be potentially lower safety class material (material cannot be verified to meet Class A, nor can it be verified <u>not</u> to meet Class A: at a minimum, the material is TVA Class B). These discrepancies were found primarily in small bore piping items (2 inch nominal size and less), with one piece of 6 inch nominal pipe included in the 6 1/2 percent. A report was issued which contains sampling results, conclusions, and bases for conclusions (Ref. 3). A second evaluation of Class A piping was performed in accordance with paragraph 1-724 of ANSI B31.7c - 1971, which identified all material not meeting Class 1 requirements in accordance with this Code and Addenda (Ref. 4). All material required by this Code and Addenda to meet B31.7 Class 1 requirements has been either verified to comply with ANSI B31.7c - 1971 or has been upgraded in place to meet the applicable requirements.

(8) Leak testing provisions of B31.1.0 were used for circumferential welds in process piping that form part of the containment isolation boundary and are located within containment penetration assemblies. 100 percent radiography was substituted for hydrostatic leak test of these welds.

Table 3.2.2-3 (Sheet 3)
(Continued)

Non-Nuclear Safety Classifications

Notes:

* - Code jurisdiction is applicable to field fabrication, assembly, examination, and testing.

** - Design engineers shall determine the specific code or standard that applies (i.e., NEMA, API, etc.).

1 - All non-nuclear safety piping systems located inside seismic category I structures are seismically supported as necessary to prevent unacceptable interactions with safety-related structures, systems or components (seismic category I (L) A or I (L) B as defined in Section 3.2.2.6 and Design Criteria SQN-DC-V-3.0, -3.2 and 13.3).

The piping class 1 (L) is subdivided as follows:

A. Where the pressure boundary integrity is required, the piping is classified as category 1 (L) A.

B. Where the pressure boundary integrity is not required during and after a seismic event but position retention is required, the piping is classified as category 1(L) B.

2 - For repairs and modifications made after June 15, 1973 the provisions of paragraph 136.4 of the Power Piping Code ASME/ANSI B31.1-1973 may be used for examination of welds (reference B45 861202 252).

3 - Analysis was performed using USAS B31.1.0-1967, supplemented by use of the provisions of Class 2, NC-3600, ASME Section III, 1971 Edition up to and including Winter 1972 Addenda.

4 - For work performed after August 6, 1974, on Class G and Class H, welder/welding operator qualification/requalification may be made per ANSI-B31.1-1973, paragraph 127.5, in accordance with ASME, Section IX-1971, plus Winter 1971 Addenda.

5 - Seismic Category I if it performs a primary safety-function, with the following exception. Safety Class 2b (TVA Class Q) Main Control Room air flow delivery components (round flexible ducting, triangular fiberglass ducting, and air bars) and the suspended ceiling which supports them are qualified to Seismic Category I(L) requirements, analyzed to ensure that the components will remain in place, the physical configuration will be maintained such that flow will not be impeded, and the ducting pressure boundary will not be lost. See Section 3.7.3.16. The air flow delivery components are constructed of standard commercial grade materials. Limited QA requirements ensure they are maintained as qualified.

3.3 WIND AND TORNADO LOADINGS

3.3.1 Wind Loadings

3.3.1.1 Design Wind Velocity

The Category I structures are designed for a 95-mph wind 30 feet above grade with a 100-year period of recurrence.

3.3.1.2 Basis for Wind Velocity Selection

The 95-mph wind was determined from Figure 1(b), ASCE Paper 3269, "Wind Forces on Structures" (see Reference 1). Historical data are presented in Section 2.3.

3.3.1.3 Vertical Velocity Distribution and Gust Factor

The 95-mph wind was applied for the full height of the structure. An approximate gust factor of 1.1 is included for all wind loads and combinations of loads where wind is involved as recommended in ASCE Paper 3269.

3.3.1.4 Determination of Applied Force

The wind loads resulting from the velocity given in Section 3.3.1.3 are determined by the method described in ASCE Paper 3269. The dynamic wind pressure, q, is defined as $q = .00256V^2$, where q is in lb/ft^2 and V is in mph. A gust factor of 1.1 is applied which redefines q as $q = .00256(1.1V)^2 = .00310V^2$. The wind pressure, p, in lb/ft^2, is defined $p = Cq$ where C is the pressure distribution coefficient (C_{pe} or C_{pi}) or the shape coefficient (C_D) determined from Table 4 in ASCE Paper 3269. For boxed shaped structures, the coefficients are slightly modified from the ASCE Paper. The values used are given below:

For the analysis of box-shaped structures, a shape coefficient (C_D) of 1.3 is used which defines the wind pressure as p = 1.3q. Of the total pressure (p = 1.3q), 0.8q is applied to the windward wall, and 0.5q is applied to the leeward wall. Concurrently, the end walls receive 0.7q negative pressure and the roof receives -0.5q uplift.

For the analysis of cylindrical structures, such as the Shield Buildings and Storage Tanks, the shape coefficients and pressure distribution coefficients are obtained from Table 4(f) of ASCE Paper 3269.

3.3.2 Tornado Loadings

3.3.2.1 Applicable Design Parameters

The design tornado is characterized by an "eye" with reduced atmospheric pressure of 3 lb/in^2 below ambient and by a "funnel" having a maximum rotational velocity of 300 mph. The tornado is assumed to have a translational speed of 60 mph. The Category I structures are designed for the effects of the 300-mph rotational wind, the 60-mph translational wind, a

negative differential pressure defined as a trapezoidal step function, its magnitude varies from zero to -3 psi in 3.0 seconds, stays at -3 psi for 3 seconds then decreases to zero in 3.0 seconds, and the tornado-generated missiles described in Section 3.5. These loadings are considered to act concurrently. Coincident wind velocities and pressure drops for the design tornado are shown in Figure 3.3.2-1.

The relationship between wind velocity and pressure in the design tornado shown in Figure 3.3.2-1 was developed based on Hoecker's studies of the Dallas tornado of 1957 (References 2 and 3).

3.3.2.2 Determination of Forces on Structures

The methods used to convert the tornado loadings into forces on Category I structures, including the distribution across the structures, was determined by following the recommendations of ASCE Paper 3269, "Wind Forces on Structures" as outlined in Section 3.3.1.4. The provisions for gust factors and variation of wind velocity with height are not applied. The dynamic wind pressure, q, is defined as $q = .00256V^2$, where q is in lb/ft^2 and V is in mph. The wind pressure, p in lb/ft^2, is defined as p = Cq, where C is the shape coefficient (C_D).

A 1.3 shape coefficient is included for box-shaped structures with vertical walls normal to the wind direction. The dynamic pressure load, p = 1.3q, due to tornadoes is applied to the structure walls and roof in the same manner as the wind loads in Section 3.3.1.

Cylindrical structures and tanks have the same shape coefficients applied as for wind loads in Section 3.3.1. The pressures are applied over the structures as shown in Table 4(f) of ASCE Paper 3269.

The effect at various combinations of tornado loadings were studied with respect to each Category I structure. The most adverse combination was selected individually for the design basis of each structure.

The tornado loadings are not considered to be coincident with accident or earthquake loadings. Venting is utilized to reduce the effective tornado-generated differential pressure in portions of the Auxiliary Building. Four hundred square feet of relief panel area are provided in the roof over the Spent Fuel Pool Room and Cask Loading Room at Elevation 791.75 for venting purposes during the tornado. The relief panels are held in place by gravity. An upward pressure of 0.25 lb/in^2 is sufficient to offset the weight of the panels and cause them to be lifted from their normal positions. Two corners of each panel are chained to the roof to prevent the panel from becoming a missile after it relieves.

The Shutdown Board Room and, in general, the area between columns q and u at Elevation 734.0 are not part of that portion of the Auxiliary Building intentionally vented for tornado depressurization; however, this area and the remainder of the building will depressurize through the vent area provided by the air intake openings, through ventilation penetrations, and through the 734 foot elevation equipment hatch. In addition, the ERCW Pumping Station depressurizes due to the vent areas provided by the ventilation openings. The Diesel Generator Building depressurizes due to the vent areas provided by the ventilation openings and a Main Control Room manual action to open the Air Intake Dampers during a tornado event.

Analyses indicate that the effective tornado-generated pressure differential will not exceed 100 lb/ft^2 acting on the roof and exterior walls of the Spent Fuel Pool Room and cask loading area. The roof is the limiting structural element in this condition and is designed to withstand an upward-acting pressure of 180 lb/ft^2. Air velocity induced by venting is expected to be high at the vent opening, but decrease rapidly within a few feet of the opening. No hazard to equipment is foreseen since the vents are located in the Auxiliary Building roof, well away from any essential equipment.

Pressure differentials and assorted air velocities are expected in all areas which depressurize due to the venting of the building. Structures in these areas have been evaluated for the differential pressure from depressurization. In the room(s) where the differential pressure exceeds the wall design, administrative operating instructions will ensure that the doors will remain open during a tornado event to reduce the differential pressure to an acceptable value. No hazard to equipment in these areas is foreseen due to the small pressure differential and low air velocities. Walls, ceilings, and floors separating areas experiencing depressurization during a tornado from areas not experiencing depressurization are designed to withstand the effects of total tornado-generated pressure differential of 3 lb/in^2. The analytical model employed in determining the effective differential pressures utilizes isentropic, perfect gas relations in a step-wise, quasi-steady first law analysis. The analysis determined pressure and temperature variations within the structure induced by the tornado defined in Section 3.3.2.1.

3.3.2.3 Ability of Category I Structures to Perform Despite Failure of Structures Not Designed for Tornado Loads

An investigation of the effect of tornado loading on the Turbine Building was made to determine the extent of failure of the structure as to collapse or to the possibility of generating missiles that could damage Category I structures and impair their ability to perform their intended design function.

The following information was determined:

1. The metal siding panels will fail at loads considerably below the design tornado loading and will become missiles that could impact the Control Building. The siding will fail before the main girts are overloaded enough to cause failure. The failure of the parapet girts is likely, resulting in the release of 16WF15.5 in 4-foot lengths, 8WF11.5 in 8-foot lengths, 18 by 3/8 plate in varying lengths, ST4WF8.5 in 7-foot lengths. The walls and roof of the Control Building were investigated for the above missiles and found to be adequately designed to resist the missiles.

2. Following the failure of the siding, the structural steel framing of the building will be exposed to tornado forces acting upon the steel structure, equipment, piping, and other items of wind resistance. At the maximum design tornado winds, the structure will have some points of local yielding in connections as forces are redistributed throughout the bracing and rigid frames. The resistance of the structure at this point will be sufficient to prevent collapse onto the Control Building.

3. The Turbine Room cranes, if not anchored, could possibly be blown from the crane girders, either falling on the operating floor or out the end of the building onto the Control Building roof.

   To preclude the occurrence of this event, the cranes will be anchored to stops at one end of the runway at any time during tornado alerts, watches, and tornadoes.

4. The Potable Water Tanks and Gland Seal Water Tanks at Elevation 773 floor could be blown to the Control Building roof along with air intake hoods, auxiliary boiler stack, and heating and vent equipment on the Elevation 773 floor.

   The Control Building roof was determined to be adequately designed to resist the described events.

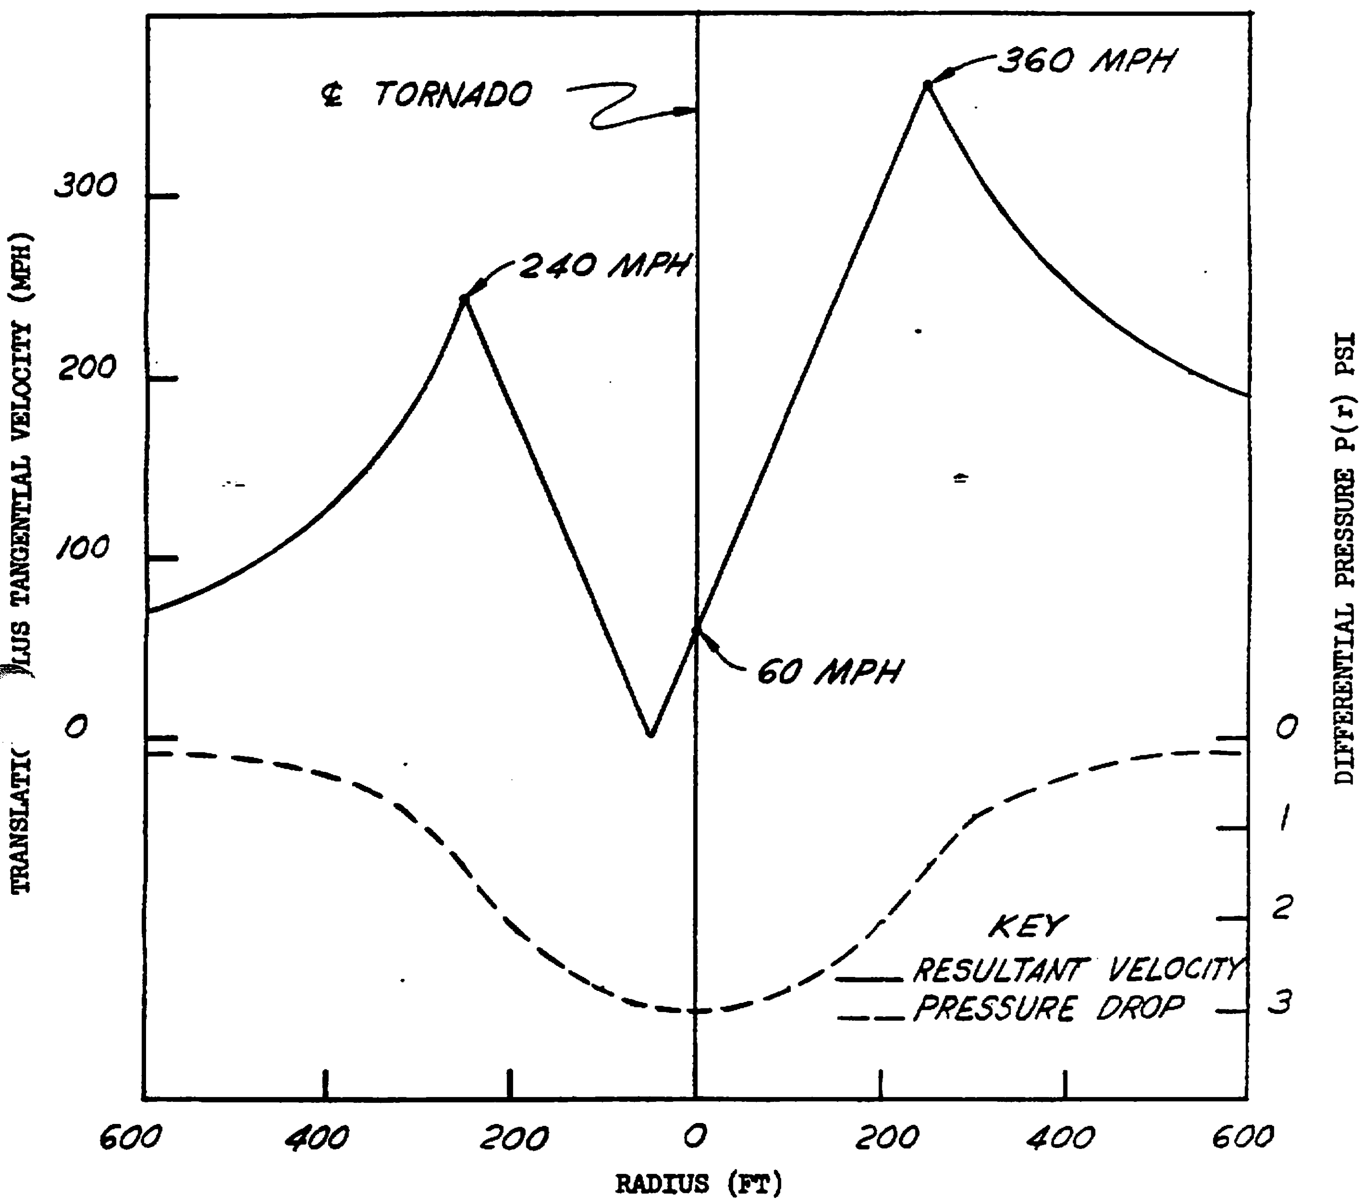

Figure 3.3.2-1 Variations of Differential Pressure and Tangential plus Translational Velocity as a Function of the Distance from the Center of the Tornado

3.4 WATER LEVEL (FLOOD) DESIGN

3.4.1 Flood Elevations

The maximum site flood elevations are discussed in Section 2.4 and Appendix 2.4A. The specific elevations used in the design of the Category I structures are described in Section 3.8.

3.4.2 Flood Force Application

The dynamic loads of the wind waves were determined and applied to the appropriate Category I structures using the methods outlined in the U.S. Army Coastal Engineering Research Center Technical Report No. 4, "Shore Protection, Planning, and Design," Third Edition, 1966.

3.4.3 Flood Protection

The flood protection requirements for Category I systems and components are described in section 2.4.

3.5 MISSILE PROTECTION

Category I structures and components have been analyzed and designed to be protected against a wide spectrum of credible missiles. Failure of certain rotating or pressurized components or equipment is credible and will presumably lead to generation of missiles. In addition, noncredible missiles are identified and justification given for them not being a credible source of missiles. Tornado-generated missiles and missiles resulting from activities particular to the site are also discussed in this section. Characteristics of all credible missiles are discussed in detail, and their effect on the performance of vital components and systems is evaluated. It is shown that the missile protection criteria to which the plant has been analyzed and protected against, comply with the intent of Criterion 4 of 10 CFR 50, Appendix A, General Design Criteria for Nuclear Power Plants.

The design bases of the plant are listed below. These are followed by a presentation of missile barrier loadings, missile selection, selected missiles, barrier design procedures, and missile barrier features.

Design Basis 1

1. Protection shall be provided against potential missiles that could cause a LOCA.

2. Protection shall be provided against potential missiles that could result in the loss of ability to control the consequences of a LOCA, including both the necessity for core cooling and for retention of containment integrity.

3. Protection shall be provided against potential missiles that could jeopardize functions necessary to bring the reactor to a safe shutdown condition during normal or abnormal conditions.

The relationship that missiles have to single failure criteria is:

Design Basis 2

1. A missile that may be generated from the Reactor Coolant System, coincident with a LOCA, shall be considered a part of the LOCA for single failure assumption purposes.

2. If a missile is generated and causes failure of an adjacent system, then that is considered to be a single failure for which the adjacent system must be designed. No other simultaneous or subsequent failures of the adjacent system shall be assumed for design purposes.

Protection against a potential missile may be provided by, but not necessarily be limited to, any one or combination of the following protection methods:

Design Basis 3

1. Compartmentalization - Enclosure of missile source or equipment requiring protection in compartments whose walls prevent penetration by the missile.

2. Barriers - Erection of missile barriers either at the missile source or at the equipment to be protected.

3. Separation - Sufficient separation of redundant systems or complete train separation of components in a safety network so that a potential missile cannot damage both redundant trains of the system and prevent safe shutdown of the reactor.

4. Distance - Location of equipment beyond the range of a potential missile.

5. Restraints - Securing potential missiles by means of restraints.

6. Strategic orientation - Facing equipment and components of equipment in a direction that will direct the potential missile away from equipment.

7. Equipment design - Design equipment to withstand impact of potential missile without loss of function.

The above gives methods to provide protection against postulated missiles; however, a very basic premise for protection is to design components and equipment so that they will have a low potential for generation of missiles. In general, the design that results in reduction of missile generation potential promotes the long life and usability of a component, and is well within permissible limits of accepted codes and standards. The following general methods are used in the design, manufacture, and inspection of equipment:

Design Basis 4

1. Equipment and sections of piping with potential for over pressurization will be provided with ASME Section III Code acceptable pressure relief valves. These valves will prevent pressure buildup in equipment or piping sections beyond the design limits of the materials involved.

2. All components and equipment of the various systems will be designed and built to the standard established by the ASME or other equivalent industrial standard. A stringent Quality Control Program will be also enforced during manufacture, testing, and installation.

3. Volumetric and ultrasonic testing where required by code, coupled with periodic inservice inspections of materials used in components and equipment, adds further assurance that any material flaws that could permit the generation of missiles will be detected.

Postulated missiles will be analyzed to disclose those against which protection should be provided. The analyses will be based on the examination of components and equipment of

energy sources that could be converted to kinetic energy of the potential missile. The following energies shall be considered:

Design Basis 5

1. Stored strain energy - Associated with nuts, bolts, and studs.

2. Contained fluid energy - Associated with equipment and components that contain fluids under pressure.

3. Rotational energy - Associated with equipment such as the reactor coolant pump motor flywheel. (Consideration for the reactor coolant pump motor flywheel is given in Subsection 5.2.6.)

A postulated missile may be disqualified from further consideration if any of the following design conditions are met:

Design Basis 6

1. Sufficient distance exists between the postulated missile and the equipment and components so that damage would not result in conditions 1, 2, or 3 of Design Basis 1. Sufficient distance is defined as a distance that, if traveled by the missile, will render it incapable of causing these conditions.

2. Barriers inherent to the plant design can be identified and associated with potential missiles so that, because of the barrier, the postulated missile is rendered incapable of causing conditions 1, 2, or 3 of the Design Basis 1. A valid barrier in this case is defined as a structure that is capable of absorbing the effect of the missile impact and not resulting in any of these conditions.

3. Enclosure of a postulated missile source can be identified and associated with the missile so that the walls of the enclosure can absorb the effects and prevent damages by the missile without causing any of conditions 1, 2, or 3 of Design Basis 1.

4. Restraints inherent to plant design can be identified and associated with a postulated missile so that, because of the restraint, the missile is incapable of being generated.

5. A postulated missile source associated with components and equipment that is oriented as a result of inherent plant design so that the path of the missile is away from equipment to be protected. The path of the missile must be directed into an area so that conditions 1, 2, or 3 of Design Basis 1 will not occur if the potential missile is generated.

6. Equipment or components that are specifically designed against generation of missiles, or that are specifically designed to be capable of withstanding missile impact without resulting in the occurrence of conditions 1, 2, or 3 of Design Basis 1.

3.5.1 Missile Barrier and Loadings

A tabulation of the structures, shields, systems, and barriers that have been designed for missile protection is presented in Table 3.5.1-1 along with the types of missiles they will be protected against.

3.5.2 Missile Selection

The specific missiles which each system, structure, shield, or barrier listed in Table 3.5.1-1 are protected against are discussed in this section along with the basis for selection as a credible missile. In addition, certain components are justified as not being credible missiles.

3.5.2.1 Control Rod Drive Mechanism

The control rod drive mechanism is a source of three types of missiles: the housing plug, drive shaft, and drive shaft latched to the drive mechanism. It is postulated that the top plug on the control rod drive mechanism will become loose and be forced upward by the water pressure. Then the following sequence of events is assumed: The drive shaft and control rod cluster would be forced out of the core by the differential pressure across the drive shaft. The drive shaft and control rod cluster, latched together, are assumed fully inserted when the accident starts. After approximately 12 feet of travel, the rod cluster control spider would hit the underside of the upper support plate. Upon impact, the flexure arms in the coupling joining the drive shaft and control cluster would fracture, completely freeing the drive shaft from the control rod cluster. The control rod cluster would be completely stopped by the upper support plate; however, the drive shaft would continue to be accelerated upward, leave the reactor vessel, and hit the missile shield structure.

The missile characteristics of the control rod drive mechanism housing plug missile are given in Table 3.5.2-1. The velocity of the plug has been calculated by equating the increase of the plug momentum to the decrease in water momentum. The reactor coolant discharge rate from the break has been calculated using the Burnell equation (Reference 1). The coolant pressure has been assumed constant at the initial value. No spreading of the water jet has been assumed. The missile characteristics of the drive shaft (with the disconnect rod) latched to the drive mechanism are also given in Table 3.5.2-1.

3.5.2.2 Valves

Valves are not considered credible sources of missiles. Each valve inside the crane wall has been reviewed to determine if the bonnet or stem could potentially become a missile. For further discussion on valves, see Paragraph 3.5.2.18.

3.5.2.3 Temperature and Pressure Sensing Assemblies

Potential sources of jet-propelled missiles from the Reactor Coolant System are the temperature and pressure-sensing assemblies attached to the Reactor Coolant Loop, the temperature-sensing assemblies attached to the Reactor Coolant Pumps and instrumentation assemblies attached to the pressurizer. These sources are not considered as credible missiles.

3.5.2.4 Pressurizer Heaters

Pressurizer heaters are not considered as credible missiles.

3.5.2.5 Electrical Cables

Electrical cables inside buildings are not protected against damage from internal missiles. However, separation and redundancy of vital cables are such that any single failure within the protection system will not prevent proper protective action at the system level when required.

Electrical cables in Category I structures are protected from tornado missiles. This includes cables in yard manholes, handholes, and underground conduit banks which connect to the Diesel Generator Building, Essential Raw Cooling Water Pumping Station, and Condenser Cooling Water Pumping Station.

3.5.2.6 Steel Containment Structure

Any credible missile generated within the containment structure will not impair the integrity of the steel containment structure. Protection against credible missiles located in the lower compartment is accomplished by locating a steel-reinforced concrete wall (crane wall), a steel-reinforced concrete slab (divider deck), and steel-reinforced concrete removable blocks (control rod drive mechanism missile shield), between the Primary Reactor Coolant System and the containment structure. Additionally, since there are openings in the crane wall, protection for the containment structure is also accomplished by orienting potential missiles, especially valve components, so that their anticipated trajectory will not permit them to pass through these openings.

Some components are located in the space between the crane wall and the containment structure. Protection is accomplished by orienting potential missiles so that their anticipated trajectories are away from the containment structure.

Even though the preceding methods have been used to protect the containment structure from potential internal missiles, the basic approach has been to assure design adequacy against generation of missiles rather than to allow a missile to be generated and then try to contain the effects.

The control rod drive mechanism missile shield will be located above the reactor vessel and will prevent the credible missiles of the Control Rod Drive System from striking the inside surface of the containment structure or the containment spray headers.

Valve bonnets and stems inside the steel containment structure, should they become missiles, would not cause failure of the containment shell or vital systems inside the containment shell.

3.5.2.7 Shield Building

None of the missiles generated within the containment will penetrate the containment structure. Therefore, it is not necessary to design the Shield Building against these missiles. There are, however, a number of missiles external to the reactor containment that the Shield Building must be designed against.

Source of missiles outside the reactor containment include:

1. A portion of a disc or casing fragments of a main turbine.

2. Credible tornado-generated missiles which are identified in Table 3.5.5-2.

The small air exhaust opening at the top of the shield building will be protected from vertically descending tornado missile of one inch diam. x 3 feet long "steel rod."

The integrity of the Shield Building will not be impaired by tornado-generated missiles. This is accomplished by designing the Shield Building of steel-reinforced concrete to be capable of withstanding the impact of tornado-generated missiles. Additionally, this means that the Shield Building protects the steel containment structure from tornado-generated missiles. The probability of a credible missile from the main turbine hitting the Shield Building and producing unacceptable damage to safety related equipment is so low that it is considered as incredible (Subsection 10.2.3).

3.5.2.8 Ice Condenser Containment System

External and internal missiles are not of significance for the Ice Condenser Containment System. Tornado-generated missiles will be intercepted by the Shield Building, and the trajectory of missiles generated within the bottom region of the lower compartment is such that the missiles will not pass through the inlet door openings in the lower crane wall and directly strike the steel containment structure. The latter situation is shown in Figure 3.5.2-1. As can be seen in the figure, the location of main portions of the Reactor Coolant System and of the other systems which connect to it are below elevation 695.0, whereas the openings for the ice condenser lower inlet doors are between elevations 723'-5" and 730'-8".

3.5.2.9 Emergency Core Cooling System

The Emergency Core Cooling System (Subsection 6.3) includes four accumulator tanks which are located in separate rooms between the crane wall and the containment structure. The crane wall protects these tanks and their associated valves and piping from credible missiles generated within the lower compartment, and the Shield Building protects them from external missiles. The active components of the system (pumps, motors, and heat exchangers) are located in separate rooms in the Auxiliary Building. Therefore, these active components are protected from missiles generated within the lower compartment. Further, these vital components are protected from tornado-generated missiles by the Auxiliary Building and the two floors of steel-reinforced concrete above them. There is an adequate supply of borated water protected against tornado missiles to provide makeup to the Primary System required for a safe shutdown of the plant.

The accumulator tanks and associated check valves and piping are not credible sources of missiles for the containment structure. Components are prevented from becoming a source of damaging missiles by orienting potential missiles so that their anticipated trajectory is away from the containment structure.

3.5.2.10 Containment Spray System

For the Containment Spray System (Subsection 6.2.2), the spray nozzles and piping in the upper compartment of the containment structure are protected from missiles generated in the lower compartment by the steel-reinforced concrete divider deck and missile shield, and by the steel-reinforced concrete walls of the upper portions of the steam generators and pressurizer. No credible missiles will be generated inside the upper compartment of the containment structure. Protection from tornado-generated missiles is provided by the Shield Building. The pumps and motors of the Containment Spray System are located in separate rooms in the Auxiliary Building. These components are therefore protected from missiles generated in the lower reactor compartment. They are also protected from tornado-generated missiles by at least two floors of steel-reinforced concrete of the Auxiliary Building.

3.5.2.11 Containment Isolation System

Isolation valves of the Containment Isolation System (Subsection 6.2.4) are located in three regions: (1) inside the containment structure, (2) between the containment structure and the Shield Building, and (3) outside the Shield Building.

The isolation valves which are located inside the containment structure are protected from credible missiles generated in the lower compartment by the crane wall, and protected from tornado-generated missiles by the Shield Building.

Similarly, isolation valves which are located in the annular region between the containment structure and the Shield Building are protected by the crane wall and by the Shield Building.

There are no credible sources of missiles in the annular region.

For containment isolation valves located outside the Shield Building (in the main steam and main feedwater lines) protection is provided by the West Steam Valve Room (for those lines which penetrate the containment and Shield Buildings near azimuth 0°), and by the separate structure, called the East Steam Valve Room, adjacent to the Shield Building (for those lines which penetrate near azimuth 180°). The general arrangements for these lines are shown in Figures 3.5.2-2 and 3.5.2-3, respectively.

As can be seen in Figure 3.5.2-2, the isolation valves in the lines penetrating near azimuth 0° are near the bottom of the West Steam Valve Room and are thereby protected from tornado-generated missiles of other than vertical descent by the floors and walls of the Auxiliary Building. See Section 3.5.5 for further discussion.

Also, as seen in Figure 3.5.2-3, the isolation valves in the East Steam Valve Room are near the bottom of the room. The exterior walls of this structure have been designed to withstand the spectrum of credible tornado-generated missiles. In addition, the vent near ground level has an offset to prevent missiles on a straight line trajectory from passing through the vent. See Section 3.5.5 for further discussion.

3.5.2.12 Diesel Generator Building

Four emergency diesel generators, which are required to supply emergency power to certain engineered safety features, are located inside a separate structure, the Diesel Generator Building. Interior walls of reinforced concrete separate these generators. The exterior walls, roofs, and doors of this building will not fail as a result of a tornado and provide protection against the missiles in Tables 3.5.5-2 and 3.5.5-5. The tornado missile criteria are discussed in greater detail in Subsection 3.5.5.

The fuel oil vent piping protruding from the east wall of the Diesel Generator Building at Elevation 734.5 feet and through the roof of the Diesel Generator Building near the east wall is provided with protection against tornado generated missiles. The tornado missile barriers are designed to provide adequate protection against all applicable missiles described in Subsection 3.5.5.

3.5.2.13 Control Bay

The control bay is protected against tornado-generated missiles by the steel-reinforced concrete ceilings and walls of the Control Building. Credible missiles generated in other portions of the plant are intercepted by the crane wall, containment structure, or steel-reinforced concrete walls and floors of the Auxiliary Building. The orientation of the Control Building with respect to the axis of rotation of the main turbines is such that it is a very low probability that a failed portion of a turbine disc would cause fragments that would strike the Control Building. The exterior walls have been designed to withstand the spectrum of credible tornado-generated missiles. There are no credible internal missiles generated within the control bay.

3.5.2.14 Spent Fuel Pool

The spent fuel pit (Subsection 9.1.2), is located in the Auxiliary Building. In addition, up to 225 spent fuel assemblies may be stored in a rack to be fabricated in the future for placement in the cask loading area of the cask pit adjacent to the spent fuel pool. Protection against missiles from other portions of the plant is provided by at least one wall of steel-reinforced concrete walls or slabs. Protection against tornado-generated missiles is provided by the Auxiliary Building and by its location between the two Shield Buildings. The tornado missile criteria are discussed in greater detail in Subsection 3.5.5.

An analysis, which included probability of a turbine disc failure and impact probability as a function of angular orientation with turbine axis of rotation, has shown that the probability of a turbine missile hitting the spent fuel pit is sufficiently low.

3.5.2.15 The Auxiliary Building

The Auxiliary Building is designed against damages by tornado-driven missiles. This capability is provided by the walls and roof being constructed of steel-reinforced concrete. Damage of vital systems by internally generated missiles is negated by reinforced walls and floors in the building. The spent fuel pool is discussed in Subsection 3.5.2.14. Any openings in the roof of the auxiliary building through which tornado borne missile (of one inch diameter steel bar x 3 feet long in size) can penetrate and disable vital safety gear are reinforced via covering or grating to stop these missiles.

3.5.2.16 The Control Building

The Control Building walls and roof are made of steel-reinforced concrete to protect against tornado-driven missiles. The control bay is covered in Subsection 3.5.2.13.

3.5.2.17 Intake Structure

The essential raw cooling water pumps (Subsection 9.2.2) are located at the ERCW pumping station and are exposed to the atmosphere. The pumps are designed to withstand the wind forces induced by a tornado. In addition, protection against tornado-generated missiles is provided by a structural steel grillwork system composed of 21 x 49 wide - flange beams spanning across the roof and over the pumps. A turbine missile analysis described in Subsection 10.2.3 showed that the probability of damaging vital equipment is acceptably low. However, this analysis was performed for ERCW pumps located in the CCW pumping station rather than in the current ERCW pumping station. Since the ERCW pumping station is located much further away than the CCW pumping station, the probability of damaging vital equipment is even lower than before.

3.5.2.18 Components Not Credible Sources of Missiles Inside Containment

Catastrophic failure of the reactor vessel, steam generators, pressurizer, reactor coolant pump casing, reactor coolant pump flywheel (Subsection 5.2.6), accumulators, heat exchangers, and piping leading to generation of missiles is not postulated. Massive and rapid failure of these components is not credible because of the material characteristics; inspection; quality control during fabrication, erection, and operation; conservative design; and prudent operation as applied to the particular component.

Gross failure of a control rod mechanism housing sufficient to allow a control rod to be rapidly ejected from the core is not considered credible for the following reasons:

1. All full-length control rod mechanisms are shop tested at 4105 lb/in^2g, respectively.

2. The mechanism housings are individually hydrotested to 3107 lb/in^2g as they are installed on the reactor vessel to the head adapters and checked during the hydrotest of the completed Reactor Coolant System.

3. Stress levels in the mechanism are not affected by system transients at power or by thermal movement of the coolant loops.

4. The mechanism housings are made of type 304 stainless steel. This material exhibits excellent fracture notch toughness at all temperatures that will be encountered.

For all valves not addressed in Paragraph 3.5.2.2, the stems are not considered to be a credible source of missiles. All the isolation valves in the Reactor Coolant System have stems with a back seat. This effectively eliminates the possibility of ejecting valve stems even if the stem threads fail. Analysis shows that the back seat or the upset end would not penetrate the bonnet. Additional interference is encountered with air and motor-operated valves.

Valves with nominal diameter larger than 2 inches have been designed against bonnet body connection failure and subsequent bonnet ejection by means of:

1. Using the design practice of ASME Section VIII (1968), which limits the allowable stress of bolting material to a conservative or low value.

2. Using the design practice of ASME Section VIII (1968), for flange design.

3. By controlling the load during the bonnet body connection stud-tightening process.

The pressure containing parts of these valves are designed per Code Class I Requirements established by the ANSI B16.5 (1968).

The proper procedures and the use of calibrated torque wrenches, with indication of the applied torque, limit the prestress of the studs to the allowable limits established in the ASME Code. This stress level is far below the material yield. The complete valves are hydrotested per the ANSI B16.5 (1968). The stainless steel bodies and bonnets are volumetrically and surface tested to verify soundness.

Valves with nominal diameter of 2 inches, or smaller, are forged and have screwed bonnet with canopy seal. The canopy seal is the pressure boundary while the bonnet threads are designed to withstand the hydrostatic end force. The pressure-containing parts are designed per criteria established by the ANSI B16.5 (1968) specification.

3.5.2.19 <u>Missiles From Main Turbine</u>

Turbine missiles are discussed in detail in Subsection 10.2.3.

3.5.2.20 <u>Nearby Site Activity Generated Missiles</u>

There are no credible sources of nearby site activity generated missiles. There are no airports located within 5 miles of the plant site. No relocation of existing airports into this area or development of new airports is planned in the foreseeable future, according to the Tennessee Aeronautics Commission.

There is no potential for damage to the Sequoyah Plant because of the transportation of explosives to or from the Volunteer Army Ammunition (VAA) plant 8 miles away.

3.5.2.21 Tornado-Generated Missiles

The design of barriers for tornado-generated missiles is discussed in Subsection 3.5.5. The missile spectra for which the various Category I structures are qualified are presented in Tables 3.5.5-2, 3.5.5-4, and 3.5.5-5.

3.5.2.22 Condensate Storage Tanks

The FLEX credited water volume contained in the Condensate Storage Tanks (CSTs) is protected by a tornado wind driven missile barrier constructed around the tanks. The barrier protects the tanks from failure that would cause a loss of contents exceeding the turbine-driven auxiliary feedwater pump suction requirements for the duration of the beyond design basis external event. The missile spectrum for which the protection was designed is presented in Table 3.5.5-2. The protection is provided by a specially designed steel-reinforced concrete barrier wall. A missile trajectory above the wall via which a tornado borne missile could penetrate the tank is above the minimum required water level of the CSTs. Because it is denser than water, a missile that penetrates above the water level will sink to the bottom of the tank and not interfere with, or enter, the suction piping.

3.5.3 Selected Missiles

This subsection determines the missile threat for credible missiles that were presented in subsection 3.5.2.

Missiles are generally characterized by size, weight, origin, impact area, velocity, and impact energy. Missiles may also be classified by the potential energy source which served as the driving force: stored strain energy, contained fluid energy (jet-propelled and piston-type missile), and rotational energy. A list of missiles and important parameters is given in Table 3.5.2-1.

The analytical techniques used for each missile classification will be described by listing the basic equations used for analyzing the missiles under each classification.

The approach is to assume that a worst-case missile is generated and to directly analyze the missile velocity. Once the velocity has been conservatively calculated, the missile's energy can be estimated and the potential effects can be assessed.

1. Class I missiles - Resulting from stored strain energy

   a. The equation for velocity:

$$V = \sqrt{gE/W}\ \varepsilon \quad or\ V = \sqrt{g/(EW)}\ \sigma$$

where V = velocity of missile, ft/s

ε = strain, in./in.

σ = ultimate tensile stress, lbf/ft^2

E = modulus of elasticity, lbf/ft^2

g = gravity constant, (lbm-ft)/(lbf-sec^2) = 32.2

W = mass density of projectile, lbm/ft^3

b. The equation for kinetic energy:

$$KE = mV^2/2$$

These equations provide a conservative analysis of missile energy because (1) the ultimate tensile stress (σ ult) or strain (ε ult) for the material is used, resulting in a larger amount of energy than would actually be present at fracture, and (2) all strain energy is converted to kinetic energy with no consideration for energy losses due to friction, relaxation, heating of the material, or air resistance.

2. Class II missiles - Resulting from contained fluid energy, piston-type missiles

a. Equation for velocity:

$$V = \sqrt{2PA_oL / m}$$

where V = velocity of missile at end of piston stroke, ft/s

P = system pressure, lb/ft^2

A_o= missile area under pressure, ft^2

L = length of stroke, ft

m = mass of missile, lbf-s^2/ft

b. Equation for kinetic energy:

$$KE = mV^2/2$$

The equations provide a conservative analysis of the missile energy since no consideration is given for energy losses due to friction or air resistance.

3. Class III missiles - Resulting from contained fluid energy, jet-propelled missiles

a. Equation for velocity:

$$\left(1-\frac{V}{V_f}\right) - ln\left(1-\frac{V}{V_f}\right) = K_1 - \frac{K_2}{r_o + x\tan\beta}$$

$$where\ K_1 = \left(1-\frac{V_o}{V_f}\right) - ln\left(1-\frac{V_o}{V_f}\right) + \frac{K_2}{r_0}$$

$$K_2 = \frac{A_o \ A_m \ e_f}{M\pi \ (\tan\beta)}$$

V = missile velocity at distance x, ft/s

V_f = jet velocity, ft/s

r_o = radius of throat, ft

x = distance traveled, ft

ß = angle of jet expansion, degrees from normal

V_o = initial velocity of missile, ft/s

e_f = density of fluid jet, lbf-s^2/ft^4

A_o = missile area under pressure, throat area, ft^2

A_m = cross-sectional area of missile, ft^2

M = mass of missile, lbf-s^2/ft

b. Equation for kinetic energy:

$$KE = mV^2/2$$

These equations provide a conservative estimate of the missile energy since no consideration is given for energy losses due to friction or air resistance.

4. Class IV missiles - Resulting from rotational energy

The reactor coolant pump flywheel is not a credible missile source (Subsection 5.2.6) and does not have to be protected against. Turbine disc failure is discussed in Subsection 10.2.3. The probability of a disc damaging a vital system is extremely small.

3.5.4 Barrier Design Procedures

Penetration into Concrete Barriers

The following paragraph is provided for historical purposes: In computing penetration into concrete walls, a comparison was made of formulas listed in ORNL-NSIC-22, "Missile Generation and Protection in Light-Water-Cooled Power Reactor Plants." Four equations were studied in ORNL-NSIC-22 in connection with penetration in concrete. Two of these, the Army Corps of Engineers formula and the National Defense Research Committee formula, do not apply for

impact velocities under 500 ft/s and thus are not applicable here (velocity of 300 mph = 440 ft/s). The remaining two equations are the Modified Petry Formula and the Ballistic Research Laboratory formula. These two formulas were compared for a 6-inch-diameter missile of 100 pounds and a 16-inch-diameter missile of 2500 pounds with velocities in the range from 0 to 500 ft/s. As seen in Figures 3.5.4-1 and 3.5.4-2, the Petry Formula is the most conservative for velocities greater than 150 to 200 mph for material constant, $K=4.76 \times 10^{-3}$.

The following describes the barrier design procedures utilized for concrete barriers. The depth to which a missile penetrated a concrete barrier was estimated by use of the Modified Petry Formula (Reference 2).

$$D' = KAV' \left[1 + e^{-4(a-2)} \right]$$

where D' = depth of penetration into finite medium

K = a material constant

$$V' = \log_{10} \left(1 + \frac{V^2}{215{,}000}\right)$$

V = impact velocity

A = weight of missile/impact area of missile

$$a = \frac{T}{KAV'}$$

T = wall thickness

The results are given in Figures 3.5.4-3 and 3.5.4-4 for missiles 1, 2, and 4 of the original spectrum of missiles of Table 3.5.5-1. The penetration of the automobile (missile 3 of Table 3.5.5-1) into a 18-inch concrete wall is negligible. According to C. V. Moore (Reference 3), spalling on the inside face of a wall does not occur for penetrations less than two-thirds the wall thickness. Therefore, the structural barrier thickness was always at least 1.5 times the penetration depth. Penetration analysis using Modified Petry formula assumes nondeformable missiles for conservatism.

<u>Penetration into Steel Barriers</u>

The credible missiles inside the containment as defined in Table 3.5.2-1 have been investigated to determine their penetration characteristics. Penetration depths, or minimum thicknesses to

just perforate, have been calculated based upon three commonly used equations for steel targets. They are:

1. The Stanford Equation.
2. The Ballistics Research Laboratory Equation.
3. The Recht and Ipson Equation.

The minimum thicknesses to just perforate a plate having the characteristics of SA516-GR60 carbon steel represent the largest values obtained from the above three equations. The worst case involves a penetration depth that is 45 percent of the actual containment thickness. Therefore, it is concluded that none of the credible missiles pose a threat to the integrity of the containment.

<u>Missile Impact Loads and Structural Responses</u>

The following describes the methods by which missile impact loads were calculated for the tornado missiles of Table 3.5.5-1. Subsection 3.5.5 discusses the modification of the tornado missile design basis following NRC review action in 1975-1976.

Missile impact loads, where required, were calculated based upon several applicable techniques. Impact loads for all missiles of Table 3.5.5-1, except the 4000-pound automobile at 50 mph, were determined by the relationships presented in Reference 7.

The Sequoyah Shield Building and Auxiliary Control Building were designed to resist a 4000-pound automobile impacting at a velocity of 73.3 ft/s (50 mph), at any point up to 25 feet above the ground surface. The time history of the impact force was determined from deceleration-time curves obtained from full-scale tests of automobiles impacting flat (vertical) rigid barriers. The tests were sponsored by the U.S. Department of Transportation, National Highway Safety Bureau (References 4 and 5). The force-time history of the impact is given by the product of the mass of the automobile and the deceleration.

To determine the maximum possible force to be used in the design, the stiffness and effective mass of the impacted structure at the point of impact must be considered. This was accomplished by using the "shock spectrum method" described as follows. First, a shock spectrum was determined by calculating the maximum responses of a family of single degree of freedom (lumped mass) models to the force-time history of the impact as a function of frequency or natural period. Next, the impact surface was modeled as a single degree of freedom system with a stiffness corresponding to the stiffness of the structure at the point of impact. The stiffness of the Shield Building was determined from the paper "Stresses from Radial Loads on Cylindrical Pressure Vessels," by P. P. Bijlaard (Reference 6). The stiffness of a point on the side of the Auxiliary Control Building was determined using classical plate theory. The effective mass was determined in accordance with the recommendations of Reference 7.

The mass and stiffness properties are used to calculate the natural frequency of the system. Having determined the natural period of the single degree of freedom model of the impacted

structure, the corresponding dynamic amplification factor (DLF) was determined from the shock spectra. The pseudostatic impact load was determined by multiplying the peak dynamic impact load by the DLF.

Values obtained from this technique have been corraborated with subsequent reports by the National Highway Safety Bureau. In Reference 5, time histories of forces are presented for several automobile crash tests which are closely confirmatory. The pseudostatic impact loads obtained by the previously described methods were then applied to the structures. The structures were analyzed for the effect of the loads by conventional linear elastic methods.

The structural steel grillage roof system for the ERCW Pumping Station was designed for impact from the tornado missiles listed in FSAR Table 3.5.5-4. The EPRI testing results (Reference 8) were used to determine the possible maximum impact force for the steel grillage roof system. The force-time history of the end impact loading was further refined to account for the stiffness of the missile and the target. The impulse-momentum principle (Reference 9) was used to analyze the midspan and end impacts. For the midspan impact, the response of the elastic-plastic single-degree system was considered along with a maximum ductility ratio of $\mu = 20$ for bending deformation (Reference 11). For end impact, the connection deformation (Reference 12) was also included in the calculation of the resistance of the elastic-plastic system and the maximum ductility ratio of $\mu = 5$ for shear deformation (Reference 10) was used.

Separation and Orientation Procedures

None of the credible missiles described in Subsection 3.5.2, internal or external, will impair the capability of the engineered safety features to shut down the reactor or to maintain the reactor in a safe shutdown mode indefinitely. For portions of the engineered safety features located within the containment structure, protection against missiles generated inside containment is accomplished with the basic approach of assuring design adequacy against generation of credible missiles rather than to allow missile formation and try to contain the subsequent effects. Further, valves are oriented so that the trajectory of missiles will not likely pass through openings in the crane wall; and the valve bonnets and stems will not penetrate the containment shell should they strike it. For these same engineered safety features, protection against tornado-generated missiles is provided by the Shield Building. If one of the pressurizer heaters in the bottom of the pressurizer should become loose and become a jet-propelled missile, it would move downward and strike the floor beneath the pressurizer without jeopardizing the capability to bring the reactor to a safe shutdown.

For those portions of the engineered safety features required for shutdown of the reactor and/or indefinite maintenance of the reactor in the safe shutdown mode located outside the Shield Building, protection is provided against tornado-generated missiles. Protection is provided by locating these features within structures which have been designed to withstand damage by the appropriate spectrum of credible tornado-generated missiles.

It is concluded that the plant complies with the intent of Criterion 4 of the 10 CFR 50, Appendix A.

3.5.5 Missile Barrier Features

Engineering drawings showing the layout and principal design features of all major structures are given in Section 1.2.

General

The original Category I structures at Sequoyah were designed to resist the spectrum of four missiles shown in Table 3.5.5-1. This spectrum was approved for use at Sequoyah by the Atomic Energy Commission prior to the issuance of a construction permit. In 1975-1976, the NRC requested an assessment of the degree of comparability of protection against tornado missiles provided by the original spectrum with that provided by designs then under review. The comparison was performed for two missiles; a 1-inch diameter steel rod and a utility pole. As a result of that review, the original structures were shown to have sufficient thickness to resist penetration and backface spalling for these missiles. Table 3.5.5-2 shows the original design (A1-A4) and evaluation (A5 and A6) missiles for the original structures. The review of the Diesel Generator Building doors led to a requirement that the missiles used for the design of the building (Table 3.5.5-1, except the auto) are to be imposed on the doors in addition to the three original missiles (D1, D2, and D3) used for the doors. This change is shown in Table 3.5.5-5 as missiles D4, D5, and D6. Since the ERCW Pumping Station was an addition, the design is more representative of SRP requirements. It is designed to resist the missile spectrum of Tables 3.5.5-4.

Listed below are the approximate velocities below which perforation or the generation of secondary missiles due to spalling of the concrete are not calculated to occur for the two missiles identified. The velocities were calculated on the basis of penetration depths predicted by the Modified Petry Method. A k-factor of 2.82×10^{-3} ft^3/lb, obtained from the original paper by Amirikian (Reference 2), was used. The Modified Petry Method is discussed further in Section 3.5.4.

Missile Description	Panel Thickness	Velocity Below Which Spalling Will Not Occur
Steel rod, 1-inch diameter x 3 feet long, weight 8 pounds	18 inches	260 ft/s
	12 inches	210 ft/s
	12 inches with metal deck	230 ft/s
Utility pole, 13-1/2-inch diameter, 35 feet long, weight 1490 pounds, up to 30-foot elevation above plant grade	18 inches	255 ft/s
	12 inches	200 ft/s

Table 3.5.5-3 is a tabulation of the walls and roofs less than 2-feet thick for Category I structures and appurtenances at the Sequoyah Nuclear Plant. It is not critical that some of the

wall and roof panels, such as the stair penthouse for the Auxiliary Building, resist tornado-generated missiles as these panels do not protect safety-related equipment. However, such panels are included in order to provide a complete response to this question.

The right-hand column of Table 3.5.5-3 indicates whether the wall or roof protects equipment important to safety in a tornado event. This determination was made on the basis of the appendix to Regulatory Guide 1.117. The separation of vital equipment behind wall and roof panels less than 2-feet thick is discussed below. The item numbers correspond to those of Table 3.5.5-3.

I. <u>General Cases</u>

1.(1) A1 to A15 Portion of q-Line Wall. Reference Figure 1.2.3-2.

The vital equipment protected by this wall includes the 125-V batteries, chargers, and inverters, the 480-V transformers and electrical boards, and air-conditioning equipment. The q-line wall is 5-feet thick up to 7 feet above the base elevation for this equipment. The 18-inch wall begins where the 5-foot wall terminates. All of the equipment of different channel or train assignments is separated by reinforced concrete block walls.

1.(5) Upper Portion of A5 and All Line Walls. Reference Figures 1.2.3-1 and 1.2.3-3.

These walls protect the auxiliary control air compressors and spent fuel pool from tornado missiles. The redundant air compressors are separated by approximately 26 feet and are protected from horizontal tornado missiles.

1.(7) Air-Conditioning Equipment Rooms. Reference Figure 1.2.3-1.

The Train B air-conditioning equipment rooms on roof elevation 763.0 are separated by 126 feet. The air-conditioning equipment for the redundant train of equipment is located on the floor beneath this roof and is laterally separated from the rooms on the roof.

1.(9) Roof Elevation 763.0. References Figures 1.2.3-1 and 1.2.3-2.

The vital equipment below this roof includes the 125-V batteries, chargers, inverters, the 480-V transformers and electrical boards, and air-conditioning equipment. All of this equipment of different train assignments is separated by reinforced concrete block walls. In the vicinity of the 480-V shutdown board transformer rooms, there are eight 4-foot by 8-foot air intake openings and 14 4-foot by 4-foot air exhaust openings in the roof. In the vicinity of each Train A air-conditioning equipment room there is a 2-foot by 6-foot and a 50-inch by 50-inch ventilation opening in the roof. In the area under the elevation 763.0 roof, the Class 1E conduits and cable trays of different train assignments are laterally separated except for five locations.

1.(10) Roof Elevation 778.0. Reference Figures 1.2.3-1 and 1.2.3-2.

The hydrogen recombiner power cabinets are located in the rooms under these roofs. The redundant cabinets are separated by approximately 24 feet. There are four locations under both roofs where Class 1E conduits and cable trays are not laterally separated.

1.(11) Roof Elevation 791.75. Reference Figures 1.2.3-1 and 1.2.3-3.

The spent fuel pool is located 57 feet beneath this roof. The redundant auxiliary control air compressors are located under this roof and are separated by approximately 26 feet. Possible tornado missiles entering through the tornado pressure relief panel openings on the west end of the Auxiliary Building roof will not strike the auxiliary control air compressor in the west end of elevation 734.0 of the Auxiliary Building. Missiles entering through the tornado pressure relief panel openings on the east end of the elevation 791.75 roof and traveling in a straight line have only a very small angle of intersection with the stored spent fuel. Missiles entering through the tornado pressure relief panel openings on the west end of the elevation 791.75 roof and traveling in a straight line would not intersect any essential equipment. The HEPA filter room is not essential for safe shutdown and is constructed of steel angles and plates. The component surge tank is protected by the elevation 763.0 reinforced concrete slab with the HEPA filter enclosure and a 2-inch steel grating providing shielding across the opening above the tank. The essential control air is protected almost completely by the extremely small angle that a missile trajectory would have to follow in order to impact this equipment. Equipment beneath the elevation 734.0 floor is protected by the 18-inch to 36-inch thick concrete floor.

1.(13) U-line Wall Between A2 and A3 Lines. Reference Figure 1.2.3-2.

This wall protects the same equipment as item 1.(10).

1.(14) U-line Wall Between A13 and A14 Lines. Reference Figure 1.2.3-2.

This wall protects the same equipment as item 1.(10).

2.(1) Diesel Generator Building Walls. Reference Figure 1.2.3-17.

These walls protect the diesel generator sets and their auxiliaries. The diesel generator sets are located in individual rooms separated by 12-inch thick reinforced concrete walls. See also Special Case II.D in this response.

2.(2) Diesel Generator Building Roof. Reference Figure 1.2.3-17.

The main roof protects the diesel auxiliary boards, building ventilation fans, and the diesel air intake and exhaust units. The equipment serving the respective diesel generator sets is located in individual rooms separated by 12-inch thick reinforced concrete walls.

There are four 2-feet, 7-inch square roof penetrations for intake vents for the electric board rooms. These vents are located on the roof within the area enclosed by the 3-foot high, 8-inch thick concrete parapet. Additionally, there are two 3-feet by 30-inch roof penetrations in two of these board room areas for personnel access hatches and a 22-1/2-inch square exhaust penetration in each air filter room. Two other small ventilators are in the roof but these are not near vital equipment.

3.(1) West Steam Valve Room Blowout Lids. Reference Figure 1.2.3-1.

There is one main feedwater isolation valve located in the area under the steel blow-out panels provided for steamline break pressure relief of each west steam valve room. The valve and the 16-inch line downstream of the valve are protected from any missile penetrating the panels by the 36-inch main steamline located above the isolation valve and by the 14-inch wide flange beams provided for pipe break restraints (The main steamline in this area is downstream of the main steam isolation valves and, therefore, missile protection is not required for this portion of piping). The motor operator for the feedwater isolation valve is not under the main steamline and pipe restraint steel.

3.(2) East Steam Valve Rooms Exterior Walls. Reference Figure 1.2.3-1.

These rooms contain main steam relief and safety valves, and main steam and feedwater isolation valves. The roof of each room consists of a diaphragm-type, light gauge metal decking and is supported by four 24-inch wide flange beams. The main steam safety and relief valves are located about 20 feet and 16 feet, respectively, below the decking. Additionally, the roofs are partially covered by a 12-inch thick concrete awning which covers about one-third of the building. The adjacent Reactor Building shield wall, which extends 81 feet above the decking, further restricts the angle of possible missile entry. The main steam and main feedwater isolation valves are located below the safety and relief valves and are further protected from missile damage by four levels of wide flange beams (33-inch to 8-inch size), provided for pipe break restraint and support functions.

3.(3) West Steam Valve Room Roof. Reference Figure 1.2.3-1.

The roofs of the West Steam Valve Rooms consist of a diaphragm type, light gauge metal decking supported by three 24-inch wide flange beams. The main steam safety and relief valves are located about 40-1/2 feet and 36 feet, respectively, below the decking. In between the decking and valves is a 1-1/2-inch steel grating floor supported by three 24-inch wide flange beams and many 8-inch steel channels. The decking is enclosed on one side by the Reactor Building shield wall which extends 60 feet above the decking. The main steam and main feedwater isolation valves and auxiliary feedwater turbine supply piping are located below the safety and relief valves and are further protected from missile damage by five levels of wide flange beams (33-inch to 8-inch size), provided for pipe break restraint and support functions. The steam exhausts from the steam-driven auxiliary feedwater pump is carried vertically through the west steam valve room by 8-inch piping which terminates 2 inches above the decking.

4. Control Building Air Intake Covering. Reference Figure 1.2.3-1.

   The concrete covering protects two 35-inch by 35-inch openings in the Control Building roof. The openings are over a condensing unit of the Control Building air-conditioning system.

5. ERCW Intake Station Parapet Walls. Reference Figures 1.2.3-14, -15, -16. See also Special Case II.A in this response.

   The redundant trains of ERCW equipment within these walls are located in areas separated by 18-inch thick reinforced concrete walls.

6. Interim Pumping Station Parapet Walls.

   These walls no longer protect ERCW equipment.

8. Pipe Tunnels. Reference Figure 3.8.4-3.

   A portion of both trains of the ERCW piping is routed through both pipe tunnels. The tunnel roofs have an earth cover averaging 1-1/2 feet.

9. Category I Yard Manholes and Handholes. Reference Figures 3.8.4-5 & -6.

   The redundant trains of Class 1E electrical cable are routed through Category I manholes and handholes which are either entirely separate or designed with separating, reinforced concrete walls at least 9-inches thick between the trains. Cables in Manholes 7B, 8B, 9A, 10A, 13 A & B, 14 A & B, and Handhole 3 are protected against tornado missiles by a concrete slab at grade and steel plate barriers over the access openings. Manhole 12 is protected by steel plate barriers over the access openings. Additional protection for Manhole 12 is provided by the fact that the access passageways consist of 12 inch thick walls that extend 4 feet below grade before opening into the manhole chamber. Manhole Group 32, and Handhole Groups 54 thru 56 are protected by 18 inch concrete covers. Handhole 29 is protected by a 12 inch concrete cover.

   Manhole Group 31 and Handhole Groups 52 and 53 are protected by concrete covers which are 2 feet thick or greater.

10. ERCW Overflow Box.

   The discharge water of both trains of the ERCW System passes through this box. The roof protects the discharge from being blocked by tornado missiles. (See Figure 3.8.4-10.)

II. Special Cases

A. ERCW Pumping Station

The location of the ERCW pumps on the deck of the ERCW intake station is shown in Figure 1.2.3-14. This figure also shows the location of the 18-inch

thick missile shield wall around the exterior of the station and the shield walls separating Train A and B pumps within the exterior walls. The thickness of these walls has been increased to 18 inches and the height of these walls have been increased to provide a beam seat for structural steel grillage roof system. The structural steel grillage roof system consists of a series of wide flange beams spaced about 9 inches on center and the longitudinal axis of the wide flange beams is rotated 45°. The roof system is calculated to withstand the missiles of spectrum B of Table 3.5.5-4.

B. Interim ERCW Pumping Station

This structure no longer contains the ERCW pumps. It is a Category I structure identified in Table 3.2.1-1 as the Condenser Cooling Water Intake Pumping Structure. It is designed for the missiles of Table 3.5.5-2.

C. CCW Discharge Gates

The Discharge Gates are not safety-related.

D. Diesel Generators

As shown in FSAR Figure 1.2.3-17, the diesel generators are totally enclosed in a reinforced concrete structure designed to protect the diesel generators. These figures also illustrate the missile shield protection over the air intake and exhaust penetrations.

The steel doors and steel bulkhead provided protection from missiles D1, D2, and D3 of Table 3.5.5-5. Following a NRC review in 1975-1976 the level of missile protection required was upgraded to include missiles D4, D5, and D6 of spectrum D. The steel doors and bulkheads were not adequate to withstand the additional missiles. Therefore, precast concrete bulkheads were placed in front of the door openings to provide the needed tornado missile protection. The precast concrete bulkheads consist of several individual sections stacked into place and bolted in position to the concrete walls. They will be removed only for major repair of the diesel generators.

The precast concrete bulkheads are 14-inches thick which is adequate to prevent penetration from the missiles in spectrum D. The 14-inch thickness is not sufficient to prevent some scabbing. However, the steel doors and bulkheads consist of exterior and interior skin plates, each 1/4-inch thick. Therefore, the thickness of the doors and bulkheads is sufficient to prevent scabbed particles from entering the diesel generator compartments. In addition, the steel doors open only to the exterior of the building, which means that the doors will always be closed when the precast concrete bulkheads are in place. The steel doors and bulkheads are also part of the building security system, which ensures that they will be closed during normal operation.

The diesel generator exhaust stacks are 22 inches in diameter and 1/4-inch thick. They extend 2 feet above the roof with a 12-inch-high splash guard to prevent entry of rainwater around the exhaust. The exhaust is protected from horizontal tornado missiles by the

3-foot-high parapet wall around the roof of the Diesel Generator Building. The top of the parapet wall is 48.5 feet above plant grade. From spectrum A (Table 3.5.5-2) the only credible missile at that elevation is the 1-inch-diameter steel rod.

Buried Piping

Tornado missile protection for all safety-related buried piping is provided by one of the five protective schemes described below.

1. 10 feet of compacted fine-grained soil.
2. 7 feet of compacted crushed stone.
3. 18 inches of conventional unreinforced concrete.
4. 18 inches of roller-compacted unreinforced concrete.
5. 7 feet of stone larger in size than 1032 for the dike area.

In each scheme, a 12-inch cushion of either compacted sand or fine-grained earthfill is required over the top of the pipe.

The acceptability of each scheme has been verified by a full-scale test program (Reference 13) in which missiles from the NRC spectrum were dropped from a helicopter into test pits of crushed stone or earthfill and onto concrete slabs. The missiles used in the testing were:

1. A 1500-pound utility pole,
2. A 12-inch-diameter schedule 40 steel pipe,
3. A 1-inch-diameter steel rod,
4. A 3-inch-diameter schedule 40 steel pipe, and
5. A 6-inch-diameter schedule 40 steel pipe.

Of these missiles, the 12-inch pipe and utility pole caused the greatest penetration depths. Impact velocities of 200-215 ft/s were achieved for both the utility pole and 12-inch pipe, which equals or exceeds the design velocities for those missiles. The protective thicknesses listed above are based on the maximum thicknesses observed in the test program and are, therefore, conservatively chosen.

TABLE 3.5.5-1

TORNADO MISSILE SPECTRUM FOR
CATEGORY I STRUCTURES - ORIGINAL DESIGN*

1. A 2-inch x 4-inch x 12-foot board weighing 40 lb/ft^3, end-on at a speed of 300 mi/h.

2. A crosstie, 7 inches x 9 inches x 8-1/2 feet weighing 50 lb/ft^3, end-on at 300 mi/h.

3. An automobile weighing 4000 pounds at a speed of 50 mi/h, 25 feet off the ground.

4. A steel pipe 2 inches in diameter x 7 feet long, end-on at 100 mi/h. The pipe will be assumed to penetrate in the same manner as a solid rod because in small diameter pipes it is unreasonable to assume that penetration takes place by coring.

*Note: This table is provided for historical purposes only. This was the spectrum of record when the construction permit for Sequoyah was issued.

TABLE 3.5.5-2

SEQUOYAH NUCLEAR PLANT
TORNADO MISSILE SPECTRUM A
FOR CATEGORY I STRUCTURES[1]

Missile[2]	Description	Design Velocity ft/s (mi/h)
A1	Wood plank, 2 inches x 4 inches x 12 feet long, weight 27 pounds	440 (300)
A2	Cross tie, 7 inches x 9 inches x 8.5 feet long, weight 186 pounds	440 (300)
A3	Automobile, weight 4000 pounds, 25 feet above grade	73 (50)
A4	Steel pipe, 2-inch diameter x 7 feet long, weight 26 pounds	147 (100)
A5	Steel rod, 1-inch diameter x 3 feet long, weight 8 pounds	210 (143)
A6	Utility pole, 13.5-inch diameter x 35 feet long, weight 1490 pounds, up to 30 feet above plant grade	200 (136)

Notes:

[1]Excluding the new ERCW pumping station and diesel generator equipment doors. In addition to the Category I structures, this missile spectrum also applies to the barrier for the Condensate Storage Tanks as described in Subsection 3.5.2.22.

[2]Missiles A1 through A4 were considered in original design for horizontal direction only. Missiles A5 and A6 were based on structural adequacy of as designed structures for local effects only (see discussion in section 3.5.5) and are applied in all directions.

TABLE 3.5.5-3 (Sheet 1)

TABULATION OF WALLS AND ROOFS OF CATEGORY I STRUCTURES WHICH ARE LESS THAN 2 FEET THICK

Location and Description		Thickness	Protects Equipment Important to Safety (Reference Regulatory Guide 1.117)
1. Auxiliary Building			
(1)	Wall on q-line between column lines A1 and A15 from elevation 756.0 to 762.0	18 inches	Yes
(2)	Walls of exhaust stack above roof at elevation 763.0	18 inches	No
(3)	Walls and roof of stair penthouse and airlock above roof elevation 791.75	12 inches	No
(4)	Walls on t-line between A5, A6, and A10, and all from elevation 763.0 to 790.63	12 inches	No
(5)	Upper portions of A5 and all line walls above elevation 765.83	18 inches	Yes
(6)	Walls of additional equipment buildings	18 inches	No
(7)	Walls and roof of air-conditioning equipment rooms	18 inches	Yes
(8)	Roof elevation 706.0 outside A1 and A15 lines	Slopes 16 inches to 18 inches	No
(9)	Roof elevation 763.0	12 inches	Yes
(10)	Roof elevation 778.0	12 inches	Yes
(11)	Roof elevation 791.75 (with metal deck)	Slopes 9-1/2 inches to 13-1/2 inches	Yes
(12)	Roofs of additional equipment building	12 inches	No

TABLE 3.5.5-3 (Sheet 2)

TABULATION OF WALLS AND ROOFS OF CATEGORY I STRUCTURES WHICH ARE LESS THAN 2 FEET THICK

Location and Description		Thickness	Protects Equipment Important to Safety (Reference Regulatory Guide 1.117)
(13)	East-west wall under roof at elevation 778.0, between A2 and A3 lines	12 inches	Yes
(14)	East-west wall under roof at elevation 778.0, between A13 and A14 lines	12 inches	Yes
(15)	North-south wall under roof at elevation 778.0, adjacent to north additional equipment building	18 inches	No
(16)	Air intake canopies on A1 and A15 lines	12 inches	No
(17)	Parapet walls on roof	Varies 9 inches to 12 inches	No
2.	Diesel Generator Building		
(1)	Main walls	18 inches	Yes
(2)	Main roof	Slopes 10-1/2 inches to 12 inches	Yes
(3)	Appendage outside main building		
	Walls	12 inches and 18 inches	No
	Roof	12 inches and 18 inches	No
3.	Main Steam Valve Rooms		
(1)	Blowout lids in roof of West Main Steam Valve Rooms, elevation 729.0	1/2 inch steel plate	Yes
(2)	Some of the exterior walls of the East Main Steam Valve Rooms	12 inches and 18 inches	Yes

TABLE 3.5.5-3 (Sheet 3)

TABULATION OF WALLS AND ROOFS OF CATEGORY I STRUCTURES WHICH ARE LESS THAN 2 FEET THICK

Location and Description	Thickness	Protects Equipment Important to Safety (Reference Regulatory Guide 1.117)
(3) West Main Steam Valve Room roof, elevation 765.0	See Note 1	Yes
4. Control Building		
Roof over the new air intake on top of Control Building with variable thickness	14 inches to 17 inches	Yes
5. New ERCW Pumping Station		
Parapet walls supporting steel grillage roof system	18 inches	Yes
6. Interim Pumping Station		
Parapet walls	21 inches	No
7. CO Storage Building		
Walls and roof	18 inches	No
8. Pipe tunnels to refueling water storage tank and primary makeup water storage tank		
Walls and roofs	Varies, 18 inches minimum	Yes
9. Class 1E electrical manholes and handholes		
Walls and roofs	See Note 1	Yes
10. ERCW overflow box		
Roof Walls (underground)	18 inches 6 inches minimum	Yes

3.6 PROTECTION AGAINST EFFECTS ASSOCIATED WITH THE POSTULATED RUPTURE OF PIPING

3.6.1 Systems in Which Design Basis Piping Breaks Occur

3.6.1.1 Main Reactor Coolant Piping System

The dynamic effects of double-ended postulated pipe ruptures in the reactor coolant loops have been eliminated from the design basis of the Sequoyah Nuclear Plant by the application of leak before break technology in accordance with the final rule change to General Design Criterion 4 (Federal Register Volume 52, Number 207, October 27, 1987, 41288). Authorization for their elimination is provided in Reference 2 and is based on fracture mechanics analyses results presented in Westinghouse WCAP-12011 (Proprietary) and WCAP-12012 (Non-Proprietary), "Technical Justification for Eliminating Large Primary Loop Pipe Rupture as the Structural Design for the Sequoyah Units 1 & 2" (Reference 3).

Design basis analyses were originally conducted based on the initial postulated double-ended breaks. With the application of leak before break technology, the pipe breaks described in Table 3.6.2-1 have been used to demonstrate the adequacy and acceptability of the plant design. These analyses shall remain the analyses of record unless indicated otherwise in this safety analysis report. Any future applications of, or relief taken based on the leak before break technology will be addressed on a case-by-case basis in a future update to this document.

As stipulated in the final rule change to GDC-4, a non-mechanistic double-ended rupture of the largest pipe in the reactor coolant system is still postulated for the purposes of containment design, ECCS design, and environmental qualification of electrical and mechanical equipment.

Previously postulated breaks in branch lines attached to the reactor coolant loops remain unaffected by this revision.

3.6.1.2 Other Piping Systems

Basic criteria used to evaluate effects resulting from a pipe failure inside containment (including the annulus and main steam valve rooms) at the Sequoyah Nuclear Plant are discussed below. The evaluation for pipe rupture outside containment and outside the main steam valve rooms is considered separately and is reported in TVA report No. CEB 72-22. While this report addresses protection against the dynamic effects of pipe failures, it also refers to associated evaluations for moderate and high energy line break flooding, as well as environmental studies for compliance with 10 CFR 50.49. These evaluations along with Design Criteria SQN-DC-V-13.9.3 and SQN-DC-V-21.0 document the basis for the Auxiliary Building High Energy Line Break (HELB) Detection System to provide main control room (MCR) indication upon detection of a HELB in the Auxiliary Building. This function is to ensure that environmental conditions remain bounded.

The criteria specifically defines acceptable consequences following a pipe failure, interaction effects of a whipping pipe, jet impingement, and environmental considerations. It includes criteria for postulating breaks for all piping systems except the main reactor coolant piping. Reactor coolant branch lines that connect to the main reactor coolant piping, including the pressurizer surge line are considered within the scope of "other piping systems." Assumptions regarding break size, shape, orientation, and location are in accordance with the intent of Regulatory Guide 1.46 (Rev. 0) and with the intent of guides transmitted to TVA by the NRC (AEC) in the December 1972 letter and with errata submitted in January 1973.

These criteria are intended to be conservative and allow a high margin of safety to be demonstrated. For those pipe failures where portions of these criteria lead to unacceptable consequences, further analyses based on more realistic assumptions will be performed. However, any less conservative criteria are adequately justified and fully documented for each case.

Definitions

The following definitions of pertinent terms are used in these criteria:

1. Inside Containment

For the purpose of these criteria, inside containment is defined to include all pipes and fittings inside the containment vessel and in the annulus and main steam valve rooms.

2. Pipe Failure

An instantaneous circumferential rupture, longitudinal split, or critical cracking of a pipe.

3. Pipe Whip

The movement of a pipe, subsequent to the formation of a plastic hinge, caused by the blowdown thrust resulting from a circumferential rupture or longitudinal split.

4. Jet Impingement

The hydraulic forces and temperature effects on components or structures produced by the direct impingement of a jet of process fluid (liquid or gas) emitting from a pipe failure.

5. Environmental Effects

The wetting, steaming, or flooding conditions, combustible fluid conditions, and temperature, pressure, or relative humidity changes within the zone of influence of a pipe failure in any area.

6. Zone of Influence

The maximum physical range of the direct effects of pipe whip, jet impingement, and/or environmental effects resulting from a pipe failure.

7. Single Active Failure

A single active failure is an occurrence which results in the loss of capability of a component (electrical, mechanical, instrumentation or control) to perform its intended active function upon command.

8. Reactor Coolant Pressure Boundary (RCPB)

The RCPB is the pressure retaining portion of the Reactor Coolant System and attached systems up to and including:

a. The outermost containment isolation valve in systems which penetrate primary reactor containment.

b. Second of two valves normally closed during normal reactor operation in systems which do not penetrate primary reactor containment.

c. Reactor Coolant System safety and relief valves.

9. Loss-of-Coolant Accident (LOCA)

A LOCA is the failure of RCPB piping that exceeds 3/8 inch inside pipe diameter and cannot be isolated. For a given mode of plant operation, the boundary of possible failure locations incapable of isolation (with single active failure) for piping connections extending from the Reactor Coolant System shall be limited, where applicable, to include only the following:

a. First locked closed or administratively closed isolation valve (pressurizer safety valves are included under this case).

b. Second of two normally open and remotely operable isolation valves capable of verification that they will close.

c. First normally closed check valve capable of verification that it is closed (incoming lines only).

d. Second of two normally open check valves capable of verification that they will close (incoming lines only).

e. First normally open and remotely operable isolation valve following a normally open check valve if both are capable of verification that they will close (incoming lines only).

If a pipe failure beyond the above defined boundary of possible failure locations could result in a normally open boundary valve failing to close, then the boundary of possible failure locations must be extended outward as necessary to include only valves which are not so affected.

10. Shutdown Logic Diagram

A logic diagram that establishes system requirements for reactor scram and shutdown to cold conditions following a given postulated accident.

11. Interaction Matrix

A matrix used to evaluate the extent of interaction between the pipe failure (source of interaction) and structures, systems, and components that are in the zone of influence of the pipe failure.

12. High-Energy Pipes

High-energy pipes are defined as those pipes which are in normal plant operation at a maximum temperature that is equal to or greater than 200°F and a maximum pressure that is equal to or greater than 275-lb/in^{2}g. The following are exceptions to this definition:

a. Piping components that experience the above conditions less than 1% of the plant operating life are excluded from this definition and are treated as low-energy piping. The RHR System is an example of such piping.

b. The connecting piping from the Safety Injection System accumulators to the Reactor Coolant System piping is considered as high-energy pipe. (This exception is based on the fact that a driving head is continued to be maintained during blowdown of the system.)

The definition of high-energy pipes is in agreement with criteria approved by the Nuclear Regulatory Commission and used for Browns Ferry Nuclear Plant. Those criteria for the Browns Ferry Nuclear Plant were submitted to the Commission during June 1973. Since the Sequoyah Nuclear Plant is of the same vintage as the Browns Ferry Nuclear Plant, the criteria for defining high-energy pipes are deemed to be acceptable.

Table 3.6.1-1 is a complete list (including maximum operating temperature and pressure) of all the piping systems inside containment where the TVA definition of high-energy piping is different from the one provided in Regulatory Guide 1.46.

Figure 3.6.1-1 illustrates the difference between the high-energy piping definition stated in Regulatory Guide 1.46 and that used in the Sequoyah Nuclear Plant pipe rupture analyses. The high-energy piping definition per Regulatory Guide 1.46 considers two regions of temperatures and pressure combinations that TVA has not classified as high energy.

One of these pressure temperature combinations (see Figure 3.6.1-1, Region A) has a maximum operating temperature equal to or greater than 200°F and pressure less than 275-lb/in^{2}g. This condition does not exist in any of the piping analyzed and therefore would not be of any consequence.

The other pressure temperature combination (see Figure 3.6.1-1, Region B) has a maximum operating pressure equal to or greater than 275 psig and temperature less than 200°F. The high-pressure piping associated with this region is a consequence of either a pump-driving head or pressure leakage past a valve that is in a line connected to the RCPB. The piping sections that are pressurized by a pump-driving head were investigated and the results indicated that the force associated with the pump-driving head at pump runout is not sufficient to cause equipment damage. The other category of piping, that pressurized by valve leakage because of the small leakage rate, does not have a jet driving force of sufficient duration to cause equipment damage. This extremely short jet duration is a result of the limited reservoir in the pipe section and the noncompressible nature of water.

There is one additional difference between the high-energy piping definition stated in Regulatory Guide 1.46 and that used in the pipe rupture analysis for Sequoyah Nuclear Plant. TVA excludes

piping runs from the definition of high-energy piping if they exceed the TVA classification of temperature and pressure less than 1% of the plant operating life. This exclusion is based upon the very low probability of experiencing a design basis rupture in a piping run while in this infrequent operational mode. This exclusion is consistent with the Nuclear Regulatory Commission's position for excluding very low probability events from consideration in safety analyses.

Therefore, based upon a general survey of the plant, it is concluded that an equivalent level of plant safety exists through use of the TVA criteria as would result if the TVA criteria precisely conformed to Regulatory Guide 1.46.

13. Low-Energy Pipes

Low-energy pipes are defined as those pipes which are in normal plant operation at a maximum temperature that is less than 200°F or a maximum pressure that is less than 275-lb/in^{2}g. Accumulator discharge piping that connects to Reactor Coolant Piping is excluded from this definition (see Item 12 above).

14. Engineered Safety Systems

Systems (mechanical, electrical, and instrumentation and control) designed to provide either a passive or active safety-related function to prevent and/or mitigate the consequences of postulated accidents.

15. Acceptable Interaction

An interaction for which, from a systems standpoint, the net required safety functions of systems, structures, and components are not impaired.

16. Active Component

Any component which must perform a mechanical motion or change of state during the course of accomplishing a safety function required to mitigate the effects of a given event.

17. Impact Barrier

An engineered structure located to limit pipe motion and designed to withstand the impact of a whipping pipe.

18. Interaction Evaluation Sheet

An itemized evaluation of interactions (shown on the interaction matrix) that indicates which interactions are acceptable or unacceptable, from a system standpoint, and which interactions result in intolerable damage.

19. Jet Deflector

A barrier which shields a target from the forces and environmental conditions within a jet.

20. Pipe Sleeve

A metal sleeve that encloses a portion of a process pipe that is designed to restrict jet forces and effects resulting from pipe failure.

21. Pipe Whip Restraint

An engineered structure which permits limited pipe motion and rotation and which limits or prevents pipe whip.

22. Plastic Hinge

A phenomenon resulting from a condition wherein a pipe receives external bending and/or torsional loading which causes a fully yielded cross section at one or more cross sections in the pipe.

23. Terminal Ends

Extremities of piping runs that connect to structures, components (e.g., vessels, pumps, etc.) branch connections, or pipe anchors that act as rigid constraints to piping thermal expansion. Inside containment a branch connection is not considered as a terminal end if each of the following are met:

a. That branch is modeled with the main piping run.

b. A rigorous ASME Class 1, 2, or 3, or a rigorous ANSI B31.1.0 analysis is conducted.

c. The nominal size of the branch line, in the vicinity of the branch connection, is greater than or equal to one-half the nominal size of the run.

24. Main Steam and Main Feedwater System Boundaries

The main steam and feedwater boundaries include tributary piping such as steam supply to the auxiliary feedwater turbine driven pump and the auxiliary feedwater discharge piping. The steam generator blowdown piping attached to the steam generator is classified as a feedwater type rupture. For branch lines connected to these systems, the boundary extends up to and including the first valve that is normally closed, or the second normally open check valve capable of providing isolation, or the second normally open valve capable of automatic closure.

3.6.2 Design Basis Pipe Break Criteria

3.6.2.1 Main Reactor Coolant Piping System

See Section 3.6.1.1.

3.6.2.2 Other Pipe Systems (Inside Containment)

3.6.2.2.1 Acceptability Criteria

In evaluating the consequential effects of pipe failure, multiple system or component failures resulting from the pipe failure is considered a part of the pipe failure. Any consequential effect of a subsequent single active failure is considered as part of the failure. The following criteria are not violated as a result of a postulated pipe failure.

The capability for automatic reactor scram and the ability to achieve and maintain a safe shutdown condition is not jeopardized even if the pipe failure is followed by a single active failure. The system requirements and available redundancy is that shown on a shutdown logic diagram, or an equipment list which defines the components that are necessary to mitigate the consequence of the postulated accident.

Radiation and environmental conditions within the control room or any location where manual action is required to achieve a safe shutdown condition is such as to assure the required habitability.

For a loss-of-coolant accident (LOCA), the following additional criteria apply:

1. Loss-of-containment leaktightness is prevented.

2. Failure of the steam-feedwater lines is prevented.

3. Propagation of the break to the unaffected reactor coolant loops is prevented.

Uncontrolled blowdown of more than one steam generator is prevented. (Potential multi-steam generator blowdown also includes failure of the main steam and feedwater system boundaries as defined in subsection 3.6.1.2(24)).

A main steam or feedwater pipe failure does not cause a LOCA. In evaluating instrument sense line interactions, redundancy of the lines and the ability to transmit adequate signals shall be evaluated in addition to consideration of the lines as extensions of the systems they sense. Evaluation of sense lines shall include those potential interactions identified above.

3.6.2.2.2 Pipe Failure Types, Sizes, and Orientation

1. Circumferential Rupture

   The break area is the cross-sectional flow area of the pipe at the break location. The plane of the break is normal to the pipe flow axis. Flow may be out of both ends of the break. This break is applicable to piping and branch runs whose diameter is greater than 1 inch nominal pipe size, and is postulated in high-energy piping at failure locations identified in Section 3.6.2.2.5.

2. Longitudinal Split

   The break area is assumed to be equal to the pipe flow area at the break location. The length of the break is assumed to be two inside pipe diameters and is parallel with the pipe flow axis. It may be located at any location around the circumference of the pipe. This break is applicable to piping and branch runs whose diameter is 4 inch nominal and larger.

3. Critical Crack

   The critical crack is assumed to have an opening length of one-half the pipe inside diameter and a width of one-half the wall thickness. It may be located at any point and oriented in any direction along the surface. Critical cracks are not postulated in piping 1 inch nominal diameter and less. It is applicable to low-energy piping but may be postulated in high-energy piping at particularly susceptible areas where the consequences could be severe.

3.6.2.2.3 <u>Failure Time</u>

Regardless of pipe failure type, the failure shall be assumed to open to its defined size instantaneously (developed within 1 millisecond).

3.6.2.2.4 <u>Failure Consequences</u>

The failure interactions that are evaluated to determine the consequences of failure are dependent upon the energy level of the pipe considered. They are as follows:

1. High-Energy Piping

   a. Pipe Whip Interaction
   b. Jet Impingement Interaction
   c. Environmental Interaction

2. Low-Energy Piping

   a. Jet Impingement Interaction (only if pressure exceeds 275 psig)
   b. Environmental Interaction

Jet impingement loads from cracks are considered on targets susceptible to load damage from these cracks only where the consequences could be severe.

3.6.2.2.5 <u>Failure Location</u>

Pipe failures in high-energy piping (excluding high-energy nonnuclear safety piping; i.e., main steam, extraction steam, condensate, feedwater, high-pressure drains, and vents) are postulated at the following locations (all safety-related piping has been designed in accordance with ANSI B31.1.0):

1. The terminal ends of piping or branch runs.

2. Any intermediate locations between terminal ends where the stresses calculated in accordance with ANSI B31.1.0 derived on an elastically calculated basis including loadings of a one-half shutdown earthquake and normal operational plant loading conditions exceeds 0.8 (S_h+ S_A).

3. Under regulatory requirements in effect prior to issuance of Reference 1 in section 3.6.9, the following criteria governed the postulation of arbitrary intermediate breaks:

   "If stress levels are such that a minimum of two intermediate locations between terminal points are not established in item 2 above, then additional breaks are postulated at the locations of highest combined stress level until the minimum is satisfied. However, for straight branch runs, no intermediate breaks are postulated unless the length of the run exceeds 20 pipe diameters or the requirements of item 2 above."

   In accordance with the revised requirements of Reference 1, postulation of break locations is now required only at terminal ends and at intermediate locations where the calculated stress exceeds the limits noted in item 2 above. These revised criteria will be implemented at SQN on a case-by-case basis where some benefit may be realized from the elimination of a previously postulated arbitrary intermediate break (AIB). Under such circumstances, the actions taken may include removal or inactivation of any mitigative devices installed as a result of that AIB. Each action of this type will be evaluated to ensure that there is no conflict with the current license or technical specifications.

4. Line-supported valves sometimes form the interface between high-energy lines and low-energy lines. In this case, terminal as described in item 1 does not exist at the line-supported valve. Prior to the issuance of Reference 1, the following alternate criteria were applied to piping runs or branches which have a high/low-energy interface with no stresses exceeding the limits stated in item 2:

Case 1: No terminal point in the high-energy portion.

a. For one or no elbow, one break is postulated at the highest stress point in the high energy portion.

b. For two or more elbows, two breaks are postulated at the highest stress point in the high energy portion.

Case 2: One terminal point in the high-energy portion.

a. For one or no elbow, one break is postulated at the terminal point in the high-energy portion.

b. For two elbows, one terminal point break and one intermediate point is postulated at the highest stress point in the high-energy portion.

c. For three or more elbows, one terminal point break and two intermediate points are postulated at the high-stress points in the high-energy portion.

Pipe failures in high-energy nonnuclear safety and high-energy field routed piping is postulated at all inline fittings and terminal ends. Circumferential ruptures and longitudinal splits are the failure types postulated. This procedure may be used as an alternate method for postulating breaks in other high-energy lines also.

The following exceptions are applicable for high energy piping:

a. Longitudinal splits are not postulated at:

   (1) Terminal ends or branch connections.

   (2) At intermediate locations where the criterion for a minimum number of break locations is applied (i.e., combined stresses do not exceed 0.8 (S_h + S_A).

b. If the stresses exceed 0.8 (S_h + S_A), longitudinal splits are not postulated if the stress in the axial direction is greater than or equal to 1.5 times the stress in the circumferential direction; and circumferential ruptures are not postulated if the stress in the circumferential direction is greater than or equal to 1.5 times the stress in the axial direction.

c. For high energy piping seismically analyzed in accordance with ANSI B31.1, critical cracks need not be postulated in piping with a nominal diameter greater than 1-inch where the primary plus secondary stress as defined in subsection 3.6.2.2.5(2.) is below 0.4 (S_h + S_A).

Low-energy piping (including low-energy nonnuclear safety and low-energy field routed piping) is not postulated to whip but is considered to fail (critical crack) at the most adverse locations with regard to jet impingement and environmental interactions. Jet impingement and environmental effects of a break size equal to a critical crack are evaluated for the worst case normal plant operating condition to determine if reactor scram and safe shutdown can be achieved with a subsequent worst single active failure. As a minimum, the ability to achieve a scram and safe shutdown condition is demonstrated including a subsequent worst single active failure.

For low energy piping seismically analyzed in accordance with ANSI B31.1, critical cracks may be excluded in piping with a nominal diameter greater than 1-inch where the following rules apply:

   a. The piping systems are located in or adjacent to areas containing structures, systems, and/or components important to safety provided they are enveloped by previously postulated high energy breaks in the same region, or

   b. Where the primary plus secondary stress as defined in subsection 3.6.2.2.5(2.) is below 0.4 (S_h + S_A).

The criteria for piping which extends from the containment penetrations to the first isolation valve outside containment are identical to that used for the remainder of the piping. Break exclusion criteria in these areas were not utilized for Sequoyah Nuclear Plant.

3.6.2.2.6 <u>Reanalyzed Piping</u>

When high energy piping has been analyzed, break locations identified, postulated breaks evaluated, and mitigative devices designed, reanalysis of the piping systems will alter the

previous pipe break locations and/or types only if:

a. There has been a significant geometry change in the routing of the high energy piping in the vicinity of the original intermediate breaks, or

b. The reanalysis results in stresses for which breaks must be postulated [section 3.6.2.2.5(2)] at any new intermediate locations in the high energy piping. In other words, if the allowable stress level [section 3.6.2.2.5(2)] in the high energy piping is exceeded at specific intermediate points in the reanalyzed piping, and that level was not exceeded at those points in a previous analysis, then additional break locations or revised type of breaks, as needed, will be evaluated at only those specific points.

3.6.3 Design Loading Combinations

3.6.3.1 Main Reactor Coolant Piping System

The design loading combinations for the Reactor Coolant piping are given in Section 5.2.

3.6.3.2 Other Piping Systems (Inside Containment)

3.6.3.2.1 Interaction Criteria

The following criteria define how interactions are evaluated in an interaction matrix.

3.6.3.2.2 Pipe Whip Interaction

A whipping pipe is considered to inflict no damage on other pipes and associated supports of equal or greater size and wall thickness.

An active component (electrical, mechanical, instrumentation, or control) is assumed incapable of performing its active function following impact by a whipping pipe.

Electrical cabling and wiring (including instrumentation and control) is considered to lose function upon impact by a whipping pipe.

Structural components are assumed to fail upon experiencing loads resulting from pipe impact that exceed the design allowable loading.

3.6.3.2.3 Jet Impingement Interactions

Piping subjected to jet impingement is assumed to fail if the pipe stress exceeds the allowables for the extreme loading condition as defined for the applicable piping classification. This evaluation is conducted using a screening criteria for separation distance based on the minimum distance required to assure that the stress associated with the jet load plus normal loads does not exceed the faulted allowable stress for the piping.

Piping and associated supports subjected to a jet force from a break in piping of equal or lesser nominal size and wall thickness are assumed to experience no unacceptable damage.

Electrical cabling and wiring (including instrumentation and control) that are not protected by an adequate conduit or cable tray design shall be considered to lose function, unless it is shown to be insensitive to the imposed environment and loadings. Conduit and instrument sense lines shall be assumed to fail if the stress resulting from jet loading exceeds the allowable for the extreme loading condition as defined for the applicable conduit and/or instrument sense line material and classification. This evaluation is conducted using separation screening criteria similar to that used for piping above.

Active components (electrical, mechanical, instrumentation, and control) are assumed incapable of performing their function if submerged in a jet, unless the component is shown to be insensitive to the imposed environment and loadings.

When the jet consists of steam or flashing subcooled liquid, unprotected equipment/components located at a distance greater than 10 diameters (broken pipe ID) from a large break (circumferential rupture or longitudinal split) opening or an equivalent break diameter from a critical crack (see subsection 3.6.2.2.2 for break sizes), shall be assumed to be undamaged by the jet without further analyses, provided that the environmental qualification of the target has not been exceeded.

Concrete erosion that may result from jet impingement is assumed to be of insufficient magnitude to jeopardize structural integrity.

3.6.3.2.4 Environmental Interaction

Electrical cabling and wiring (including instrumentation and control) is considered to lose function upon exceeding any of its environmental ratings.

An active component (electrical, mechanical, instrumentation, and control) is assumed incapable of performing its active function upon experiencing environmental conditions exceeding any of its environmental ratings. However, credit for the component may be taken if sufficient time is available for accomplishing its function before environmental ratings are exceeded.

Although the separation distance may be greater than 10 break diameters to preclude physical damage to unprotected targets, as stated in subsection 3.6.3.2.3, targets are evaluated to assure that their environmental rating is not exceeded.

Structural and concrete components are assumed to fail upon experiencing environmental loading conditions that exceed design limits.

3.6.3.2.5 Pipe Whip Restraint Design

The maximum design limits which are generally representative of those used in the design of pipe whip restraints are shown in the following table:

Type of Design	Energy Absorbing	Elastic
Loads considered	D, L, T_a, R_a, P_a, Y_r, Y_j, Y_m, and F_{eqs}	D, L, T_a, R_a, P_a, Y_r, Y_j, Y_m, and F_{eqs}

Stress/strain limits	50% uniform ultimate strain	1.5 S_m or 1.2 S_y, but not to exceed 0.7 S_u

The above elastic design limits are representative of those identified by Westinghouse in WCAP-8172-A for linear component supports associated with the primary loop (including those which also act as pipe whip restraints). For TVA scope of design, other than the primary loop, the applied load is limited to 0.9Y where Y is the maximum section strength based on plastic design with flow stress equal to 1.15 S_y (15% increase due to the high rate of strain and strain hardening). Plastic design methods are those described in Part 2 of AISC "Specification for the Design, Fabrication, and Erection of Structural Steel for Buildings," February 12, 1969.

Note: Earthquake and pipe rupture are not assumed to exist concurrently when evaluating the pipe whip restraints.

Stress/strain limits for crushable material utilized in restraint design are based on manufacturing data, analyses, and tests.

D = Dead load

L = Live Load

T_a = Thermal load resulting from postulated break

P_a = Pressure load resulting from postulated break

R_a = Pipe reactions resulting from postulated break

Y_r = Pipe restraint reactions resulting from postulated break

Y_j = Jet impingement load generated by postulated break

Y_m = Pipe whip impact load resulting from postulated break

F_{eqs} = Loads generated by safe shutdown earthquake

S_m = Design stress-intensity value at given temperature

S_y = Yield stress value at given temperature

S_u = Minimum ultimate tensile strength value at given temperature

Restraint design information for outside containment is contained in TVA report No. CEB 72-22.

3.6.4 Dynamic Analyses

3.6.4.1 Main Reactor Coolant System

See Section 3.6.1.1.

3.6.4.2 Other Piping Systems (Inside Containment)

The following other piping systems inside containment and inside the main steam valve rooms are considered for the effects of postulated ruptures upon plant shutdown:

Main Steam
Main Feedwater
Steam Generator Blowdown
Auxiliary Feedwater
Chemical and Volume Control
Component Cooling Water
Demineralized Water
Essential Raw Cooling Water
Primary Water
Residual Heat Removal
Safety Injection
Service Air
Waste Disposal
Containment Spray
Reactor Coolant
Spent Fuel Pool Cooling and Cleanup
Floor and Equipment Drains

The pressure time history, jet impingement load on targets, and the thrust resulting from the blowdown of postulated ruptures in piping systems is determined by thermal and hydraulic analyses or conservative simplified analyses.

In general, the loading that may result from a break in large high-energy lines is determined using a dynamic blowdown analysis. Other piping was analyzed using either a dynamic blowdown or a conservative static blowdown analysis. The method for analyzing the interaction effects of a whipping pipe with a restraint is one of the following:

1. Lumped parameter method

2. Equivalent static method

3. Energy balance method

For small high-energy lines, a conservative static analysis model is utilized.

3.6.4.2.1 Jet Impingement

A static analysis is used to determine jet impingement forces on distant objects. The magnitude of the impingement force is determined by integrating the jet pressure over the area of the object fronting into the jet stream. This method of analysis is for all jet impingement forces on distant objects. The assumption that the total jet thrust at all cross sections perpendicular to the axis of the jet are equal is used to determine the jet pressures at required distances from the fluid exit.

The pressure, however, is computed by two separate methods. For the large high-energy lines, a computer code is used to predict a time history of the jet thrust at the exit of the rupture from which, knowing jet cross-sectional area, the pressures are computed. Figure 3.6.4-1 shows a typical thrust-time history. Characteristically, the thrust is equal to line pressure times the area at the instant of rupture, and begins increasing thereafter as the fluid is accelerated out of the break. Within a short time, however, choking takes place at the break and the thrust drops sharply. After choking, a quasi-steady state thrust is established, and a gradual thrust (and pressure) decay begins as the fluid inventory in the system is depleted. Jet expansion half-angles of 20° and the assumption that the total jet thrust at all cross sections perpendicular to the axis of the jets are equal is used to determine the jet pressures at required distances from the fluid exit.

The following general criteria govern the time history analyses:

A. Analysis considers flow from both sides of break where there is significant stored fluid energy.

B. Discharge coefficients are equal to 1.0 for all breaks.

C. Credit is taken for flow limiters, line restrictions and pipe friction as applicable.

D. Breaks are assumed to occur instantaneously.

E. Initial condition for break is the worst case operational condition.

The program output includes time history values of mass flow, thrust, pressure, temperature, enthalpy and other thermodynamic quantities at specified points in the system and at the break.

For other lines and as an alternative to the computer analysis, the total thrust force, T, acting on the pipe at the break is conservatively taken as:

$T = 2.0\,(P_o - P_e)A$ (Subcooled blowdown)

$T = 1.26\,(P_o - P_e)A$ (Saturated, flashing, or superheated blowdown)

where

P_e = Initial atmospheric pressure

P_o = Initial line pressure

A = Break area

This thrust is considered as an instantaneously (developed within 1 millisecond) applied constant force.

The size, distance, and orientation of the target object with respect to the jet direction are considered in determining the magnitude of the jet impingement force. Specifically, drag coefficients which consider geometry and nonorthogonality of the target object with respect to the jet axis are used.

In addition, the calculated jet impingement force reflects the following:

A. When the effective target area is greater than the jet area at the point of impingement, the fluid momentum is completely canceled. In other words, the progress of the jet is effectively checked.

B. When the effective target area is very small compared with the jet area at the point of impingement, any change in the jet pressure caused by such a target is considered negligible for the purpose of evaluating loads on subsequent targets, so long as the jet is not bifurcated or otherwise altered.

C. Dynamic loading effects of the jet on the structure is considered by use of appropriate amplification factors. An amplification factor of 2.0 is normally used.

Several jet expansion half-angles are used in the industry for determining impingement pressures (see Figure 3.6.4-2). Large half-angles produce rapid decay of pressure and a large number of targets because of greater expansion of the jet envelope. Small half-angles, however, result in very large forces at great distances from the postulated break and a relatively small number of targets. TVA uses a 20° half-angle expansion for the evaluation of Sequoyah Nuclear Plant.

A general survey of the plant inside containment, including the adjacent main steam isolation valve buildings, has been conducted to identify structures, systems, and components in which a problem might result if a jet cone angle model currently accepted by the NRC (10° half-angle) was used instead of the TVA accepted 20° half-angle conical model. It is concluded from the survey made that the NRC model would yield essentially a similar set of evaluation results and that the protection requirements currently being implemented provide either equivalent or essentially identical protection. This conclusion is based upon the fact that since systems and components are in close proximity inside these structures the loading effect was generally unacceptable in nearly all cases for the 20° jet model. Protection requirements currently being incorporated are designed to either redirect the jet or assure the loading does not result in unacceptable consequence to the adjacent components. While the 10° model would yield a lesser number of components impinged upon and conceivably fewer protection requirements, essentially identical protective devices would be required.

Therefore, no significant change in protective requirements for structures, systems, and components would result if the NRC currently accepted jet model was used for the evaluation of the Sequoyah Nuclear Plant inside containment or inside the main steam isolation valve buildings.

3.6.4.2.2 Pipe Whip Evaluation

A pipe whip evaluation is performed for each of the postulated high-energy design basis ruptures. The initial portion of this evaluation consists of analyses to determine those pipe runs

and branches where pipe whip would actually result from rupture. The predicted pipe whips are then investigated with respect to their potential for damage to essential plant equipment and structures. Finally, locations and design loads are developed for pipe whip restraints required to prevent unacceptable damage to equipment and structures.

In general, the analyses for large high-energy lines, for which pipe whip would represent substantial plant damage potential, is carried out using a computer program. The analyses for smaller lines make use of simplified techniques using dynamic load factors. The following general criteria is applied to the entire pipe whip evaluation:

A. The dynamic nature of the piping thrust load is considered.

B. Nonlinear (elastic-plastic strain hardening) pipe and restraint material properties are considered.

C. Pipe whip is considered to result in unrestrained motion of the pipe along a path governed by the hinge mechanism and the direction of the vector thrust of the break force.

D. The effect of rapid strain rate on material properties is considered. In the absence of justification to the contrary, a 10% increase in yield and ultimate stress under dynamic load is assumed.

For large high-pressure steam lines, postulated breaks produce very high blowdown forces. The gaps provided for thermal expansion cause amplification of these forces, and the magnitude of the amplification is dependent upon the amount of gap provided for the particular line. For the large number of restraints required to contain the pipes against postulated pipe failure, two approaches are available:

(1) Design the restraints, supplementary steel, embedments, and building elements to accommodate large dynamic load factors and minimize the detail of analyses and design used for the restraints.

(2) Design the supplementary steel, embedments, and building elements to accommodate a lesser dynamic load factor (2.0) and perform more refined design of the restraints. This design utilized techniques such as inelastic considerations, crushable materials, etc., and sufficient analyses to demonstrate that the load factor of 2.0 is not exceeded in the actual design.

A dynamic load factor of 3.0 (option 1 above) is used for small lines and wherever technical and economic considerations allow. For very large lines, option 2 is implemented.

For each rupture, for which it is determined that pipe whip can occur, a listing of all possible interactions is prepared. The result is a matrix showing all ruptures versus all targets. Further analyses determine the acceptability of each interaction with respect to the overall capability of achieving a safe shutdown of the plant.

In cases where it is determined that damage resulting from pipe whip is not acceptable, pipe whip restraints or other preventive measures are developed. The pipe whip restraints are

designed with an initial clearance to prevent interference with the pipe in normal operation. Impact effects due to this clearance are considered. The restraint design considers elastic-linear strain hardening of the material.

3.6.4.2.3 Structural Evaluation

A structural evaluation is performed to assess the effects of the postulated pipe break on essential plant structures. This evaluation includes:

A. Analysis of structural components and structures for pipe whip impacts and jet impingements.

B. Analysis of structures and structural support systems for pipe whip restraint and jet impingement barrier reaction loads.

C. Analysis of piping anchor structures for pipe break loads.

The following criteria are applied in the structural evaluation:

A. Damage to any structure, caused either directly or indirectly via failure of an adjacent structure, does not impair function of any system or component required for protection, mitigation of consequences, or safe shutdown following the pipe break.

B. Pipe break does not result in collapse of any Category I structures.

C. The structural integrity of the primary containment fission product barrier is maintained.

D. The structural integrity and habitability of the control room and the shutdown board room is preserved.

E. Structural analyses for pipe rupture loads are generally performed using limit analyses techniques, such as collapse load analysis for beams and frames and yield line theory for concrete slabs. Account is taken for resistance of structural elements in their plastic range.

F. Maximum section strength of concrete structures is computed using the ultimate strength design method. Maximum section strength of steel members is based upon the assumption of elastic-perfectly plastic material properties and plastic design criteria (Reference Section 3.6.3.2.5).

In general, for large high-energy lines whose failure could cause substantial plant damage, either the lumped-parameter or the energy-balance analysis model is used. For other systems, the static analysis model is used. Dynamic response amplification is accounted for by multiplication of loads by appropriate dynamic factors.

3.6.5 Protective Measures

3.6.5.1 Main Reactor Coolant Piping System

Per Section 3.6.1.1, the dynamic effects of ruptures in the primary coolant loop have been eliminated.

The following Section describes the remaining protective measures/devices.

3.6.5.1.1 Pipe Restraint Design Criteria

All main coolant loop pipe whip restraints are inactive.

3.6.5.1.2 Protective Provisions for Vital Equipment

In addition to pipe restraints, barriers and layout are used to provide protection from the effects of pipe rupture. In reviewing the mechanical aspects of these lines, it is demonstrated by Westinghouse Nuclear Energy System tests that lines hitting equal or larger size lines of same schedule do not cause failure of the line being hit, e.g., a 1-inch line, should it fail, does not cause subsequent failure of a 1 inch or larger size line. The reverse, however, is assumed to be probable, i.e., a 4-inch line, should it fail and whip as a result of the fluid discharged through the line, could break smaller size lines such as neighboring 3-inch or 2-inch lines.

Whipping in bending of a broken stainless steel pipe section such as used in the Reactor Coolant System does not cause this section to become a missile. This design basis is demonstrated by performing bending tests on large and small diameter, heavy and thin-walled stainless steel pipes.

3.6.5.1.3 Criteria for Separation of Redundant Features

There are no redundant features associated with the Main Reactor Coolant Piping System.

3.6.5.1.4 Separation of Piping

This topic is not applicable to the Main Reactor Coolant Piping System.

3.6.5.1.5 Pipe Restraints and Locations

In the original construction of Unit 1 and Unit 2, there were three piping restraints for the main reactor coolant piping. These were located on the crossover leg pipe; one at each end of the horizontal run and the other at the center of the vertical run on the steam generator side. As illustrated in Figure 5.2.1-4, the crossover vertical run restraint and both the crossover horizontal run restraints were deactivated as a result of activities performed by the Unit 1 and Unit 2 Steam Generator Replacements.

These supports are discussed further in Section 5.2.

3.6.5.2 Other Piping Systems

For examples of piping inside containment see Sections 3.6.7.6 and 3.6.7.7. For piping outside containment refer to TVA report No. CEB 72-22.

3.6.6 Assumptions

The following assumptions are made relative to plant operation before and after a pipe failure.

3.6.6.1 Plant Operating Mode

At the time of pipe failure, the plant will, in general, be assumed to be in any mode of normal plant operation. For safety-related piping components, the normal plant mode of operation including the 1/2 SSE which produces the highest stress levels is the applicable mode for postulating the pipe failure locations.

Examples of possible normal plant operating modes are:

1. Plant startup
2. Shutdown cooling
3. Cold shutdown
4. Operation at power
5. Hot standby
6. Testing
7. Refueling

3.6.6.2 Offsite Power

If determined to be a worst case, offsite power, in addition to the single active failure, is assumed to be unavailable during a portion of or throughout the sequence of events that follow a pipe failure. If, however, a detailed analysis can be provided to show that a loss of offsite power is not a consequence of the pipe failure, then a loss of offsite power is not assumed.

3.6.6.3 Unintended Operation of Equipment

The performance of an unintended active function by affected equipment in the zone of influence of a pipe failure is not considered unless the evaluation indicates specific cause/effect reasons for such occurrences.

3.6.6.4 Operator Response

It is assumed that a proper sequence of events is initiated by the operator to bring the plant to a safe condition with the capability of going to a safe shutdown if required. However, it is assumed that no action is initiated for at least ten minutes after pipe failure.

3.6.7 System Evaluation

3.6.7.1 General

The evaluation presented herein was conducted specifically for Unit 1 of the Sequoyah Nuclear Plant. However, because of the similarity with Unit 2, all relevant conclusions presented for Unit 1 are generally applicable for Unit 2.

3.6.7.2 Objective

The objective of this study is to determine if the plant could be placed in and maintained in a safe shutdown condition following a postulated pipe failure in any of the high or low-energy piping inside containment or inside the main steam valve rooms. Pipe failures are evaluated in accordance with subsections 3.6.2 and 3.6.3. Each postulated pipe failure inside containment and inside the main steam valve rooms is examined to assure that the consequences of the failure could be effectively mitigated. The evaluation for pipe rupture outside containment and outside the main steam valve rooms is considered separately and is reported in TVA report No. CEB 72-22.

3.6.7.3 Guiding Philosophy

The methods used to postulate breaks, identify interactions, evaluate damage, and determine the consequences are rigorously systematic. Two considerations are paramount: (a) assurance that all credible dynamic effects of the postulated breaks are addressed, and (b) assurance that protection is provided for those systems and components which are essential in safety system response to a particular postulated event.

3.6.7.4 Exclusions

3.6.7.4.1 Field Routed Systems

Field routed piping and cabling are generically considered as targets of pipe failure effects, with the piping also considered as a source. Final field routes were determined during plant construction. Therefore, selection of individual targets and evaluation of the effects of failure in field routed systems were accomplished during an engineering followup with field evaluation to assure conformance to separation data on Units 1 and 2. Notification of the completion of the evaluation of field routed piping, inside containment and inside the main steam valve rooms, was provided to NRC by letter on December 16, 1983.

3.6.7.4.2 Flooding

Flooding resulting from postulated ruptures of the primary loop is more severe than flooding from any other break postulated .

The primary loop flooding is considered as the limiting condition in the design of the facility. There are no components within the containment in which flooding would jeopardize the ability to shut down the plant and maintain it in a safe shutdown condition.

3.6.7.4.3 Containment Pressurization

Pressurization of containment resulting from a postulated pipe rupture is not considered in this evaluation. The effect of a postulated primary loop rupture formed the pressurization design bases for the containment design.

3.6.7.5 Evaluation Procedure

Safety functions are identified for each initiating event by means of shutdown logic diagrams (SLD). The SLD identifies at least one success path from the postulated event to each protective function required to prevent the event's potentially unacceptable results. Each SLD includes the set of all safety systems necessary to provide the protective function specified at the end of the success path.

An interaction matrix is constructed for each postulated pipe rupture inside containment. The matrix consists of a chart showing every credible interaction for each postulated break.

All possible interactions are evaluated to determine their credibility, damage potential, and acceptability from the standpoint of safe shutdown capability.

3.6.7.6 Main Steam

3.6.7.6.1 Description of Piping System

The main steam supply system is a high-energy system designed to conduct steam from the steam generator outlets to the turbines and to the condenser steam dump system. This system also supplies steam to feedwater pump turbines, auxiliary feedwater pump turbines, and turbine seals.

The main steam supply system includes self-actuating safety valves to provide emergency pressure relief for steam generators, and atmospheric relief valves to provide the means for plant cooldown by steam discharge to the atmosphere if the turbine bypass system is not available.

The major portion of this system evaluated herein is 32" OD lines which begin at the steam generator outlets, descend to the crane wall penetration, extend through the guard pipes and bellows, penetrate the freestanding containment vessel and shield wall, then terminate at the flued anchor after traversing the main steam valve rooms. At the flued anchor the piping changes from TVA Class B to TVA Class H.

3.6.7.6.2 Protection Requirements

A rupture in a main steam line does not result in any of the following unacceptable events:

1. Initiate a LOCA.

2. Impair containment integrity to the limits that the intent of 10 CFR 100 is violated.

3. Render inoperative any engineered safeguard system.

4. Cause failure of any other steam or feedwater line that could result in an uncontrolled blowdown of more than one steam generator.

5. Reduce flow capability of the Auxiliary Feedwater System below minimum requirements.

3.6.7.6.3 Postulated Break Locations

Figures 3.6.7-1 and 3.6.7-2 show the approximate routing of the main steam lines from each steam generator to the flued head anchors in the outside wall of each main steam valve room. Also shown in these figures are locations of the break points postulated for each main steam piping run considered in this report. Table 3.6.7-1 shows the combined stress values for the postulated main steam line ruptures. (Note: The stress values listed are for example and historical purposes only)

3.6.7.6.4 Protective Measures

Pipe rupture restraints, sleeves, and jet deflectors are used to mitigate the consequences of postulated main steam line ruptures.

Figures 3.6.7-1 and 3.6.7-2 indicate the approximate locations and the type of mitigation component for each postulated break location.

Table 3.6.7-2 is a checklist showing that protection is provided for all unacceptable consequences of main steam line ruptures.

3.6.7.7 Main Feedwater

3.6.7.7.1 Description of Piping System

The feedwater system is designed to supply a sufficient quantity of feedwater to the steam generator secondary side inlet during all normal operating conditions.

The feedwater system delivers water to the steam generators at an elevated temperature and pressure. These lines are high energy from the feedwater pumps to the inlet of the steam generators.

The major portion of the feedwater piping evaluated herein is 16" OD lines designated as a TVA Class B system. The evaluated portion begins at the flued anchor at the exterior wall of the main steam room. The piping continues through the valve rooms (and isolation valves) and through guard pipes and bellows, penetrates the shield wall, the containment liner, crane wall, and terminates at the inlet of the steam generator. The piping termination at the Unit 2, Loops 2, 3, and 4 and Unit 1, Loops 1, 2, 3, and 4 steam generator feedwater nozzle is a specially designed elbow with an integral thermal liner for the purpose of mitigating thermal fatigue cracking. For further information regarding the elbow/liner, see Table 3.2.1-2. The piping termination at the Unit 2, Loop 1 steam generator feedwater nozzle is a short radius elbow without an integral thermal liner installed during the U2R18 outage in November 2012. As documented in 13.9.1 Appendix A, Section A.2.2.2, a fatigue analysis was performed on this elbow and the elbow has acceptable fatigue usage for the 40-year design cycles of the Replacement Steam Generator.

3.6.7.7.2 Protection Requirements

Same as Section 3.6.7.6.

3.6.7.7.3 Postulated Break Locations

Figures 3.6.7-1 and 3.6.7-2 show the routing of the feedwater lines from the steam generators to the flued head anchors in the exterior walls of the main steam valve rooms. Postulated break locations are shown in these figures for all feedwater ruptures considered herein. Table 3.6.7-3 shows the combined stresses of the main feedwater postulated break points. (Note: The stress values listed are for example and historical purposes only)

3.6.7.7.4 Protective Measures

Pipe rupture restraints, sleeves, and jet deflectors are used to mitigate the consequences of postulated main feedwater line ruptures.

Figures 3.6.7-1 and 3.6.7-2 indicate the approximate locations and the type of mitigation component for each postulated break location.

Table 3.6.7-2 is a checklist showing that protection is provided for all unacceptable consequences of main feedwater ruptures.

3.6.8 Welds

Welding for pipe rupture mitigative structures designed to the requirements of AISC was in accordance with the American Welding Society (AWS), "Structural Welding Code," AWS D1.1-72 as implemented by TVA General Construction Specification G-29C. Nuclear Construction Issues Group documents NCIG-01, Revision 2, may be used after June 26, 1985, to evaluate weldments that were designed and fabricated to the requirements of AISC/AWS. When invoked, NCIG provisions will be implemented as follows:

1. An engineering evaluation of the structures will be performed and documented to determine that the provisions of NCIG-01 are consistent with the engineering considerations used for the design basis.

2. The applicability of the NCIG documents will be specified in controlled design output documents such as drawings and construction specifications.

3. Inspectors performing visual weld examination to the criteria of NCIG-01 will be trained in the subject criteria. Training of inspectors will be documented.

Hydraulic models are used to generate time-dependent hydraulic forcing functions used in the analysis of the reactor coolant loop for each break size.

TABLE 3.6.7-1

SUMMARY OF COMBINED STRESSES AT BREAK LOCATIONS FOR MAIN STEAM LINES

Piping for Steam Generator	Break Location Joint No.	Combined Stress lb/in^2	Type Break
	S1-1	18,800	Terminal end
No. 1 (Figure 3.6.7-1)	S1-4	11,810	Terminal end
	S2-1	17,830	Terminal end
No. 2 (Figure 3.6.7-2)	S2-4	27,980	Terminal end
	S3-1	19,190	Terminal end
No. 3 (Figure 3.6.7-2)	S3-4	18,350	Terminal end
	S4-1	19,060	Terminal end
No. 4 (Figure 3.6.7-1)	S4-4	12,060	Terminal end

Note: $0.8 (S_h + S_A) = 35{,}000$ lb/in^2

All breaks are circumferential.

* Postulation of an arbitrary intermediate break is no longer required per reference 1 in section 3.6.9 and as noted in section 3.6.2.2.5 of this document. This break and any attendant devices designed solely to mitigate this break may be deleted on a future date based upon TVA's judgment that the action would result in enhanced plant operability or maintainability or reduced worker radiation exposure (where applicable).

TABLE 3.6.7-2

CHECKLIST OF PROTECTION PROVIDED AGAINST UNACCEPTABLE CONSEQUENCES OF MAIN STEAM AND FEEDWATER LINE RUPTURES

	Systems Analyzed							
	Main Steam Loops				Main Feedwater Loops			
Unacceptable Event	1	2	3	4	1	2	3	4
Prevent loss-of-coolant accident	X	X	X	X	X	X	X	X
Prevent the loss of essential safety systems	X	X	X	X	X	X	X	X
Prevent the blowdown of more than one steam generator	X	X	X	X	X	X	X	X
Isolate feed to affected steam generator	X	X	X	X	X	X	X	X
Prevent blowdown through feedwater system after main steam line rupture	N/A	N/A	N/A	N/A	X	X	X	X
Prevent blowdown through main steam line after main feedwater rupture	X	X	X	X	N/A	N/A	N/A	N/A
Protect secondary pressure control	X	X	X	X	X	X	X	X
Protect auxiliary feedwater to three steam generators	X	X	X	X	X	X	X	X
Protect the pressure retaining integrity of the containment vessel	X	X	X	X	X	X	X	X
Protect jet impingement (and resulting ice condenser "melt-through") of critical crack on ice condenser lower inlet door	X	X	X	X	X	X	X	X

X - Indicates protection provided against unacceptable event.

NA - Not Applicable.

3.7 SEISMIC DESIGN

3.7.1 Seismic Design for Structures

Structures for which this seismic design is applicable are listed in Table 3.7.1-1. The structures shown in Table 3.7.1-1 were included in the original plant design. All of these structures were analyzed and designed according to the same criteria.

3.7.1.1 Design Response Spectra

See Section 2.5.2.4 for the discussion and description of the design response spectra.

3.7.1.2 Design Response Spectra Derivation

See Section 2.5.2.4 for discussion of derivation of the response spectra. The system period intervals at which the spectra of the four artificial earthquakes were calculated are listed in Table 3.7.1-2.

3.7.1.3 Critical Damping Values

Table 3.7.1-3 lists the damping ratios used for the dynamic analyses of Category I structures shown in Table 3.7.1-1 and for the systems and components in these structures. Soil damping is also included in Table 3.7.1-3. For applicable stress criteria see Section 3.8.

3.7.1.4 Bases for Site Dependent Analysis

A site dependent analysis was not used to develop the shape of the design response spectra. However, in response to NRC questions about the adequacy of the seismic basis, a site specific analysis was performed. 84th percentile spectra were developed for this site specific analysis. The 84th percentile spectra were used to verify the adequacy of the seismic design for the major Category I structures. See Section 2.5.2.4 for the design response spectra.

3.7.1.5 Soil-Supported Category I Structures

Table 3.7.1-1 lists all Category I structures which were included in the original design of the plant. Table 3.7.1-4 lists all of the soil-supported Category I structures which are listed in Table 3.7.1-1. This table lists the structures with the depth of soil over bedrock. Pile- and caisson-supported Category I structures of Table 3.7.1-1 are listed in Table 3.7.1-5.

3.7.1.6 Soil Structure Interaction

For Category I structures (see Table 3.7.1-1) founded upon soils the rock motion was amplified to obtain the ground surface motion by considering the soil deposit as an elastic medium and making a dynamic analysis of a slice of unit thickness using only the horizontal shearing resistance of the soil. The four artificial earthquakes mentioned in Section 2.5.2.4 were considered as the input motion at the top of rock. Once the time history of surface accelerations was known, a response spectrum was produced for the analysis of the soil-supported structure.

The vertical surface motion was obtained by amplifying two-thirds of the horizontal rock motion vertically through the soil column as mentioned above.

The soil amplification analysis is affected by the accuracy of in situ soil measurements, slanted soil layers, soil density variations, and depth of the soil deposit. Therefore, for structures supported on a soil deposit with variations in properties and depths of the soil deposit beneath the structure, parameters were varied to obtain different ground motion spectra. An envelope was drawn from these spectra resulting in the final ground motion spectrum used in analyzing the structure. The soil supported structures were analyzed using the lumped mass and soil spring model shown schematically in Figure 3.7.1-1.

By doing the above for soil-supported structures, the maximum amplification of the ground response was obtained and the peak width of the ground response spectrum was wide enough to allow for variations in the frequencies of the structure due to variations in soil parameters.

For the rockfill dike near the ERCW Pump Station, as shown in Figure 3.7.1-2, the soil amplification was computed using a two dimensional finite element program. The four artificial earthquakes mentioned in section 2.5.2.4 were used as the input motion at the top of rock: The properties of the model were varied to envelope the variation of the soil and rockfill properties. The output (accelerations, stresses, strain, etc.) from the four earthquake analyses for each material variation were averaged. The averaged output for each material variation were compared and the maximum output was used in the stability analysis of the dike (refer to Paragraph 2.5.6.2.3).

3.7.2 Seismic System Analysis

The analysis of Category I systems and components is accomplished, where applicable, using the response spectra or time-history approach (Refs. 10, 11, 12) which utilizes the natural period, mode shapes, and appropriate damping factors of the particular system. Where analytical methods of analysis do not produce results of a sufficient confidence level, dynamic testing of equipment is used to ensure functional integrity. The seismic analysis methods used for the Category I structures, systems, and components are covered in this section.

3.7.2.1 Category I Systems and Components Supplied by Westinghouse/Framatome

An important step in the seismic analysis of Category I systems is the procedure used for modeling. The system is represented by lumped masses and a set of springs idealizing the stiffness properties of the system. Modeling techniques are presented in References 13 and 22.

3.7.2.1.1 Category I Piping Supplied by Westinghouse

The seismic response of Seismic Category I piping and components within Westinghouse scope of responsibility is determined as part of a multidegree of freedom model which includes the support characteristics. This model is a multimass mathematical representation of the system. A sufficient number of masses are included to ensure an accurate determination of the dynamic response.

Horizontal and vertical seismic envelope spectra are prepared which encompass the floor response spectra at the elevations where the piping system attaches to the building structure. The system is analyzed for the simultaneous occurrence of these horizontal and vertical seismic input motions. The results for the vertical excitation are added directly to the results for north-south and east-west excitations. The larger of the two values so determined at each point in the model is considered as the earthquake response. The envelope spectra are compared with the horizontal and vertical floor response spectra developed from the building time-history analyses to assure conservatism of the spectra used.

3.7.2.1.2 Seismic Analysis of Reactor Vessel Internals

A standard Reactor Building with the reactor vessel support, the standard four loop plant reactor vessel, and the reactor internals are included in the multimass mathematical model used to determine the dynamic response of the reactor internals. The mathematical model of the building, attached to rock, is similar to that used to evaluate the building structure. The reactor internals are modeled as a single degree of freedom system for vertical earthquake analysis, since previous analyses have shown that this is its behavior. The reactor internals are mathematically modeled by beams, concentrated masses, and linear springs for horizontal earthquake analysis.

All masses, water, and metal are included in the mathematical model. All beam elements have the component weight or mass distributed uniformly, e.g,, the fuel assembly mass and barrel mass. Additionally, wherever components are attached uniformly their mass is included as an additional uniform mass, e.g., baffles and formers acting on the core barrel. The water near and about the beam elements is also included as a distributed mass. Horizontal components are considered as a concentrated mass acting on the barrel. This concentrated mass also includes components attached to the horizontal members since these are the media through which the reaction is transmitted. The water near and about these separated components is considered as being additive at these concentrated mass points.

The concentrated masses attached to the barrel represent the following:

1. The upper core support structure, including the upper vessel head and one-half the upper internals;

2. The upper core plate, including one-half the thermal shield and the other half of the upper internals;

3. The lower core plate, including one-half of the lower core support columns;

4. The lower one-half of the thermal shield;

5. The lower core support, including the lower instrumentation and the remaining half of the lower core support columns.

The modulus of elasticity is chosen at its hot value for the three major materials found in the vessel, internals, and fuel assemblies. In considering shear deformation, the appropriate

cross-sectional area is selected along with a value for Poisson's ratio. The fuel assembly moment of inertia is derived from experimental results by static and dynamic tests performed on fuel assembly models. These tests provide stiffness values for use in this analysis. The fuel assemblies are assumed to act together and are represented by a single beam. Figure 3.7.2-1 shows the mathematical model used.

The analysis is performed for the simultaneous occurrence of horizontal and vertical seismic input motions. The results for the vertical excitation are added directly to the results for north-south and east-west excitations. The larger of the two values so determined at each point in the model is considered as the earthquake response.

The first mode of vibration of the reactor internals obtained from the eigenvalue- eigenvector solution using the model of Figure 3.7.2-1 is shown in Figure 3.7.2-2. The response of the internals is obtained by adding the maxima of the responses for each mode or by taking the square root of the sum of their squares (SRSS).

The results obtained from the linear analysis indicate that during an earthquake, the relative displacements between the components may close the gaps and consequently the structures can impinge on each other. It is clear that linear analysis does not provide information about the impact forces generated when components impinge each other, but has the advantage of simplicity and provides information about the natural frequency of the system. Therefore, for those cases where components would be expected to impinge each other, linear analysis is applied but the gaps are conservatively treated as being closed. Reference 15 provides further details.

The criterion for normal plus 1/2-SSE loadings is that the stresses are limited to those given by the ASME Nuclear Power Plant Components Code for upset conditions. These limits are intended to assure that the reactor will be able to continue or resume operation. For the normal plus SSE and the normal plus SSE plus DBA loading conditions, the criterion for acceptability in regard to mechanical integrity analyses is that adequate core cooling and core shutdown must be assured. This implies that the deformation of the reactor internals must be sufficiently small so that the geometry remains substantially intact. Consequently, the limitations established on the internals are concerned principally with the maximum allowable deflections and/or stability of the parts. The deflections caused by the SSE are small in comparison to those caused by the DBA. Accordingly, faulted limits for the internals are covered in Section 3.9.3.

3.7.2.1.3 Seismic Analysis of Ice Condenser

Linear Seismic Analysis

The lattice frame-ice basket-lower support structural assembly is modeled as an interconnected system without gaps. A linear elastic dynamic analysis is performed using the response spectra defined for the site.

Each level of lattice frames encompasses an approximate 300 degree horizontal arc and consists of 72 lattice frames. One level of eight levels of lattice frames was modeled so that the structural coupling between individual lattice frames could be evaluated.

The dynamic model used to determine the horizontal response characteristics of one level of lattice frames is shown in Figure 3.7.2-3. It is a lumped mass beam representation. Cantilever beam elements are used to represent the bending and shear stiffness of six interconnected lattice frames as shown in Figure 3.7.2-4. For the model shown in Figure 3.7.2-3, the mass associated with a set of six lattice frames is lumped at the end of the cantilever beam. The length used for the cantilever beam is representative of the distance to the center of gravity of the ice baskets associated with one lattice frame. The lumped masses are connected by tie members representing the combined coupling stiffness of six lattice frames.

In order to determine proper lattice frame stiffness, the lattice frame structure was modeled in detail using the finite element computer code STRUDL. A typical model of the lattice frame is shown in Figure 3.7.2-5. The wall panel is represented by stiffness elements in the model. Therefore, the stiffness values determined include the effect of the wall panel.

A Westinghouse computer program was used to obtain the dynamic response characteristics of one level of lattice frames. It was determined that the structural coupling between individual lattice frames is negligible and that the fundamental response of the ice bed-lattice frame is essentially that of the individual lattice frames acting independently. Therefore, a lattice frame can be uncoupled from those in its same level for modeling purposes.

A multilevel horizontal dynamic model is used to obtain the horizontal seismic response of the lattice-frame ice basket assembly. This model is shown in Figure 3.7.2-6. Each level is represented by one lattice frame. Their stiffness properties are introduced into the model using stiffness element. The ice baskets are lumped in groups of nine and represented by lumped mass beam elements. A response spectra analysis was done using a computer program which performs conventional modal analysis. The model was analyzed for out-of-plane as well as in-plane motion to give tangential and radial loads, respectively.

Non-linear Seismic Analysis

A clearance or gap is required at the ice basket supports for installation and maintenance reasons. A schematic view of the ice basket gap is shown in Figure 3.7.2-7. The design value for the gap is 1/4 inch radially or 1/2 inch on the diameter.

The effect of the gap during a seismic excitation is two fold. First, impact loads will be applied to the ice basket as it bounces within the clearance, which produce higher loads in the ice basket than would exist if there were no gap. Second, the repetitive impacting at the ice basket supports will dissipate substantial amounts of energy. Stated differently, there will be higher damping within the structure than would exist if there were no gaps. This effect is illustrated with actual test results in Figure 3.7.2-8.

Analytical Procedure and Typical Results

Using typical results obtained from the non-linear dynamic model, the procedure used in the nonlinear analysis will now be discussed. First, the input acceleration time histories are converted to displacement time histories by double integration as shown in Figures 3.7.2-9 through 3.7.2-11. The displacement time histories were then input to the non-linear dynamic model. Results are shown in Figures 3.7.2-12 through 3.7.2-14 for the case corresponding to a 1/2-inch gap between the ice basket and lattice frame for tangential excitation.

Figure 3.7.2-12 shows the output displacement time history of the ice basket mass superimposed on the input displacement. It shows that the response generally follows the input displacements except for some amplification in the neighborhood of the peaks.

Figure 3.7.2-13 shows the impact loads on the ice baskets for this particular case. Note the short duration time of the impact loads.

Figure 3.7.2-14 shows the forces induced in the wall panels on the crane wall side as obtained from the non-linear dynamic model.

Horizontal Seismic Response Spectra Analysis Parameters

The response spectra defined for the crane wall at elevation 773.0 were used for the analysis. Shown in Figure 3.7.2-6 is the relation of elevation 773.0 and the multilevel horizontal dynamic model. The response spectra associated with this elevation were used for the analysis because the lattice frames at this elevation have a full mass contribution associated with them and therefore these spectra are representative of the input motion to the major portion of the assembly.

The equipment damping values used were 5 percent for 1/2 SSE and 10 percent for SSE.

Time-History Dynamic Input

Crane wall seismic time histories for the 1/2 SSE and SSE in the east-west and north-south directions were developed using four synthesized earthquakes. These earthquakes are the same as used to develop the Sequoyah response spectra. These time histories were the actual earthquake records as modified by the building, i.e., as filtered through the building to the points of interest on the crane wall.

The structural response was computed for each earthquake and then averaged by computing the arithmetic mean of the four sets of response values. The seismic design loads are based on the seismic loads obtained by averaging. This procedure is consistent with the method used to develop the response spectra.

Design Load Verification Analyses

As noted previously, it has been found that the seismic loads obtained from the nonlinear dynamic model are in good agreement with the loads obtained from more complex beam models. For this reason the nonlinear dynamic model has been used as the basic model to develop the seismic design loads.

The non-linear dynamic model was analyzed with zero gap and the results compared to the response spectra modal analysis results. Satisfactory agreement was obtained between time history and response spectrum modal analysis as seen in Figures 3.7.2-15 through 3.7.2-22. The damping valves used were the same as discussed in Sections 3.7.2.1.3. As expected, the seismic load obtained from the time-history analyses was always greater than the response spectra seismic loads. Therefore, results from the time-history analyses are clearly conservative compared to the response spectra results.

Non-linear seismic results obtained using the nonlinear dynamic model are shown in Figures 3.7.2-15 through 3.7.2-30. Figures 3.7.2-15 through 3.7.2-22 are plots of the seismic wall panel load versus gap size for the radial and tangential case. Given in Figures 3.7.2-23 through 3.7.2-30 are plots of seismic impact load between basket and lattice frame versus gap size for the radial and tangential case.

The lattice frame wall panel stiffnesses are given in Table 3.7.2-1. These values are consistent with stiffnesses obtained from tests. The results shown were obtained using time histories associated with elevation 784.8 above the ice condenser structure.

Analyses were made using the non-linear dynamic model and time histories associated with elevations 784.8 and 773.0 on the crane wall so that the design loads developed would be based on the most conservative seismic response. It should be noted that the two highest points on the crane wall were used since they have the largest seismic response characteristics. Their response characteristics are slightly different which require that both time histories be used. The results obtained from the two sets of time histories were similar with slight variations.

The seismic design loads developed for the ice condenser structure were based on a nominal 1/2-inch diametral gap size. This design point is used since the ice baskets, as a whole, will in all probability respond closest to this point for a nominal diametral gap of 1/2 inch. Note that a resonance condition exists at a gap size of approximately 0.06 inch for the radial case which causes the seismic loads to increase. However, the increase is not significant since the load falls off rapidly with a small change in gap size. Furthermore, the gap size of 0.06 inch is nowhere near the design gap of 1/2 inch. In addition, the predicted seismic load obtained by averaging the four TVA earthquakes for the zero gap size is below the design load.

Note that the expected seismic loads, based on a nominal 1/2-inch gap, are well below the design loads established. These design loads were established by taking the maximum seismic loads using time histories at elevations 773.0 and 784.8 on the crane wall.

Summarized below are applicable dynamic behavior characteristics which have been determined from previous studies reported in Reference 9.

The wall panel loads determined for a 1/2-inch nominal gap were found to be unaffected by large changes in impact damping. Loads were imperceptibly different using 10 percent and 50 percent impact damping.

The excitation function used in the non-linear analyses is crane wall displacement. In order to obtain the time-displacement record, the acceleration is integrated twice. The validity of double integration of accelerations to displacements has been checked by double differentiation of the displacements back to acceleration. It was found that the peak accelerations agree within about 5 percent as shown in Figures 3.7.2-31 and 3.7.2-32.

As noted previously, the design loads were defined for a nominal 1/2-inch gap with all baskets in phase. In order to verify that misalignment of the baskets or partially stuck baskets do not produce higher seismic loads, verification analyses were performed. The conclusions reached are:

1. The effect of stuck baskets due to freeze over has been examined by varying the lattice frame and ice basket masses over a range of values. The nonlinear dynamic model was used for these studies. It was found that the wall panel load decreases with increasing freeze over.

2. The effect of vertical misalignment and stuck baskets was examined with the 12-foot beam model. A decrease of more than 15 percent of all panel load was obtained for the case of zero gap at the top and bottom of the basket and 1/2-inch gap at center.

The effect of sublimation as well as ice melt during and after DBA on the seismic loads has been evaluated. These studies have shown that the seismic loads are smaller than those determined without sublimation or ice melt. This is due to the reduced ice mass and an increased energy loss in the fracturing of ice. Thus, the case of SSE during and after a DBA is not a limiting condition. It should be further noted that after a DBA the ice in the lower portion of the ice condenser has been used and no longer exits. Thus, the seismic loads in the lower portion of the ice condenser are significantly reduced.

The above studies lend substantial support to the conclusion that the basis for seismic design load calculation is in fact correct. The complexity of the nonlinear analysis is such that it is quite important to be able to relate the results to physically intuitive behavior. The results from these verification analyses are relatable.

Use of Constant Vertical Load Factors

Vertical seismic response accelerations were established using two-thirds of the horizontal seismic response spectra.

The combined floor and lower support structure were modeled in the vertical direction. The full weight of the baskets and ice were considered. It was found that the fundamental frequency, the dominant mode of the combined structure in the vertical direction, is above 9 Hz. There is no amplification of the crane wall in the vertical direction at the elevation of the lower support structure. Therefore, the vertical response spectra at this elevation have the shape of the vertical ground response spectra. The seismic response of the lower support-ice basket-supporting floor structural system is based on the one dominant mode. A participation factor of 1.5 was applied to this mode.

Comparison of Responses

The lattice frames, ice baskets, wall panels on the crane wall side, and lower support of the ice condenser structure form a complex structural system. In order to perform a realistic seismic analysis of this structure, it was necessary to do response spectra modal analysis as well as

time-history analyses. It is not feasible to perform a response spectrum modal analysis when considering gaps because the structure is nonlinear, thus requiring a dynamic analysis. However, it is important to obtain a reasonable comparison between response spectra results and the results from the nonlinear analysis for zero gaps. Nonlinear time-history analyses were performed in order to evaluate the effects of the gaps which exist between the lattice frames and ice baskets.

Seismic Design Loads

Seismic design loads have been developed for the lattice frames, ice baskets, and the wall panels; and are shown in Figures 3.7.2-15 through 3.7.2-30.

The nonlinear analyses performed to develop seismic design loads used 2 percent structural damping and 10 percent impact damping, and a nominal gap size of 1/2 inch on the diameter between the baskets and the lattice frames. Crane wall seismic time histories associated with the top elevations of the ice condenser structure were used in these analyses. Damping values of 5 percent for 1/2 SSE and 10 percent for SSE were established for response spectrum analysis recognizing the influence of the gap.

Table 3.7.2-1 gives a summary of parameter ranges used in the seismic analyses. The parameter ranges are intended to be broad enough to encompass the final design parameters. As discussed in Chapter 6, the structural properties of the Ice Condenser System have been evaluated by tests and analysis.

Procedure Used to Lump Masses

The basic nonlinear dynamic analytical model used to develop the design loads was a two mass model shown in Figure 3.7.2-33. It is composed of two nonlinear elements which represent the local impact stiffness between the lattice frame and the ice basket and a spring representing the stiffness of the coupled lattice frame and wall panel. The two masses represent the lattice frame and 27 ice baskets of 6 foot length. This is the same model as described in Reference 9. An extensive detailed seismic analytical study has been performed, presented in Reference 9, to substantiate the use of the two mass model to develop seismic design loads for the Ice Condenser System. Five nonlinear dynamic models were used:

1. 2 mass model

2. 12-foot beam model

3. 9 mass radial phasing model

4. 3 mass tangential phasing model

5. 48-foot beam model

These models are fully described in Reference 9. It was concluded from these studies that the seismic loads obtained from the two mass model are in good agreement with the loads obtained from the more complex beam models. Therefore, the two mass model of Figure 3.7.2-33, hereafter referred to as the nonlinear dynamic model, has been used to develop seismic design loads for the Sequoyah Ice Condenser System.

3.7.2.1.4 Unit 1 and Unit 2 Reactor Coolant System Seismic Analysis Method with Replacement Steam Generators

Replacement of the Unit 1 and Unit 2 Steam Generators had the potential to significantly redistribute loads on the Steam Generator Primary Nozzles and Steam Generator Supports due to differences in the weight, center of gravity, shell geometry, and shell materials between the Original and Replacement Steam Generators. Therefore isolated mathematical models of the original Unit 1 and Unit 2 Steam Generators and the Unit 1 and Unit 2 Replacement Steam Generators were created and used to calculate loads on the Steam Generator Hot and Cold Leg Nozzles as well as the Steam Generator Upper and Lower Supports. The loads for the Replacement Steam Generators were compared to the loads for the Original Steam Generators in order to predict load and or stress increases as described in Sections 5.2.1.8. Natural frequencies of the Original and Replacement Steam Generators were calculated, and based on these results it was concluded that the Original and Replacement Steam Generators models were essentially the same dynamically. Section 5.2.1.8 describes the qualification method for the Unit 1 and Unit 2 Reactor Coolant System with Replacement Steam Generators.

3.7.2.1.5 Unit 1 and Unit 2 Replacement Steam Generator Seismic Analysis Modeling

A multi-mass RSG dynamic model was built for use in the RCS evaluation using the ANSYS general structures code, Version 5.5. It is a 3-dimensional model consisting of a six-mass beam model representing the RSG shell, upper and lower heads, nozzels and supports. Each lumped mass has X, Y, and Z mass inertia, and two lumped masses have rotary Y mass inertia, for a total of 20 dynamic degrees of freedom. The model conserves the total weight and CG of the RSG by transferring the tube bundle mass into the lumped shell masses. Since the RSG internals and shell are represented in this model as one series of beams rather than two series of co-axial beams, it is called a “one-stick” model. The six masses in the one-stick model maintain the total RSG weight and CG at normal operation (NOP).

The one-stick model was reduced from a more detailed two stick model of the RSG, in which the RSG tube bundle/shroud and the shell were represented as connected co-axial beams. The one stick model is further reduced when it is used in conjunction with the other RCS components in the RCS evaluation.

Figure 3.7.2-79 shows the one-stick model with details of the RSG supports. The RSG model origin is the RSG vertical centerline at 0.38” below the lower face of the lower support pads. The orientation of the model is as follows:

Global +X = horizontal from RSG vertical centerline to RV vertical centerline
Global +Y = up
Global +Z = orthogonal to X and Y

3.7.2.2 Category I Structures Listed

The seismic analyses of Category I structures were based upon dynamic analysis using the lumped mass normal mode method with idealized mathematical models. The inertial properties of the models were characterized by the mass, eccentricity, and mass moment of inertia of each mass point. Mass points were located at floor slabs, changes in geometry, and at intermediate points to accurately model the structure.

The stiffness properties were characterized by the moment of inertia, area, shear shape factor, torsion constant, Young's modulus, and shear modulus. All significant modes of vibration were considered in determining the total response. For structures with significant built-in asymmetry, coupled translation and torsion were considered. For the shield building an eccentricity of 5 percent of the diameter was assumed. For the steel containment vessel, actual eccentricities were calculated at various levels in the structure. The largest eccentricities were due to the personnel locks and equipment hatch and ranged up to 13 percent of the diameter. Structural response was calculated in both the east-west and north-south directions except where symmetry justified one direction.

Longitudinal (vertical) modes were computed for structures and their effects included in the structural response.

The response of Category I structures was computed by either the time-history modal analysis or the response spectrum modal analysis method. For the time-history method, the response (deflections, shears, etc.,) was calculated using four artificial earthquakes (Section 2.5.2.4) at a maximum integration interval of 0.01 second. Maximum values were calculated at each mass point for each earthquake and the arithmetically averaged response from the four earthquakes was used in the design.

For the response spectrum method, the modal response was computed in each component mode. The total response was found by taking the square root of the sum of the squares of the modal responses.

The response spectrum method was used only in calculating angular acceleration in asymmetric structures, for soil-supported structures, and for comparison with the results from the time-history method (e.g., see Section 3.7.2.3.10).

In computing seismic response, each of the two major horizontal directions of the structures were considered separately but simultaneously with the vertical direction. The moment, shear, and vertical load at the base of the structure due to earthquakes were used in combinations with other appropriate loads in determining overturning moments.

The response was calculated for the 1/2 SSE and the SSE except where the same percentage of critical structural damping was specified for both earthquakes. Where the 1/2 SSE and SSE structural damping are the same, response was calculated for the 1/2 SSE and/or the SSE (the SSE results equal twice the 1/2 SSE).

The damping ratios used in the dynamic analyses of the structures are shown in Section 3.7.1.3, Table 3.7.1-3.

3.7.2.2.1 Change in Elastic Modulus of Concrete

During the review cycle of final safety analysis report drafts for Section 3.7, Seismic Design, and Section 3.8, Design of Category I Structures, it was noted that the design strength given of the concrete mix for the Reactor Building interior concrete structure (both Units 1 and 2) was not the same as the design strength used in calculating the concrete elastic modulus used in the dynamic seismic analysis of this structure.

Additional investigation resulted in the determination that at the beginning of the design program for the Sequoyah plant, the specified design strength for the structure was the same as that used in calculating the elastic modulus. At some time later in the design program, but after completion of the dynamic seismic analysis, the design strength for the concrete mix was specified to be a higher value than that specified originally. This increase was not caused by the seismic analysis results but rather by high shear stresses at embedment anchorages for piping and equipment as a result of jet forces from pipe and equipment supports.

After the change in the design strength was made, it was not recognized at that time this change had implications on the previously completed seismic analysis of the interior concrete structure, with a consequent implication on the response of the structure as well as the response of all Category I piping and equipment anchored to this structure. As stated above, this discrepancy of design values was discovered during review of FSAR drafts.

During the course of the reanalysis of the Reactor Building, it was determined that for seismic analysis a modulus based on expected long-term concrete strengths would be more appropriate than an analysis based on 28-day design strengths (since we have found that continuing hydration does occur in the relatively massive concrete members associated with these structures). Modulus for seismic analysis should, therefore, be based on previous test experience for 180-day strengths with the fly-ash concrete using the ACI 318-63 Code formula in Section 1102.

This decision extended the problem to include all Category I structures since the 28-day specified strength was used in determining the concrete modulus for all of these structures in the original seismic analyses. Consequently, all Category I structures were examined and the Auxiliary Control Building and additional equipment buildings were included in the reevaluation. Information on the additional equipment buildings is presented in this section.

Table 3.7.2-2 lists all Category I structures and the reasons for exclusion of those not considered in the reevaluation.

The Reactor Building interior concrete structure, Auxiliary Control Building, and additional equipment buildings were evaluated for the revised structural responses. The revised structural responses were generally less than those used originally in the design of the structures, and the structures were found to be completely adequate.

The major effect on floor response spectra was a shift in the period at which peak response occurred, which corresponded to the shift in the natural period of the structure. The peak values remained essentially unchanged or reduced in some cases. This was caused primarily by fluctuations in the earthquake records used. This shift in the period of the peak, where significant, necessitated the reevaluation of all Category I equipment and piping supported or attached to the structures.

The effects of the revised moduli of elasticity of concrete on the seismic analyses of the Reactor Building interior concrete structures, Auxiliary Control Building, and the additional equipment buildings and the consequential effects on the structural response and equipment and piping systems have been thoroughly evaluated. The structures, equipment, and piping systems important to safety are adequate under the revised loadings.

All tables, where required, have been revised to reflect the change in modulus. The tables for those structures found to be unaffected as listed in Table 3.7.2-2 have not been revised.

3.7.2.2.2 Category I Rock-Supported Structures

Category I structures which are rock-supported are listed in Table 3.7.1-1. The in-situ measured shear wave velocity for the rock has an average value of 7000 ft/s. Based upon reference 4, buildings founded upon rock having this shear wave velocity may be considered to have a fixed base when performing analyses.

For structures surrounded by soil, the effect of the soil stiffness on the structural response was determined by replacing the soil with springs of equivalent stiffness. Due to seismic motion, the soil pressure against structures was increased above the static soil pressure. The magnitude of this increase was determined by using the shaking table experiments performed for the design of TVA's Kentucky hydro project (Reference 1). For a ground acceleration of 0.18 g, the static soil pressure was increased 46 percent for a dry fill and 22 percent for a saturated fill. This incremental increase was combined with the static pressure as a triangle of pressure whose apex is at the rock surface and maximum ordinate is at the ground surface. In addition to the soil pressure increase as described above for a saturated fill, the hydrostatic pressure of water within the fill was increased 22 percent. This incremental increase was combined with the static water pressure as a triangle of pressure whose apex is at the water surface and maximum ordinate is at the rock surface or bottom of structure. Calculations using the shaking table experiment results have been confirmed using information in Reference 8. A more detailed description of the seismic analyses of Category I rock-supported structures is discussed below.

Shield Building

Two separate, distinct analyses were performed on the reinforced concrete structure to determine the response of the structure to horizontal motion when modeled as a cantilever beam and the response of the dome to vertical motion when modeled as a shell.

The idealized lumped mass cantilever model of the structure is shown in Figure 3.7.2-34. The dome was considered a rigid body in this case and its weight added to mass point 25. The dynamic analysis was performed by the time-history modal analysis technique. Element and mass point properties used are shown in Table 3.7.2-6. Although no structural eccentricities exist in the building, the analysis considered accidental torsion effects with an eccentricity of mass of 5 percent of the diameter of the cylindrical shell. Periods for the normal modes of vibrations are listed in Table 3.7.2-7.

The in situ measured shear wave velocity for the rock under the Reactor Building has an average value of 7000 ft/s. Reference 4 states "it was noted that foundation media with a shear wave velocity of 6000 ft/s closely approximate a rigid foundation." The above, plus the fact that the base mat is anchored into the rock by grouted rock anchors, makes rocking of the building insignificant.

Vertical modes of vibration were calculated for comparison with the results for the dome as a shell. The rigid body simulation of the dome as performed in the analysis of the cantilever beam model does not provide an accurate representation of the response of the dome to vertical earthquake excitation. Thus, an analogy was developed using shell theory to determine the earthquake moments and forces in the dome. Figure 3.7.2-35 illustrates the logic performed in the analysis. The shell model is shown in Figure 3.7.2-36 The lumped mass model is shown in Figure 3.7.2-37.

The structural response for the cantilever and shell model was for both the 1/2 SSE and the SSE.

Response spectra were produced at selected points in the building for motion in the north-south, east-west, and vertical directions. As a minimum, these spectra were generated for damping ratios of 0.005, 0.01, and 0.02.

Interior Concrete Structure

The idealized lumped mass model of the reinforced concrete structure used in the dynamic earthquake analysis is shown in Figure 3.7.2-38. Element properties are given in Table 3.7.2-10 and mass-point properties in Table 3.7.2-11. The fixed base assumption was justified due to the magnitude of the shear wave velocity of the rock (7000 ft/s) as explained in Reference 4.

The dynamic earthquake analysis was performed by the time-history modal analysis technique. The results were computed for both the 1/2 SSE and SSE conditions. The effects of torsion and longitudinal motion were considered. Periods for the normal modes of vibrations are listed in Table 3.7.2-12.

Response spectra were produced at selected points in the building for motion in the north-south, east-west, and vertical directions. As a minimum, these spectra were generated for damping ratios of 0.005, 0.01, and 0.02.

Steel Containment Vessel

The dynamic analysis of the containment vessel was performed by the time-history modal

analysis method. The results were computed for the 1/2 SSE condition, and results for the SSE were obtained by doubling the values from the 1/2 SSE. The effects of torsion and longitudinal motion were considered. The idealized lumped mass model used in the analysis is shown in Figure 3.7.2-39. The element and mass-point properties are given in Tables 3.7.2-13 and 3.7.2-14, respectively. Periods for normal modes of vibration are listed in Table 3.7.2-15.

A dynamic shell analysis was made as an independent check on the results of the analysis treating the containment vessel as a lumped mass cantilever beam. The finite element model shown in Figure 3.7.2-40 was used in the shell analysis. It was found for seismic loads that both methods of analysis gave approximately the same results.

Response spectra were produced at selected points in the building for motion in the north-south, east-west, and vertical directions. As a minimum, these spectra were generated for damping ratios of 0.005, 0.01, and 0.02.

Auxiliary Control Building

The idealized lumped mass model of the reinforced concrete structure is shown in Figure 3.7.2-41. The fixed base assumption was again justified due to the magnitude of the shear wave velocity of the rock (7000 ft/s).

The dynamic analysis was performed by the time-history modal analysis technique. The results were computed for the SSE condition, and results for the 1/2 SSE were obtained by halving the values from the SSE. Element properties are given in Table 3.7.2-16 and mass point properties in Table 3.7.2-17. The effects of torsion and longitudinal motion were considered. Periods for the normal modes of vibrations are listed in Table 3.7.2-18.

Response spectra were produced at selected points in the building for motion in the north-south, east-west, and vertical directions. As a minimum, these spectra were generated for damping ratios of 0.005, 0.01, and 0.02.

Additional Equipment Buildings

Both Unit 1 and Unit 2 additional equipment buildings are reinforced concrete structures supported on rock. The idealized lumped mass models and sectional elevations are shown in Figures 3.7.2-42 and 3.7.2-43 for unit 1 and unit 2, respectively. Element properties which were used in the analysis are shown in Tables 3.7.2-19 and 3.7.2-20 for unit 1 and unit 2, respectively. The inertial properties of the structures are shown in Tables 3.7.2-21 and 3.7.2-22.

The dynamic analysis of each structure was done by the normal mode time-history method. A structural damping ratio of 0.05 was used for all modes of vibration for both the 1/2 SSE and SSE calculations.

The unit 1 structure is relatively symmetric in the north-south and east-west directions. Therefore, motion in these directions induces negligible torsion. The unit 2 structure is also relatively symmetric in the north-south direction. However, the unsymetrical conditions below elevation 706.0 in the east-west direction induce torsional responses in the structure for motion along this axis.

For both structures a study was conducted to determine the proper restraint conditions at the base for each direction of motion. In this study, an iterative procedure was used to determine the rocking spring constant at the base which corresponds to the actual base compression area. From this study, it was determined that the restraint conditions had an effect on the structural responses and the instructure response spectra only in the north-south direction for unit 2 when compared to the results for a fixed-base analysis. Therefore, for unit 2 in the north-south direction, the flexible base conditions were used to calculate the structural responses and the instructure response spectra.

An investigation of the stiffening effects of the exterior soil fill on the structural responses was conducted. The spring constants for the soil outside the structures were calculated from the dynamic modulus of the soil. Also, the additional stiffening effects from the soil fill below elevation 706.0 within each structure was investigated. It was found that the additional stiffening attributed to the soil from these two investigations had negligible effects on the structural responses.

The results of the dynamic analysis were computed for 1/2 SSE excitation; SSE response values can be obtained by doubling the 1/2 SSE values. The modal periods of motion and the corresponding participation factors for each direction of motion for both structures are listed in Tables 3.7.2-23 and 3.7.2-24. Floor response spectra in the north-south direction of motion for unit 2 are composite spectra which envelope the individual spectra generated for the extreme ranges of the transient base condition of the structure in this direction. Response spectra were produced at selected points in the building for motion in the north-south, east-west, and vertical directions. As a minimum, these spectra were generated for damping ratios of 0.005, 0.01, and 0.02.

Intake Pumping Station

The idealized lumped mass model of the reinforced concrete structure used in the analysis is shown in Figure 3.7.2-44. The results were computed for the 1/2 SSE condition, and results for the SSE were obtained by doubling these. Element properties are given in Table 3.7.2-25 and mass points properties in Table 3.7.2-26. The effects of longitudinal motion and soil restraint were considered. Periods for natural modes of vibration are listed in Table 3.7.2-27.

The structure was analyzed using the Uniform Building Code with the provisions of Zone 2 although at the time of design the plant was located in Zone 1. The results obtained from this analysis were used in the design of the structure.

ERCW Pumping Station

The idealized lumped mass model of the ERCW pumping station, opposite a sectional view of the actual structure, is shown in Figure 3.7.2-45. The seismic analysis was performed using the time-history modal analysis technique. The element properties are given in Table 3.7.2-28 and mass point properties in Table 3.7.2-29. Periods for the normal modes of vibration are listed in Table 3.7.2-30.

Results were computed for the 1/2 SSE condition and results for the SSE condition obtained by doubling these. Hydrodynamic effects of the water surrounding the structure at various elevations were considered using the Kentucky shaking table results (Reference 1). Response spectra were produced at selected points in the building for motion in the north-south, east-west, and vertical directions. As a minimum, these spectra were generated for damping ratios of 0.005, 0.01, and 0.02.

Intake Pumping Station - Retaining Walls

The reinforced concrete retaining walls were analyzed using a representative 1-foot-wide section considering the effects of the soil behind the walls and also as a freestanding wall. Both analyses indicated that the walls were rigid having the same accelerations as the rock on which they are supported.

The increased soil pressures due to the earthquake were obtained using the results from the shaking table experiments performed for the design of TVA's Kentucky hydro project (Reference 1).

Cells Providing Access to the ERCW Pumping Station

As shown in Figure 3.7.2-46 access to the ERCW pumping station is provided by a dike road, which is supported by several cofferdam cells adjacent to the pumping station. The cells are constructed of tremie concrete set in circular sheet pile forms and carry electrical conduits and mechanical piping internally. The cells are 32 feet, 7-1/2 inches in diameter and approximately 56 feet in height supported on rock.

Because the cells are constructed of tremie concrete and the geometric configuration of these cells, the design basis seismic analysis was based on the cells acting as a single unit. The analysis indicated a rigid body behavior. The seismic effects of the soil and water surrounding these cells were obtained by using the results from the shaking table experiments performed for the design of TVA's Kentucky hydro project (Reference 1).

Supplemental analyses were performed to demonstrate that an individual cell was inherently stable when subjected to the SSE. These analyses showed that the deflections at the level of the encased ERCW pipes were small and did not have an adverse effect upon the pipes.

Because of its proximity to the ERCW pumping station (Figure 3.7.2-46), the skimmer wall cell closest to the pumping station was seismically analyzed. Originally, the cell had a diameter of 22 feet with a height of about 60 feet. It is supported on rock and constructed of crushed stone contained by a sheet pile cell, capped by concrete at top and bottom. The seismic analysis revealed possible overturning problems with this cell. Therefore, the diameter of the cell has been increased to 45 feet to make it stable during both a 1/2 SSE and an SSE.

3.7.2.2.3 Category I Soil-Supported Structures

Category I structures which are soil supported are listed in Table 3.7.1-4. For structures founded on soil, the acceleration at top of rock was considered to be amplified through the soil

as discussed in Section 3.7.1.6. The translational and rocking soil springs included in the lumped mass model of the structure to characterize soil structure interaction were calculated using References 3, 5, 18, and 19. The damping ratio used for soil-supported structures depended upon the predominant type of motion as explained in Reference 3, 18, and 19.

A more detailed description of the seismic analyses of Category I soil- supported structures is discussed below.

Diesel-Generator Building

The idealized lumped mass model of the reinforced concrete structure used in the analysis is shown in Figure 3.7.2-47 Element properties are given in Table 3.7.2-31 and mass point properties in Table 3.7.2-32. The effects of horizontal translation and rocking of base were considered.

The predominate motion of the structures was a translatory rigid body motion. Motion of this type results in large damping; therefore, a damping ratio of 0.10 was used for the analysis. Longitudinal motion was also considered. Periods for the normal modes of vibrations are listed in Table 3.7.2-33. Response spectra were produced at selected points in the building for motion in the north-south, east-west, and vertical directions. As a minimum, these spectra were generated for damping ratios of 0.005, 0.01, and 0.02.

Refueling Water Tanks and Pipe Tunnels

The refueling water tanks are supported on a soil deposit. A ground motion spectrum was developed, as discussed in Section 3.7.1.6, to be used in the design of the refueling water tanks.

To address NRC concerns during the integrated design inspection, additional seismic analyses of the refueling water storage tank were performed. Lateral and rocking springs were calculated considering the effect of soil layering rather than the original elastic half-space assumption. Composite modal damping was used in combination with realistic soil damping (references 5, 18, and 19). A limitation of 10 percent composite modal damping was imposed for any individual mode.

The pipe tunnels leading from the Auxiliary Building to the refueling water and primary water tanks are in a soil deposit with an average depth of approximately 30 feet with the top of the tunnels being about 1.5 feet below the ground surface. Two methods were used to assess the earthquake effects on the tunnels.

First, the tunnels were assumed to have the same motion as the soil deposit. The soil deposit was analyzed as explained in Section 3.7.1.6. The accelerations obtained for the soil deposit at the level of the tunnel were used to calculate the inertia force per unit area on the tunnel, and also to calculate the increase in the static soil pressure using the shaking table experiments performed for the design of TVA's Kentucky hydro project (Reference 1).

In the second method, the tunnels were assumed to act as a free beam on an elastic foundation. The seismic response of the lumped mass beam on an elastic foundation was calculated and the maximum uniform loading acting on the sides of the tunnel was found.

The first method gave the most conservative results and was used in the seismic design of the tunnels.

Underground Electrical Concrete Conduit Banks

The underground electrical concrete conduit banks which lead from the Auxiliary Building to the Diesel Generator Building and the intake pumping station were seismically analyzed as described in Section 3.10.2.

The conduit banks leading to the ERCW pumping station were analyzed by the same method with the exception that those portions contained in the ERCW access dike were analyzed as described below.

ERCW Electrical Conduit Bank (in ERCW Access Dike)

The ERCW electrical conduit bank passes through the ERCW access dike parallel to and above the pile-supported piping slab discussed in Section 3.7.2.2.4. The bank is supported from the piping slab by concrete bents at intervals along the slab. Near the access dike-shoreline interface, the piping slab terminates. Beyond that point, the conduit bank is supported by pile-supported bents until the shoreline is reached. Cross sections of the access dike showing the relationship of the conduit banks and the piping slab are shown on Section C5-C5 of Figure 3.8.4-9. The location of the conduit bank along the longitudinal centerline of the access dike is shown on Section A5-A5 of Figure 3.8.4-9.

The electrical conduit bank was analyzed in the same manner as described in Section 3.7.2.2.4 for the ERCW piping slab. Unlike the piping slab, the conduit bank is a continuous structure. Therefore, the conduit bank is designed for the maximum curvature induced by the sinusoidal displacement profile.

The concrete support bent for the conduit bank is a simple frame structure which is structurally connected to the piping slab. For motion in the direction transverse to the access dike centerline, the bent is assumed to conform to the deformed shape of the dike in that direction. Forces in the bent are computed from that displaced shape.

The pile-supported bent is analyzed in the same manner as described in Section 3.7.2.2.4 for the pile supports for the piping slab. The bent consists of steel piles and a horizontal concrete beam on which the conduit bank rests. Forces in the bent are computed from the displaced shape imposed on it.

The conduit bank is analyzed vertically as a continuous slab supported at 30-foot intervals. No contact between the conduit bank and the rockfill under it is assumed. The slab is designed for the dead load of rockfill which it supports and the vertical acceleration of the dike.

Class IE Electrical Systems Manholes and Handholes

These manholes and handholes are rigid structures which have the same motion as the soil deposits where they are located. The soil deposits were analyzed as explained in Section 3.7.1.6. The accelerations obtained for the soil deposit at the level of the manholes and handholes were used to determine the inertia force on the structures and to calculate the increase in the static soil pressure using the shaking table experiments performed for the design of TVA's Kentucky hydro project (Reference 1).

3.7.2.2.4 Category I Pile- and Caisson-Supported Structures

Category I structures which are pile- and caisson-supported are listed in Table 3.7.1-5. For structures founded on piles, the acceleration at top of rock was considered to be amplified through the soil as discussed in Section 3.7.1.6. The translational and rocking foundation springs included in the lumped mass model of the structure to characterize soil-structure interaction were calculated using References 5 and 17. The damping ratio used for soil-supported structures depended upon the predominant type of motion as explained in Reference 3.

A more detailed description of the seismic analyses of Category I pile-supported structures is discussed below.

Waste Packaging Area

The Waste Packaging Building is a reinforced concrete structure adjacent to the east end of the Auxiliary Building. An expansion joint capable of permitting relative motion between the structures is provided. The foundation of the building consists of HP12x74 bearing piles driven through 30 feet of backfill material to refusal in sound rock.

The idealized lumped mass model of the structure used is shown in Figure 3.7.2-48. The element, mass point, and foundation spring properties are given in Tables 3.7.2-34, 3.7.2-35, and 3.7.2-36, respectively.

The response spectra used in the analysis of the soil- and pile-supported structure were obtained by amplifying the bedrock motion through the soil by linear analysis as prescribed in Section 3.7.1.6. The maximum horizontal acceleration at top of rock is 0.09 g and 0.18 g for the 1/2 SSE and SSE, respectively. The vertical acceleration at top of rock is taken as two-thirds of the horizontal. Four artificial earthquakes were used as input at top of rock. The results of this amplification indicates a peak in the response spectra at a period of approximately 0.1 second as shown in Figure 3.7.2-49.

Since the amount of settlement between the base slab and foundation media in the presence of the piles is difficult to determine, yet has major influence on the response of the structure, the degree of contact between the base slab, and the foundation media was taken to cause the worst conditions.

The soil springs were selected to provide a natural period of soil and pile structural system near the peak in the response spectrum.

The building is supported on a pile foundation to minimize settlement. This foundation, including the soil, was represented by rotational and translational springs. Two limiting cases were considered since the amount of contact between the base slab and the soil is difficult to determine, yet it has a major influence on the response of the structure. First, the stiffness of the foundation was determined assuming no contact between the base slab and the soil. This was accomplished by using a modulus of subgrade reaction approach (Reference 17) to evaluate the resistance to horizontal motion of piles supported in an elastic medium. The effect of pile group was taken into account in the evaluation of the subgrade modulus. This case yields a set of equivalent springs which are relatively flexible. For the second case, the effect of full contact between the base slab and soil was added to the results of the first case thereby setting a limit on the maximum stiffness of the foundation. The soil stiffness for the case of the base in full contact with the soil was computed using the procedures of Reference 5. From this analysis of varying the foundation conditions, it was determined that the natural periods of vibration fall to the right of the peak of the averaged ground response spectrum. Therefore, the soil properties which result in structural periods close to the region of peak amplification were used to determine the horizontal structural response.

The results of the analysis indicate a large portion of the structural displacement is due to base translation and base rotation. Since this corresponds to high damping in the soil, a modal damping of 10% was used. The horizontal response spectra at the base slab elevation for a modal damping of 10% is shown in Figure 3.7.2-49. The vertical response spectrum was taken as two-thirds of the horizontal rock response spectrum acting through the end bearing piles. As mentioned previously, the ground surface response spectrum was determined by a linear amplification of the bedrock motion. This response spectrum was broadened by $\pm$10 percent in order to obtain a design response spectra. The broadened curve was used as input to the dynamic seismic analysis. The critical supporting condition in the vertical direction corresponded to the structure being pile supported only. This produced the softest supporting condition resulting in a period of 0.087 second and the largest vertical load in the structure.

Condensate Demineralizer Waste Evaporator Building

The Condensate Demineralizer Waste Evaporator Building is a reinforced concrete and steel structure adjacent to the additional Equipment Building and the waste-packaging area. Expansion joints capable of permitting relative motion between the structures are provided. The foundation of the building consists of HP12x74 bearing piles driven through 30 feet of backfill material to refusal in sound rock.

The dynamic earthquake analysis was performed using the normal mode time-history method. The idealized lumped mass model of the structure, piles, and soil is shown in Figure 3.7.2-50. The element, mass point, and foundation spring stiffness properties of the model are given in Tables 3.7.2-37, 3.7.2-38, and 3.7.2- 39, respectively. A damping ratio of 10 percent was used to represent the damping of the structure, piles, and soil system.

The earthquake motion used in the analysis was determined by amplifying four artificial earthquakes input at top of rock through the supporting soil. The maximum top-of-rock horizontal accelerations for these earthquakes are 0.09 g and 0.18 g for the 1/2 SSE and the SSE, respectively. The vertical motions are two-thirds of the horizontal.

The amplification of these earthquakes through the soil is performed by considering the soil as an elastic medium and making a dynamic analysis of a slice of unit thickness considering only the horizontal resistance of the soil (see Section 3.7.1.6). A damping ratio of 10 percent is used for the soil. From this analysis four corresponding top-of-ground earthquake motions are obtained for use as input to the structural model. The vertical motion at top of ground is assumed to be two-thirds of the horizontal motion.

The shear wave velocity of the soil is assumed to be approximately 1150 ft/s, which was determined from geophysical testing in and around the main plant area. Due to uncertainties in the determination of the soil properties, the shear wave velocity of the in situ soil is varied by + 30 percent when calculating the horizontal ground surface motions and when computing stiffness values for the translational and rotational soil springs of the lumped mass model. A comparison of the averaged response spectrum of the four artificial earthquakes for each of the shear wave velocity variations mentioned above with consideration of the frequency range of interest for response computations shows that the earthquake motions for a shear wave velocity of approximately 800 ft/s (-30 percent variation) is the most critical since it envelopes the averaged response spectra for the other variations. Therefore, only the top-of-ground time histories for a shear wave velocity of 800 ft/s were used in the subsequent computations of structural response and floor response spectra. The averaged ground response spectrum for this case exhibits a peak at a period of approximately 0.15 second, as shown in Figure 3.7.2-51 for the 1/2 SSE.

The building is supported on a pile foundation to minimize settlement. This foundation, including the soil, was represented by rotational and translational springs. Two limiting cases were considered since the amount of contact between the base slab and the soil is difficult to determine, yet it has a major influence on the response of the structure. First, the stiffness of the foundation was determined assuming no contact between the base slab and the soil. This was accomplished by using a modulus of subgrade reaction approach (Reference 17) to evaluate the resistance to horizontal motion of piles supported in an elastic medium. This case yields a set of equivalent springs which are relatively flexible. For the second case, the effect of full contact between the base slab and soil was added to the results of the first case thereby setting a limit on the maximum stiffness of the foundation. The soil stiffness for the case of the base in full contact with the soil was computed using the procedures of Reference 5. From this analysis of varying the foundation conditions, it was determined that the natural periods of vibration fall to the right of the peak of the averaged ground response spectrum (Figure 3.7.2-51). Therefore, the soil properties which result in structural periods closest to the region of peak amplification were used to determine the horizontal structural response.

The response of the structure in the vertical direction was also determined with consideration of the effect of pile and soil stiffness on the total response. The softest case was the consideration of the axial stiffness of the supporting piles without any contact between the base slab and soil.

The natural period of vibration for this case was 0.064 second. Since this natural period falls to the left of the peak of the averaged ground response spectrum (Figure 3.7.2-51) and is for the softest support stiffness, it is the period which results in the highest vertical structural responses.

The natural periods of the structural model are shown in Table 3.7.2-40. The structural responses in the two transverse horizontal directions were calculated. The envelope of the results for the two cases of no contact and full contact between the soil and the base slab was used in design.

The structure itself is rigid in the vertical direction but will respond as a one degree of freedom system coupled with the axial stiffness of the pile system assuming no contact between the base slab and in situ soil. From this analysis it was determined that the structure and piles should be designed for a vertical acceleration of 0.18 g for the 1/2 SSE.

Floor response spectra for the base slab (elevation 707.5) and the second story floor slab (elevation 734.5) were calculated. These spectra are envelopes of the two cases of no contact and full contact between the soil and base slab. The response spectra were broadened + 10 percent. Vertical floor response spectra were taken as two-thirds of the envelope of the horizontal north-south and east-west acceleration response spectra. A vertical specific analysis of the building-pile system was performed to demonstrate the adequacy of this assumption.

East Steam Valve Room

The east steam valve room is a trisided reinforced concrete structure that is supported on backfill and eight concrete caissons (Figure 3.7.2-52). Horizontal and rotational spring constants representing the soil and caisson interaction for three soil conditions are calculated and input as supporting elements for a lumped mass beam model of the structure. Vertical extensional springs were calculated considering the caissons acting independently of the soil. The valve room base slab is connected by a rigid diaphragm to a massive thrust block. The thrust block is modeled using beam elements while the diaphragm is treated as a rigid link. The idealized lumped mass and spring model of the valve room is shown in Figure 3.7.2-53. Element properties are shown in Tables 3.7.2-41 and 3.7.2-42 and mass point properties in Table 3.7.2-43. Table 3.7.2-44 lists the spring constants used to represent the soil-caisson system.

From the dynamic analysis, it was found that the structure responded horizontally to a combination of rigid body rocking and translation of the base and to structure-base interaction. Since a damping value of 10 percent is allowed for the first type motion while only 5 percent is allowed for the second, it was decided to use 5 percent for all modes for consistency and simplicity. Longitudinal motion of the structure was also considered in the analysis. Frequencies of the normal modes for the soil conditions considered are listed in Table 3.7.2-45.

Pile-Supported ERCW Piping Support Slab (in ERCW Access Dike)

The ERCW piping support slab is a segmented, reinforced concrete structure which passes through the ERCW access dike. The slab terminates at the first of the ERCW access roadway

cells. The slab is supported by steel H-piles driven through the access dike to refusal. The slab is provided to prevent the imposition of excess deformations from settlement of the access dike on the ERCW piping. Typical cross sections of the ERCW access dike showing the location of the piping support slab and pile supports are shown on Section C5-C5 of Figure 3.8.4-9. The orientation of the slab along the longitudinal axis of the access dike and the spacing of the pile supports is shown on Section A5-A5 of Figure 3.8.4-9.

The seismic analysis of this structure was accomplished in two parts; one part being an analysis of the steel piles supporting the slab, and the other part being an analysis of the slab itself. The method of analysis for each is described below.

The steel piles are relatively flexible when compared to the stiffness and mass of the ERCW access dike. Therefore, the piles were analyzed by assuming that the piles conformed to the deformed shape of the dike in the direction transverse to the centerline of the dike. Induced forces in the piles are a function of the curvature at any point in the pile caused by the imposed displacement profiles.

The piping support slab was assumed to conform to the deformed shape of the access dike along the longitudinal axis of the dike. That deformed shape imposes a sinusoidal displacement pattern on the slab. The maximum curvature induced in the slab is computed from the imposed displacement pattern. From that curvature, the forces in the slab may be computed. Since the piping support slab is segmented, the maximum curvature induced in any one portion of the slab is reduced. The degree of reduction of induced curvature increases as the segment length decreases. All of the slab segments are designed for the same maximum moment which could be induced in any segment.

The slab is analyzed vertically as a continuous slab supported at intervals by piles. No contact is assumed between the slab and the rockfill under it. The slab is designed to resist the computed vertical accelerations in addition to the dead load of rockfill above the slab, the ERCW piping, and the ERCW electrical conduit bank which it supports.

3.7.2.2.5 Non-Category I Structures

The Turbine and Service Buildings are analyzed for a total lateral base shear computed as the product of the mass of the structure and the ground acceleration for the SSE. The total lateral shear is distributed in the height of the structure according to the provisions of the uniform building code.

The LLRW Facility was analyzed for the design basis earthquake (DBE). The DBE was defined as a top-of-ground motion with three statistically independent orthogonal components. The ZPA acceleration was specified as 0.30g. The response spectrum was taken in accordance with Regulatory Guide 1.60, Rev. 1.

The seismic design of the Unit 1 and Unit 2 Old Steam Generator Storage Facilities (OSGSFs) is in accordance with Section 1607.4 of the 1999 Edition of the Standard Building Code. The minimum seismic coefficient for the Unit 1 and Unit 2 OSGSFs was determined to be 0.06g. See References 26 and 27.

The seismic design of the FLEX Equipment Storage Building (FESB) is in accordance with ASCE 7-10. See Reference 28.

3.7.2.3 Seismic Analysis Methods for Category I Structures

Category I structures for which these seismic analysis methods apply are listed in Table 3.7.1-1

3.7.2.3.1 Natural Frequencies and Seismic Excitation

The periods for the normal modes of vibration for the Category I structures are given in tables as referenced in subsection 3.7.2.2.

The interior concrete structure is used to illustrate the mode shapes, responses, and floor response spectra at critical plant equipment elevations. The first three mode shapes for the north-south direction and the first five mode shapes for the east-west direction are shown in Figures 3.7.2-54 through 3.7.2- 61. Torsion was considered in the east-west direction. The accelerations, displacements, shears, and moments for the two major directions from the SSE are shown in Figures 3.7.2-62 through 3.7.2-69. The angular accelerations, angular displacements, and torque in the east-west direction are shown in Figures 3.7.2-70 through 3.7.2-72. The floor response spectra for the SSE at elevation 692.0 and 732.63 with 1.0 percent damping are shown in Figures 3.7.2-73 through 3.7.2-76.

3.7.2.3.2 Procedures Used to Lump Masses

For the Category I structures, the mass points were located at floor slabs, changes in geometry, and at intermediate points to accurately model the structure. The equipment mass was considered in the lumped masses at the points of support. The stiffness of supported equipment was not considered in the lumped mass model of the structure. Table 3.7.2-11, the mass point properties of the interior concrete structure, lists both the total weight of the mass points and the appropriate equipment weights at the mass points.

The regular lumping techniques, which consist of lumping the continuous mass distribution at discrete joints referred to in Subsection 3.7.2.2 as mass point, were used in constructing some of the mathematical modes of systems and components supplied by Westinghouse. The location of the lumped masses are chosen at floor levels and points considered of critical interest, such as equipment. The lumped masses were computed from tributary structure dead loads and fixed equipment loads. Although a mechanical component may be analyzed using a mathematical model with as much complexity as allowed by the capacity of the computer and the computer code, the analysis is meaningful only when this detailed model also represents the effective utilization of the theory on which the computer code is built. Specifically, there were at least three things that were considered when establishing the mathematical model. They were:

1. The limiting values for items such as the degrees of freedom, sections, members, anchors, joints, bellows, etc;

2. The maximum allowable ratio of member rigidity;

3. The basic theory limitations. The computer code such as WESTDYN (Reference 14) and WECAN (Reference 25) can then be used to obtain the natural frequencies, mode shapes, absolute and relative displacements, absolute accelerations, and the stresses. The equipment design was determined adequate from the stress margin and by displacements limited to the operating tolerance.

3.7.2.3.3 Rocking and Translational Response Summary

A fixed-base assumption was made in the mathematical models for the rock-supported structures.

Soil-structure interaction was included for all soil supported structures. See Sections 3.7.1.6 and 3.7.2.2.3 for discussion of the analyses along with the mathematical models and damping values used.

3.7.2.3.4 Methods Used to Couple Soil with Seismic System Structures

The analyses of soil-supported structures was performed as explained in Sections 3.7.1.6 and 3.7.2.2.3. A finite element analysis was not performed to couple soil with structures.

3.7.2.3.5 Development of Floor Response Spectra

Response spectra for use in computing the response of structural appurtenances, or of equipment attached to Category I structures were produced by the time-history modal analysis technique. The four artificially produced accelerograms (Section 2.5.2.4) were the input motion at top of rock. To obtain a set of response spectra for one mass point for one direction of motion, the procedure outlined in Figure 3.7.2-77 was used.

Spectral values were computed for 55 periods using the distribution shown in Table 3.7.1-2. In all time-history calculations, a time interval of 0.010 second was used.

As a minimum, response spectra were computed for percentages of critical equipment damping of 0.5, 1.0, and 2.0. The response was calculated for the 1/2 SSE and the SSE except where the same percentage of critical structural damping was specified for both earthquakes. Where the 1/2 SSE and SSE structural damping are the same, response was calculated for the 1/2 SSE and/or the SSE (the SSE results equal twice the 1/2 SSE). See Table 3.7.1-3 for damping ratios used in piping analysis.

Horizontal response spectra were produced at the foundation level and at all major floors and at other points of interest within the structure for both east-west and north-south directions, except where symmetry justifies one direction.

As a minimum, vertical response spectra were produced at the foundation level and at the point of maximum structural amplification. The response spectra for rock was used throughout that portion of the structure where no structural amplification occurred. For other points, values were interpolated linearly between the response spectra for rock and for the point of maximum structural amplification.

3.7.2.3.6 Differential Seismic Movement of Interconnected Components

See Section 3.7.3.6.

3.7.2.3.7 Effects of Variations on Floor Response Spectra

For the soil-supported structures in which floor response spectra were produced, the soil properties were varied, and soil structure interaction was considered as discussed in Sections 3.7.1.6 and 3.7.2.2.3.

The peaks of the floor response spectra were widened by ±10 percent on the period or frequency scale to account for variations and uncertainties in the structural properties. As an option, response peak shifting as defined in ASME Code Case N-397 was used in some cases.

The majority of the Category I structures are supported on rock. As a result, the effects of soil-structure interaction are not a factor in widening the peaks of the floor spectra for these structures. For those structures which are not supported on rock, the foundation conditions were varied over a wide range, and floor spectra which envelope these conditions were developed before the widening criteria were applied.

In the analysis of the Category I structures, studies were made to ensure that enough mass points were used to sufficiently model the dynamic behavior of the structures. Also during the course of the analyses, numerous revisions were made in the structure which illustrate that reasonable variations in the structural material properties do not significantly change the period of vibrations of the structures.

Based on the above analyses, ±10 percent widening of the peaks of the floor spectra or peak shifting is sufficient to account for the variations and uncertainties in the structural properties.

3.7.2.3.8 Use of Constant Vertical Load Factors

A vertical lumped mass dynamic analysis was performed for all the Category I structures to determine the vertical loads. Constant vertical load factors were not used unless the dynamic analysis indicated the structure behaved as a rigid body in the vertical direction.

Constant vertical load factors were not used as the vertical floor response load for the seismic design of Category I systems and components within Westinghouse scope of responsibility.

Category I systems and components, when analyzed for vertical motion, used lump mass dynamic techniques. The results for each horizontal earthquake analysis were separately added on an absolute basis to those from the vertical earthquake analysis. The appropriate floor response spectra was used for the analysis. The dynamic mathematical model properly accounts for the amplification of the supports of the systems and components.

3.7.2.3.9 Method Used to Account for Torsional Effects

The dynamic analysis of structures is discussed in Section 3.7.2.1. The structures were analyzed for torsional effects using a lumped mass cantilever beam model which adequately represents all stiffness and inertial characteristics. This includes the inclusion of the torsional moment of inertia, eccentricity, and mass moment of inertia.

In the process of preparing lumped mass mathematical models for the structures, the location of both the center of rotation, and center of mass for each floor were computed.

The models described above were subjected to seismic excitations and the resultant responses in the form of frequencies, mode shapes, and stresses were obtained.

3.7.2.3.10 Comparison of Responses

Figure 3.7.2-78 shows a comparison of the accelerations obtained from the modal analysis time history and the response spectrum methods for the Auxiliary Control Building.

3.7.2.3.11 Methods for Seismic Analysis of Dams

Since no dams are utilized to impound bodies of water to serve as heat sinks, this section is not applicable to this power plant.

3.7.2.3.12 Methods to Determine Category I Structure Overturning Moments

From the dynamic analyses of the structures, the seismic moments, shears, and vertical loads were determined at the base of the structure.

The seismic moments, shears, and vertical loads were used in combination with other appropriate loads in determining total overturning effects as discussed in Section 3.8.

3.7.2.3.13 Analysis Procedure for Damping

None of the models used for Category I structures were coupled together, therefore, the damping values used were as shown in Section 3.7.1.3.

For systems and components with different elements coupled together in the same dynamic model, the lower percent damping was used in the analysis, or composite modal damping was computed using the individual component damping ratios as prescribed in Table 3.7.1-3.

IEEE 344-1975 provides the general basis for damping ratios used in analysis for seismic qualification of Category I equipment, including fluid system components such as pumps, valves, and tanks (refer to Table 3.7.1-3). The seismic qualification of safety-related equipment/components at SQN has been evaluated against IEEE 344-1975 and Regulatory Guide 1.100 (Reference 1). The NRC's Seismic Qualification Review Team (SQRT) conducted the evaluation during the licensing phase. The SQRT concluded that the SQN components/equipment, originally qualified in accordance with IEEE 344-1971, satisfies the requirements of IEEE 344-1975 and Regulatory Guide 1.100 (Reference 2). The results of the NRC SQRT audit provide justification for using damping ratios from IEEE 344-1975 in the analysis of Category I equipment for the design basis seismic events. However, after April 1993, the damping ratios used in analysis for equipment, components, and their supports will be as given in Table 3.7.1-3A (see Ref. 21).

Ensure the following two items are met when using Code Case N411:

1) Use the code case for piping systems analyzed by response spectrum methods and not those using time-history analysis methods;

2) When alternate damping criteria of this code are used, they will be used in their entirety in a given analysis and shall not be a mixture of Regulatory Guide 1.6.1 criteria and the alternated criteria of this code case.

3.7.3 Seismic Subsystem Analysis

3.7.3.1 Determination of Number of Earthquake Cycles

3.7.3.1.1 Category I Systems and Components Other Than NSSS

During the design life of the plant (40 years), two earthquakes of 1/2-SSE magnitude and one SSE are postulated to occur. This was based upon a study of seismic history in the Southern

Appalachian Province over a 100 year period. Based on this study, each occurrence is conservatively assumed to have a time duration of 15 seconds of strong excitation.

For Class A, Category I components, an evaluation of predominant frequencies revealed that the most significant response of components is conservatively considered using an average frequency of 20 Hz. Therefore, the number of cycles considered for the 1/2 SSE and the SSE are 600 cycles and 300 cycles, respectively.

Stresses in Class B, C, and D components are well within elastic limits and, as such, the equipment is capable of withstanding a very large number of seismic disturbances before a stress reduction factor (f) must be considered.

3.7.3.1.2 NSSS System

Where fatigue analyses of mechanical systems and components are required, Westinghouse specifies in the equipment specification the number of cycles of the 1/2 SSE to be considered. The number of cycles considered for the NSSS components are given in Table 5.2.1-1. The fatigue analyses are performed and presented as part of the components stress report.

3.7.3.2 Basis for Frequency Selection

The method used to analyze systems for dynamic loadings is the modal response spectrum method. Considerations used in preparing dynamic models for coupled and uncoupled systems are discussed in Section 3.7.3.6.

The system or component model is subjected to loadings in the form of accelerations that represent the seismic environment of its supports. Since the response spectrum employed is representative of the building elevation at the equipment location considered, structural amplifications are reflected in the spectra. Therefore, the input acceleration values taken from the building response spectra and utilized as input to the dynamic analysis of the subsystem assures the component model is loaded in a representative manner and the proper amplifications determined.

For other mechanical components, the building resonant frequency is usually avoided either by increasing or decreasing the stiffness and/or mass characteristics of the subsystem. Where this was found to be impractical or impossible, the subsystem component was analyzed and designed for the amplified appropriate loading.

3.7.3.3 Modal Response Combinations (TVA Analysis)

For piping, all modal responses, such as displacements, shear, moments, stresses, and/or accelerations, are combined using the method of the square root of the sum of the squares (SRSS) except that for modes with closely spaced frequencies the absolute sum of the modal responses is used. The method is also described in Section 3.7.3.6. For components and equipment procured prior to September 1974 and qualified by response spectrum analysis, modal responses were combined by the SRSS method without consideration of closely spaced modes.

Subsequent to September 1974, absolute summation of modes spaced within ten percent (based on period) was required.

3.7.3.4 Modal Response of Closely Spaced Frequencies (NSSS Analysis)

For analyses within the Westinghouse scope of responsibility, the total seismic response for each analysis was obtained by combining the individual modal responses utilizing the square root sum of the squares. For systems having modes with closely spaced frequencies, this method was modified to include the possible effect of these modes. The groups of closely spaced modes were chosen such that the difference between the frequencies of the first mode and the last mode in the group does not exceed 10 percent of the lower frequency. Combined total response or systems which have such closely spaced modal frequencies were obtained by adding to the square root of the sum of the squares of all modes the product of the responses of the modes in each group of closely spaced modes and a coupling factor ε. This can be represented mathematically as:

where: $$R_T^2 = \sum_{i=1}^{N} R_i^2 + 2\sum_{j=1}^{S} \sum_{K=M_j}^{N_j-1} \sum_{l=K+1}^{N_j} R_K R_l \varepsilon_{kl}$$

R_T = total response

R_I = absolute value of response of mode i

N = total number of modes considered

S = number of groups of closely spaced modes

M_j = lowest modal number associated with group j of closely spaced modes

N_j = highest modal number associated with group j of closely spaced modes

ε_{kl} = coupling factor with

$$\varepsilon_{kl} = \left\{ 1 + \left[\frac{\omega'_K - \omega'_l}{\beta'_K \omega_K + \beta'_l \omega_l} \right]^2 \right\}^{-1}$$

and

$$\omega'_K = \omega_K \left[1 - \left(\beta'_K \right)^2 \right]^{1/2}$$

$$\beta'_K = \beta_K + \frac{2}{\omega_K \tau_d}$$

ω_K = frequency of closed spaced modes K(rad/sec)

β_K = fraction of critical damping in closely spaced mode K

τ_d = duration of the earthquake (sec.)

3.7.3.5 Equivalent Static Loads

A simplified seismic analysis, where floor response accelerations coincident with the first natural frequency are applied as static coefficients, is used only if it has been demonstrated that the component or equipment is rigid ($\geq$ 25 Hz), or is adequately represented by a single degree of freedom model, and is shown to possess no more than one mode in each orthogonal axis in the flexible response range (< 25 Hz). If no assessment of the dynamic characteristics (resonant frequencies) of the component or equipment is made, the peak acceleration of the applicable floor spectrum is increased by a factor of 1.5. The equivalent static loads in this case are determined from the increased acceleration level.

3.7.3.6 Seismic Analysis of System Piping

The analysis of classified fluid system components other than the Reactor Coolant System will consider both static and dynamic loadings. The loading combinations considered and the allowable stress limits are provided in Table 3.9.2-5. Thermal expansion, dead load, and normal operational stresses due to system pressurization are analyzed per ANSI B31.1.0-1967 Code requirements, and the seismic analysis was performed as described herein. At locations of large change in flexibility within a given piping system, stresses due to all loadings are appropriately combined with the seismic stresses in accordance with Code requirements.

All piping systems important to safety that have been designed to remain functional in the event of a safe shutdown earthquake (SSE) are designated as Category I.

Those portions of structures, systems, or components which perform secondary safety functions and which are not essential to safe shutdown and isolation of the reactor but whose failure could jeopardize, to an unacceptable extent, the achievement of a primary safety function are considered Category I (L) safety related.

Where pressure boundary integrity is required, the piping is classified as Category I (L) A. For Category I (L) A, all piping and tubing shall be analyzed to meet the requirements for Category I except that ASME Section III subsection NC Equation 9 needs not to be evaluated for the upset condition.

Where pressure boundary integrity is not required during and after a seismic event, and where position retention is required, the piping is classified as Category I (L) B. The position retention method provides normal support for the self-weight and seismic support of the piping to ensure that the piping maintains position sufficient to prevent damage to adjacent piping or equipment performing a primary safety function.

3.7.3.6.1 Method of Analysis

Most piping systems 6 inches and greater in diameter and many of the more critical smaller lines are mathematically modeled and a complete rigorous dynamic analysis is performed. An approximate dynamic analysis is performed on the balance of the critical systems. The approximate method is described in Section 3.7.3.9. The analysis of buried piping is described in Section 3.7.3.12.

A rigorous dynamic seismic analysis is performed on applicable piping systems by the response spectrum method. Each pipe system is idealized as a mathematical model consisting of lumped masses connected by weightless elastic members. Lumped masses and elastic members adequately represent the dynamic and elastic characteristics of the pipe system. Using the elastic properties of the pipe, the flexibility matrix for the pipe is determined. The flexibility calculations include the effects of the torsional and bending deformations. The stiffness of curved members, valves, branch connections, etc., are taken into consideration.

Once the flexibility and mass matrices of the mathematical model are determined, the frequencies and mode shapes for all significant modes of vibration are determined. All significant modes having a period greater than 0.03 seconds are used in the analysis. The mode shapes and frequencies are solved in accordance with the following equation.

$$(K - w_n^2 M)\ \phi_n = 0$$

where: K = Square stiffness matrix of the piping system

M = Mass matrix for the piping system

w_n = Frequency for the n^{th} mode

ϕ_n = Mode shape matrix of the n^{th} mode

After the frequency is determined for each mode, the participation factors can be calculated by the following equation:

$$\Gamma_{njk} = \frac{\phi_n^T\ M\gamma_{jk}}{\phi_n^T\ M\phi_n}$$

where: Γ_{njk} = participation factor for mode n in the jth direction of support zone k.

γ_{jk} = displacement matrix of all modes due to a unit displacement of the jth direction restrained degrees of freedom in zone k.

Support Zone = A set of restrained nodes which move together during a dynamic event.

Using these results and the corresponding spectral accelerations of the mode for the direction and support zone being excited, the response for each mode is determined by the following equation:

$$(V_{in})_{jk} = \frac{\Gamma_{njk} \quad \phi_{in} \quad S_{anjk}}{w_n^2}$$

where: $(V_{in})_{jk}$ = displacement of mass i for mode n for an earthquake in the jth direction of zone k.

ϕ_{in} = value of mass i in ϕ_n

S_{anjk} = Spectral acceleration for mode n for an earthquake in the jth direction of zone k.

Using these results, the maximum displacement for each mode is calculated for each mass point in accordance with the following equation:

$$(V_{in})_j = \left[\sum_{k=1}^{nz} (V_{in})_{jk}^2 \right]^{1/2}$$

where: $(V_{in})_j$ = displacement of mass i for mode n for an earthquake in the jth direction.

nz = number of support zones used for the pipe loop.

The maximum displacements for each mode for the combined two dimensional earthquake are calculated as follows:

$$V_{in} = \sqrt{(V_{in})_x^2 + (V_{in})_y^2}$$

where: V_{in} = Maximum displacement of mass i for mode n

The total displacement for each mass is determined by taking the square root of the sum of the squares of the maximum deflection for each mode:

$$V_i = \sqrt{\sum V_{in}^2} \quad *$$

where: V_i = Maximum displacement of mass i due to all modes calculated

*Except that for modes with closely spaced frequencies, the absolute sum of the modal responses shall be used.

The inertia forces for each direction of earthquake for each mode are then determined from:

$$Q_n = KV_n$$

where: Q_n = Inertia force matrix for mode n

V_n = Displacement matrix for mode n

K = Square stiffness matrix of the pipe loop

Each mode's contribution to the total displacement, internal forces, moments, and stresses is determined from standard structural analysis methods using the inertia forces for each mode as an external loading condition. The total combined results are obtained by taking the square root of the sum of the squares of each parameter under consideration, in a manner similar to that done for displacements.

Seismic Analysis of Piping Systems That Span Two or More Seismic Support Zones Such as Buildings, Portions of Buildings or Primary Components

Each building, portion of building, or primary component may be considered a separate support zone. The worst enveloped response spectrum to which any portion of the pipe in that zone is subjected, is used to represent the input motion in that zone.

For the evaluation of relative support motions in the seismic analysis of piping systems interconnecting two or more seismic support zones, the maximum relative movement between component supports is assumed and the piping system is subjected to movements through the piping system supports and restraints. Separate cases for building north-south earthquake and building east-west earthquake are considered. Support movements are based on the maximum of the floor movements immediately above and below the support location. The stresses in the piping resulting from these imposed restraint movements are considered as secondary stresses and are assumed to act concurrently with the thermal stresses.

3.7.3.7 Basis for Computing Combined Response

Category I piping systems are evaluated for excitation in each of two orthogonal horizontal directions and are individually combined with the excitation in the vertical direction. The stresses, moments, etc., at any point in the piping system are taken to be the largest value resulting from either of these combinations.

3.7.3.8 Amplified Seismic Response

Response spectra for Category I structures have been developed for the two orthogonal horizontal directions. For Category I equipment and piping that is installed in regions of the structure where vertical rigidity exists, vertical loads are conservatively assumed to be equal to two-thirds of the building horizontal ground response. In regions where the structure is flexible in the vertical direction, appropriate response spectra have been developed to represent the building response at the elevations in question.

For piping, the seismic analysis results (displacements, stresses, moments, etc.) are obtained from application of vertical response combined by the square root of the sum of the squares with each of the two orthogonal horizontal responses. For floor mounted equipment, vertical response is combined with each of the two orthogonal horizontal responses by absolute summation. In either case, the larger of the two combined responses is taken as the limiting case for design of the piping, components, or equipment.

3.7.3.9 Use of Alternate Dynamic Analysis

In order to determine the seismic capability of smaller piping systems (generally less than 6-inch diameter), a conservative approximate analysis is employed which includes the deadweight of the pipe as well as horizontal and vertical seismic loadings. Justification for the approximate method has been demonstrated by performing a dynamic analysis for representative systems to show that the approximate method is conservative.

Reference 20 provides NRC acceptance of TVA's Alternate Analysis methodology.

3.7.3.10 Modal Period Variation

The response spectra used in the mathematical models for Category I piping and components have been modified to take into consideration variations that may affect where peaks occur. The design spectrum envelope was widened by at least 10 percent by period or response peak shifting (as defined in ASME Code Case N-397) was used in order to account for uncertainties in the structural model and input. For all rigid and flexible equipment, the maximum acceleration was obtained from the spectrum response curves developed for the applicable elevation.

3.7.3.11 Torsional Effects of Eccentric Masses

Eccentric masses are modeled in the piping mathematical model as cantilevered weightless rods with a length equal to the distance from the center of gravity of the mass to the pipe flow axis.

3.7.3.12 Buried Seismic Category I Piping Systems

Category I buried piping which penetrates structures where fill settlement or seismic movements are expected to be high is protected from differential movement of the soil and structure by a guard box and flexible joints or by an oversized pipe sleeve with or without flexible joints. The guard box is supported by and moves with the soil. One open end of the box butts against, but is not connected to, the building. Large pipes which may be overstressed by the differential movement of the structure and the soil-bearing end of the guard box are provided with two flexible couplings. One coupling is located near the structure and the other near the soil-bearing end of the guard box. The guard box provides adequate clearance to permit one joint to move with the structure and one with the soil without contacting the pipe.

An oversized pipe sleeve is also supported and moves with the soil. One open end of the pipe sleeve butts against, but is not connected to, the building or a flexible joint at the face of the building. The purpose, as with the guard box, is to allow the process pipe to accommodate the relative building-soil movements without overstressing at the building to soil interface.

For seismic-classed, buried piping that penetrates structures in areas where very little fill is involved and seismic movements are low, protection from differential movement of the soil and structure is provided by an oversized opening in the structure. The annular space between the pipe and opening is filled with a resilient material. The first support inside the structure is located to allow for relative movement of the pipe and structure. The soil-structure interface is treated as an anchor, and stresses are limited to Code allowables.

Where practical, seismic-classed buried piping is routed to avoid areas of weak soils. Where weak soils are encountered, the bad material is removed and replaced by backfill. The backfill was placed to standards that ensure suitable bearing conditions, therefore, the transition from one material to another, i.e., insitu soil to backfill should not be a problem. In lieu of the above, in some cases an analysis was performed to show that the pipe has sufficient strength to bridge the discontinuity and support the soil above the pipe without exceeding the allowable stress of the piping material.

Buried piping complies with the loading conditions and stress limits given in Section 3.9.2.5.2 and is analyzed seismically as follows.

The soil is considered to be a horizontal 1-layer system which responds to the earthquake by moving in a continuous sinusoidal plane wave and supported by a second layer or base material. The top layer is assumed to pick up accelerations from the base material.

Utilizing the average values for the shear wave velocity and density for the top layers, the ground deformation pattern in terms of wave length and amplitude is determined. The buried pipes are assumed to deform along with the surrounding soil layers. No relative displacement between the soil and the buried piping is considered.

3.7.3.13 Interaction of Other Piping with Category I Piping

The seismic-induced effects of non-Category I piping systems on Category I piping is accounted for by including in the analysis of the Category I piping a length of the non-Category I system

equal to at least the first seismic restraint or anchor beyond the point of change in classification. Normally, a valve serves as a seismic-nonseismic boundary in a fluid system. The valve capability to maintain a pressure boundary in the event of a seismic event is assured by seismically designing piping on the nonclassified side through the first seismic restraint or anchor beyond the valve.

3.7.3.14 Field Location of Supports and Restraints

Criteria have been developed for field use in locating supports for Category I, TVA Class B, C, and D process and instrument piping. The applicability of the criteria according to line size, schedule, temperature, pressure, and location is described in Section 3.9.2.6.

The criteria was based upon a detailed analytical study that evaluated the important parameters which included dead and live weights, seismic, and thermal considerations for a range of operating temperatures and a given maximum operating pressure. In order to maintain stresses in the piping components to well within the ANSI B31.1.0-1967 Power Piping Code limits, support requirements were determined for a range of line sizes and materials that are used in the plant. Data was generated for each pipe size according to the alternate dynamic analysis method, Subsection 3.7.3.9.

3.7.3.15 Seismic Analysis for Fuel Elements, Control Rod Assemblies, and Control Rod Drives

Fuel assembly component stresses induced by horizontal seismic disturbances are analyzed through the use of finite element computer modeling. The time-history floor response based on a standard seismic time history normalized to SSE levels is used as the seismic input. The reactor internals and the fuel assemblies are modeled as spring and lumped mass systems. The seismic response of the fuel assemblies is analyzed to determine design adequacy. A detailed discussion of the analyses performed for typical fuel assemblies is contained in References 16 and 22.

The Control Rod Drive Mechanisms (CRDM) are seismically analyzed to confirm that system stresses under seismic conditions do not exceed allowable levels as defined by the ASME Boiler and Pressure Vessel Code, Section III for "Upset" and "Faulted" conditions. Based on these stress criteria, the allowable seismic stresses in terms of bending moments in the structure are determined. The CRDM is mathematically modeled as a system of lumped and distributed masses. The model is analyzed under appropriate seismic excitation and the resultant seismic bending moments along the length of the CRDM are calculated. These values are then compared to the allowable seismic bending moments along the length of the CRDM. These values are then compared to the allowable seismic bending moments for the equipment, to assure adequacy of the design.

3.7.3.16 Seismic Qualification of Main Control Room Suspended Ceiling and Air Flow Delivery Components

Flexible ducting, triangular ducting, and air bar linear diffusers deliver air flow from the sheet metal ducts located above the Main Control Room (MCR) suspended ceiling to the air space below the ceiling. These air flow delivery components have been seismically qualified to ensure position retention and structural integrity such that pressure boundary and air flow delivery are maintained during and after the Safe Shutdown Earthquake (SSE).

Seismic qualification of the suspended ceiling and the air flow delivery components has been accomplished by rigorous time history analysis using the ANSYS computer code. The analysis models non-linear response due to gaps, friction, ceiling support wires, and geometric effects of the ceiling grid work. The seismic time histories correspond to the control building response to the SSE at the floor

elevation above the suspended ceiling. The time histories were adjusted to account for ±10 percent frequency uncertainty. A factor of safety of at least 1.3 for seismic qualification of the ceiling and air flow delivery components was demonstrated by increasing the time history motions by 30 percent and verifying that the seismic demand is less than the capacity of the ceiling grid members (including air bars), support wires, and flexible and triangular ducts. The ceiling grid member and support wire capacities are based on classical structural analysis formulas. The flexible and triangular duct capacities were based on analysis for potential failure modes, industry precedents, and the analytical determination that the ceiling grid work remains stable. Other suspended ceiling components, including luminous panels, were shown to retain their position during and after the SSE.

3.7.4 Seismic Instrumentation Program

Seismic instrumentation is provided in order to assess the effects on the plant of earthquakes. The Seismic Monitoring System is not safety-related; nor does it have any effect on safety-related systems or equipment. The components of the seismic monitoring system were selected to emphasize accuracy and reliability, while at the same time minimizing the maintenance and surveillance resources required to support the system. The instrumentation program is described in the following sections.

3.7.4.1 Comparison with NRC Regulatory Guide 1.12

The instrumentation is described in Section 3.7.4.2 below and meets the intent of NRC Regulatory Guide 1.12, Revision 1 (April 1974), although the array of instruments differs. The instrumentation described below is consistent with the guidance in Sections C.1.b and C.1.c of RG 1.12 R1 with regard to the number and locations of triaxial response spectrum recorders. However, the function of the response spectrum recorders is now provided by event analysis software capabilities described in Section 3.7.4.2.5b below. Accelerometers and accelerographs at the locations noted below will record accelerograms for which event analysis software will provide a timely display of spectral content. The accuracy and reliability of the instrumentation below exceed that of the Response Spectrum Recorders discussed in RG 1.12 R1.

The instrumentation described below is not consistent with the guidance in Section C.1.a of RG 1.12 R1 with regard to the installation of triaxial peak accelerographs. These peak accelerographs (usually "scratch gages") have been shown to have questionable accuracy, are difficult to maintain, and have minimal value in post-earthquake evaluations. Therefore, this function is deleted from the upgraded seismic monitoring system.

In summary, the instrumentation described below meets the intent of RG 1.12 R1.

3.7.4.2 Location and Description of Instrumentation

The instrumentation consists of the following:

NOTE: The full scale range of the seismic monitoring instrumentation as shown in the following text represents absolute values.

1. A strong motion triaxial accelerometer in the Unit 1 Reactor Building on the base slab at elevation 680.0 in the annulus between the Shield Building wall and the containment vessel. The full scale range of the transducer is from 0g to 1.0g with a bandwidth of 0 Hz to 50 Hz and a temperature effect of less than 2 percent per 100°F change. The accelerometer is connected to a digital recorder, as described in item 5.

2. A strong motion triaxial accelerometer installed inside the crane wall in the Unit 1 Reactor Building on the floor slab at elevation 734.0. This accelerometer and the accelerometer discussed in item 1 have identical response characteristics and are oriented with their recording axes aligned. This accelerometer is also connected to a second digital recorder, as described in item 5.

3. A strong motion triaxial accelerograph, with a full-scale range of 0-2g, inside the Diesel Generator Building on the base slab at elevation 722.0. The internal recorder is capable of digitally recording a minimum of 25 minutes of data with a minimum of 3 seconds of pre-event memory and 5 seconds of post-event memory. An internal seismic trigger with a bandwidth of 0.1Hz - 12.5 Hz actuates the recording system when a threshold acceleration level is sensed. The unit is equipped with an internal rechargeable battery and an external plug-in type battery charger.

4. A strong motion triaxial accelerograph inside the Auxiliary Building on the floor slab at elevation 734.0. This unit is identical in capability to that described in item 3.

5. A seismic instrumentation panelboard located at elevation 685.0 in the Unit 1 Control Building in the Auxiliary Instrument Room between columns C4 and C5. The panelboard houses a centralized seismic monitoring system consisting of a Recorder Panel, a Central Controller, a Display Panel, an Alarm Panel, and a Printer Panel. A description of each item mounted on the panelboard is given below.

a) A Recorder Panel containing two digital recorders capable of a minimum of 18-bit resolution. The two strong motion accelerometers of items 1 and 2 above provide input to the recorders. Each recorder is capable of digitally recording a minimum of 25 minutes of data with a minimum of 3 seconds of pre-event memory and 5 seconds of post-event memory. Each recorder has an internal trigger with a bandwidth of 0.1 to 12.5 Hz which constantly monitors its interconnected triaxial accelerometer. When one of the recorders senses a seismic event, an interconnect network causes the other recorder to trigger and record data at the same time to ensure time-synchronized event-data files. The triggers threshold is 0.01g. A signal is also sent to the Alarm Panel to indicate that the system is recording (see item 5c). The recorders can operate for a minimum of 24 hours on internal batteries.

b) A Central Controller consisting of an industrial computer and custom software, which provides a user interface in a multi-tasking operating system that supports simultaneous acquisition and interrogation. The controller is powered by 120V AC power. The Central Controller retrieves data files from the digital recorders after an event and performs automatic analysis of the data. The event-analysis capabilities include computation of the Cumulative Absolute Velocity (CAV), spectral content of the recorded data, and comparison to the site 1/2 SSE design basis response spectrum. The Central Controller's software capabilities also include automatic event alarm and annunciation (see item 5c). The event analysis functions of the Central Controller may be performed off-line, if necessary.

c) An Alarm Panel containing visual alarms to locally indicate that a seismic event has been recorded, the 1/2 SSE site design response spectrum has been exceeded in a damaging frequency range, and to indicate either loss of AC or DC power. The seismic event alarm is triggered by the Recorder Panel; while the 1/2 SSE exceedance alarm is triggered by the Central Controller. Activation of either the event alarm or exceedance alarm also causes corresponding windows on an annunciator panel in the Main Control Room to illuminate.

d) A Display Panel to provide a visual display for operation of the centralized system.

e) A Printer panel to provide a permanent copy of operational data and event analysis results.

6. Annunciator lights mounted on a window box located in the Main Control Room, Unit 1, Control Building. The messages displayed on the annunciator windows in the Main Control Room indicate seismic event occurrence and 1/2 SSE Response Spectra Exceedance.

The basis for the selection of the Reactor Building for installation of seismic instrumentation is that it is the rock-supported building most important to safety. The basis for the selection of the Diesel Generator Building is that it is the soil-supported building most important to safety. The basis for the selection of the Auxiliary Building is that it is a rock-supported structure outside containment.

3.7.4.3 Control Room Operator Notification

The operator receives two annunciation signals in the Main Control Room. The first annunciation is provided by the Recorder Panel described in item 5a, Section 3.7.4.2, which informs the operator that a seismic event is being recorded. This annunciation indicates that one or both of the triggers for the two digital recorders sensed seismic motion in excess of 0.01g.

The second annunciation signal is received later and is provided by the Central Controller described in item 5b, Section 3.7.4.2, and is only received if the event-analysis software indicates that the site 1/2 SSE site design basis response spectrum has been exceeded in a potentially damaging frequency range, as described in Section 3.7.4.4.

The basis for establishing the 1/2-SSE design basis response spectrum for the levels at which control room operator notification is required is that the design of structures, systems, and components (SSC) for loading combinations, which include 1/2 SSE, are to design basis allowable stress levels which are well within the elastic limit of the materials.

3.7.4.4 Controlled Shutdown Logic

The operator will utilize input from multiple sources to determine the need for a controlled shutdown following the seismic event. The decision for a controlled shutdown will be based primarily on an assessment of the actual damage potential of the event, which will be available within 4 hours, and on the results of short-term inspections, which will be available within 8 hours. The operator may also confirm that ground motion was sensed by plant personnel and/or confirm the occurrence of the seismic event with the National Earthquake Information Center. The purpose of these actions 1) to perform a preliminary assessment of the effect of the earthquake on the physical condition of SSC, and 2) to determine if shutdown of the plant is warranted based on observed damage to SSC, or because the 1/2 SSE has been exceeded.

The walkdowns of plant SSC in accessible areas of the plant will be performed within 8 hours following the seismic event. The walkdowns will be performed using the general guidance in Chapter 4 of EPRI Report NP-6695 (ref. 3.7.4.5-2). These walkdowns will include a check of the neutron flux monitoring sensors for changes and an inspection of the containment isolation system to ensure continued containment integrity. The walkdown data will be compared to data previously obtained from baseline and Maintenance Rule inspections in order to obtain a clear understanding of any seismic induced damage.

The assessment of the damage potential of the event will be made within 4 hours following the event using the OBE (i.e., 1/2 SSE) Exceedance Criteria developed by the Electric Power Research Institute (EPRI) and documented in references 3.7.4.5-1 thru 5. As noted above, the indication of damage potential will be provided by event-analysis software installed on the centralized seismic monitoring system described in Section 3.7.4.2. The analysis will be performed for the uncorrected accelerograms recorded from the strong motion triaxial accelerometer located in the annulus of the Unit 1 Reactor Building on the base slab (item 1 of Section 3.7.4.2). Use of the uncorrected accelerograms is known to be conservative. The basis for use of the seismic motion on the Reactor Building base slab is that the site 1/2 SSE design response spectrum is defined at top-of-rock, which corresponds to the Reactor Building base slab location.

The EPRI OBE Exceedance Criteria uses two indicators of damage potential. The first indicator of damage potential is specified as the CAV, or cumulative absolute velocity, of the accelerogram. A meaningful usage of the CAV requires that the recorded data be obtained by an accelerometer mounted in the free-field. As noted above, the 1/2 SSE design spectrum for Sequoyah is defined as occurring at top-of-rock (i.e., foundation level of the rock-supported structures); whereas, free-field is defined as top-of-soil at sufficient distance from nearby structures to preclude interference/interaction effects. The Seismic Monitoring System for Sequoyah does not have a free-field accelerometer. Therefore, the shutdown logic adopted for Sequoyah will concede CAV exceedance and base the assessment of damage potential solely on the second indicator, as discussed below.

In the absence of data from a free-field accelerometer, the second indicator is an evaluation of the frequency range in which the OBE spectrum is exceeded. This criteria is based on research which indicates that exceedances above a frequency of 10 Hz are not damaging to nuclear plant structures, systems, and components (SSC). The following two measures of damage potential are used.

- The 1/2 SSE site design basis response spectrum is exceeded if the 5 percent damping response spectra generated for any one of the three components of the uncorrected accelerograms from the Reactor Building foundation accelerometer is larger than:

    1. The corresponding 1/2 SSE design basis response spectral acceleration in a frequency range between 2-10 Hz, or
    2. The corresponding 1/2 SSE design basis response spectral velocity for frequencies between 1-2 Hz.

Therefore, Sequoyah will base the assessment of damage potential of the event on either a spectral acceleration exceedance between 2-10 Hz or a spectral velocity exceedance between 1-2 Hz.

Once the results of the walkdown and the assessment of damage potential of the event are available, the operators will determine 1) if a controlled shutdown is required and 2) the condition of the equipment needed to safely achieve shutdown. If the assessment of damage potential indicates that the 1/2 SSE Exceedance Criteria were not met, and the walkdown results are favorable, the plant will continue to operate. Basing shutdown logic on the actual damage potential of the event and on the results of short-term inspections reduces shutdown risk by avoidance of unnecessary shutdowns while ensuring that the operator has the information on plant status necessary to make an informed shutdown decision.

Post-shutdown actions, including retrieval of data, recalibration of seismic instruments, and comparison of measured and predicted responses will be based on the guidance in Chapters 5 and 6 of EPRI Report NP-6695 (Ref. 3.7.4.5-2).

3.7.5 Seismic Design Control Measures

3.7.5.1 Westinghouse Control Measures

Seismic Category I mechanical equipment supplied by Westinghouse has been qualified in accordance with the applicable seismic qualification requirements contained in Sections 3.7.2 and 3.7.3. Westinghouse provided a Certificate of Compliance, by letter dated February 16, 1988, from T. A. Lordi to J. B. Hosmer, certifying that all equipment supplied by Westinghouse is in conformance with the FSAR. An in-house Westinghouse document, cited in that letter, provides a basis for that certification. TVA has reviewed that document for methodology and applicability, and concluded that the analyses results presented in it comply with the FSAR requirements.

Documentation provided to TVA also demonstrates that Westinghouse was implementing a vendor audit program during the time equipment was procured and supplied to TVA for Sequoyah. By letters dated April 20, 1988 and June 1, 1988, from T. A. Lordi to J. B. Hosmer, Westinghouse provided a list of Quality Releases for some equipment and a QA checklist used by Westinghouse QA auditors circa 1970 to audit its vendors. Westinghouse stated that a sampling review of its quality records indicate that its vendors were audited; (1) to assure they had an acceptable QA program (to ensure requirements of the purchase specification would be met) (2) to ensure that their QA program was being properly implemented, and (3) that data submittals required by the purchase order specifications were reviewed as a precondition for issuance of equipment quality releases. Since the procurement specifications prescribed the load capacities at the specific locations necessary for the equipment to have the capacity to withstand plant specific seismic loads, Westinghouse concludes, and TVA concurs, that the above listed QA activities provided assurance that the equipment met the seismic design requirements.

Seismic Category I instrumentation and electrical equipment supplied by Westinghouse has been qualified as described and documented in a series of WCAPs referenced in Section 3.10. These documents provide the bases for establishing seismic qualification of Westinghouse supplied instrumentation and electrical equipment for Sequoyah.

3.7.5.2 TVA Control Measures

The procedure described below has been implemented by TVA to ensure that equipment purchased by TVA has satisfied seismic design requirements.

Seismic qualification requirements were included in TVA procurement contracts. For Sequoyah components and equipment, TVA provided vendors with direction and design information for performing seismic qualification which was consistent with IEEE Standard 344-1971 and Sections 3.7.2, 3.7.3, and 3.10. In TVA's specifications to the vendors, each vendor was required to submit design calculations which were independently reviewed and certified to ensure compliance with all contract requirements. If adequate independent review was not furnished by the vendor, TVA performed the independent review. TVA inspectors reviewed contractor fabrication processes and witnessed tests. TVA also hired component qualification engineers experienced in stress analysis, dynamic analysis, and testing to review vendor seismic qualification of equipment and to provide direction and design input to the specifications. Vendor seismic qualification documents were reviewed by established interface review (squadcheck) procedures. The procurement branch routed documentation to the appropriate engineering organization for review. The review comments were attached to the squadcheck and routed back to the responsible procurement branch.

Seismic design, review, and control procedures were formalized by issuance of Engineering Procedure (EP) 3.02 in 1977. This procedure was replaced in 1985 with discipline interface document CEB-DI-121.03, "Seismic Design, Review, and Control." Programmatically, the evaluation of vendor-generated seismic analyses and/or testing of components was conducted by the component qualification engineers of TVA's Civil Engineering Branch to ensure compliance with applicable design criteria and the FSAR. This review met the intent of an ASME Owner's review by present standards. In addition, the depth of review included a technical assessment to satisfy the TVA reviewer of the component's design adequacy. The TVA review process also included a review by the section supervisor before final approval of the vendor submittal. An arithmetic check was not typically performed unless the magnitude of numbers presented appeared to be unreasonable. Minor corrections were made directly on the vendor document submitted for review, and the document was approved with such corrections as noted. Major discrepancies resulted in the document being returned to the vendor for correction. The document was then resubmitted to TVA for further review.

NEDP-9 “Seismic/Structural Qualification” is the current TVA engineering procedure for seismic design, review, and control. Use of that procedure, or subsequent procedure, will ensure that equipment purchased by TVA will satisfy seismic requirements.

Waste Packaging Area	30 feet ±
Condensate Demineralizer Waste Evaporator Building	30 feet ±
East Steam Valve Room	20-25 feet ±
ERCW Pipe Support Slab	45-70 feet ±

TABLE 3.7.2-1

SUMMARY OF VARIED PARAMETER RANGES USED IN THE SEISMIC ANALYSIS OF THE ICE CONDENSER BASKET SUPPORT FRAME

Item	Description	Sequoyah Parameters
1	Lower Support Structure Stiffness	
	a. Radial Direction	430,000 lb/in
	b. Tangential Direction	670,000 lb/in
2	Lattice Frame Wall Panels Combined Stiffness	
	a. Radial Direction	50,000 lb/in
	b. Tangential Direction	23,900 lb/in
3	Local Impact Stiffness	
	a. Radial Direction	4.8 to 9.2 Kip/in
	b. Tangential Direction	4.8 to 11.8 Kip/in
4	Ice Basket Weight with Ice	37 lb/ft
5	Gap Size	0.05 inch
6	Ice Basket Stiffness	
	a. Bending Rigidity (EI)	330×10^6 lb/in^2
	b. Shear Rigidity (GA_s)	

where: E = modulus of elasticity

I = moment of inertia

G = shear modulus

A_s = shear area

TABLE 3.7.2-2 (Sheet 1)

SEQUOYAH NUCLEAR PLANT
CATEGORY I STRUCTURES AFFECTED BY CONCRETE MODULUS CHANGE
FOR STRUCTURES LISTED IN TABLE 3.7.1-1

Structure	Reanalysis Yes	Reanalysis No	Reason
Reactor Buildings - Units 1 & 2			
Shield Buildings		X	Modulus changed from 3.8 x 10^6 lb/in^2 to 4.1 x 10^6 lb/in^2. The effects of this change are negligible.
Interior Concrete Structures	X		Modulus changed from 3.2 x 10^6 lb/in^2 to 4.8 x 10^6 lb/in^2.
Auxiliary-Control Building	X		Modulus changed from 3.2 x 10^6 lb/in^2 to 4.8 x 10^6 lb/in^2.
Intake Pumping Station		X	Structure is rigid; therefore, the modulus change has no effect.
Intake Pumping Station Retaining Walls		X	Same as intake pumping station.
Diesel-Generator Building		X	Motion is due to soil-structure interaction and the building modes are rigid.
Waste Packaging Area		X	Same as diesel-generator building.
Steam Valve Room		X	Same as diesel-generator building.
Refueling Water Tanks and Pipe Tunnels		X	Motion of soil is predominate effect on structures.
Portable Diesel Pump* and Pipe Tunnels		X	Same as intake pumping station.

* Portable diesel pump is not required after operation of ERCW intake pumping station.

TABLE 3.7.2-2 (Sheet 2)

Structure	Reanalysis Yes	Reanalysis No	Reason
Liquid CO_2 Storage Vault		X	Same as intake pumping station.
Additional Equipment Buildings	X		Modulus changed from 3.2×10^6 lb/in^2 to 4.1×10^6 lb/in^2 plus numerous structural layout changes were made.

3.8 DESIGN OF CATEGORY I STRUCTURES

3.8.1 Concrete Containment

The Reactor Building is a Category I structure in its entirety and is designed to remain functional in the event of a SSE, or tornado, or a flood.

3.8.1.1 Shield Building

The Shield Building, shown in Figures 1.2.3-11, -12, and -13, is a reinforced concrete structure surrounding the steel containment structure and is designed to provide: radiation shielding from accident conditions, radiation shielding from parts of the Reactor Coolant System during operation, and protection of the steel containment vessel from low temperatures, adverse atmospheric conditions, external missiles, and flood. The Shield Building provides barrier for the annulus ventilation system which also serves as a redundant second containment barrier for control of leakage. The Shield Building is a reinforced concrete cylinder supported by a circular base slab and covered at the top with a spherical dome. It is located adjacent to the Auxiliary Building, Valve Room Buildings, and the Additional Equipment Building, as shown in Figure 1.2.3-1. It is physically separated from these buildings by a 1-inch expansion joint. Only the base slab resists the LOCA pressure load which is transmitted to it through a steel plate liner anchored to its top face and also through the anchors of the steel containment shell, interior structures and piping and equipment supports to the base slab. For further discussion of the base slab see Section 3.8.5.1.

The cylinder wall is approximately 150 feet in height from the liner on the base slab to the spring line of the dome. It has an inside diameter of 125 feet-1 inch and a thickness of 3 feet. The approximate inside height is 175 feet from the liner on the base slab to the dome apex. Conventional steel reinforcing bars were used throughout the structure and were placed in a horizontal and vertical pattern in each face of the cylinder wall. The area of reinforcement in each direction of each face is not less than 0.0015 times the gross concrete area.

The effects of penetrations through the wall were considered. Penetrations, 12 inches or less in diameter, do not significantly disturb the reinforcing pattern in the wall. Therefore, no special reinforcing considerations were made at these areas.

For penetrations larger than 12 inches, reinforcing is terminated at the opening. Supplemental reinforcing is added, both vertically and horizontally, to replace the reinforcing terminated. The amount of supplemental reinforcing added is equal to or greater than the amount of reinforcing removed and is placed adjacent to the penetration. In addition, rectangular and square box-outs in the wall have diagonal reinforcing across the corners. All reinforcing bars were lap spliced in accordance with ACI 318-63 requirements for Strength Design.

Reinforcing steel bars in the dome were arranged in a radial and circumferential pattern. A grid pattern was used at the crown of the dome.

A ring tension beam is provided at the dome-cylinder junction to resist the outward thrust from the dome roof. The tensile force in the ring beam is resisted by 24 No. 11 reinforcing bars. These bars are spliced by lapping 8 feet 6 inches. Laps are uniformly staggered around the

circumference of the ring beam so that at any cross section only four bars are spliced out of the total 24 bars. That is, at any section, 20 bars are continuous and unspliced. These continuous, unspliced bars alone will carry the imposed load with only a 20 percent increase in stress. Stirrups enclosing the main reinforcement are spaced on 15-inch centers.

To facilitate removal of the old steam generators (OSGs) and installation of the replacement steam generators (RSGs) during the Unit 1 and Unit 2 steam generator replacement (SGR), two construction openings were cut in the concrete shield building dome of each unit. These openings were restored by splicing new reinforcing bar to the existing reinforcing bar using Bar-Lock couplers and pouring new concrete to close the openings.

3.8.1.1.1 Equipment Hatch Doors and Sleeves

An equipment hatch door and one sleeve are provided for each Reactor Unit. The steel sleeve forms an access through the Shield Building wall to the equipment hatch in the containment vessel for access to upper containment. Each sleeve extends from inside the Shield Building to the shielded passageway leading to the Auxiliary Building floor Elevation 734. Each door is of the hinged, double-leaf, marine type with seals for providing an airtight closure between the annulus surrounding the steel containment vessel and the inside of the Auxiliary Building. A door will normally be opened only when the reactor is in the shutdown, depressurized condition such that secondary containment is not required.

The sleeves, embedded in the Shield Building walls, are of welded steel construction, rectangular in cross section. The doors are hinged to the sleeves on the end toward the outside of the Shield Building wall and are of welded construction consisting of structural shapes with a steel skin plate.

Sealing of a door when closed is by means of solid, molded rubber seals mounted on the door. The seals contact the edge of the sleeve at the top and sides, a removable seal bar at the floor level, and a sealing bar at the meeting line of the two leaves.

The sealing bar at the meeting line is mounted on one of the leaves. Penetrations through the doors are sealed with solid rubber 0-ring type seals.

The doors are opened and closed manually. Latching of the doors in the closed position is accomplished by multiple hand-lever operated dogs acting on wedge surfaces around the perimeter and meeting edges of the door leaves. The doors are provided with concrete missile shield blocks on their Auxiliary Building side.

The doors and sleeves will maintain their structural and leak tight integrity and remain operational after being subjected to the environmental or accident conditions listed in Section 3.8.1.4.

3.8.1.2 Applicable Codes, Standards, and Specifications

The structural design of the Reinforced Concrete Shield Building is in compliance with the American Concrete Institute 318-63 building code working stress design requirements. All reinforcing steel conforms to the requirements of ASTM Designation A 615, Grade 60. Construction was carried out under the requirements of TVA Construction Specification G-2.

Unless otherwise indicated, the design and construction of the Shield Building was based upon the appropriate sections of the following codes, standards, and specifications.

Modifications to these codes, standards, and specifications are made where necessary to meet the specific requirements of the structures. Where date of edition, copyright, or addendum is specified, earlier versions of the listed documents were not used. In some instances, later revisions of the listed documents were used where design safety was not compromised.

3.8.1.3 Loads and Loading Combinations

The Shield Building dome and cylinder wall are subjected to the following loads:

Dead Load

This includes weight of the concrete structure plus any other permanent load contributing to stress, such as equipment, piping, and cable trays suspended from the structure.

Earth Pressure

The static soil pressure was computed using TVA General Earth Pressure Design Standards incorporating Coulomb's "Wedge of Pressure" theory. Standard soil properties for fine grained rolled fill are as follows:

Angle of internal friction = 32°

Angle of friction between soil and building	= 16°
Dry weight	= 120 lb/ft^3
Buoyant weight	= 65 lb/ft^3

Due to adjacent structures the soil does not completely surround the Shield Building but lies in a 185.5° segment around it. The soil was backfilled to a height of 29 feet above the base slab. A surcharge of 200 lb/ft^2 was used.

Hydrostatic Pressure

Uplift forces and lateral static pressure were computed using the full hydrostatic head measured from the water surface. The following water surface elevations were used in determining hydrostatic heads:

Design flood (flood of record)	= Elevation 687.0
Maximum probable flood	= Elevation 700.0
Probable maximum flood with wave runup (PMF)	= Elevation 726.8

(The PMF included the complete loss of the nearest upstream dam [Watts Bar] and 4.2 feet of wave runup. The 1998 reanalysis determined that the new PMF with wave runup is EL. 723.8. See Section 2.4.3. This reanalysis does not include the complete loss of Watts Bar Dam). Due to water seals between the Shield Building and adjacent structures, the lateral hydrostatic pressure was applied only to one-half of the circumference for the design flood and maximum probable flood.

For the PMF the adjacent structures are allowed to flood, and lateral hydrostatic pressure was applied around the full circumference.

Loss-of-Coolant Accident (LOCA)

In addition to the reactions of the containment vessel and interior concrete due to the LOCA pressure transients, the LOCA will produce uplift forces (2400 kips) on the steam generator or reactor coolant pump anchors in the base slab. The LOCA also increases the temperature in the annulus space between the containment vessel and the Shield Building. This produces a non-linear temperature gradient across the cylinder wall and dome. A typical gradient is shown in Figure 3.8.1-1. The base slab design and analysis also took into consideration the flooded conditions and high temperatures inside containment associated with long-term LOCA effects.

Normal Temperature Gradient

The temperature gradient for normal plant operation was considered as uniformly varying through the section. The maximum temperature gradient occurs just above grade when the plant is in operation and a minimum ambient temperature exists. In this case, the maximum normal temperature difference across the wall is 85°F and is shown on Figure 3.8.1-1. The minimum normal temperature difference is 35°F and occurs below grade.

One-Half Safe Shutdown Earthquake (1/2 SSE)

The plant was designed to remain operational for a 1/2 SSE. The 1/2 SSE has a maximum acceleration of 0.09g horizontally and 0.06g vertically. In addition to the maximum values of the structural response in terms of displacement, acceleration, shear, moment, torque and axial force, the soil pressure and hydrostatic pressures were increased due to seismic motions. The static soil pressure was increased 23 percent for a dry fill and 11 percent for a saturated fill. This incremental increase was a triangle of pressure with the apex at the rock surface and the maximum ordinate at the ground surface. The hydrostatic pressure of the water within the fill was increased by 11 percent. This incremental increase was a triangle of pressure with the apex at the water surface and maximum ordinate at the rock surface. The magnitude of these increases were determined by shaking table experiments performed for another TVA project.

Safe Shutdown Earthquake (SSE)

The plant was designed to have the capability for safe shutdown for the SSE (maximum acceleration of 0.18g horizontally and 0.12g vertically). The incremental pressure increase for soil and hydrostatic pressure was twice that for the 1/2 SSE.

Snow

The roofs of the structures are designed for snow load of 20 lb/ft^2 and for live loads ranging from 50 lb/ft^2 to 100 lb/ft^2.

Using the density of water as 62.5 lb/ft^3, a minimum live load of 50 lb/ft^2 and normal stress levels the structural roofs can retain is 10.7 inches of water. For severe environmental conditions or conditions which would block both the Roof Drain System and the scuppers, an increase in the allowable stresses is justified. Using the minimum live load of 50 lb/ft^2 and allowing an increase in the working stress of the reinforcing steel from 0.4 yield to 0.9 yield, the following table indicates the equivalent water depth that the roof structures can retain.

Slab Thickness	Dead Load	Live Load	Load .4fy	Total Load .9fy	Total Overload	Equivalent Water Load
(Inches)	(lb/ft^2)	(lb/ft^2)	(lb/ft^2)	(lb/ft^2)	(lb/ft^2)	(Inches)
6	75	50	125	280+	205	39
12	150	50	200	450	300	57
18	225	50	275	620	395	76
24	300	50	350	785+	485	93

The above table is not a design basis for the roofs of the safety-related structures but is given to indicate the capability of the structures to withstand the equivalent water loads from severe conditions. It is concluded that the roofs of the safety related structures can support not only

normal 100-year recurrence loads but can also support severe environmental loadings or severe loadings due to blockage of both the Roof Drain System and the scuppers.

See Section 2.3 for meteorological information.

Tornado

The tornado was assumed to have an “eye” whose pressure is 3 lb/in^2 below ambient, a “funnel” having a rotational velocity of 300 mph, and a translational speed of 60 mph as described in Section 3.3.2. The Shield Building was designed for wind loads corresponding to 360 mph and a maximum internal pressure of 3 lb/in^2. Maximum wind velocity and maximum internal pressure loadings do not coincide. Coincident wind velocities and pressure drops from the design tornado are shown in Figure 3.3.2-1. The ultimate capacity of the structure in flexure or shear is not exceeded in the zones of maximum stress under the combined pressure and wind velocity loadings of Figure 3.3.2-1.

The adjacent structures so disturb the flow that the only method to determine the actual pressure distribution on the structure is by a model test. In lieu of model test, several cases of extreme pressure distributions were analyzed in an attempt to bracket the actual stresses. The wind load was based on Figure 1(b), ASCE Paper 3269, Wind Forces on Structures, as described in Section 3.3.2. The tornado missiles are described in Section 3.5.

Vacuum Relief

The Vacuum Relief System equalizes containment and annulus atmospheric air pressure. It was necessary that the pressure be equalized between the containment vessel and annulus atmosphere to ensure that the containment vessel external design pressure is not exceeded. This system required that the Shield Building be designed for a 2.0 lb/in^2 external pressure.

Construction Loads

The dome was poured in two lifts. The first lift was a 9-inch pour supported by shoring from the containment vessel. The first lift was designed to support the wet concrete dead load of the second lift plus a construction load of 50 lb/ft^2.

Design loading combinations are shown in Tables 3.8.1-1 and 3.8.1-2.

3.8.1.4 Design and Analysis Procedures

Base Slab

The base slab was analyzed as a slab on an elastic foundation (considering the properties of the rock). The slab was divided into wedge-shaped radial strips. For unsymmetrical loading, the deflections of adjacent wedges were imposed upon circumferential strips. The analysis was made using computer code, “Finite Element Stress Analysis (AMG033).” The base slab is further discussed in Section 3.8.5.

Cylinder Wall and Dome

The stiffness of the cylinder wall is small in comparison to that of the base slab and the cylinder wall was assumed fixed at the base. The height of the wall was such that the effect of discontinuity at one end was negligible when considering discontinuity at the other end.

For symmetrical loadings, the edge forces at the points of discontinuity were determined by writing the equations of the Primary System and the equations of compatibility. The discontinuity stresses from the edge forces were superimposed on the membrane stresses. The above analysis was checked by two independent computer analyses ("Axisymmetric Finite Element Analysis, AMG032" and GENSHL 2). Unsymmetrical loadings, such as wind, were analyzed by using computer code, GENSHL. These loads were approximated through a Fourier series.

Creep and Shrinkage Effects

Creep was not considered in the design of the Shield Building. Sustained loads are essentially the dead weight loads of the structure itself with subsequent stress levels too low to influence creep deformations to any significant degree particularly since these deformations do not cause differential settlements in the structure.

Shrinkage effects are considered in the design of all structures by estimating the temperature change from peak hydration temperatures to final operating temperature conditions. In addition drying shrinkage effects are considered in all members which have an average drying path of less than 15 inches. The methods used to consider these effects are explained in an ACI Committee 207 report, "Effect of Restraint, Volume Change, and Reinforcement on Cracking of Massive Concrete" published in the July 1973 issue of the ACI Journal.

The effects of base restraint on the cracking of a circular structure is essentially the same as the effects on a wall of equal thickness whose length is equal to the outside diameter of the circular structure. For circular structures the total shrinkage reinforcement requirement is proportioned to each face in proportion to the respective radial dimensions.

The Shield Building was not only designed to restrict shrinkage cracking to a minimum acceptable size, but was waterproofed on the exterior portion below grade to eliminate possible seepage. The portion above grade is essentially out of the restraint zone and should therefore be relatively free from shrinkage cracking.

Tangential Shear

The tangential and longitudinal shears induced by earthquake and wind forces were assumed to vary from zero over a thickness of wall located at the extremes of a diameter normal to the neutral axis to a maximum on a wall thickness located at the extremes of a diameter parallel to the neutral axis. Distribution was assumed proportional to the cosine of the polar angle measured from the parallel to the neutral axis with a maximum allowable shear stress in the concrete limited to 275 lb/in^2 as recommended by the SEAOC Code.

Seismic

The seismic response of the Shield Building was based upon idealized models and computer use of the time-history method using four artificial earthquake records. The response was computed for each record and then averaged by computing the arithmetic mean of the four sets of the response values.

The dynamic analysis was done by the normal mode method. This consists of writing the equations of motion of the system, assuming a separable SQN solution and solving the resulting space-dependent and time-dependent differential equations.

The structural response was calculated for both the 1/2 SSE and the SSE. Damping values of 2 percent and 5 percent for the 1/2 SSE and SSE, respectively, were used. See Section 3.7 for a detailed description of the seismic analysis.

Equipment Hatch Doors and Sleeves

For the closed position, the structural members of the door leaves were designed as simple beams under uniformly distributed loading with the end reactions carried by the sleeve. Loads at the dogging wedges were carried to the sleeve as concentrated loads.

For the open position, the door leaves were treated as cantilever structures, and the hinge members and sleeve were designed for the resulting concentrated loads.

Under normal operating conditions, no air pressure is exerted on the doors. Under accident or tornado conditions, the doors are subjected to air pressure. Environmental and accident conditions which were considered in the design of the doors and sleeves are as follows:

1. 1/2 SSE and SSE with accelerations as hereinafter defined.

2. Because of the vacuum relief system, an inadvertent release of the cooling sprays in the containment vessel will cause a pressure drop within the annulus surrounding it and result in an air pressure load of 2 lb/in^2 on the Auxiliary Building side of the doors and sleeves. Duration of this condition will be for a few hours maximum.

3. A tornado condition which causes a pressure drop within the Auxiliary Building will result in a pressure of 3 lb/in^2 on the annulus side of the doors. Duration will be for seconds only.

4. A LOCA in the containment vessel which will result in a pressure equal to ¾ inch of water on the Auxiliary Building side of the doors. A partial vacuum is created in the annulus by vacuum pumps, and this condition may exist for a period of several months.

Earthquake accelerations used in design of the doors and sleeves were determined by dynamic analysis of the supporting structure of the Shield Building. Accelerations at the centerline of the equipment hatch for ½ SSE are as follows:

Lateral (north-south)	0.175 g
Lateral (east-west)	0.175 g
Vertical	0.060 g

Accelerations at the centerline of equipment hatch for a SSE are as follows:

Lateral (north-south)	0.255 g
Lateral (east-west)	0.255 g
Vertical	0.120 g

These accelerations were used as static loads for determining component and member sizes. After establishing the component and member sizes, a dynamic analysis, using appropriate response spectrum, was made of each sleeve and its doors to determine that allowable stresses had not been exceeded.

3.8.1.5 Structural Acceptance Criteria

Controlling Conditions[1] - Shield Building Structure

[1]The principal stresses resulting from GENSHL analysis of wind load and pressure inside may result in local tension zones which may govern reinforcement requirements.

The SSE (combination 3 from Table 3.8.1-1) produced the largest overturning moment. For this combination the percent of base in compression was 71 and the factor of safety for overturning was 2.1.

The uplift on the equipment from the LOCA combined with the 1/2 SSE controlled the design of the base slab.

Minimum bending steel requirements of 0.65 square inches per foot (minimum steel ratio of 0.0015 in each face in both vertical and horizontal directions) controlled the inside face vertical steel requirements throughout the shell the outside face vertical steel requirements above grade, and the inside and outside face horizontal steel requirements above grade to Elevations 819.0 and 813.0, respectively.

The 1/2 SSE (load combination 2) controlled the design of the vertical reinforcement at the base of the cylinder wall. Due to earth and hydrostatic pressure horizontal reinforcement requirements were greatest 14 feet above the base of the cylinder wall at Elevation 690.

Load combinations 1 and 4 (see Table 3.8.1-1) controlled the reinforcement design in the dome and the upper portion of the cylinder wall.

Controlling design stresses are presented as a percent of the allowable stress in the following table. Those stresses which are the highest percent of allowable stresses are assumed to control. Design stresses less than 50 percent of allowable are not given. This table is based upon original design calculations and does not reflect later calculations. These later calculations were due to changes in loading concrete strength evaluations, or modifications, and are documents in calculation packages.

Table of Controlling Stresses in Percent of Allowable Stress

Location	fc Vertical	fc Horizontal	fs Vertical	fs Horizontal
Base of Wall	90.0	---	95	---
Elevation 690	88	---	56	87.5
Elevation 722	55	---	--	67.5
Elevation 790	55	---	--	71.5
Ring Beam	--	---	61	95

	fc	fs
	Meridional	Meridional
Dome	80.5	84.5
	Hoop	Hoop
	----	80.5

The peak hydration temperature in the Shield Building from which subsequent temperature gradients were considered was 100°F ± 5°F. The zone of restraint essentially responsible for induced shrinkage stress is principally below grade. Under DBA (LOCA) thermal gradients the average temperature of the wall below grade approaches the hydration temperature and therefore shrinkage stresses are relieved for all practical purposes such that shrinkage stresses remain only under normal operating thermal gradients which produce an average wall temperature of 67.5°. From this the net temperature drop for shrinkage stresses is approximately 33°F. Under these conditions the controlling stress in the steel at the most critical location (Elevation 690) is 92 percent of allowable.

The SSE produced a maximum shear stress at the base of the wall of 156 lb/in^2 which was 57 percent of the allowable. Investigation of principal stresses resulting from combined shear, radial, and meridional stress was not considered necessary because of the low allowable shear stresses and with more than 70 percent of the base in compression under these conditions, a cursory investigation indicates that principal tensile stresses would be considerably less than the allowable concrete stress in shear.

The effects of repeated reactor shutdowns and startups during the plant's life will not degrade the above margins of safety because the Shield Building is minimally affected by these operations except for interior temperature changes which are insignificant compared to normal exterior temperature variations.

Equipment Hatch Doors and Sleeves

Allowable stresses for all load combinations used for the various parts are given in Table 3.8.1-2. For normal load conditions, the allowable stresses provide safety factors of 2 to 1 on yield for structural parts and 5 to 1 on ultimate for mechanical parts. For limiting conditions such as a SSE, stresses do not exceed 0.9 yield.

3.8.1.6 Materials, Quality Control and Special Construction Techniques

3.8.1.6.1 Materials

General

Basically the two materials used in the construction of the Shield Building wall and dome were concrete and reinforcing steel. Steel was used for the structural parts of the equipment hatch doors and sleeves and rubber was used for the seals.

Concrete

Concrete mix design, placing, inspection, and testing were in accordance with TVA General Construction Specification No. G-2. Concrete work was done in accordance with ACI 318-63 “Building Code Requirements for Reinforced Concrete,” and TVA General Construction Specification No. G-2 for Plain and Reinforced Concrete. Admixtures were added to improve the quality and workability of the concrete during placement and to retard the set of the concrete. Maximum practical size aggregate and a low slump were used to minimize shrinkage and creep. All concrete materials were sampled and tested by TVA throughout the job for compliance with material specification requirements. The specified minimum compressive strength of concrete was 4000 lb/in^2. Some concrete did not meet specification requirements. This was evaluated in exhibit F of Report CEB-86-19C “Concrete Quality Evaluation” and the results documented in affected calculation packages and drawings.

Cement conformed to ASTM Specification C150-72, Type II.

Aggregates conformed to ASTM Specification C-33, “Standard Specifications for Concrete Aggregates.” Aggregates consisted of crushed stone and manufactured sand made from rock quarried from a high grade dolomite or limestone formation approved by TVA.

Water for mixing concrete and also for washing the aggregates and curing concrete was tested prior to use in accordance with Corps of Engineers test method CRD-C400. Retesting was done any time contamination of the source of supply was suspected. The quantities of fly ash and cement used were determined by making tests of trial mixes. The mix with the fly ash to cement ratio that consistently yielded the specified concrete strength and provided maximum workability was used. Fly ash conformed to TVA General Construction Specification No. G-30 for Fly Ash for Use as an Admixture in Concrete.

Air-entraining admixtures conformed to ASTM Specification C-260-69. Water-reducing agents conformed to TVA Specification for Water-Reducing Agent for Concrete for Sequoyah Nuclear Plant.

Batching, mixing and delivery equipment, including their operation, conformed to ASTM Specification C94-72 for central-mixed concrete.

During the Unit 1 steam generator replacement, concrete used for the restoration of the shield building dome construction openings was provided in accordance with Specification 24370-C-321. The concrete was designed to achieve a minimum strength of 4000 psi at seven days.

During the Unit 2 steam generator replacement, concrete used for the restoration of the shield building dome construction openings was provided in accordance with Specification 39866-SPEC-C-004. The concrete was designed to achieve a minimum strength of 4000 psi at seven days.

Reinforcing Steel

Reinforcing steel was deformed billet steel bars conforming to ASTM Designation A 615, Grade 60.

For the Unit 1 and Unit 2 steam generator replacement, reinforcing steel used in the restoration of the shield building construction openings conforms to ASTM A 615, Grade 60.

Bar-Lock Couplers

During the Unit 1 and Unit 2 steam generator replacement, Bar-Lock couplers were used to splice the new reinforcing bar to the existing reinforcing bar during the restoration of the shield building construction openings. Bar-Lock couplers are manufactured of seamless hot-rolled steel tube conforming to ASTM A-519 specification, with minimum tensile strength exceeding 100,000 psi.

Equipment Hatch Sleeves and Doors

The structural parts of the sleeves and doors are fabricated from ASTM A 36 steel.

3.8.1.6.2 Quality Control

General

The Sequoyah Quality Assurance Manual contains those procedures to be followed which provide assurance that the Shield Building is built to the desired quality level. The following is a general description of Quality Assurance Requirements required by the Quality Assurance Manual.

Concrete

The quality control and inspection procedures for concrete are detailed in TVA's General Construction Specification G-2 for Plain and Reinforced Concrete.

In general all concrete materials are purchased to standard ASTM specifications and tested by TVA laboratories for compliance.

The quality of all concrete materials are periodically checked by TVA laboratories during the progress of construction to assure continued compliance with the specifications.

TVA employed a materials engineer on each project, who was specifically responsible for maintaining quality control of all concrete.

The slip-form construction of the walls of the Shield Building was a continuous placing operation 24 hours a day. Samples for compression testing were taken at approximately 6-hour intervals such that each sample represented approximately 170 yd^3 of concrete.

Each sample was tested for slump, air content, unit weight, and compressive strength.

Quality control charts were required for each class of concrete poured, with limitations on air content, slump, and percent of strengths allowed to fall below the required strength for each concrete class.

Deviations from the requirements of TVA General Construction Specification, G-2, occurred in two areas with respect to the concrete for the Shield Buildings; (1) Modified slump requirements were provided to facilitate concrete placement, and (2) the concrete for the Unit 2 Shield Building deviated from the strength requirements of G-2.

Concrete with a slump greater than that specified for the design mix was required in order to discharge from the concrete buckets used for the slip-forming operation. The average slump was 4 inches with slumps generally ranging from 3 to 5 inches. The design mix was adjusted to compensate for the higher slump.

The concrete mix for the Unit 2 Shield Building used a different source of aggregate due to a strike at the original supplier's quarry. The mix adjustments for the change in aggregate were not fully adequate and the percent of tests less than the specified strength of 4000 psi exceeded the G-2 requirement of 10 percent at the specified age of 28 days. However, the long-term inplace strength exceeded the required strength. Also, the 90-day compressive strength based on standard cured cylinders indicated a design strength greater than 4000 psi.

Reinforcing Steel

The reinforcing steel supplier was required to submit certified mill test reports for chemical and physical properties as required by ASTM A 615-68.

TVA witnessed random mill tests on the physical properties of reinforcing steel prior to shipment. This inspection was conducted by the Inspection and Testing Branch of TVA.

Equipment Hatch Doors and Sleeves

Design by TVA and erection by TVA were in accordance with TVA's Quality Assurance Program. Design and fabrication by the Contractor were in accordance with the Contractor's Quality Assurance Program which was reviewed and approved by TVA's design engineers. The Contractor's Quality Assurance Program conformed to the criteria in Appendix B of 10 CFR 50. Fabrication procedures such as welding and nondestructive testing were included in appendixes to the Contractor's Quality Assurance Program. ASTM standards were used for all material specifications and certified mill test reports were provided by the Contractor for materials used for all load carrying members.

Material used for seals, including 0-rings, was certified by a rubber technologist as being capable of withstanding the radiation and temperature conditions existing during a LOCA.

This certification was based on testing and evaluation of seal materials performed under contract for TVA by Prespray Corporation.

3.8.1.6.3 Construction Techniques

The walls of the Shield Building from the base slab to the bottom of the ring beam were constructed by slip-form methods. The concreting was performed on a 24-hour schedule from bottom to top without stopping. Unit 1 was begun on November 30, 1970, and completed on December 11, 1970. Unit 2 began on March 15, 1971, and was completed March 25, 1971. Concrete temperatures were monitored throughout for a minimum period of 3 days during cold weather to assure satisfaction of cold weather protection requirements.

The dome roof was placed in two lifts, creating a minimum roof thickness of 2 feet, with each lift divided into three basic rings and each ring divided into radial segments. The steel containment vessel was designed to support the form work for the first 9-inch-thick lift and the first lift was then designed to support the remaining 15-inch lift with the form work removed. Delays were specified between adjacent lift pours in order to minimize the effects of initial volume changes. The second lift was not placed until the first lift had attained its specified strength.

The base slab, starter lift on the wall, and ring beam were constructed using conventional methods.

During the Unit 1 steam generator replacement, two construction openings were cut into the dome roof. These construction openings were restored by using permanent steel form plate on the inside face of the roof and placing the concrete in one lift.

3.8.1.7 Testing and Inservice Surveillance Requirements

Since the Shield Building is not a pressure containment its wall and dome will not be pressure tested.

3.8.2 Steel Containment System

3.8.2.1 Description of the Containment

The containment vessel for Sequoyah is a low-leakage, free-standing steel structure consisting of a cylindrical wall, a hemispherical dome, and a bottom liner plate encased in concrete. Figure 3.8.2-1 shows the outline and configuration of the containment vessel.

The structure consists of side walls measuring 113 feet 8-5/8 inches in height from the liner on the base to the spring line of the dome and has an inside diameter of 115 feet. The bottom liner plate is ¼ inch thick, the cylinder varies from 1-3/8 inch thickness at the bottom to 1/2 inch thick at the spring line and the dome varies from 7/16 inch thickness at the spring line to 15/16 inch thickness at the apex.

The containment vessel is provided with both circumferential and vertical stiffeners on the exterior of the shell. These stiffeners are required to satisfy design requirements for expansion and contraction, seismic forces, and pressure transient loads. The circumferential stiffeners were installed on approximately 20-foot centers during erection to insure stability and alignment of the shell. Vertical stiffeners are spaced at 4° arcs. See Section 3.8.2.4.2 for details of the design of the stiffeners. Figure 3.8.2-8 shows the arrangement of circumferential stiffeners.

During the Unit 1 and Unit 2 steam generator replacements, two construction openings were cut into the domes of each unit's steel containment vessel. These construction openings were restored by reinstalling the removed steel sections and rewelding them to the remaining structure using full penetration welds. The integrity of the restored vessel was verified by NDE and leak testing of the welds.

An equipment hatch with an inside diameter of 20 feet has been provided to enable passage of large equipment and components into the containment during plant shutdown.

Two personnel access locks were provided for each containment vessel. Each personnel lock is a welded steel assembly with a door at each end equipped with a double compressible seal to insure leak tightness of the lock. Detailed descriptions of the equipment hatch and personnel locks are presented in Chapter 6.

3.8.2.2 Applicable Codes, Standards, and Specifications

3.8.2.2.1 Codes

The design of the containment vessel meets the requirements of the ASME Code, Section III, Winter Addenda 1968, applicable sections required for a Class B nuclear vessel, including Code cases 1177-5, 1290-1, 1330-1, 1413, 1431. Additional ASME Code, Subsection NE requirements have been added since 1968.

The bottom liner plate along with nonpressure parts, such as walkways, handrail, ladders, etc., were designed in accordance with the American Institute of Steel Construction (AISC) “Specification for the Design, Fabrication, and Erection of Structural Steel for Buildings,” February 12, 1969, Part I. Where date of edition, copyright, or addendum is specified, earlier versions of the listed documents were not used. In some instances, later revisions of the listed documents were used where design safety was not compromised.

Nuclear Construction Issues Group documents NCIG-01, Revision 2, may be used after June 26, 1985, to evaluate welds in these items. When invoked, NCIG provisions will be implemented as indicated in section 3.6.8.

3.8.2.2.2 Design Specification Summary

The containment vessel, including access openings, penetrations, and vacuum relief systems, is designed so that the leakage of radioactive materials from the containment structure under conditions of pressure and temperature resulting from the largest credible energy release following a LOCA (DBA), including the calculated energy from metal-water or other chemical reactions that could occur as a consequence of failure of any single active component in the Emergency Cooling System, will not result in undue risk to the health and safety of the public, and is designed to limit to below 10 CFR 100 values, the leakage or radioactive fission products from the containment under such (DBA) conditions.

The basic structural elements considered in the design are the vertical cylinder and dome acting as one structure, and the bottom liner plate. The bottom liner plate is encased in concrete and is designed as a leak tight membrane only. The liner plate is anchored to the concrete by welding it continuously to steel members embedded in and anchored into the concrete base mat.

The containment shell is provided with circular inspection platforms on the exterior of the shell at approximately 20-foot centers which also are designed as permanent circumferential stiffeners. Additional circumferential stiffeners are provided at personnel and equipment hatches and other large attached masses along with vertical stiffeners for some distance above and below these attachments. Still additional permanent circumferential and vertical stiffeners are required for stability as discussed in Section 3.8.2.4.2. Temporary stiffening to meet tolerance requirements specified by TVA was not required in the erection of the vessel. The design provides for movements of the vessel and supports due to expansion and contraction, pressure transient loads, and seismic motion. No allowance is made for corrosion in determining the material thickness of the vessel shell.

The following pressures and temperatures were used in the design of the vessel:

Overpressure test (1)	13.5 lb/in^{2}g
Maximum internal pressure (2) (3) (4)	12.0 lb/in^{2}g at 220°F
Design internal pressure (2) (4)	10.8 lb/in^{2}g at 220°F
Leakage rate test pressure	12.0 lb/in^{2}g
Design external pressure	0.5 lb/in^{2}g
Lowest service metal temperature	30°F
Operating ambient temperature	120°F
Operating internal temperature	120°F

In addition, the evaluations of the vessel design have considered a harsh environment temperature of 327°F. (5)

(1) 1.25 Times design internal pressure as required by ASME Code, UG-100(b).

(2) See Paragraph N-1312(2) of Section III of the ASME Code which states that the “design internal pressure” of the vessel may differ from the “maximum containment pressure” but in no case shall the design internal pressure be less than 90 percent of the maximum containment internal pressure.

(3) Typical pressure transient curves are presented in Chapter 6. These curves show the transient pressure buildup in the compartments after a LOCA (DBA) before a steady-state pressure of 12.0 lb/in^{2}g is reached.

(4) Shell temperature transient curves are presented in Appendix 3.8A. These curves show the shell temperature at the lower compartment wall, upper compartment wall, and ice condenser wall. The maximum containment wall temperature is 220°F.

(5) A postulated main stream line break (MSLB) results in high environmental temperatures (327°F maximum) inside the lower compartment of the steel containment vessel. However, the coincident internal pressure is lower (reference 10).

In order to ensure the integrity of the containment, an analysis of the missile and jet forces due to pipe rupture was considered. This problem was addressed by providing barriers to protect the containment vessel. Typical barriers are the main operating floor (Elevation 733.63) and the crane support wall. An example of a special barrier is the guard pipe enclosing the main steam and feedwater pipes between the Shield Building and the crane wall.

Allowable Stress Criteria

Allowable stress criteria for the containment vessel is shown in Table 3.8.2-1. The response of the containment vessel to seismic and pressure transient loadings result in a condition in which buckling of the steel shell may occur. Since the ASME Code does not define the allowable buckling stresses for this type of loading condition, an acceptable buckling criteria with appropriate factors of safety had to be developed. A search of the literature revealed that for the most part stability studies have been limited to shells under symmetrical static loads whereas the design load conditions are asymmetrical dynamic loads. Information which takes into account factors such as the effects of boundary conditions, initial imperfections, and local buckling that greatly affect the stability are primarily based upon experimental studies. The state-of-the-art for the stability analysis and design of shell is semiemperical relations, based largely upon data from static, symmetrically loaded model tests. That was the basis for the initial buckling stress criteria which TVA developed. Later, the pressure transient loadings were revised and increased to the extent that the initial buckling stress criteria proved to be too conservative. An inefficient design for the containment vessel would have resulted if an alternate buckling stress criteria was not developed.

Therefore, TVA and CB&I contracted with Anamet Laboratories to perform a dynamic stability analysis of the containment vessel. Details of this dynamic analysis are provided in Reference 8.

Materials - General

Materials for the containment vessels, including equipment access hatches, personnel access locks, penetrations, attachments, and appurtenances meet the requirements of the following specifications of the issue in effect on the date of invitation for bids. Impact test requirements were as specified in the ASME Boiler and Pressure Vessel Code, Section III for maximum test metal temperature of 0°F. Charpy V-notch specimens, SA 370, type A, were used for impact testing materials of all product forms in accordance with the requirements of the ASME Boiler and Pressure Vessel Code, Section III. In order to provide for loss of impact properties during fabrication, all materials were furnished with an adequate test temperature margin below the minimum NDT temperature; otherwise, the specified minimum values were effectively restored by heat treatment in accordance with ASME Code requirements.

Material Designations

Plate for vessels:

Carbon steel	ASTM A 516, Grade 60, carbon steel plates for pressure vessels for moderate and lower temperature service.
	ASTM A 516, Grade 70 carbon steel plates for pressure vessels for moderate and low temperature service.

Material Designations

Austenitic stainless steel	ASTM A 240, Type 304.
Forgings:	
Carbon steel	ASTM A 350, Grade LF1 and LF2 for welding.
Austenitic stainless steel	ASTM A 182, Grade F304.
Pipe:	
Carbon steel	ASTM A 333, Grade 1, seamless.
	ASTM A 333, Grade 6, seamless.
Austenitic stainless steel	ASTM A 312, Grade TP 316, seamless, or ASTM A 358, Class 1, Grade 316.
Castings:	
Carbon steel	ASTM A 216, Grade WCB, or ASTM A 352, Grade LCB.
Carbon steel (for lock and hatch mechanisms)	ASTM A 27, Grades 70-36.
Cold finished steel (for lock and hatch mechanisms)	ASTM A 108, Grades 1018 to 1050 inclusive.
Bar and machine steel (for lock and hatch mechanisms)	ASTM A 107, special quality, carbon content not less than 0.30 percent
Fasteners:	
Carbon steel	ASTM A 320, Grade L7 or ASTM A 193,Grade B7
Austenitic stainless steel	ASTM A 193, Grade B8
Welding electrodes:	
Carbon steel	SFA-5.1, E70 Classification.
Austenitic stainless steel	SFA-5.4, E308 or E309 Classification;
	SFA-5.9, ER308 or ER309 Classification.

Structural steel:

Plates, bars, shapes (other than vessel plates)	ASTM A 36.
Threaded stud anchors	ASTM A 108.

Gasketing materials, including 0-ring seals, are of ethylene-propylene-dienemonomer (EPDM) material or other suitable elastomers in continuous rings and with a Shore A durometer hardness of 40-60. Seals and gasket material are required to withstand radiation of 10^6 rads.

Corrosion Protection

Potential corrosion of the steel containment has been considered at both the embedded bottom liner in conjunction with the concrete, at the inner face in the region of the ice condenser, and at the outer face exposed to the annulus atmosphere.

The conditions which determine corrosion are basically the electro-potential of the materials involved, the presence of oxygen and an electrolyte, temperature and any induced electro-potential from extraneous sources. These have been evaluated in the determination of corrosion.

The containment material is specification ASTM A 516, Grade 60 being a 1 percent manganese 0.3 percent silicon low carbon steel, and has interfaces with concrete. Thus no unfavorable electro-potentials exist in the materials.

The climatic conditions for Chattanooga, Tennessee, show an ambient annual temperature range of 0°F to 100°F (Reference 1). The corresponding temperature range for the steel containment in the region of the ice condenser is approximately 32°F to 120°F.

The corrosion of the steel containment face in contact with the containment concrete is not a design consideration since portland cement concrete provides good protection to embedded steel. The protective value of the concrete is ascribed to its alkalinity and relatively high electrical resistivity in atmospheric exposure.

ACI Committee 201 Report “Durability of Concrete in Service” identifies three basic conditions as being conducive to the corrosion of steel in concrete (Reference 2).

1. The presence of cracks extending from the exposed surface of the concrete to the steel.
2. Corrosion cells arising from electro-potential differences in the concrete itself.
3. Electrolysis by induced currents in the concrete or steel.

With respect to condition (1) the base consists of a 2-foot-thick concrete embedment surrounding all the steel containment. The cracking under the worst of cases is considered minimal. This quantity far surpasses minimum cover recommended by ACI 201-1 in the most corrosive marine environment.

The potential for developing corrosion cells was kept to a minimum by limiting the soluble salts and chlorides in the concrete. Further, the continuing corrosion of iron under these conditions requires that the hydrogen deposited at the cathode is freed or combined with oxygen.

Since both these mechanisms are prevented by the concrete, the corrosion cells are polarized, and the reaction is brought to a standstill.

To preclude the development of induced electric currents and in keeping with good construction practice, all electrical equipment and structures are grounded as determined by the resistivity of the foundation materials for the site. Foundation material resistivity surveys were made and the result considered in the design and determination of the extent of the grounding mat.

The seasonal variation of steel containment temperature in the region of the ice condenser gives rise to a range of relative humidity from 4 percent at 120°F to 45 percent at 32°F. This is based on saturated air leaking from the cooling ducts at a temperature of 10°F and rising to the steel containment temperature at the containment surface.

The annular region exterior to the steel containment is essentially airtight. Only during periods of shutdown during which access doors are open will this seal be broken. In the event of a pipe rupture in the annular region, water would be removed by a drainage system at the base of the annulus.

Any ingress of moisture to the interior steel containment face is prevented by sealing the outer periphery of the ice condenser adjacent to the steel containment, and by the vapor barrier on the inside face of the duct panels at the boundary of the ice bed. In the event of any abnormal ingress of moisture through the seal, the leakage air from the cooling ducts has the capacity to absorb moisture up to the limits of the relative humidities quoted above. In addition, any moisture remaining will have a tendency to migrate to the colder end of the temperature gradient; i.e., for all steel containment temperatures above 10°F, moisture will migrate towards the cooling air ducts, where it will be evaporated as the cooling air increases in temperature in the course of its passage through the ducts.

For steel containment temperatures below 32°F any moisture at the steel containment face will be frozen, this condition pertaining to relative humidities greater than 45 percent, and steel containment temperatures below 10°F when the migration of moisture could take place from the air cooling ducts to the steel containment.

In the event of actuation of the containment spray, water would be applied to the interior surface of the steel containment. Most of the water would be removed by the Drainage System and the small amount of moisture remaining would be removed from the steel containment surface by evaporation.

Several references have been established which give corrosion data for the limits of conditions described above.

For low alloy steels in any industrial atmosphere long-term tests indicate a maximum total corrosion of 0.016 inch in 40 years (based on 14g/aq dm in 18 years - Reference 3).

For dry inland conditions which more closely simulate the steel containment conditions the total corrosion for the plant lifetime is approximately 0.010 inch (References 4 and 5). This is accounted for by the fact that below relative humidities of 65 percent, iron oxide itself forms an adherent film, affording good protection to further corrosion (Reference 6). Furthermore, at temperatures below freezing, ion transport in the electrolyte is almost entirely inhibited, obviating the mechanisms of corrosion. This is supported by data for corrosion from Normal Wells - latitude 65°N, where the prolonged winter temperatures and lower annual average reduce the corrosion rate by a factor of 50 as compared with Penn State (Reference 7), which is applicable to Sequoyah Nuclear Plant.

It is concluded that the maximum total corrosion for any exposed internal surface of the steel containment in the region of the ice condenser is 0.010 to 0.015 inch over the lifetime of the plant. In general, the corrosion in the region of the ice condenser is expected to be less than in other areas of the containment, which can be readily inspected.

Protective Coatings

Protective coatings were applied to all exposed steel surfaces of the containment vessel. Surfaces embedded in concrete were not coated. Coating systems used on the inside of the containment vessel were selected on the basis of their ability to withstand not only normal operating conditions but DBA conditions as well. The coating must be able to withstand a DBA without being removed from the surface, so that it will not interfere with emergency pumping and spraying systems. The coating systems were subjected to tests designed to determine their radiation resistance, decontaminability, resistance to decontamination chemicals, and resistance to accident conditions. The accident conditions tests include exposure to steam and boric acid spray solutions under temperature-time conditions which are more severe than those that would be encountered in a DBA.

All exterior vessel shell surfaces and metal surfaces of platforms, floor plate, ladders, walkways, attachments, and accessories located in the annular space surrounding the containment vessel were cleaned in accordance with the requirements of Steel Structures Painting Council Surface Preparation Specification No. 6, Commercial Blast Cleaning, latest edition. After cleaning and having passed inspection, one complete prime shop coat of red lead oil paint (dry film thickness not less than 1-1/2 mils) was applied in accordance with Federal Specification TT-P-86e, Type II.

All interior surfaces of the containment vessel shells and metal surfaces of attachments thereto, except those parts embedded in the base slab and identified as the liner and areas within 2 inches of field-welded joints, were given one prime coat of Carboline, Carbozinc 11 within 8 hours after blast cleaning as described above. The primer was topcoated, as required, by TVA field forces with an epoxy coating.

In order to perform the Unit 1 and Unit 2 Steam Generator Replacements, two construction openings were created in each containment vessel to provide containment access to change out the steam generators. These construction openings were closed by welding the removed sections back in place. The containment vessel interior surface coating was removed adjacent to the welds and has been left uncoated. The uncoated area is monitored for degradation through implementation of Station Engineering Programs.

The surfaces of the vessel in the annular space were coated with materials selected for the ability to provide protection against atmospheric corrosion.

For additional information on protective coatings, refer to Section 6.2.1.6.

Allowable Weld Stresses

Allowable weld stresses for pressure boundary components conform to the requirements of the ASME Code for full penetration welds.

For partial depth groove welds, the allowable stress on the effective depth is:

1. An inspection factor x load factor x Sm of weaker material.
2. The inspection factor used is 0.8.
3. The load factor used is:

   1.0 for load perpendicular to axis of the weld.
   0.875 for any combination of perpendicular and parallel loads.
   0.75 for load parallel to axis of the weld.

For fillet welds the allowable stress is 0.55 Sm on the minimum leg.

Allowable weld stresses for nonpressure boundary components conform to the requirements of the AISC Code, Sections 1.5.3.1 and 1.5.3.2.

Tolerances

The containment vessel as constructed does not exceed the applicable tolerance requirements of the ASME Code for fabrication or erection.

The out-of-roundness tolerance does not exceed 1/2 of 1 percent of the nominal inside diameter.

The deviation from a vertical line of the vertical cylindrical portion adjacent to the ice condensers is limited to + 2 inches for the height of the ice condensers.

Threaded studs for attachment of ice condenser outer duct panels do not vary from their theoretical location by more than + 1/4 inch.

Penetrations do not vary from their theoretical location by more than + 1/2 inch.

3.8.2.2.3 NRC Regulatory Guides

Applicable NRC Regulatory Guides are shown below. These guides were used as the basis for design of a number of safety oriented features.

Regulatory Guide 1.4: Assumptions used for evaluating the potential radiological consequences of a LOCA for pressurized water reactors.

A dynamic analysis of the containment vessel was made for the pressure transient loadings. The containment vessel penetrations were designed to withstand the maximum internal pressure that could occur due to a LOCA and the jet forces associated with the flow from the postulated pipe rupture.

Regulatory Guide 1.28: Quality Assurance Program requirements (design and construction).

A comprehensive Quality Assurance Plan was developed for the design and construction of the Sequoyah Nuclear Plant. The Quality Assurance Plan of the Westinghouse Electric Corporation, the supplier of the Nuclear Steam Supply System, is also contained therein.

The plans were prepared to assure that the control of quality was performed and documented for each phase of material selection, fabrication, installation, and/or erection in accordance with the approved specification and drawings. The plans relate principally to the Reactor Coolant and Safety Systems, the containment and other components necessary for the safety of the nuclear portion of the plant.

The plan assures that:

1. Final design requirements and final detailed designs are in accordance with applicable regulatory requirements and design bases.

2. Components and systems to which this plan applies are identified and that final design takes into account the varying degrees of importance of components and systems as evidenced by the possible safety consequences of malfunction or failure.

3. Purchased material and components fabricated in vendor shops conform to the final design requirements.

4. Components and systems are assembled, constructed, erected, and tested in accordance with final design requirements and to requirements specified in Safety Analysis Reports for the plant.

5. The plant can be operated and maintained in accordance with requirements specified in the Safety Analysis Reports.

3.8.2.3 Loads and Loading Combinations

3.8.2.3.1 Design Loads (Other Than Pressures)

The following loads are used in the design of the containment vessel and appurtenances. See Section 3.8.2.2.2 for pressures.

Dead Loads

These loads consist of the weight of the steel containment vessel, penetration sleeves, equipment and personnel access hatches, and attachments supported by the vessel.

Live Loads

Penetration loads as applicable (including seismic).

Floor load of 100 lb/ft^2 or 1000 pounds concentrated moving loads applied to the passage area of the personnel air locks.

Construction and snow loads at 50 lb/ft^2 but not simultaneously.

Floor load of 50 lb/ft^2 plus 225 pounds per linear foot for walkways.

Thermal Stresses During Accident Condition (DBA)

The containment vessel is designed to contain all the effluent which would be released by a hypothetical LOCA (DBA). This accident assumes a sudden rupture of the Reactor Coolant System which would result in a release of steam and a steam-air mixture in the vessel. It is calculated that this mixture would cause a lower compartment temperature of 220°F and an upper compartment temperature of 140°F both occurring essentially instantaneously. After the accident an Internal Spray System will commence spraying in the upper compartment only. The spray will discharge water on the interior of the upper compartment and then drain to the lower compartment. For shell temperature transients refer to Appendix 3.8A.

Main Steam Line Break (MSLB) produces temperatures in the lower compartment of 327°F with coincident internal pressure and seismic loadings defined in load combinations 3B and 4B. The containment wall temperature is less than this value.

Hydrostatic Loads

The containment vessel is designed for three separate flooded conditions. Hydrostatic load, Case IB, accounts for the flooded condition due to spray water and ice melt from the ice condenser after the DBA. After all the ice has melted the containment will be flooded to elevation 696 feet and 3 inches. Also considered is the loading condition during meltdown (hydrostatic load, Case IA). Water will rise to a depth of 2 feet on the floor of the ice condenser. At this time, the depth of water on the containment cylindrical shell will be 9 feet 3 inches.

Hydrostatic load, Case II, accounts for the post-accident fuel recovery condition. In order to remove fuel from the containment after the DBA, the containment vessel is designed for an internal hydrostatic head of 47 feet 3 inches.

For hydrostatic load cases refer to Figure 3.8.2-1.

Ice Condenser Duct Panel Loads

The outer duct panels of the ice condenser are attached to the containment with threaded studs. These panels impart a small horizontal and vertical force on the containment shell under seismic conditions. The distribution of these loads to the shell is shown in Figure 3.8.2-1.

Equipment Loads

Equipment loads are those specified by manufacturers of the equipment.

Spray Header Loads

The Spray Header Loads used for initial design of the containment vessel are shown in Appendix E of the Tennessee Valley Authority Design Specification SNP-DS-1705-9803-02 (Reference 11).

Seismic Loads

Seismic loads were computed using the following:

1. 1/2 SSE maximum ground accelerations

   horizontal 0.09 g
   vertical 0.06 g

2. SSE maximum ground accelerations

   horizontal 0.18 g
   vertical 0.12 g

Response spectra are shown in Section 2.5.

Classifications of structures and equipment are shown in Section 3.2.1. See Section 3.7 for a detailed description of the seismic analysis. Damping ratios are shown in Section 3.7.1.

Wind Loads

The containment vessel and penetrations associated with primary containment are completely enclosed by the Shield Building, and is therefore not subject to the effects of wind and tornadoes.

However, during construction, the vessel dome is exposed to the elements for a short duration. For this construction condition, a wind load of 30 lb/ft^2 on the projected area of the vessel dome is considered.

Non-Axisymmetric Transient Pressure Loads (NASPL)

The division of the containment into compartments is described in Chapter 6. Figure 3.8.2-2 shows a layout of the containment shell, indicating the various shell areas subjected to the transient pressure loadings.

Pressure transient loads are considered for occurrence of the Design Basis Accident (double-ended rupture of the Reactor Coolant System) in all six lower compartment volumes. The curves presented in Chapter 6 represent the containment pressure transients for break locations one through six respectively. Each set of curves contains 10 plots to present 49 containment elements. The most severe containment pressure differences occur during the first 0.9 second of the blowdown. The pressures and differential pressures shown on these figures have a 20 percent margin added to accommodate tolerances in analytical constants used in the code. The initial containment pressure was assumed to be 0.3 lb/in^{2}g. This allows for an initial containment pressure before containment venting is required.

For structural design purposes the pressures represented by the curves are increased by an additional 10 percent to cover changes in such factors as equipment configuration and openings between compartments which can influence the flow characteristics of the containment space and the effect of moisture entrainment. Curves which include the effects of moisture entrainment have been investigated by TVA and CBI and do not control the design of the containment vessel for any loading condition.

Hydrogen Detonation Loads

The Hydrogen Distributed Ignition System is provided to burn hydrogen in the containment vessel before it reaches an explosive concentration level following a degraded core accident. Such a hydrogen burn can cause pressures which exceed the design pressure of the containment vessel. An evaluation was made of the containment vessel pressure capability under a postulated static internal pressure buildup and a minor local internal hydrogen detonation; not applied concurrently.

The static internal pressure analysis was performed using an elasto-plastic finite element analysis of a 2° segment of the containment vessel between Elevations 778'-6" and 793'-0" using the ANSYS finite element computer program. The model was constructed of STIF-48 plastic triangular elements with circumferential ring and vertical stiffeners modeled discretely, Figure 3.8.2-3. The ANSYS computer program is described in Appendix 3.8D.

The limiting element in the containment shell from the analysis is the 1/2" plate between the circumferential stiffeners at Elevations 778'-6" and 788'-0". The pressure capability corresponding to ASME Boiler and Pressure Vessel Code (1980 Edition), Subsection NE, Criteria, Service Levels A and C are 14.2 lb/in^{2}g and 27.5 lb/in^{2}g, respectively. Furthermore the pressure capacity just prior to the onset of large deflections at small load increments is 50 lb/in^{2}g.

To prove the adequacy of the containment against local hydrogen detonations, a pressure transient analysis was performed using a representative pressure profile and time history curve depicted in Figures 3.8.2-4 and 3.8.2-5. Using the ANSYS finite element computer code, a shell segment was modeled between azimuths 150° and 180° and between Elevations 756'-3" and 810'-3". This model utilized the STIF-43 quadrilateral shell element with the shell plate and stiffeners modeled discretely. The finite element model shown in Figure 3.8.2-6 represents the thinnest segment of the containment vessel. Direct integration of the equations of motion was utilized at a uniform time step of 0.0001 second over a total time duration of 0.10 second. A parametric study was performed to verify the validity of assumed boundary conditions.

The results of this analysis show that the containment has the capability to withstand the local hydrogen detonation considered. The maximum displacement, which occurs in the 1/2 inch plate

is 0.65 inch with the corresponding maximum membrane stress of 15.0 k/in^2. The stress meets Service Level A code allowable stress for SA516 Grade 60 shell plate. The Vacuum Relief System is discussed in section 3.8.1.3.

3.8.2.3.2 Loading Conditions

The following loading conditions are used in the design of the containment vessel:

1. Cold Shutdown Condition

Dead load of containment vessel and appurtenances.
Lateral and vertical load due to 1/2 SSE.
Personnel access lock floor live load.
Walkway live load.
Penetration loads.
Ice condenser duct load.
Thermal load due to temperature range 30°F to 120°F.
Spray Header loads.

2. Normal Operation Condition

Dead load of containment vessel and appurtenances.
Lateral and vertical load due to 1/2 SSE.
Penetration loads.
Spray header loads.
Personnel access lock floor live load.
Ice condenser duct load.
Walkway live load.
Thermal load due to temperature range 53°F to 120°F.

3A. Upset Condition (STATIC)

Dead load of containment vessel and appurtenances.
Structural design internal pressure of 10.8 psig. (90% of maximum P_a)
Lateral and vertical load due to 1/2 SSE.
Penetration loads.
Spray header loads.
Ice condenser duct load.
Thermal load due to temperature range 53°F to 220°F.
Hydrostatic load Case IA or IB (see Figure 3.8.2-1).

3B. Upset Condition (DYNAMIC)

Dead load of containment vessel and appurtenances.
Pressure transient loads (NASPL).
Lateral and vertical load due to 1/2 SSE.
Penetration loads.
Thermal load due to temperature range 53°F to 120°F.
Hydrostatic load Case IA or IB (see Figure 3.8.2-1).
Spray header loads.
Ice condenser duct load.

3C. Upset Condition (MSLB)

Dead load of containment vessel and appurtenances.
Internal pressure coincident with MSLB per reference 10.
Lateral and vertical load due to 1/2 SSE.
Spray header loads.
Ice condenser duct load.
Thermal load due to temperature range 53°F to 273.5°F.
Penetration loads.

4A. Emergency Condition (STATIC)

Loads are same as in condition 3A, except
Lateral and vertical load due to SSE.

4B. Emergency Condition (DYNAMIC)

Loads are same as in condition 3B, except
Lateral and vertical load due to SSE.

4C. Emergency Condition (MSLB)

Loads are same as in condition 3C, except
Lateral and vertical load due to SSE.

5A. Construction Condition

Dead load of containment vessel and appurtenances.
Snow load.
Wind load.
Construction load.
Walkway live load.
Personnel access lock floor live load.

5B. External Pressure Condition

Dead load of containment and appurtenances.
External design pressure of 0.5 psig.
Lateral and vertical load due to 1/2 SSE.

6A. Initial Test Condition

Dead load of containment and appurtenances.
Internal test pressure of 13.5 psig.
Snow load.
Wind load.

6B. Final Test Condition

Dead load of containment and appurtenances.
Internal test pressure of 13.5 psig.

7. Post-Accident Fuel Recovery Condition with Flooded Vessel

Dead load of containment and appurtenances.
Hydrostatic load Case II (see Figure 3.8.2-1).
Personnel access lock floor live load.

A summary of these load combinations with their corresponding allowable stress criteria is given in Tables 3.8.2-1 and 3.8.2-2.

3.8.2.4 Design and Analysis Procedure

3.8.2.4.1 Static Stress Analysis

A detailed stress analysis of all major structural components was prepared in sufficient detail to show that each of the stress limitations of Table 3.8.2-1 was satisfied.

The equivalent stress at any point of the primary containment cylindrical wall and dome is the value of stress derived from the stress condition at the point by means of a theory of failure for comparison with the mechanical properties of the material used. The theory of failure used was the maximum shear stress theory. Using this theory, normal stresses were combined with shear as applicable to derive stress intensities.

The bottom liner plate is encased in concrete and serves as a leak-tight membrane only (not a pressure vessel). The liner plate is anchored to the concrete by welding it continuously to steel members embedded in and anchored into the base mat.

The juncture of the cylinder to the base mat is a point of discontinuity.

Details of this juncture are shown in Figure 3.8.2-7. In the analysis, the juncture was considered to be a point of infinite rigidity. The cylinder at this point cannot expand or rotate under the internal pressure and temperature load conditions; hence, shear and moment are introduced into the cylinder wall. The analysis to obtain the moments and shears in the cylinder wall due to these loads at this joint was accomplished by equating the deformations of the cylinderical shell and the supported edge.

At the point the knuckle is welded to the vessel a backup stiffener is used. This stiffener gives added rigidity at the point of the weld. Additional protection of the knuckle is accomplished by encasing the knuckle in “Fiberglass” before floor concrete placement.

The embedded knuckle was designed to take interior pressure plus internal or external hydrostatic loads. It was assumed that a crack can occur in the concrete allowing pressure loads on the embedded knuckle. Anchor bolts were post-tensioned to prevent any cracking of the concrete. Thermal and pressure discontinuity stresses in the containment occur one foot above the last weld of the knuckle.

The requirements of ASME Code Case 1392 are applicable to the containment vessel in this application. The minimum thickness of the bottom configuration was determined using the design rules of ASME Code Section VIII.

Circumferential compressive stresses resulting from external pressure forces were calculated and held below the critical buckling stress by a factor of safety of four.

The primary containment vessel structure was analyzed for a steady state condition in the following manner:

1. The forces, displacements, and stresses in the structure due to wind, dead load, steady state internal or external pressure, water, and externally loaded penetrations were determined by computer. The program used was "GENSHL 5 Layered Static Shell Program" described in Appendix 3.8D.

2. This computer program allows the total mathematical model for the actual structure to be analyzed at one time. The model has a fixed base.

3. Asymmetrical thermal loading exists because of various relatively confined areas in the lower compartment and because the ice condenser does not cover the full 360° of the containment structure. The effects of this asymmetry were evaluated by computer (see Item 1).

Secondary and local stresses at penetrations subjected to applied loads were analyzed. The stresses were combined vectorially at eight points on the circumference of penetration and resolved into primary stresses at each point. The stress intensity at each point was then computed.

Penetrations not subjected to applied loads were designed by the area replacement method in accordance with Section III, ASME Boiler and Pressure Vessel Code.

When required, reinforcement was provided at penetrations to meet the requirements of the allowable stress criteria of Table 3.8.2-1. Normally, reinforcement consists of thickening the shell plate adjacent to the penetration. Large penetrations, such as the equipment and personnel access openings, required stiffeners for reinforcement.

3.8.2.4.2 Dynamic Pressure Transient Analyses

Description of Analyses

The containment fabricator, Chicago Bridge and Iron Company (CBI) was required by the specification to perform a complete design in accordance with the requirements of the ASME Boiler and Pressure Vessel Code, 1968 winter edition, for a Class B vessel. For the pressure transient analysis, CBI chose to perform this dynamic analysis treating the vessel as a lumped-mass cantilever beam model. In addition, TVA made dynamic analyses to determine the response of the containment vessel to the non-axisymmetric pressure loading (NASPL). The response of the vessel was determined by a dynamic analysis treating the vessel as a lumped-mass cantilever beam and a dynamic shell analysis.

The mathematical model of the containment vessel used in the TVA dynamic beam analysis is shown in Figure 3.8.2-8. Each mass represents the mass of the vessel, stiffeners, and attached masses. The cantilever beam model was loaded with the forces from the NASPL. The forces were resolved into X and Y components and applied as mass point loads in the north-south and east-west directions.

The response of the model to pressure transients was determined using the method of modal analysis. This consists of uncoupling the equations of motion which is accomplished by assuming that the response is a superposition of the normal modes of the system multiplied by the corresponding time-dependent generalized coordinates. The total response was then found by summing the effects of the significant modes of vibration. The modal values of shape, shear, and moment were computed and analyses were made for the response to the pressure transient loads in the X and Y directions. The final response was found by taking the vector sum of the response in both directions for all loading conditions.

This analysis was very similar to the dynamic analysis made by CBI and served an independent check of their work. The results of the two analyses were very nearly the same.

TVA was concerned that these asymmetric dynamic loads might induce significant lobar type response of the shell structure which is not given in a beam type analysis. As a result of this concern, a linear, dynamic shell analysis using the finite-element method was made.

The computer program used in the dynamic analysis of the steel containment vessel is a multipurpose computer program for linear analysis of axisymmetric structures subjected to arbitrary asymmetric loads. The program is described in the report by Sukmar Ghosh and Edward Wilson, “Dynamic Stress Analysis of Axisymmetric Structures under Arbitrary Loads,” Report No. EERC 69-10, University of California, Berkeley, 1969.

The basic structural components considered were the vertical cylinder, dome, and stiffeners acting as one structure. The vessel was idealized as an axisymmetric structure as shown in Figures 3.8.2-9 and 3.8.2-10. The finite elements are simple conical frustra.

The non-axisymmetric pressure forces were approximated by a Fourier Series. For each Fourier component the stiffness and mass matrices and corresponding load vector were solved throughout the time-history of the pressure transients. The equations of motion were solved by the direct integration method, i.e., the simultaneous solution of the equations of motion using a step-by-step integration technique. The total response of the containment was determined by summing the response of each Fourier term.

<u>Results of TVA and CBI Analyses</u>

The results of the CBI and TVA analyses were compared to choose the most conservative approach. The CBI analysis required seven circumferential stiffeners plus additional vertical stiffeners at large attached masses such as the equipment hatch and personnel locks. The TVA shell analysis, which considered ovaling and lobar types of motion as well as beam type motion, showed significant local overstresses at the base of the containment over a considerable area at

the ice condensers and in the dome. These overstresses indicated that local buckling of the thin shell created an overall instability problem which could not be ignored and that further stiffening of the vessel would be required. Consultation with Gilbert Associates and Duke Power Company verified the TVA results. This consultation also verified that the considered break in Element 1 was the controlling design loading for the containment vessel.

The design of the additional stiffening was accomplished by the following steps:

1. Dynamic shell analyses were made for various configurations of circumferential stiffeners and combinations of circumferential and vertical stiffeners. Practical considerations prohibited the use of circumferential stiffeners only and a combination of circumferential and vertical stiffeners were used to reinforce the vessel. The final stiffener configuration which satisfied the initial buckling stress criteria consisted of 17 circumferential stiffeners, and vertical stiffeners on 4° centers. The stiffener arrangement and finite element model used in the analyses are shown in Figure 3.8.2-10.

   Using the results of the TVA finite element shell analysis, both TVA and CBI have independently designed the additional stiffening and redesigned the existing stiffening to meet the design criteria within the stated allowable stresses.

2. Using the results of the TVA finite element analysis, both CBI and TVA have independently investigated the containment anchorage knuckle section, effects of local vibration of attached masses relative to the shell, and other points of discontinuity for effects of the pressure transient loading. The TVA investigation of the anchorage configuration is shown in Appendix 3.8C. This investigation shows that the anchorage is within allowable stresses.

3. The vessel has been analyzed for seismic and dead loads using the additional stiffeners in the model. The method of analysis is the same as described in Section 3.7.2.

4. Further revision of the pressure transient loadings necessitated a dynamic stability analysis of the containment vessel. Details of this stability analysis are given in Reference 8.

3.8.2.4.3 <u>Thermal Analysis</u>

A thermal analysis was performed on the containment for LOCA. A description of the shell temperature transients due to a rupture of a reactor coolant pipe is given in Appendix 3.8A. The analysis was done by inputting Fourier expansions for load components in the computer program, GENSHL 5. This is a layered static shell program from The Franklin Institute Research Laboratories by Z. Zudans, T. Y. Chu, H. M. Fishman, T. Y. Chow, and J. W. Soule. The tolerable temperature rise for the steel containment is well above these temperatures shown, as the steel shell was designed for the basic stress limits of the ASME Boiler and Pressure Vessel Code, Section III, for ASTM A-516, Grade 60 steel at 300°F.

Also, as seen by these curves, the containment shell will experience an unbalanced temperature loading for the three compartments. The temperature difference between any two adjacent points on the vessel is held within the limits of paragraph N-415.1 of the Code. For the shell analysis, the thermal load vectors were expanded into harmonic coefficients.

The stiffener thermal analysis was based on a variable temperature on the cross-section of the stiffener. The same analysis as described above for the containment was used on the stiffeners with this exception.

3.8.2.4.4 Dynamic Seismic Analysis

The dynamic analysis of the containment vessel was performed by the modal analysis method described in Section 3.7.2.

3.8.2.4.5 Penetration Analysis

The vessel manufacturer was responsible for the design of the steel containment including the reinforcement required at the penetrations (reference Appendix 3.8B). The specifications required the manufacturer to submit all preliminary design calculations for TVA's review before any material was detailed or fabricated.

In addition, TVA engineers performed an independent analysis of those steel containment vessel penetrations for which the loads increased as a result of the inertial effects of DBA and earthquake on the Piping Systems. The methods used to qualify these penetrations are similar to those used by the vessel manufacturer. However, TVA used an in-house method consistent with Table 3.8.2-1, to perform the nozzle analysis, and a AAA Technology, Incorporated program, WERCO, to perform the shell analysis.

The in-house method combines the piping reactions from the individual loadings to calculate the stresses in the nozzle at both inside and outside the limits of reinforcement using standard empirical formulae. Finally, stress intensities are calculated from these stresses using maximum shear stress theory.

The load case components from the in-house method were also used as input for the WERCO program. The WERCO program computerizes the techniques in the Welding Research Council (WRC) Bulletin 107, "Local Stresses in Spherical and Cylindrical Shells due to External Loadings," Reference 9.

Adjacent penetrations' affects were also considered where these penetrations are close enough to have significant carryover stresses.

Penetrations not subjected to applied loads were designed by the area replacement method in accordance with ASME Code Section III. Reinforcement was provided at penetrations to meet the requirements of the allowable stress criteria of Table 3.8.2-1. Normally, reinforcement consists of thickening the shell plate adjacent to the penetration. Large penetrations, such as the large equipment and personnel access openings, require stiffeners for reinforcement.

Piping Support Analysis

Rigid pipe supports were modeled utilizing the SAGS finite element program. These models were constructed of beam type elements. These supports were designed in accordance with AISC criteria and Table 3.8.2-2.

Airlock Natural Periods of Vibration

The lock is a single degree of freedom system (when considering each of the three directions of vibrations separately) and the natural periods of free vibration are determined in the following manner:

Case I & II

$$T = 2\pi\sqrt{\frac{I_0}{K}}$$

Where:	T	=	Natural Period
	I_o	=	Mass moment of inertia of appurtenance about axis of rotation
	K	=	Spring constant of elastic shell
		=	M/Θ
	M	=	Unit moment acting on appurtenance
	Θ	=	Angular rotation at shell junction

The spring constant M/Θ is determined by using "Stresses from Radial Loads and External Moments in Cylindrical Pressure Vessels," P. P. Bijlaard, Figure 3 and 7 for the B based on the proper parameters for the junction.

Case III

$$T = 2\pi\sqrt{\frac{m}{K}}$$

Where:	T	=	Natural Period
	m	=	Mass of Appurtenance
	K	=	Spring constant of elastic shell
		=	P/W
	P	=	Unit radial force acting on appurtenance
	W	=	Radial deflection at the shell

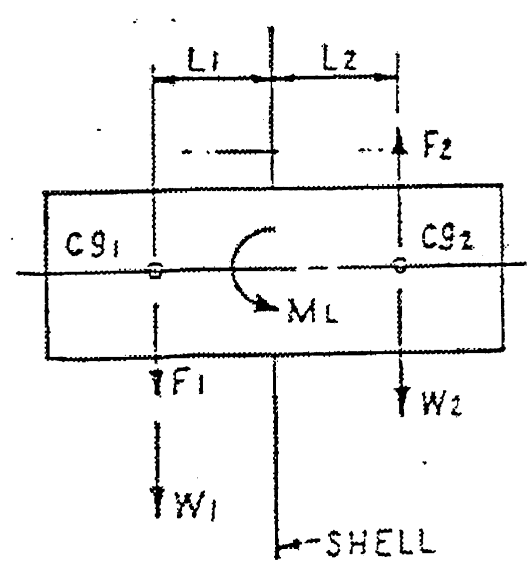
The spring constant P/W is found from Table 1 of "Stresses from Radial Loads in Cylindrical Pressure Vessels," by P. P. Bijlaard.

Forces and Moments Applied to the Shell

Once the lock accelerations are found, forces and moments to be applied to the shell are derived in the following manner:

Case I M_L = Moment applied to the shell in the meridional direction

= $(F_1 + W_1) L_1 + (F_2 - W_2) L_2$



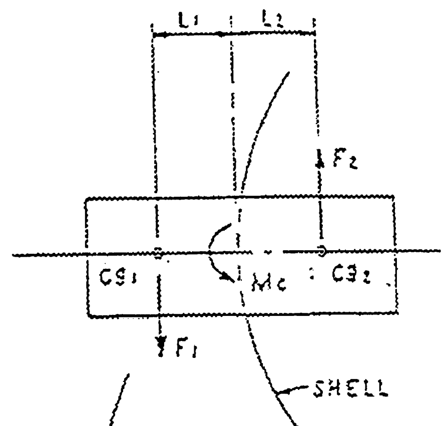
Where:

$$F_1 = \frac{W_1 a}{g} = \textit{Dynamic Force acting on lock}$$

$$F_2 = \frac{W_2 a}{g} = \textit{Dynamic Force acting on lock}$$

a = Linear acceleration of lock c.g. in meridional direction
W_1 = Weight of lock outside of shell
W_2 = Weight of lock inside of shell
g = acceleration of gravity
L_1 & L_2 = respective moment arms

Case II Mc = Moment applied to the shell in the circumferential direction
= $F_1 L_1 + F_2 L_2$



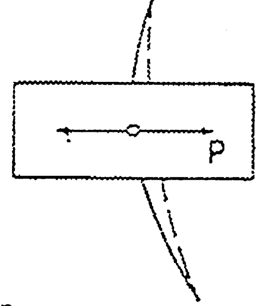
Where:

$$F_1 = \frac{W_1 a}{g} = \text{Dynamic Lock Force}$$

$$F_2 = \frac{W_2 a}{g} = \text{Dynamic Lock Force}$$

a = Linear acceleration of lock c.g. in either direction
W_1 = Weight of lock outside of shell
W_2 = Weight of lock inside of shell
L_1 & L_2 = respective moment arms

Case III P = Radial load applied to shell



$$= \left(\frac{W_1 + W_2}{g}\right) a$$

a = Linear acceleration of lock c.g. in radial direction

Note that for Cases I and II the linear accelerations are for the c.g. of the total lock. However, since this c.g. is very near the shell and would result in relatively small moments, these accelerations were conservatively applied in an additive manner to the c.g.'s of both sides of the lock to account for any rocking effect of the lock.

Shell Stresses Due to Applied Forces and Moments

Once forces and moments were determined the shell stresses due to dynamic loads from the lock were found using the methods of Welding Research Council Bulletin 107.

3.8.2.4.6 Personnel Lock Bellows Seal

Details of the expansion bellows seal between the personnel locks and the Shield Building are shown in Figure 3.8.2-11. In the design of the bellows, the following conditions were considered:

1. Operating Condition.
    a. No appreciable bellows displacement.
    b. External pressure of 3 lb/in^2 on the bellows due to tornado depressurization.
2. Cold Shutdown Condition.
    a. Thermal contraction of the vessel due to minimum service temperature of 30°F.
    b. Seismic motions of the Vessel, Lock, and Shield Building.
3. Transient Accident Condition.
    a. No appreciable temperature or pressure displacements.
    b. Seismic motion of the Vessel, Lock, and Shield Building
    c. Motion of the lock and vessel due to transient pressures.
4. Steady State Accident Condition.
    a. Thermal growth of the vessel due to 220°F vessel design temperature.
    b. Pressure growth of the vessel due to 10.8 lb/in^2g vessel pressure.
    c. Seismic motions of the Vessel, Lock, and Shield Building.
5. Two lb/in^2 vacuum in annulus.

The upper personnel lock receives the greater displacement and was used as the basis of the designs. Due to the fact that the personnel locks are nearly centered on the vessel shell, there is no appreciable independent lock motion due to vertical earthquake and horizontal earthquake perpendicular to the lock. Horizontal earthquake acting parallel to the lock does induce independent lock motion.

For computing thermal movements of the bellows, the installation temperature was assumed to be 70°F.

For the five design conditions enumerated above, the summation of the relative displacements between the Lock and the Shield Building, was used to determine the size of the bellows.

3.8.2.5 Structural Acceptance Criteria

3.8.2.5.1 Margin of Safety

A certified stress report was prepared for the vessel in accordance with the requirements of the ASME Code. This report contains several hundred pages and therefore is not included in this report.

Design values for transient pressure loads were determined by multiplying the calculated values by 1.3 as described in Section 3.8.2.3.1. A dynamic stability analysis was performed and reported in Reference 8.
.
Nonpressure parts such as walkways, handrails, ladders, etc., are designed so that the stress in the members and welds do not exceed the allowable stress criteria as set forth in the February 1969, AISC "Specification for Design, Fabrication, and Erection of Structural Steel for Buildings." The factor of safety of these allowable stresses with respect to specified minimum yield point of the material used are as defined in Section 1.5 of "Commentary on the Specification for the Design, Fabrication, and Erection of Structural Steel for Buildings."

Local areas, such as the personnel and equipment hatch areas, were checked for deformations to avoid a resonant condition. The vessel as a whole was not designed to deformation limits. Shutdowns and startups do not occur with a frequency that required a design for fatigue failure. The number of cycles will not affect the containment vessel service life.

3.8.2.5.2 Vessel Material Inspection and Test

ASTM standard test procedures were employed for the liner and shell plates to ascertain compliance with ASTM specifications. Certified copies of mill test reports of the chemical and physical properties of the steel were submitted to TVA for approval. All vessel pressure boundary material was tested (one test for each heat of steel) to determine its Nil Ductility Transition Temperature (NDTT). These tests were conducted to meet the requirements of ASME Boiler and Pressure Vessel Code, Section III, paragraph N-1211. The tests were conducted at maximum temperature of 0°F.

Ultrasonic inspection was required for all pressure boundary plates subjected to tensile forces normal to the plate surface. This inspection was performed in accordance with ASME SA-435 specification.

3.8.2.5.3 Bottom Liner Plates Test

Before concrete was placed over the bottom liner, the leak tightness of this liner was verified. All liner plate welds were vacuum box tested for leak tightness. Upon completion of a successful leak test, the welds were covered with channels, and the channels were leak tested by pressurization.

3.8.2.5.4 Vertical Wall and Dome Weld Tests

Welds in the cylinder wall and dome per ASME Code, Section III, Categories A and B, were 100 percent radiographed. Welds in Categories C and D were examined by magnetic particle, liquid penetrant, or ultrasonic methods.

3.8.2.5.5 Soap Bubble Tests

Upon completion of the construction of the containment vessel, a soap bubble test was conducted with the vessel pressurized to 5 lb/in^2g. Soap solution was applied to all weld seams and gaskets, including both doors of the personnel airlocks.

A second soap bubble inspection test was made at 12 lb/in^2g upon completion of the overpressure test in accordance with the requirements of the ASME Code.

Any leaks detected by soap bubble test which could affect the integrity of the vessel or which could result in excessive leakage during the leakage rate tests were repaired prior to proceeding with the tests.

3.8.2.5.6 Overpressure Tests

After successful completion of the initial soap bubble test, a pneumatic pressure test was made on the containment vessel and each of the personnel airlocks at a pressure of 13.5 lb/in^2g. Both the inner and outer doors of the personnel airlocks were tested at this pressure. The test pressure in the containment vessel was maintained for not less than 1 hour. The test pressure was maintained on each individual airlock door for not less than one-half hour.

3.8.2.5.7 Leakage Rate Test

Following the successful completion of the soap bubble and overpressure tests, a leakage rate test at 12 lb/in^2g pressure was performed on the containment vessel with the personnel airlock inner doors closed.

The Contractor performed the leak rate testing by the “Absolute Method,” which consists of measuring the temperature, pressure, and humidity of the contained air, and making suitable corrections for changes in temperature and humidity.

Equipment and instruments were calibrated and certified before any pressure tests were initiated.

Continuous hourly readings were taken until it was satisfactorily shown that the total leakage during a consecutive 24 hour period did not exceed 0.1 percent of the total contained weight of air at test pressure at ambient temperature in accordance with the requirements of 10 CFR 50, Appendix J.

The Contractor and Engineer’s representatives reviewed the leakage rate data during the test to determine adequacy of the test, authorize termination, or require continuation of the test.

3.8.2.5.8 Operational Testing

After completion of the airlocks, including all latching mechanisms, interlocks, etc., each airlock was given an operational test consisting of repeated operation of each door and mechanism to

determine whether all parts were operating smoothly without binding or other defects. All defects encountered were corrected and retested. The process of testing, correcting defects, and retesting was continued until no defects were detectable.

3.8.2.5.9 Leak Testing Airlocks

The airlocks were pressurized with air to 13.5 lb/in^{2}g. All welds and seals were observed for visual signs of distress or noticeable leakage. The airlock pressure was then reduced to 12 lb/in^{2}g, and a thick soap solution was applied to all welds and seals and observed for bubbles or dry flaking as indications of leaks. All leaks and questionable areas were clearly marked for identification and subsequent repair. During the overpressure testing the input door was locked with hold-down devices to prevent upsetting of the seals.

The internal pressure of the airlock was reduced to atmospheric pressure and all leaks repaired after which the airlock was again pressurized to 12 lb/in^{2}g with air and all areas suspected or known to have leaked during the previous test were retested by above soap bubble technique. This procedure was repeated until no leaks were discernible by this means of testing.

3.8.2.5.10 Penetration Tests

Type B tests were performed on all penetrations with test bellows and/or pressure taps in accordance with the requirements of 10 CFR 50, Appendix J. See Chapter 6 for imposed leak rates and tests performed on penetrations.

3.8.2.5.11 Post-Weld Heat Treatment

Field welded joints did not exceed 1-1/2 inch and therefore the containment vessel as a completed structure did not require field stress relieving. Insert plates at penetration openings did not exceed 1-1/2 inch in thickness and stress relieving was not required by ASME Code before or after they were welded to adjacent plates. Post-welded heat treatment, where required, was performed as required by and in accordance with the ASME Code.

3.8.2.5.12 Impact Testing

Charpy V-Notch impact tests were made of material, weld deposit, and the base metal weld heat affected zone employing a test temperature of not more than 30°F below minimum operating temperature. The requirements of the ASME Code were met for all materials under jurisdiction of the Code.

All weld procedure qualifications for procedures used on the containment vessel will also meet code requirements for ductility.

3.8.2.6 Design Loading Combinations and Stress Limits

Loading conditions and the design stress limits associated with allowable stress criteria for the vessel material are given in Tables 3.8.2-1 and 3.8.2-2.

3.8.3 Concrete Interior Structures

3.8.3.1 Description of the Interior Structures

3.8.3.1.1 General

This structure, shown in Figures 1.2.3-11, -12, -13 is a complex assemblage of reinforced concrete walls, slabs, and columns housed inside the steel containment vessel. It will act as a temporary barrier while routing steam to and through the ice condenser in the event of a LOCA. The reactor, four steam generators, four reactor coolant pumps, pressurizer, ice condenser, reactor instrumentation, air-handling equipment, and various other support systems are located inside this structure.

The portion of this structure which separates the upper compartment from the lower is defined as the divider barrier (see Figure 1.2.3-12). The failure of any part of the divider barrier is considered critical since it would allow LOCA steam to bypass the ice condenser, thereby increasing the pressure within the steel containment. For this reason these features of the divider barrier designed using Table 3.8.3-1 are designed more conservatively than the rest of the internal structure.

Since the ice condenser is both a structure and an Engineered Safeguard System, most detail information can be found in Section 6.5.

3.8.3.1.2 Containment Floor Structural Fill Slab

The containment floor slab is a reinforced concrete slab of 2-foot nominal thickness cast on top of the bottom liner plate. Reinforcement is provided in both faces to withstand uplift pore pressures below the liner plate and to develop restraint for uplift and rotational moments at the base of the crane wall. Earthquake shearing forces are transmitted to the base slab by shear keys under the crane wall, through a direct tie with the reactor cavity, and through direct bearing on the base of the Shield Building wall as a result of the expanded volume of the fill slab under operating temperatures. Stresses resulting from shear forces are very low since any one of the three methods is capable of transmitting the entire shearing force.

The interior concrete structure is sufficiently keyed to the reactor cavity by its configuration of walls and slabs to provide base stability against earthquake overturning moments above the bottom liner plate at Elevation 677.78. In addition, the anchorages for the Steam Generators and Reactor Coolant Pump Supports tie the containment structural fill slab to the base slab in the vicinity of the crane wall.

3.8.3.1.3 Reactor Cavity Wall

This 17-foot-inside-diameter-circular wall supports and encloses the 1400-kip reactor vessel above the lower reactor cavity. Primarily for radiation shielding this wall is 8-1/2 feet thick and extends from the base slab at Elevation 679.78 to Elevation 689.71 where it intersects the refueling canal floor slab. Neutron detector chambers reduce the effective structural thickness to 6 feet for approximately the first 10 feet of height. The next 12 feet of height has only a 4-foot 3-inch structural thickness due to the 3-foot 1-inch wide by 6-foot 6-inch high inspection cavity which surrounds the reactor vessel. This is shown in Figure 1.2.3-11.

3.8.3.1.4 Compartment Above Reactor

This compartment is approximately a 270° arc continuation of the reactor vessel annulus wall. The ends of the arc intersect the two refueling canal side walls. The inside diameter is 26 feet and the thickness is 4 feet extending from the top of the reactor vessel at approximately Elevation 702.15 to the bottom of the divider barrier slab at Elevation 731.13. This compartment is vented to the lower compartment area outside the wall by six openings which reduce the wall to five columns. These columns each have a cross sectional area of 12 square feet and extend the last 4-1/2 feet of height to the bottom of the divider barrier slab. This compartment is shown in Figure 1.2.3-11.

During reactor operation this compartment is sealed across the top by the concrete missile shield and at the refueling canal by a concrete gate.

Seals Between Upper and Lower Compartments (Divider Barrier)

See Figure 3.8.3-1.

The seals extend across the gap between the inside surface of each steel containment vessel and the concrete structure within each vessel. They are located along the bottom of the concrete floor under the ice condenser, at Elevations 720 feet, 5 inches and 727 feet, 9 inches between the ends of the ice condenser and the refueling canal concrete structure, and along the vertical sides of the refueling canal structure. These seals form part of the barrier between the upper and lower compartment of the containment vessels.

Similar seals classified as non-Category I butt against this seal at four places.

The seals consist of long strips of flexible coated fabric made of Presray Corporation EPDM Compound E603 (2 ply Dacron Coated EPDM) with both edges hemmed to form pockets into which metal clamp bars are inserted. These strips are field-spliced and glued overlay joints to form a continuous seal.

The seals are attached to the containment vessel and the interior concrete structure with bolted clamp angles, spaced 1 foot ± apart. The angles grip the clamp bars in the pockets at the seal edges.

The seals form part of the divider barrier between the upper and lower compartments of the containment vessels. During normal operating conditions, the seals prevent airflow around the ice condensers. In an accident, the seals and the other divider parts limit the amount of hot gases, steam, and vapor that can bypass the ice condensers. The seals will maintain their integrity for the first 12 hours after an accident. A small amount of leaking during this period is permissible.

The seals will maintain their integrity during earthquake conditions and effectively maintain their air seal. The seals will function effectively in a post-earthquake condition.

3.8.3.1.5 Refueling Canal Walls and Floor (Divider Barrier)

These irregular shaped walls and slabs vary in thickness and enclose an area approximately 19 feet by 36 feet. This area will be filled with water along with the compartment above the reactor during refueling operations. The water level will be about 35 feet above the canal floor. The reactor internals will be removed and stored in the refueling canal during refueling. Refueling canal walls and floor are shown in Figure 1.2.3-11.

3.8.3.1.6 Crane Wall

This approximately 3-foot-thick, 117-foot-high cylindrical wall encloses an 83-foot-inside-diameter area containing the reactor, reactor coolant pumps, steam generators,

pressurizer, and reactor coolant piping. This wall acts as the major support for the divider barrier slabs and walls. It also supports the floors and walls in the 13-foot annulus between it and the steel containment vessel. The 175-ton polar crane is mounted on top of this wall. Over the refueling canal the wall has a section removed leaving a curved beam 23 feet deep spanning an arc of 41 feet between ice condenser compartment end walls. Beginning at Elevation 723.42 the crane wall has 24, 7-foot 4-inch high by 6-foot 8-inch openings for the ice condenser inlet doors. The remaining wall consists of 25 columns each having an 8-square-foot cross section. Above the operating deck floor at Elevation 733.63, the crane wall is part of the divider barrier. It is also part of the pressurizer and steam generator compartments, which constitute part of the divider barrier, and is designed to resist the same pressures as these compartments. At the top of the crane wall the steel support beams for the ice condenser bridge crane cantilever over the ice beds causing moments in the crane wall. Lateral seismic loads from the ice beds are transmitted to the outer face of the crane wall.

Personnel Access Doors in Crane Wall

Four access doors in the lower half of the crane wall are provided in each Reactor Building at the following locations:

Floor Elevation	Azimuth
679.78	221°
679.78	299°
693.00	114° 16’-11”
722.00	299°

The doors provide passageways 3 feet-0 inch wide by 6 feet-6 inches high through the concrete crane wall for workmen and tools. When closed, the doors seal the passageways against steam jets, pressure, and missiles that may originate from pipe rupture in the compartment inside the crane wall.

Each door is manually operated and hinged to a steel frame embedded in the concrete wall. Each door consists of a steel skin plate stiffened by horizontal framing. The skin plate is faced with a cushioning structure of vertically arranged square steel tubing separated from the doors skin plate by a collapsible latticework of steel bars, the purpose of which is to absorb the energy of missiles striking the door. The cushioning structure is covered with sheet steel for appearance. Bearing of the door against the frame is through steel bars. An elastomer seal is attached to the periphery of the door to reduce the possibility of damage from jets to items beyond the door. Two lever-type latches functional from either side hold the door in the closed position. Hinges on the doors are provided with graphite impregnated bushings.

The doors, under normal operating conditions, provide an effective seal against airflow and can be operated and secured by one man from either side. For pipe rupture accidents, the doors seal

the passageways in the crane wall against missiles, jets, and pressure that may originate within the crane wall enclosure, thus preventing consequent damage to the containment vessel and to piping and machinery between the crane wall and containment vessel.

The doors will maintain their integrity and seal for not less than the first 12 hours following an accident. Limited leakage during this period is permissible.

3.8.3.1.7 Steam Generator Compartments (Divider Barrier)

Two double-compartment structures house the four steam generators in pairs on opposite sides of the building. Each structure consists of curved and straight sections of walls that vary in thickness from 2 to 4 feet. Divider barrier walls around two steam generators extend 42 feet up from the divider floor and are capped with a 3-foot-thick slab spanning over the steam generators from the crane wall. A wall between the two steam generators extends from the divider barrier walls to the crane wall, completing the double compartment. The center wall extends only 32-1/2 feet above the floor. The area above the top of this wall, except for that occupied by a main steam pipe restraint beam, will reduce the compartment pressure buildup in a single compartment by venting the steam to the other compartment. See Figures 1.2.3-11, -12, and -13.

During the Unit 1 and Unit 2 steam generator replacements, for each unit, four construction openings in the steam generator compartment concrete roofs were created to facilitate removal of the old steam generators and installation of the replacement steam generators. The compartments were restored by connecting the removed section of concrete to the remaining structure using through-bolted steel connection frames. Steel shims were placed in the gap between the removed concrete sections and the remaining structure and the gap was filled with non-shrink grout.

3.8.3.1.8 Pressurizer Compartment (Divider Barrier)

This compartment separates the pressurizer from the upper compartment. Its walls project about 38 feet above the Elevation 733.63 floor where they are capped with a 3-foot-thick slab. It is similar to the steam generator compartments except its wall thickness varies from 2 to 3 feet and the volume is much smaller, see Figure 1.2.3-12. A hatch is provided in the top of the compartment.

3.8.3.1.9 Operating Deck at Elevation 733.63 (Divider Barrier)

This 2-1/2-foot-thick irregular shaped floor is the major divider barrier between upper and lower compartments. It is supported at its outer edges by the crane wall and the compartment walls for the steam generators and pressurizer. Support near the center of the building consists of the refueling canal walls and the five columns of the upper reactor compartment. This floor contains five hatches for equipment removal. The concrete covers on these hatches are designed for the same loadings as the floor. The floor outline is shown in Figure 1.2.3-11.

3.8.3.1.10 Ice Condenser Support Floor - Elevation 721 (Divider Barrier)

This floor extends 12 feet 8 inches from the outside of the crane wall to the 4-inch expansion joint separating it from the steel containment vessel. A circumferential beam under its outer edge is cast with the floor. This edge beam is supported by concrete columns which extend down through the Elevation 693 floor to the fill slab at elevation 679.78. The floor extends 300° around the outside of the crane wall between the ice condenser end walls at azimuths 245° and 305°, as shown in Figures 1.2.3-11, -12, -13.

3.8.3.1.11 Significant Penetrations Through the Divider Barrier

Canal Gate

The canal gate consists of three removable concrete wall elements as illustrated on Figures 1.2.3-11 and 1.2.3-12. The elements are 2 feet 6 inches thick and span between 7-inches-deep slots formed in the walls of the refueling canal.

Control Rod Drive (CRD) Missile Shield

The CRD missile shield consists of three removable concrete slabs as illustrated on Figures 1.2.3-11, -12, and -13. The slabs are 3 feet 6 inches thick and are anchored to the divider barrier slab at Elevation 733.63 by anchor bolt assemblies.

Reactor Coolant Pump Access and Lower Compartment Access

Access to the reactor coolant pumps and lower compartment is provided by removable slabs. The reactor coolant pump access slabs are approximately 10 feet in diameter and the lower compartment access slab is approximately 6 by 10 feet. Both are 2 feet 6 inches thick and are anchored to the divider barrier slab by anchor bolt assemblies around the edges.

Equipment Access Floor Hatch

This hatch consists of a removable structural steel framed hatch cover and a structural steel support frame adjacent to the containment vessel. The support frame and hatch cover consist of structural steel wide flange sections covered with steel plate. To provide adequate seals between the upper and lower compartment, the side of the frame adjacent to the containment vessel was designed to span from the refueling canal wall to the divider barrier slab, a distance of approximately 5 feet. The hatch cover is anchored to the concrete structure by anchor bolt assemblies at each end of the cover.

Escape Hatch

The location of the hatch is shown on Figure 1.2.3-11. The hatch consists of a frame embedded in the divider barrier floor with a hinged and manually operated cover consisting of skin plate stiffened by framing. Quick-acting wheels are provided for opening and closing the cover from either side. Coil springs are incorporated with the hinges to reduce the force required for opening the cover.

Air Return Duct Penetration

The air return ducts penetrate the divider barrier at two different locations as indicated on Figures 1.2.3-11, -12, and -13. One penetration is at Elevation 723 and the other is at Elevation 733.63. The penetrations are 4-foot 6-inch inside diameter circular openings with flanges on both sides to provide attachment for the ventilating ducts.

3.8.3.1.12 Concrete Block Shield Walls

At two locations within the interior concrete, openings are provided in the structural walls to permit access for equipment maintenance. To minimize the effects of radiation, these openings are filled with concrete blocks. Structural steel restraints are provided to insure the stability of the walls under all load conditions.

3.8.3.2 Applicable Codes, Standards, and Specifications

Structural design of the interior concrete structures is in compliance with the American Concrete Institute 318-63 Building Code Working Stress Design Requirements for all load combinations shown in Table 3.8.3-1, including LOCA calculated pressures with moisture entrainment received from the NSSS Contractor; or the ACI-ASME (ACI 359) Article CC-3000 document, Proposed Standard Code for Concrete Reactor Vessels and Containments, and ACI 318-71 for all load combinations shown in Table 3.8.3-2, including LOCA calculated pressures.

All reinforcing steel conforms to the requirements of ASTM designation A 615, Grade 60. Construction was carried out under the requirements of TVA Construction Specifications G-2.

Unless otherwise indicated, the design and construction of the interior structures are based upon the appropriate sections of the codes shown in Section 3.8.12, with the following additions:

13. American Society of Mechanical Engineers, Boiler and Pressure Vessel Code, Sections II, III, V, VIII, and IX, 1971 Editions, as amended through summer 1972 addenda.

14. American Society for Testing and Materials, 1972 ASTM Standards.

"Recommended Lateral Force Requirements and Commentary," 1968 Edition.

17. Nuclear Construction Issues Group*

    NCIG-01, Revision 2 - Visual Welding Acceptance Criteria for Structural Welding at Nuclear Power Plants

    *The referenced NCIG documents may be used after June 26, 1985 to evaluate weldments that were designed and fabricated to the requirements of AISC/AWS. When invoked, NCIG provisions will be implemented as indicated in section 3.6.8.

18. NRC Standard Review Plan 6.2.1.2, Subcompartment Analysis

3.8.3.3 Loads and Loading Combinations

Loading combinations and allowable stresses are shown in Tables 3.8.3-1, 3.8.3-2, 3.8.3-3, 3.8.3-4, and 3.8.3-5. General loads are described below.

Dead Loads

These loads consist of the weight of the structure and equipment, plus any other permanent load contributing stress such as hydrostatic and earth pressure.

Live Loads

These loads include movable equipment loads and other loads which vary with intensity and occurrence.

Normal Temperature

These are the straight line temperature gradients which exist through member thicknesses due to differences in operating temperatures of various compartments.

LOCA Pressure

These loads are time varying pressure differentials that will result between compartments in the event of a double-ended break of a reactor coolant pipe as given in Chapter 6. They vary in magnitude depending on the location of the pipe break. During the construction of Unit 1 Reactor Building, the maximum calculated differential compartment pressures were increased by 40 percent in accordance with NRC requirements to account for uncertainties. At the Operating License stage, the design pressures equaled or exceeded the peak calculated differential pressure. Dynamic load factors were not applied in the structural analysis except for the ice condenser support floor since the vibration period of other components in the structure is small in comparison to the rate of application and duration of the pressure loads.

LOCA Temperature

Time varying, nonlinear temperature gradients due to a LOCA cause stresses in the restrained members of this structure. These gradients will vary depending upon time and member location in relation to the pipe break. Stresses were computed for these loadings using a TVA developed program which has the same basic assumptions as the (ACI 505-54) Reinforced Concrete Chimneys Code. A typical gradient for the divider floor is shown in Figure 3.8.3-2.

Creep and Shrinkage

Creep was not considered in the design of interior concrete for the reasons outlined in Section 3.8.1.4.

Shrinkage effects were considered as outlined in Section 3.8.1.4. The peak hydration temperature of the concrete used in the interior structures was estimated to be 130°F for summer placement with controlled placing temperatures of 65°F. From Figure 3.8.3-2 the average normal operating temperature for combination of shrinkage effects with other loads was 90°F resulting in a design temperature drop of 40°F. Under LOCA temperature gradients average temperatures exceed hydration temperatures and shrinkage stresses are relieved. Therefore, shrinkage effects are considered only with normal operating temperature gradients.

Hypothetical Pressure

This loading was due to a hypothetical compartment pressure used as part of the original design resulting from a double-ended break of a reactor coolant pipe if such pipe were located in either the pressurizer compartment, the steam generator compartment, or the compartment above the reactor. This loading was used as part of the original design and is not required to be considered in the evaluation and/or modification of the existing structures. This loading was the result of an agreement between Westinghouse Corporation and the Nuclear Regulatory Commission in order to provide a high degree of conservatism in the design of these compartments.

½ Safe Shutdown Earthquake **(**1/2 SSE**)**

Reference Section 3.7.2.

Safe Shutdown Earthquake (SSE)

This is the maximum postulated earthquake the plant is designed to withstand and still permit a safe shutdown. Reference Section 3.7.2.

Pipe Forces

These forces are the pressure jet effects that can occur due to breaks in systems piping. They may be the jet force impinging upon the structure, or the equipment and pipe anchorage forces as the result of such a jet. The static equivalent of the major equipment anchorage loadings were furnished by Westinghouse Corporation, the support designer.

Jet forces from postulated pipe ruptures, both longitudinal and transverse, were assumed to load the interior concrete structure.

Two loading conditions were assumed:

1. Effect of initial jet force alone on structure before the compartment transient pressure has time to build up.

2. Effect of jet force using the saturation pressure at the rupture point in combination with the uniform compartment differential pressure.

A minimum load factor k = 1.3 was used with both conditions based on localized yielding of the structural member and a ductility factor of 3. See Section 3.6.

The only jet force in the compartment above the reactor cavity is from the control rod opening. This is due to a pressure of 2250 lb/in^2. The reactor coolant pipe will not produce a jet force in this area.

Missiles

The systems located inside the reactor containment have been examined to identify and classify potential missiles. The basic approach is to assure design adequacy against generation of

missiles, rather than allow missile formation and try to contain their effects. Reference Section 3.5.

Ice Condenser Loads and Loading Combinations

The ice bed structure was designed to meet the loads described below within the behavior criteria limits presented in Table 3.8.3-5 of these criteria. The following load combinations are defined for design purposes:

1. Dead Load + 1/2 SSE loads (D + 1/2 SSE).
2. Dead Load + Accident induced loads (D + DBA).
3. Dead Load + SSE (D + SSE).
4. Dead Load + SSE + Accident induced loads (D + SSE + DBA).

The loads are defined as follows:

Dead load (D) - Weight of structural steel and full ice bed at the maximum ice load specified.

Live Load (L) - Live load includes any erection and maintenance loads, and loads during the filling and weighting operation.

Thermal Induced Load - Includes those loads resulting from differential thermal expansion during operation plus any loads induced by the cooling of ice containment from an assumed ambient temperature at the time of installation.

Accident Fluid Dynamic and Pressure Loads (DBA) - Accident pressure load includes those loads induced by any pressure differential drag loads across the ice beds, and loads due to change in momentum.

1/2 SSE - As previously defined.

SSE - As previously defined

3.8.3.4 Design and Analysis Procedures

3.8.3.4.1 General

The following discussion is a description of the original design and analyses performed to ensure that the design of the interior concrete structures complied with the applicable codes, standards, and specifications as stated in Section 3.8.3.2.

Each component of the interior concrete structure was considered individually. Its boundary conditions and degrees of fixity were established by comparative stiffness; loads were applied, and moments, shears, and direct loads determined by either moment distribution or finite element methods of analysis. Reinforcing steel was proportioned for the component sections in accordance with Table 3.8.3-1 or Table 3.8.3-2. The ultimate strength provisions of ACI 318-71 Building Code were used to check the combined effects of torsion, shear, and direct tensile loads.

During the construction stage, a factor of 1.4 was applied to the design pressures resulting from LOCA. The structure was then examined using the 40 percent margin and the recommendations

of the ACI-ASME Joint Committee contained in Proposed Standard Code for Concrete Reactor Vessels and Containment. The results are tabulated in Table 3.8.3-6. NRC Standard Review Plan 6.2.1.2, Subcompartment Analysis, Section II.B.5, permits reduction of design pressure so that the peak calculated differential pressure does not exceed the design pressure.

A completely independent design was performed on all portions of the divider barrier. Procedures used in this design and analysis are discussed in Sections 3.8.3.4.3 through 3.8.3.4.13.

3.8.3.4.2 Structural Fill Slab on Containment Floor

The fill slab is designed to span between walls with hydrostatic uplift pressure on 100 percent of its bottom face from water surface at Elevation 683. Loads from the steam generators and reactor coolant pumps are transferred directly into the base mat by continuous steel connections through the liner plate. As the base mat deflects under load, the fill slab deflects with it and is designed for these deflections. The fill slab is also designed for loads imposed upon it by the reactor coolant pipe crossover supports. Classical deflection formulas were used to determine moments, shears, and reactions. The finite element method of analysis was used to determine direct stresses in shear keys.

3.8.3.4.3 Reactor Cavity Wall

A guillotine break in the reactor piping at the reactor pressure vessel nozzle was identified as the DBA for the reactor cavity structure. Motion limiters were installed in the pipe sleeves on all the primary coolant pipes to reduce the asymmetric pressure by restricting the lateral movement of a broken pipe to less than one-half inch with a resulting break area of 100 square inches. The pressures for this break are discussed in Section 6.2.

An independent design review of the reactor cavity structure was performed to assure the adequacy of the structure for the resultant loading.

Original Design

A linear temperature gradient will occur during reactor operation. In the event of a LOCA the reactor is shut down and time varying nonlinear gradients similar to those in Figure 3.8.3-2 will occur in the wall. All temperature gradient cases are considered in the design up to a time of 48 hours following a LOCA.

Radiation generated heat on the structures is considered only for the primary shield immediately next to the reactor vessel. There the radiation generated heat is obtained as a function of position of the reactor core with respect to the structure and the temperature distribution is calculated. The effect of the temperature on the structure is then evaluated.

The average temperature of the wall during reactor operation exceeds hydration temperatures during construction. Therefore, tensile stress from temperature considerations will be less than

the stress induced by the temperature gradient. Long time creep relaxation can be expected to substantially reduce temperature stresses; however, such a reduction was not utilized since the effective operating temperature differential across the wall of the reactor cavity was only 35°F. The 8 1/2 foot thick portion of the wall is basically a thick cylinder for which simple expressions were derived to determine the ring moments and tensile stresses induced by the pressure loading and thermal gradients. The 4-foot structural portion from the top of the 8 1/2 foot thick ring to the top of the reactor continues essentially in the same shape and configurations as the compartment above the reactor; being fixed at its base by the 8 1/2 foot ring and the fuel pool floor and supported at the top by the operating floor. The wall was divided into segments and analyzed by the STRUDL II shallow-shell program for distributing moments and shears in both the vertical and horizontal directions. In addition, the large restraint forces from the steam generators and reactor coolant pumps were checked using ring action and flat plate formulas.

Independent Review

The structural model used in the independent review of the resultant loading was a three-dimensional assemblage of intersecting walls simulated by multiple layers of solid isoparametric finite elements. The general purpose computer program ANSYS, a well documented and widely used program, was used to calculate the stress intensity.

The analysis of the reactor cavity was approached from the standpoint that a dynamic and inelastic type analysis would be required. However, comparison of the natural frequencies of the structure and the shock spectra of the pressure transients as forcing functions indicated that dynamic amplification was negligible. A preliminary static analysis indicated that with the exception of several local regions the stress levels were within the allowable cracking stress of the concrete. Consequently, a final static elastic analysis was performed using the time varying pressures and associated reactor coolant loop concentrated loads.

A detailed analysis to determine unit stresses in the concrete and reinforcing steel was based on a cracked section and evaluated using the allowable stresses given in Table 3.8.3-1 and Table 3.8.3-2.

3.8.3.4.4 Compartment Above Reactor

This compartment is designed to resist the maximum internal differential pressure. This compartment was originally designed to resist a maximum hypothetical pressure of 65 lb/in^2, combined with dead load only.

The compartment will also be subjected to water pressure when the refueling canal is full of water and refueling of the reactor is taking place. Wave effects of the water during earthquake are taken into account.

This compartment was analyzed in conjunction with the refueling canal walls as described in Section 3.8.3.4.6.

3.8.3.4.5 Seals Between Upper and Lower Compartments

The flexible coated fabric part of the seal was considered as a thin-wall half cylinder as the fabric width was sized to form an approximate semicircle when subject to internal pressure. With the semicircle, there is adequate slack in the seals to provide for relative movement between the attaching surfaces during all conditions without damage to the seals.

The design of the seals was by TVA without the use of a computer program.

Earthquakes are the only natural environmental conditions which apply to the seals. The seals, being inside the containment vessel, are protected from floods, wind, tornadoes, snow, and ice. The seals are not in the area affected by missiles and therefore were not designed for missiles.

The design life of the seal materials in the expected radiation environment and at 120°F is eight years. However, replacement will be determined by the results of testing specimen coupons hung throughout the Reactor Building.

Minimum properties of the seal material are as follows for (a) the original material and (b) the same material after exposures equivalent to combined normal and accident conditions.

Tensile Strength	Original	After Exposure
Pounds per inch		Not Applicable
Pounds per square inch		Not Applicable[1]
Elongation		Not Applicable[1]
Durometer	Not Applicable[1]	
Pneumatic Burst	Will not rupture at 60 lb/in[1]	Will not rupture at 15 lb/in^2

[1]Material is coated fabric.

3.8.3.4.6 Refueling Canal Walls and Floor (Divider Barrier)

Primary Design

The canal walls and slab are designed to take the gravity and earthquake forces from the internals' storage stand. The face of the walls inside the lower compartment will be subject to LOCA pressures and localized jet forces due to a LOCA.

The walls of the refueling canal and the upper reactor cavity were analyzed as a unit. These walls were analytically modeled using STRUDL program finite element capabilities. Shallow shell curved-rectangular elements were used in the mesh assembly and spring constants were used to represent the stiffnesses of walls and slabs where the structure was supported from the crane wall and divider barrier floor.

The refueling canal slab was analyzed using the STRUDL flat plate rectangular elements.

Independent Review

1. Refueling Canal Floor

The refueling canal floor due to its irregular shape and support conditions was designed in three sections, where each section was also an irregular shaped slab. The larger section adjacent to the reactor cavity was designed using the finite element plate bending program GENDEK 3. The other two smaller sections were designed using the simpler, and more conservative, strip analysis.

The computer program GENDEK 3 used in the analysis and design of the refueling canal floor, and other elements of the independent design of the divider barrier, was originally developed by E. L. Wilson, University of California, Berkeley, 1969. The program will handle slabs of arbitrary geometry under lateral loads including slabs which are stiffened by discrete ribs. The slab is idealized by a mesh of plate bending finite elements. Variation in slab properties from element to element is permitted. The program makes use of the Felippa Q-19 quadrilateral plate bending element with orthotropic elastic properties.

2. Refueling Canal Walls

Several approaches were used in the design of these complex walls. The refueling canal walls and upper reactor cavity were modeled as a monolithic structure and analyzed with the computer program STRUDL II using flat plate and curved rectangular shell elements. Special attention was given to the stresses at points of stress concentrations with the use of a finite element plane stress program AMG033. Additional checks of the design values were made by modeling portions of the refueling canal walls as a plate using the plate bending program GENDEK 3.

STRUDL II computer program is well documented and will not be described here. AMG033 is a Plane Stress-Plane Strain finite element program developed by Rohm and Haas Company, Redstone Arsenal Research Division, Huntsville, Alabama, and described in Special Report No. S-76 “Application of the Finite Element Method to Stress Analysis of Solid Propellant Rock Grains” by Eric B. Becker and John J. Brisbane.

3.8.3.4.7 Crane Wall

Wall Below Operation Deck

In the lower compartment the crane wall is subject to jet forces due to a possible break in the reactor coolant or main steam piping. The largest of these postulated jet forces occurs at a crossover leg between a steam generator and a reactor coolant pump. Other areas at the crane wall in the lower compartment are exposed to LOCA pressure differentials.

The steam generators and reactor coolant pumps are braced laterally with restraints anchored into the crane wall. These restraints impose large concentrated forces on the wall.

Crane wall temperature gradients, before and after a LOCA, were investigated. At several elevations in the crane wall, maximum and minimum vertical loads were computed using results from the earthquake analysis prepared by TVA. In addition, various parts of the crane wall were designed to handle concentrated loads, 100 to 300 kips, resulting from breaks in small piping systems.

The crane wall was analyzed by isolating areas spanning between slabs and cross walls. Moments, shears, and axial forces were calculated using the STRUDL finite element program. Fixed-end moments were distributed between adjacent sections of wall using conventional distribution methods.

Columns between ice condenser doors are subjected to moments distributed from the ice condenser floor and divider barrier floor, as well as moments, shears, and axial forces from the wall sections above and below the columns. The columns were designed for these moments, shears, and axial forces plus earthquake loads. When combining torsional and direct tension forces on the columns, the ACI 318-71 Building Code was used in proportioning the reinforcing steel.

Personnel Access Doors in the Crane Wall

Main structural members of the doors were considered as simple beams. Energy absorbing members were considered as collapsible members. Members of the embedded frames were considered as being rigidly supported by concrete. Loads from the embedded frames are transferred to the concrete by embedded anchors.

Design of the doors and embedded frames was by TVA without the use of a computer program. Design of collapsible members on the doors was based on tests made by Oak Ridge National Laboratory. Results of these tests are recorded in their publication titled Structural Analysis of Shipping Casks, Volume 9, “Energy Absorption Capabilities of Plastically Deformed Struts Under Specified Impact Loading Conditions.” Collapsible members were sized to limit loads transmitted to the embedded frame to 13,000 pounds per linear foot.

The doors were designed to function during normal conditions, earthquakes, and pipe rupture accidents.

Earthquakes are the only natural environmental condition which applies to the doors. Being inside the containment vessels, the doors are protected from flood, wind, tornado, ice, and snow.

The doors will be closed any time reactor containment is required, except when a workman is passing through the access.

When containment is not required, the doors are not required to seal or to retain their integrity. Since the doors are left open only when containment is not required, seismic qualifications of the doors in the open position is not required.

Earthquake loads used in designing the doors were from accelerations determined for the crane wall at the horizontal centerline of each door by dynamic analysis of the Reactor Building for a 1/2 SSE and a SSE. These acceleration loads were used as static loads since the doors are firmly secured to the wall when closed.

Earthquake accelerations are as follows:

1/2 SSE

Elevation at Centerline Door	Lateral (N-S)	Lateral E-W)	Vertical
683.53	0.09 g	0.09 g	0.06 g
696.75	0.09 g	0.09 g	0.06 g
725.75	0.14 g	0.14 g	0.06 g

SSE

Elevation at Centerline Door	Lateral (N-S)	Lateral (E-W)	Vertical
683.53	0.18 g	0.18 g	0.12 g
696.75	0.18 g	0.18 g	0.12 g
725.75	0.23 g	0.22 g	0.12 g

Some air leakage may occur at the periphery of the doors during earthquakes, but this leakage will not exceed the permissible leakage area of 30 square inches per door.

Under normal conditions, seals on the doors will have a life of not less than 10 years, and the other parts of the doors will have a life of not less than 40 years. Some air leakage may occur at the periphery of the doors, but this leakage will not exceed the permissible leakage area for normal operation of 10 square inches per door.

Wall Above the Operating Deck (Divider Barrier)

Primary Design

Under accident conditions the crane wall above the operating deck is designed for maximum pressure differentials between the ice condenser compartments and the inside of the crane wall. It is also designed for the loads imposed on the wall by the lattice frame anchorages of the ice condenser. Maximum and minimum vertical loads imposed by the earthquake analysis are combined with these loads for the maximum stress conditions. The end walls of the ice condenser and the spacing of the steam generator and pressurizer walls stiffen the crane wall to such an extent that these loads essentially span horizontally between these supporting walls.

The stud loadings on the wall from the lattice frame may either add to or subtract from the pressure loading depending on whether the maximum pressure is inside the crane wall or in the ice compartment.

The upper restraint of the steam generators is designed such that the crane wall only receives load from a steam line break. Seismic restraints in the radial direction are transmitted through hydraulic snubbers to the floor of the operating deck. In the other direction they are transmitted to the walls of the steam generator compartment. The two steam generator restraint loads on the crane wall are assumed to occur coincidentally with the maximum pressure differential in the steam generator compartment.

During construction a 36-foot-wide opening, used for moving major equipment into the building, was left in the crane wall at approximately the 90° azimuth. This opening began at Elevation 733.63 and extended 46 feet high. This leaves a 3-foot-wide, 17-foot-deep curved beam spanning a 37-1/2-foot arc over the opening. This beam and the permanent beam over the refueling canal are designed to carry the construction loads of the polar crane, approximately 1200 kips maximum while installing major equipment. The permanent beam is also designed to take the reactions from the cantilevered beams supporting the ice condenser bridge crane. The analysis of these beams was made using manual calculations and STRUDL programs.

Independent Design

Crane Wall

The crane wall is subjected to forces induced by gross motion of the interior concrete structure resulting from 1/2 SSE, SSE, and DBA in addition to the forces and moments which act over localized areas. Modal analysis was used to determine response of the interior concrete structure. The design for localized loading was accomplished by isolating the areas affected. The edge conditions were simulated and finite element plate bending analyses were made using GENDEK 3. These loaded areas were generally bounded by slabs and compartment walls. Analysis of a 1-foot-wide strip was also used to determine the distribution of moments caused by slabs and walls connected with the crane wall.

Crane Wall in Steam Generator Compartment

The portion of the crane wall within the steam generator compartment was designed as a flat slab using the plate bending program GENDEK 3. The lower boundary condition was approximated by extending the finite element model to include the crane wall columns which lie below the steam generator compartment. Other loads supported by this portion of the crane wall as a part of the interior concrete structure were also considered in the design.

3.8.3.4.8 Steam Generator Compartments (Divider Barrier)

Primary Design

These compartments are designed to resist the maximum internal differential pressure and the jet force that would result following a main steam pipe break inside any single compartment.

Thermal effects accompanying a pipe break (See Figure 3.8.3-2) are also accounted for. A single compartment was also designed to resist 43 lb/in^2 hypothetical pressure combined with dead load only. This hypothetical loading was used as part of the original design and is not required to be considered in the evaluation and/or modification of the existing structures.

The center wall and the beam below the top slab are used as anchor points for main steam pipe restraints. These restraints prevent pipe whip in case of a pipe break and transmit forces in any direction to the wall.

These compartments span mainly in the horizontal direction resulting in tensile stress and horizontal moments in the walls near the center of their height. Close to the ends of the compartments discontinuity stresses, similar to those of a flat head cylinder, result in the vertical direction.

The STRUDL frame program was used to find the maximum horizontal forces in the walls by modeling a vertical 1-foot height of wall including a 112° sector of crane wall. Short chord lengths were used to represent curved sections of walls. The shallow shell and flat plate finite element STRUDL programs were used to analyze individual sections of the walls for moments and shears in both directions. The top slab was analyzed using a combined member-grid and flat plate finite element STRUDL program. Manual calculations were done at various locations to ensure computer accuracy. The inverted "tee" shaped beam which stiffens the top slab was analyzed for the dynamic effects of a main steam pipe breaking and striking the flange of the beam.

Independent Design

1. Roof Slab

   The roof slab was analyzed as a plate using the finite element plate bending program, GENDEK 3. The roof slab was analyzed both as a beam-stiffened slab and a uniform slab, neglecting the effects of the beam. The edges were considered fixed.

2. Enclosure Walls and Separation Wall

   The steam generator compartment walls were designed as a mixed model using the finite element features of STRUDL II. This mixed model was composed of flat plate and curved shell elements and was considered fixed at all points of intersections with the other components of the divider barrier. A further check was made by using the frame analysis features of STRUDL II and modeling a 1-foot-wide vertical section of both compartment walls and the separator wall as a series of beam elements fixed at the crane wall.

   The separator wall was also analyzed as a plate using GENDEK 3 with the edges fixed at the crane wall and enclosure wall and free at the top and bottom.

Reanalysis Due to Unit 1 and Unit 2 Steam Generator Replacement

The modified configuration of the Unit 1 steam generator compartment was analyzed for design loads using a 3D finite element ANSYS (Version 5.6) model. As part of performing the Unit 2 steam generator replacement, the ANSYS model applied to the Unit 1 steam generator replacement modifications of the steam generator compartment roofs was verified to be applicable to the similar modifications performed on the Unit 2 steam generator compartment roofs. Although the roof slab remains the focus of the evaluation, the model included five components - the 3 feet thick roof slab, entire steam generator compartment wall, center wall, 180° sector of the crane wall, and the whip restraint beam; to obtain an accurate representation of the system. The material properties used in the model for the concrete were consistent with those used in the original analysis. The concrete strength used in the roof evaluation is the in-place compressive strength of the steam generator compartment roof concrete at 90 days, which is 5700 psi.

The modified steam generator compartment roof was analyzed for the following design loads: dead load, live load, design pressure differential of 24 psi from a DBA (main steam pipe break), operating and accident temperature effects, seismic effects (OBE and SSE), and pipe thrust load on the whip-restraint beam from a broken main steam pipe. The modified steam generator compartment roof was evaluated to the load combinations and allowable stresses tabulated in Table 3.8.3-2A.

An exception from Table 3.8.3-2, which was used in the original evaluation of the interior concrete including the SG compartments, was taken for the load factors associated with the Yr load (reactor load due to fluid discharge on broken pipe, which in the present case is the pipe thrust load) for the Abnormal and Abnormal/Severe Environmental Load Categories as described below. The load combinations in Table 3.8.3-2 are based on Table CC-3200-1 of Reverence 3.8.3.9.1. The Yr load is combined with load factors of 1.5 and 1.25 that are associated with the DBA design pressures for the Abnormal and Abnormal/Severe Environmental Load Categories, respectively. Since the Yr load lasts at its peak value only for a very short duration and the time taken to build up the abnormal DBA pressure is much longer, the Yr load is important only for evaluating local effects and hence it is overly conservative to combine the Yr load with such extreme factored DBA pressures. Therefore, the load combinations used in this evaluation for the Abnormal and Abnormal/Severe Environmental Load Categories were based on Table CC-3230-1 of Reference 3.8.3.9.2, which superseded Reference 3.8.3.9.1, and are presented in Table 3.8.3-2A.

3.8.3.4.9 Pressurizer Compartment (Divider Barrier)

Primary Design

This compartment is design to resist the maximum internal differential pressure. The original controlling design loading is the 167 psi hypothetical pressure combined with dead load. Methods of analysis were similar to those of the steam generator compartments.

Independent Design

The same general procedures were used to design the Pressurizer Compartment as were used to design the steam generator compartment.

The roof slab was designed as a fixed-end slab with the use of GENDEK 3. The enclosure wall was designed by using STRUDL II, and the crane wall portion of the pressure compartment was designed as a slab using GENDEK 3. A check was made by analyzing a 1-foot-wide section of the enclosure wall, the crane wall within the compartment, and segments of the crane wall on each side of the pressurizer using STRUDL II.

3.8.3.4.10 Operating Deck at Elevation 733.63 (Divider Barrier)

Primary Design

The floor is designed for the maximum differential pressure and thermal effects due to a LOCA plus the saturation jet pressure acting over a local area. An instantaneous jet pressure locally is also a major design loading acting up on the floor. Upward loads from the missile shield are taken by this floor around the reactor cavity where the shield is bolted down.

This floor is designed for a 1000 lb/ft^2 live load plus several concentrated loads from the reactor head set-down which occur during refueling and periodic maintenance of the equipment.

During construction the floor had no edge support at the steam generator and pressurizer compartment walls, since the first lifts of these walls were carried by the floor itself. This special construction condition was examined separately using a 300 lb/ft^2 design live load in addition to the wet weight of the first 5-foot pour of walls.

The floor analyses were made using the STRUDL finite element program for flat plates utilizing both rectangular and triangular elements to assemble the irregular shape. Moments were distributed by manual methods at the juncture of the slab with the compartments and refueling canal walls.

Anchorage for the upper steam generator restraints is provided in this floor. These anchorage points have approximately a 5000-kip design force due to a LOCA combined with SSE. This force is horizontal to the floor and applied at points where openings create horizontal single span beams. These beams were analyzed using STRUDL and manual methods.

Independent Design

Analysis for normal loads were made using both GENDEK 3 and STRUDL II computer programs. Two finite element models were made of the portion of the operating deck between 0 and 180 degrees and a third model was used to analyze the deck between 180 and 360 degrees. Analyses were made with the boundary at the reactor cavity both fixed and hinged. A fixed edge condition was assumed at the crane wall, steam generator, and pressurizer compartments.

The operating deck is subjected to inplane forces from the upper steam generator support loads. A finite element plane stress analysis using the computer program AMG033 was used to design for this condition.

3.8.3.4.11 Ice Condenser Support Floor - Elevation 721 (Divider Barrier)

Primary Design

The finite element program ICES STRUDL II was primarily used in the analysis and design of the Elevation 721 floor. The outer circumferential beam was represented along with the floor by using a combined flat plate and grid member system. The supporting columns were modeled by using spring constants for rotation and deflection. Shear and moment values were obtained by modeling support points at the crane wall and cross walls with spring constants. Shear values were calculated from the vertical spring deflections.

Independent Design

The ice condenser floor was analyzed as a circumferentially beam- stiffened curved slab with continuous supports along the inner radius and ends and supported by columns along the outer radius. Analysis was made considering the columns flexible. The analysis was made using the computer programs GENDEK 3 and STRUDL II. The bracket that runs circumferentially on the outside of the crane wall directly under the ice condenser floor was analyzed as a plane stress problem using AMG033.

A dynamic analysis for use in determining dynamic amplification of the differential pressure transient forces during LOCA was made using STRUDL II.

3.8.3.4.12 Ice Condenser

Analysis, meeting the criteria presented in Section 3.8.3.5 has been done on the basis of Elastic System and component analyses. Limit load analysis was used as an alternate to the elastic analysis. Limit loads are defined using limit analysis by calculating the lower bound of the collapse load of the structure. Load factors are applied to the defined design basis loads and compared to the limit loads. The load factors determined for design basis load are used to provide margins of safety of the structure against collapse. A load factor of 1.43 was used when considering the mechanical loads due to dead weight and 1/2 SSE. A load factor of 1.3 was used for D + SSE and D + DBA. The material was assumed to behave in an

elastic-perfectly-plastic manner. The minimum specified yield strength was used. Mechanical plus thermal induced load combination and fatigue was analyzed in an elastic basis and satisfy the limits of Section 3.8.3.5. The stress analyses and results are described in Sections 3.7 and 6.5.

Experimental or Test Verification of Design

In lieu of analysis, experimental verification of design using actual or simulated load conditions was used. In testing, account was taken of size effect and dimensional tolerances (similitude relationships) which exist between the actual component and the test models, to assure that the loads obtained from the test are a conservative representation of the load carrying capability of the actual component under postulated loading. The load factors associated with such verification are: 1.87 for D + SSE, 1.43 for D + DBA or D + SSE, and 1.3 for D + SSE + DBA.

A single test sample is permitted but in such cases test results were reduced by 10 percent. Otherwise at least three samples were tested and the design was based on the minimum loading carrying capability.

Additional analysis results are described in Section 6.5.

3.8.3.4.13 Penetrations Through the Divider Barrier

Canal Gate

Primary Design

The canal gate sections are designed to span as simply supported beams across the refueling canal; a clear span of approximately 19 feet. Hand calculations using conventional methods were used for this design. The canal gate was designed to withstand a pressure differential between the compartment above the reactor and the upper compartment due to a LOCA. The canal gate sections had to withstand concentrated forces and moments from the UHI pipe restraints which are anchored thereon and which are the result of pipe rupture and seismic. The effect of seismic action on the canal gate sections is considered as well as the effect of maximum temperature differential across the gate.

Independent Analysis

The canal gate was designed as a simply supported plate spanning between the two refueling canal walls. The canal gate is required to maintain integrity between the upper and lower compartments during a LOCA and was designed for the maximum probable differential pressure. Concentrated loads imposed on this gate by the UHI piping were also considered. The effects of seismic and thermal action were evaluated.

Moments and shears were calculated using conventional hand methods. The evaluation of concrete and reinforcing steel stresses was based on a cracked section and the allowable stresses of Tables 3.8.3-1 and 3.8.3-2.

Control Rod Drive (CRD) Missile Shield

Primary Design

The CRD missile shield sections are designed to span as simply supported slabs across the compartment above the reactor. The slabs are held down at the ends by anchor bolts embedded in the operating deck slab. The missile shield is designed to withstand a maximum LOCA differential pressure between the compartment above the reactor and the upper compartment. The missile shield is subject to loading from the CRD mechanism as a missile. An accompanying jet force due to pressure escaping through the head of the reactor is also considered. The slabs are investigated for the maximum penetration resulting from the missile effects of the control rod drive shaft. The underside of the slab is faced with a 1-inch-thick steel plate to aid in resisting missile penetration. The penetration depths are calculated by use of the Petry formula and a formula by C. V. Moore, "The Design of Barricades for Hazardous Pressure Systems," Nuclear Engineering and Design 5 (1967), 81-97, North-Holland Publishing Company, Amsterdam. The calculated penetration depth is 2.2 inches into the 3-foot 6-inch thick slab. The effect of maximum temperature differential across the missile shield is also considered in the design.

Independent Design

The missile shield sections were analyzed as simply supported slabs spanning the compartment above the reactor. This shield must resist the maximum probable differential pressure from a LOCA to maintain integrity between the lower and upper compartments. Additionally, it must resist certain missiles from the control rod drive mechanism. Penetration into the steel plate and concrete were calculated and equivalent static loads for the impacting missiles were calculated and evaluated. Thermal stresses resulting from temperature differentials between lower and upper volumes were considered in the stress evaluation.

Concrete and reinforcing steel stresses were determined considering a cracked section and the stress allowables of Tables 3.8.3-1 and 3.8.3-2.

Reactor Coolant Pump Access and Lower Compartment Access Hatches

Primary Design

The reactor coolant pump access and lower compartment access slabs are designed to span simply supported between anchor bolts. The slabs are designed for both downward and upward loads acting on them. The downward loads are dead load and a 1000 lb/ft^2 live load. For upward loads, the slabs are designed to carry a differential pressure between the lower and upper compartments due to a LOCA. A jet impingement loading associated with this LOCA is also considered. The effect of maximum temperature differential as well as seismic effects on the slabs are accounted for in the design.

Independent Design

The reactor coolant pump access hatch and the lower compartment equipment access hatch were analyzed and designed as simply supported circular and rectangular plates. Maximum

moments and shear forces were obtained from a plate bending analysis. Dead, live, seismic, and thermal loads were combined with differential pressures and jet forces due to a postulated LOCA to give controlling factored and unfactored load cases. Shear stresses at the periphery of the hatch openings in the operating deck and stress levels in the perimeter anchor bolts were checked to insure compliance with criteria of Tables 3.8.3-1 and 3.8.3-2.

Equipment Access Hatch

The hatch cover is designed to span as a simply supported beam between the anchor bolt assemblies with the anchor bolts designed to withstand a load at least 5 percent greater than that calculated for the end reactions resulting from the actual load on the hatch. The controlling design condition is Design Basis LOCA Pressure - Dead Load + 1/2 SSE. Maximum differential temperature is considered in the design, but does not occur coincidentally with the maximum differential Design Basis LOCA Pressure. Calculated and allowable stresses are given in Table 3.8.3-7.

Escape Hatch

Structural components of the hatch have been designed such that the allowable stresses given in Table 3.8.3-8 will not be exceeded.

Air Return Duct Penetrations

The controlling design condition is Design Basis LOCA Pressure - Dead Load + SSE Loads. Maximum differential temperature is considered in the design, but does not occur coincidentally with a jet force or the maximum differential Design Basis LOCA Pressure. Calculated and allowable stresses are given in Table 3.8.3-9.

3.8.3.4.14 Concrete Block Shield Walls

To insure the stability of the concrete blocks during all loading conditions, structural steel restraints are provided. These satisfy all the requirements of the American Institute of Steel Construction (AISC) Code for design of steel components.

3.8.3.4.15 Divider Barrier Ultimate Capacity

Sections 3.8.3.4.1 through 3.8.3.4.14 describe the analysis and design of the structural components of the interior concrete structure in accordance with the load combinations of Tables 3.8.3-1 and 3.8.3-2. Additionally, each component was investigated to determine its ultimate pressure capacity. This determination is associated with the postulated pressure increase due to a possible hydrogen conflagration following a hydrogen generating accident. Whenever possible, conservative one-way-working models were used. However, some components were evaluated using slab yield-line theory.

3.8.3.5 Structural Acceptance Criteria

3.8.3.5.1 General

Structure

Working stress design and ultimate strength design methods in accordance with the applicable ACI codes were used. Where torsional shear was combined with direct tension the ACI 318-71 Building Code was used.

A comparison of the original available design stress margins for some design features for the load combinations of Tables 3.8.3-1 and 3.8.3-2 are listed in Table 3.8.3-6.

3.8.3.5.2 Structural Fill Slab on Containment Floor

Loading combinations 1, 2, 3 and 5, given in Table 3.8.3-1, each controlled the design at local areas of the floor slab. During the original design (construction permit) phase with 40 percent added to LOCA pressure, the controlling combination was "Abnormal/Extreme Environmental." See Table 3.8.3-3 and 3.8.3-10.

Shear transfer through the fill slab was discussed in Section 3.8.3.1.2.

3.8.3.5.3 Reactor Cavity Wall and Compartment Above Reactor

Loading combinations 1, 2, 3, and 5 in Table 3.8.3-1 were considered in the design. During the original design (construction permit) phase with calculated values of LOCA increased by 40 percent, the controlling load combination from Table 3.8.3-2 was "Abnormal." See Tables 3.8.3-6 and 3.8.3-10. The 4-foot structural thickness provided substantially more depth than required for limiting peripheral shear stresses of anchorage embedments for the restraints.

Earthquake shears for the interior structures were distributed to the various walls in proportion to the effective shear area of the walls using shape factors to arrive at the relative shear stiffness or effective shear areas of the various wall sections depending on the shape of each section. The allowable shear stress is based on the Structural Engineers Association of California Code recommendations.

Columns were designed for the effect of earthquake shears by considering the net deflections at the bottom and top of the columns from the seismic analysis and designing for the difference.

3.8.3.5.4 Refueling Canal Walls and Floor

Loading combinations 1, 2, 3, 4, and 5 in Table 3.8.3-1 were examined. During the original design (construction permit) phase, with calculated values of LOCA increased by 40 percent, the controlling load combinations from Table 3.8.3-2 were "Abnormal" and "Abnormal/Severe Environmental." See Tables 3.8.3-6 and 3.8.3-10.

3.8.3.5.5 Crane Wall

The crane wall was analyzed for loading combinations one through five from Table 3.8.3-1. During the original design (construction permit) phase, with calculated values of LOCA increased

by 40 percent, the controlling load combinations from Table 3.8.3-2 were "Abnormal/Extreme Environmental," "Abnormal/Severe Environmental," and "Abnormal." See Tables 3.8.3-6 and 3.8.3-10.

3.8.3.5.6 Steam Generator and Pressurizer Compartment

Loading combinations 1 through 5 from Table 3.8.3-1 were examined. During the original design (construction permit) phase, with calculated values of LOCA increased by 40 percent, the controlling load combination from Table 3.8.3-2 was "Abnormal." See Tables 3.8.3-6 and 3.8.3-10.

Shears were distributed as described in Subsection 3.8.3.5.3.

3.8.3.5.7 Operating Deck at Elevation 733.63

Loading combinations 1 through 5 from Table 3.8.3-1 were examined for the floor. During the original design (construction permit) phase with calculated values of LOCA pressure load increased by 40 percent, the controlling load combination from Table 3.8.3-2 was "Abnormal." See Tables 3.8.3-6 and 3.8.3-10.

3.8.3.5.8 Personnel Access Doors in Crane Wall

Allowable stresses for non-collapsible members for all load combinations used for the various parts are given in Table 3.8.3-4. Normal load conditions are shown for mechanical members only, as loads on structural members during normal conditions are negligible. For normal load conditions, factors of safety for mechanical parts are 5 to 1 from ultimate. For limiting conditions such as a SSE for mechanical and structural members only, stresses do not exceed 0.9 yield. Pipe rupture accidents apply to structural members only, as forces from jets and missiles are taken by the structural frame.

For collapsible members during a pipe rupture accident, stresses exceed yield and members are plastically deformed. Plastic deformation of energy absorbing members does not affect the sealing integrity of the doors.

3.8.3.5.9 Penetrations Through the Divider Barrier

Canal Gate and Control Rod Drive (CRD) Missile Shield

Loading combinations 1 through 5 from Table 3.8.3-1 were examined. During the original design (construction permit) phase, with calculated values of LOCA pressure increased by 40 percent, the controlling load combination from Table 3.8.3-2 was "Abnormal/Severe Environmental." See Tables 3.8.3-6 and 3.8.3-10.

Reactor Coolant Pump and Lower Compartment Access Hatches

Loading combinations 1 through 5 Table 3.8.3-1 were examined. During the original design

(construction permit) phase, with calculated values of LOCA pressure increased by 40 percent, the controlling load combination from Table 3.8.3-2 was "Abnormal/Severe Environmental."

Escape Hatch

Loading combinations I through III in Table 3.8.3-8 were examined. Loading combination II was the controlling case for design phase.

3.8.3.5.10 Seals Between Upper and Lower Compartments

The seals are subject to radiation as outlined herein during normal operating conditions. Under normal, earthquake, and accident conditions, the stress in the flexible fabric does not exceed 0.33 ultimate. Strength of the fabric material under normal and accident conditions was determined by laboratory test.

The seals are not required to maintain their integrity during a fire. It is assumed that a fire and an accident which require sealing will not occur simultaneously since the reactor will be shut down immediately if a fire develops.

3.8.3.5.11 Ice Condenser

Table 3.8.3-5 provides a summary of the allowable limits to be used in the design of the ice condenser components.

For all cases the stress analysis was performed by considering the load combinations producing the largest possible stress values.

When limit analysis is performed on the ice condenser structure, or parts thereof, using the Alternate Analytical Criteria method, Section 3.8.3.4.12, justification will be provided to show that the results of the Elastic Systems analysis are valid.

Stress Criteria

The stress limits for elastic analysis are:

1. D + 1/2 SSE

   Stress shall be limited to normal AISC, Part I Specification allowables (S). The members and their connections shall be designed to satisfy the requirements of Part I, Sections 1.5, 1.6, 1.7, 1.8, 1.9, 1.10, 1.15, 1.16, 1.17, 1.20, 1.21, and 1.22 of the AISC Specification (stress increase in Sections 1.5 and 1.6 is disallowed for these loads). Where the requirements of Section 1.20 are not met, differential thermal expansion stresses shall be evaluated and the maximum range of the sum of mechanical and thermal induced stresses shall be limited to three times the appropriate allowable stresses provided in Sections 1.5 and 1.6 of AISC Specification.

2. D + SSE, D + DBA

   Stresses shall be limited to normal AISC Specification allowables given in Sections 1.5 and 1.6, increased by 33 percent (1.33S). No evaluation of thermal induced stresses or fatigue is required. In a few areas, where the stresses exceed 1.33S but are below 1.5S, these cases will be presented to the NRC for their review.

3. D + SSE + DBA

   Stresses shall be limited to normal AISC Specification allowables given in Sections 1.5 and 1.6, increased by 65 percent (1.65S). No evaluation of thermal induced stresses or fatigue is required.

   For all cases, direct (membrane) mechanical stresses shall not exceed 0.7 S_u, where S_u is the ultimate tensile strength of the material.

The summary of the ice condenser allowable limits is given in Table 3.8.3-5.

3.8.3.6 Materials, Quality Control, and Special Construction Techniques

3.8.3.6.1 Materials

Concrete

This structure is designed using air entrained concrete with fly ash and additives. Compressive strength requirements varied throughout the structure depending on design loads.

Concrete materials were essentially as described in Section 3.8.1.6.1; however, minimum strength requirements varied with loading conditions. The basic strength requirement of the interior concrete structures was 5000 lb/in^2 primarily because of localized shear requirements. Higher strengths were required in some areas such as the crane wall columns at the ice condenser floor where 8000 lb/in^2 concrete was used. Where higher strengths were required, the age requirement for strength was 90 days to take advantage of the strength contribution of fly ash between 28 and 90 days. Lower strength concrete was used in the reactor cavity and el. 693 floor slabs, where 4000 and 3000 lb/in^2 strengths were used, respectively.

Reinforcing Steel

All reinforcing steel conform to ASTM Designation A 615, Grade 60.

Personnel Access Doors in Crane Wall

ASTM standards were used for all material specifications and certified mill test reports were provided by the Contractor for materials used for all load carrying members.

Seals Between Upper and Lower Compartments

The seals consist of long strips of flexible coated fabric with both edges hemmed to form pockets into which metal clamp bars are inserted. The coated fabric is dacron, coated on both sides with hydrocarbon rubber (ethylene-propylene-diene-polymer). The rubber is compound E603 by the Presray Company.

Escape Hatches in Elevation 733.63 Floor

ASTM standards were used for all material specifications and certified mill test reports were provided by the contractor for materials used for all load carrying members.

3.8.3.6.2 Quality Control

Concrete

The concrete quality requirements applied to the interior concrete structures were the same as provided in section 3.8.1.6.2 for the concrete shield building.

Some concrete mixes did not meet the TVA General Construction Specification No. G-2 requirement for strength during some time periods. The percent of tests less than the specified strength exceeded the G-2 requirement of 10 percent. All concrete pours placed during "low strength" time periods were evaluated.

The "low strength" periods for the mixes with specified strengths of 4000 and 5000 psi at 28 days were evaluated by determining estimated inplace design strengths based on the size of the member and the long-term strength gain based on a site testing program. The structure was evaluated for a reduced design strength if the inplace strength was less than required by the calculations or less than specified on the design drawings. The estimated inplace strengths were also verified by the results of 90 day strength tests on standard cured cylinders made at the time of the concrete placement.

A concrete mix with a specified strength of 8000 psi at 90 days was used for the crane wall columns and some slabs and walls in ice condenser area. This mix did not generally achieve the required strength. An evaluation of the strength results was performed and the structures evaluated for reduced equivalent specified strengths (6800 psi to 7600 psi depending on the time period).

Personnel Access Doors in Crane Wall, Escape Hatch in Elevation 733.63 Floor

Design by TVA and erection by TVA were in accordance with TVA's Quality Assurance Program. Design and fabrication by the Contractor were in accordance with the Contractor's Quality Assurance Program which was reviewed and approved by TVA's Design Engineers. The Contractor's Quality Assurance Program covers the criteria in Appendix B of 10 CFR 50. Fabrication procedures such as welding and nondestructive testing were included in appendices to the contractor's Quality Assurance Program.

ASTM standards were used for all material specifications and certified mill test reports were provided by the contractor for materials used for all load carrying members.

Seals Between Upper and Lower Compartments

The flexible coated fabric used for seals was certified by a qualified rubber technologist as being adequate for the normal and accident conditions. In addition, certified mill test reports were provided by the contractor for materials used for all load carrying members.

Testing of the seals in place under accident conditions is not feasible; therefore, laboratory testing was necessary. The flexible seal material was tested by The Presray Corporation under contract with TVA. Testing was performed with radiation, temperature, and pressure conditions as listed herein before for accident conditions. After exposure to accident conditions for temperature and radiation, the tensile strength of the material was sufficient to provide a factor of safety of not less than 3 to 1 for the load produced by accident pressure.

3.8.3.6.3 Construction Technique

No unusual construction procedures were employed in the construction of the interior structures.

Seals Between Upper and Lower Compartments

On periodic unit shutdowns, visual inspections of the seals are to be made. Parts inspected are to include all bolted connections, clamp bars, metal to fabric joints, and the rubber-coated fabric. The seals are to be replaced if they show any evidence of deterioration.

Escape Hatches in Elevation 733.63 Floor

Periodic visual inspections of the hatch covers are to be made. Parts inspected during the visual inspection are to include all bolted connections, structural members for paint deterioration, latching mechanisms, hinges, limit switches, and rubber seals.

The seals are to be carefully inspected for cracks, blemishes, or any other indications of deterioration of the rubber and for properly seating at the sealing surfaces.

3.8.3.6.4 Ice Condenser

Structural steels for ice condenser components are selected from the various steels listed in the AISC Specification. When materials such as steel sheets, stainless steel or non-ferrous metals are required and are not listed in the AISC Specification, these materials are chosen from ASTM specifications. Proprietary materials such as insulating materials, gaskets, and adhesives are listed with the manufacturers' name on the component drawings.

Material certifications for chemical analysis and tensile properties will be required with testing procedure and acceptance standards meeting the AISC or ASTM requirements.

Because the concept of non-ductile fracture of ferritic steel is not a part of the AISC Code and Westinghouse recognizes its importance in certain ice condenser components where heavy plates and structurals are used, such as the lower support structure, Charpy V-notch (CVN) energy absorption requirements are stipulated as shown in Table 3.8.3-11.

These criteria apply to the design of the following ice condenser components:

1. Ice basket and coupling.

2. Lattice frame and columns including attachments and bolts.

3. Structural steel supporting structures comprising the lower support structure, door frames, and bolts.

4. Wall panels and cooling duct support studs attached to the crane wall and end walls.

5. The supports of auxiliary components which are located within the ice condenser cavity but which have no safety function.

The various candidate materials, i.e., steel sheets, structural shapes, plates and bolting used in the Ice Condenser System are selected on the following bases:

1. Provide satisfactory service performance under design loading and environment and pressure or construction performance.

2. Assure adequate fracture toughness characteristics at ice condenser design conditions.

3. Be readily fabricated, welded, and erected.

4. Be readily coated for corrosion resistance when required.

The candidate materials are of high quality and were made by steelmaking practices specified by Westinghouse. Principal candidate materials meeting the above bases are listed below. Other materials for specific applications are selected on a case-by-case basis.

<u>Sheets</u>

Carbon steel sheets are commercial quality (CQ), drawing quality (DQ), or drawing quality-special killed (DQ-SK). The selection of the quality depends upon the part being formed. When higher strength, structural quality sheets are required, ASTM Specification A 607 is used. AISI Type 409 modified stainless steel is a potential alternate sheet material for the ice baskets.

The ice baskets will be made from perforated sheet material. The wall duct panels will be made from sheet material and the cradle supports from structural sections and plates.

Structural Sections, Plates, and Bar Flats

Structural sections, plates, and bar flats are generally high-strength, low-alloy steels selected for suitable strength, toughness, formability, and weldability.

The high-strength low-alloy steels are A 441, A 588, A 572, or A 633. These steels are readily oxygen cut and possess good weldability.

Bolting

High-strength alloy steel Type A 320 L7 bolting for low temperature service, is used for the lower support structure. Stocked bolting made from A 325, A 449, and ASTM A 354, Grade BD (SAE J429, Grade 8) materials is used for other parts. The above bolts must meet CVB 20 ft-lb at -20°F, for sizes greater than 1 inch in diameter.

Non-metallic materials such as gaskets, insulation, adhesives, and spacers are selected for specific uses. Freedom from detrimental radiation effects is required.

All structural welding shall be in accordance with the AWS Structural Code for Welding, D1.1 (AWS Code). The AWS Code is an overall welding system for the design of welded connections, technique, workmanship, qualification, and inspection for buildings, bridges, and tubular structures.

The quality of welds for the Ice Condenser System is based on paragraph 9.25 of the AWS Code.

Resistance welding shall be in accordance with AWS, Recommended Practices for Resistance Welding, C1.1.

Magnetic particle examination will be performed on at least 5 percent of the welds in each critical member of the lower support structure. Magnetic particle or liquid penetrant examinations where applicable, will be performed on 5 percent of the welds in each critical member of the balance of the ice condenser structure. The welds selected for examination were designated in the design specifications. The non-destructive examination methods and acceptance standards are given in Section 6 and paragraph 9.25, Quality of Welds, of the AWS Code.

3.8.3.7 Testing and Inservice Surveillance Requirements

Testing of the interior concrete structures is not planned. A completely independent design has been prepared for divider barrier features in order to ensure that during a LOCA the escaping steam will not bypass the ice condenser.

Personnel Access Doors in Crane Wall

Periodic visual inspections of the doors are to be made. Parts inspected during the visual inspection are to include all bolted connections, structural members for paint deterioration, latches, hinges, and elastomer seals. The seals are to be carefully inspected for cracks, blemishes, or any other indications of deterioration of the elastomer and for proper seating at the sealing surfaces.

3.8.3.8 Environmental Effects

The atmosphere in the ice bed environment is at 10°F and the absolute humidity is very low. Therefore, corrosion of uncoated carbon steel is negligible.

To ensure that corrosion was minimized while the components of the ice condenser were in storage at the site or in operation in the containment, components were galvanized, painted, or placed in a protective container. Galvanizing was in accordance with ASTM A 123 or A 386.

Materials such as stainless steels with low corrosion rates were used without protective coatings.

Corrosion has been considered in the detailed design of the ice condenser components, and it has been determined that the performance characteristics of the ice condenser materials of construction are not impaired by long-term exposure to the ice condenser environment.

Since metal corrosion rates are directly proportional to temperature and humidity, corrosion of ice condenser components at operating temperatures has been assumed to be almost non-existent. Data available in the open literature does not reflect the exact temperature range and chemistry conditions that are expected to exist in the ice condenser, but does indicate that corrosion rates decreased with decreasing temperatures for the materials and conditions being considered. Although the data in the literature indicated that corrosion of components is not expected, Westinghouse has chosen to employ several preventive measures in the construction of the Ice Condenser System. To inhibit corrosion, galvanizing is being used on the ice baskets. Westinghouse has performed tests which show that galvanized material would not be expected to fail due to corrosion during a 40-year exposure to a 5-15°F ice condenser refrigerated air environment. Other structural members were either galvanized, protected by corrosion resistant paints that meet the requirements of ANSI 101.2-1972 (Protective Coatings (Paints) for Light Water Nuclear Reactor Containment Facilities) as a minimum, or have been constructed of corrosion resistant steel.

With due consideration of the non-corrosive environment, and judicious selection of component materials based upon sound engineering judgment, the structural integrity of the ice condenser components will not be jeopardized, and the design criteria for the plant will be met.

3.8.3.9 References

1. Proposed ASME Section III, Division 2, 1973.
2. ASME Section III, Division 2, 1975.

3.8.4 Other Category I Structures

The Category I structures other than the primary containment structures are listed as follows:

1. Auxiliary Control Building.

    a. Control Bay Portion.
    b. Auxiliary Building Portion.
    c. Waste Packaging Area.
    d. Condensate Demineralizer Waste Evaporator Building Portion.
    e. Additional Equipment Building Portion.

2. Condenser Cooling Water Pumping Station and Retaining Walls.

3. Diesel Generator Building.

4. Category I Water Tanks and Pipe Tunnels.

5. Class IE Electrical Systems Structures.

6. East Steam Valve Room.

7. Essential Raw Cooling Water (ERCW) Pumping Station, Access Cells, & Protective Dike.

8. ERCW Discharge Box.

3.8.4.1 Description of the Structures

3.8.4.1.1 Auxiliary Control Building

The building consists of five major divisions: The Control Bay portion, the Auxiliary Building portion, the Waste Packaging Area, the Condensate Demineralizer Waste Evaporator Building portion, and the Additional Equipment Building portion. This building is a multistory reinforced concrete structure which provides housing for the Engineered Safety Feature Systems, etc., which are necessary to the two Reactor Units.

Certain floors in the Control Bay, the Condensate Demineralizer Waste Evaporator Building, and the roof of the fuel handling bay are supported by structural steel framing. Refer to Figures 1.2.3-1 through 1.2.3-9 for the general layout and configuration of the structure.

Control Bay Portion

The control bay portion is a multistory reinforced concrete structure that is built integrally with the Auxiliary Building portion. The structure is separated from the Turbine Building by a 2-inch expansion joint filled with fiberglass insulation which prevents interaction of the two buildings

when subjected to seismic motion. The structure was built in two stages. The first stage structure was a skeleton structure whose sole purpose was to provide a high platform for operation of the construction gantry crane. The completed stage is the final configuration.

Structural steel framing in the Control Bay consists of four steel framed bays of 25 feet-0 inch by 45 feet at Elevation 706.0 and the entire floor at Elevation 732.0.

At Elevation 706.0 the two exterior bays on both ends of the building are pipe run areas and consequently the floor is 1-1/2-inch deep steel grating on steel beams. Intermediate steel columns were used to reduce the beam size required.

The floor at Elevation 732.0 in the interior bays (between column lines C3 and C11) is 8-inch thick reinforced concrete slab cast on metal decking. The floor in the two exterior bays (between column lines C1 and C3 and C11 and C13) is reinforced concrete slab acting compositely with steel beams encased in concrete.

Control Room Shield Doors

The two doors are located inside the main control room at floor Elevation 732.0 at the doorways served by pressure-confining personnel access doors C36 and C54. The shield doors are manually operated from inside the control room. No seals are required on the shield doors as they do not serve any pressure confining function.

The doors can provide radiation shielding for personnel inside the main control room during a post-LOCA period. See FSAR Section 12.1.2 for radiation shielding requirements.

The two doors are identical except opposite hand and operate in opposite hand directions. Each door is a rectangular, structural steel frame with a skinplate on each side, thus forming a hollow box which is filled with lead shot to provide the required shielding.

Each door is suspended from above by two monorail-type trolleys operating on a standard structural I beam. The trolley closest to the leading edge of each door is of the geared, hand chain-driven type for opening and closing the door.

Manually operated, screw down dogs are provided at the top and bottom of each door for firmly securing the doors in either the open or closed position.

Auxiliary Building Portion

Structure

The building is a multistory reinforced concrete structure which provides housing for the engineered safety feature systems, which are necessary to the two reactor units. The Auxiliary Building structure is attached to the Control Building and located between the Reactor Buildings as shown between column lines q and y and A1 and A15 in Figure 1.2.3-1 through -9. In the final constructed state, the Control Building portion acts integrally with the Auxiliary Building portion. The Auxiliary Building is separated from the Reactor Buildings by a 1-inch expansion

joint and from the Additional Equipment Buildings by a 2-inch expansion joint each of which is filled with material that prevents interaction of the buildings when subjected to seismic motion.

The spent fuel pit and fuel transfer canal is housed within the Auxiliary Building. The massive reinforced concrete walls and slab are built integrally with the Auxiliary Building as illustrated by Figure 1.2.3-8.

Structural steel framing was used to support the Auxiliary Building roof over the area serviced by the Main Building crane because of the clear span requirements. This area is approximately 223 feet long and 80 feet wide. The roof is a reinforced concrete slab constructed on metal roof decking that is supported by steel purlins and steel roof trusses.

Railway Access Hatch Covers

Six hinged covers shown in Figures 1.2.3-3 and 1.2.3-8 combine to close the railroad access hatch opening in the floor of the Auxiliary Building at floor Elevation 734.0. With the six covers in the raised position, a clear opening of approximately 15 feet-6 inches by 68 feet-3 inches is provided over the railroad tracks. All spent fuel casks, new fuel shipments, and major items of equipment entering or leaving the Auxiliary Building above the Elevation 734.0 floor must go through this hatchway.

The hatch covers and their embedded frame provide a semi-airtight closure and operate in conjunction with the railroad access door to provide an airlock.

An Electrical Interlock System is provided to interlock the operation of the access hatch covers with the operation of the railroad access door. Two limit switches, connected in series to provide redundancy, are provided with each hatch cover and arranged to trip when a hatch cover begins to open. The interlocking of these switches with switches on the door prevents the door from being opened when any hatch cover is open or partially open. In like manner, switches on the door prevent opening of any hatch cover when the door is open or partially open.

The hatch covers are required to maintain their integrity and Category I function only when closed. When closed, there is no load on the operating machinery and it has no function to perform. Therefore, the operating machinery is not considered as Category I.

Railroad Access Door

The railroad access door for the Auxiliary Building provides closure for the access opening in the north wall at the railroad tracks which are at Elevation 706.0. The door and its embedded frame provide a semi-airtight closure and operate in conjunction with the railroad access hatch covers to provide an airlock.

With the door fully opened, the clear opening in the wall is 16 feet wide and 20 feet high. All new or spent fuel shipments and major equipment entering or leaving the Auxiliary Building by truck or other means passes through this door.

The door and door track are constructed of welded steel. The door, rectangular in cross section, is constructed of horizontal and vertical members with diagonal bracing as required for strength and rigidity. The exterior side of the door is covered with a steel skin plate. The embedded frame for the door is constructed of welded steel and is anchored to the concrete.

The door seals in the closed position with the side and top seals compressed against sealing surfaces on the embedded frame and the bottom seal compressed against an embedded sill plate. A sloped track guides the door rollers and positions the door so that the top and side seals contact the sealing surfaces only when the door is in or near the closed position.

An electric hoist unit opens and closes the door by lifting and lowering it vertically through a slot in the Elevation 734.0 floor. The hoist unit is mounted on the inside wall above the door slot. The door passes through this slot, and extensions of the frame act as guides for the door in the raised position.

The area above the floor at Elevation 734.0, occupied by the hoist and the door in its raised position, is enclosed with an airtight structural steel enclosure with gaskets provided on the access covers necessary for servicing the hoist unit and door.

<u>Pressure Confining Personnel Doors</u>

This section covers the following pressure confining personnel access control doors located in the Auxiliary Control Building. Door numbers listed for the doors are the designations used in in the plant.

1. The doors for stairs 7 and 8 penthouses at Elevation 749.0, doors A184 and A191.

2. The double doors to the personnel and equipment access rooms, elevation 734.0 (one for each unit), doors A152 and A159.

3. The double doors at the Ice Condenser Equipment Room, Elevation 734.0, door A155.

4. The double doors to the Emergency Gas Treatment Filter Room, Elevation 734.0, door A158.

5. The doors to the Reactor Building Access Room at Elevation 734.0 (one for each unit), doors A156 and A157.

6. The doors for stairs 3 and 4 penthouses at Elevation 734.0, doors A154 and A173.

7. The double doors to the elevator shaft at Elevation 734.0, door A153.

8. The N-line control bay doors at Elevation 732.0 (two double doors with bidirectional pressure requirements, doors C36 and C54) and elevation 706.0 (two double doors with bidirectional pressure requirements, doors C29 and C34).

9. The double doors to the heating and ventilating spaces at Elevation 714.0 (one for each unit), doors A123 and A132.

10. The door separating the Additional Equipment Building and the airlock at Elevation 714.0 (one for each unit, bidirectional pressure requirements), doors A214 and A215.

11. The door to the Cask Decontamination Room, Elevation 705.0, door A115.

12. The doors in the X-line wall of the cask loading area at Elevation 706.0 (one single door A113 and one double door A114).

13. The water tight doors leading to the instrument room at Elevation 685.0; one in N-line wall, C27, and one in C3-line wall, C14.

14. The doors to the Main Steam and Feedwater Valve Rooms at Elevation 706.0 (one for each unit), doors A101 and A105.

15. The water tight double doors at the main entrance from the Service Building, Elevation 690.0, door A57.

16. The water tight annulus access doors (one per unit, doors A65 and A78) and doors to the Reactor Building Access Rooms (one per unit, doors A64 and A77) at Elevation 690.0.

17. The water tight airlock door to the Radiochemical Laboratory at Elevation 690.0, door A55.

The doors are hinged, manually operated type metal doors, complete with frames and closers. The frames are either welded to plates, bolted to the concrete walls, embedded in concrete walls, or welded to embedded plates. Both single and double doors are involved. Double doors consist of an active and inactive leaf, with the active leaf being used for normal traffic. Doors C27, A55, A57, A65 and A78 have a single skin plate with horizontal stiffeners. All other doors are the flush type. Securing for tornado, annulus pressure drop, or flood is done by a normal latching mechanism except for doors C27, A55, A57, A65 and A78 which are secured by the use of hand-operated dogs. All doors affected by tornadoes are secured during tornado warning and doors A65 and A78 are secured during external flood warnings. Doors A55, A57, C27, and C14 will protect essential safety equipment in the auxiliary and control buildings to elevation 706.0 from internal floodwaters in the turbine building caused by a rupture in the Condenser Circulating Water system (CCWS).

During normal operation the doors provide personnel and equipment access. Doors A55, A57, A64, A65, A77, A78, A101, A105, A113, A114, A123, A132, A214, and 215 are also components of the building airlocks which serve to maintain a slight negative pressure in the Auxiliary and Reactor Buildings. These doors are equipped with electrical interlocks to assure that one of each pair of interlocked doors is always closed.

Spent Fuel Pool Gates

The fuel transfer canal gate as shown in Figure 3.8.4-11, when in the installed position, forms the boundary between the fuel transfer canal and the spent fuel pool. This gate is used for

dewatering the fuel transfer canal for maintenance or after refueling operation. This gate is installed or removed under balanced head. The cask loading area gate is abandoned in the open storage position. Both gates are of similar construction and are seismic Category I.

Waste Packaging Area

The waste packaging area is a one-story reinforced concrete structure supported on H-bearing piles and is located on the east end of the Auxiliary Building as shown in Figure 1.2.3-7. The roof of the structure slopes about 24° and consists of a series of precast beams tied together by a mat of reinforcing steel welded to plates embedded in the beams and topped by 4-inches of poured-in-place concrete. The structure is separated from the Auxiliary Building and the Condensate Demineralizer Waste Evaporator Building by a 2-inch expansion joint filled with fiberglass insulation which prevents interaction of the buildings when subjected to seismic motion.

Condensate Demineralizer Waste Evaporator Building Portion

The Condensate Demineralizer Waste Evaporator Building portion is a two-story reinforced concrete structure which houses equipment necessary for processing condensate demineralizer wastes and for serving as a backup in processing floor drain wastes. The structure is supported on H-bearing piles and is located on the southeast side of the Auxiliary Building as shown in Figure 1.2.3-7. The building is separated from the waste packaging area and the Additional Equipment Building by a 2-inch expansion joint filled with fiberglass material which prevents interaction of the buildings if subjected to seismic motion.

Additional Equipment Building Portion

The Additional Equipment Building portion consists of multistory reinforced concrete structures, one for each unit, which were added to accommodate additional accumulators for each unit and for the transfer of ice condenser equipment. The structures are located adjacent to the Reactor Buildings and near the east end of the Main Auxiliary Building as shown in Figures 1.2.3-1 through 1.2.3-6. Each building is founded on sound rock and is separated from the Condensate Demineralizer Waste Evaporator Building (Unit 2 structure only), the Reactor Building, and the Auxiliary Building by a 2-inch expansion joint filled with fiberglass insulation which prevents interaction of the buildings when subjected to seismic motion.

West Main Steam Valve Rooms

The west steam valve rooms are the compartments of the auxiliary building which house the isolation valves for the main steam lines penetrating the west side of the reactor building. From these rooms the main steam lines exit the auxiliary building.

To protect the west steam valve rooms from over-pressurization due to postulated large high energy pipe breaks, the roofs of the west steam valve rooms at Elevation 779 and the pressure relief hatches at Elevation 729 are designed to initiate pressure relief at a maximum of .5 psi (72 psf) differential pressure.

Additionally, to maintain the Environmental Qualification of the components located inside the valve rooms, the roof and hatches are designed to blow-away and provide and maintain the necessary flow areas after pipe breaks required by the Superheat Analysis.

3.8.4.1.2 Condenser Cooling Water Pumping Station and Retaining Walls

Pumping Station

The building is a reinforced concrete box-type structure housing the condenser circulating water pumps, cooling tower makeup pumps, and fire protection / flood mode pumps. The structure is founded on rock and back-filled on three sides to approximately the elevation of the top deck.

The structure is built without contraction or expansion joints. In the northwest-southeast direction, it is stiffened by two full height walls and three partial height walls extending the full length of the structure. In the northeast-southwest direction, the structure is stiffened by the many walls and piers making up the six pump bays. Refer to Figures 1.2.3-18 and 1.2.3-19 for details.

Retaining Walls

The retaining walls are rock founded, reinforced concrete cantilever walls located at each end of the forebay side of the intake pumping station. These walls retain the earthfill adjacent to the intake pumping station.

3.8.4.1.3 Diesel Generator Building

The building is a two-story rectangular reinforced concrete box-type structure which houses the diesel generators and their auxiliary equipment. Interior walls of reinforced concrete separate the diesel generators into four compartments. Diesel fuel storage tanks are embedded in the base slab. A concrete apron extending 13 feet from the edge of the structure is used to decrease the bearing on the subgrade to less than the allowable capacity. The entire structure is supported on soil. No connection of pipes or conduit were made until after completion of the structure and initial settlement stabilized. For general layout and configuration of the structure, see Figure 1.2.3-17.

Diesel Generator Building Doors and Bulkheads

The four doors shown in Figure 3.8.4-2 at Elevation 722.0 in the east wall of the Diesel Generator Building along with removable steel bulkheads above the doors provide closures for the 11 feet 10 inches high by 8 feet 8 inches wide access openings to the Diesel Generator Units. The access openings provide for passage of large tools and repair parts for the diesel generators. The doors are normally closed and latched. The bulkheads are bolted in position and are removed only for major repair of the diesel generators. The doors and bulkheads, in conjunction with the precast concrete barrier in front of them, protect the generators from damage by tornadoes, missiles, wind, snow, ice, and rain and form a part of the security system to prevent entry into the Diesel Generator Building by unauthorized persons.

Each steel bulkhead above the door is a structural steel frame 4 feet 4 inches high by 9 feet 6 inches wide. It is covered on both sides with a steel skin plate and provided with a crushable strip on the inner side along the top and sides. Turnbuckles support the steel bulkheads vertically and they are held horizontally by bolted clamps at the sides and top.

Each door is 7 feet 10 inches high and consists of two leaves which are manually operated and hinged at the outer sides to an embedded steel frame. The two leaves bear against steel bars at the outer sides and bottom, against each other at the center, and against a steel angle at the top. The bars are welded to the embedded frame and the angle to the bulkhead above the door.

Each door leaf is a structural steel frame covered on both sides with a steel skin plate and provided with a crushable strip around its periphery where it bears against lateral support. Both leaves are provided with latches which are operated from the inside only.

The crushable strip around the periphery of the doors and bulkheads is a latticework which is designed to absorb energy from missile impact. The doors and bulkheads may be deformed by the missiles but will remain in position.

The precast concrete bulkheads consist of several individual sections stacked into place and bolted in position to the concrete walls. They will be removed only for major repair of the diesel generators. These bulkheads provide protection from missile spectrum D of Table 3.5.5-5, as discussed in Section 3.5.5, Part II(D).

3.8.4.1.4 Category I Water Tanks and Pipe Tunnels

There is one refueling water storage tank (RWST) for each unit at Sequoyah Nuclear Plant. (The functional requirements for this tank are discussed in Chapter 6). Pipes extending from RWST to the Auxiliary Building are housed in reinforced concrete tunnels which vary in width and height.

Refueling Water Storage Tank (RWST)

The RWST is a seismic Category I structure but is not tornado Category I. A storage basin is provided around the tank to retain sufficient borated water in the event the tank is ruptured by a tornado missile or other initiating event. Details of the storage basin and the technical basis for it are discussed in Chapter 6. The minimum volume of contained water in the RWST is specified in the plant's Technical Specifications. The minimum and maximum volume of contained water in the RWST is also specified in Chapter 6. RWST is a cylindrical vessel whose longitudinal axis is oriented in the vertical direction.

The end of the cylinder which forms the base or bottom of the tank is completely enclosed with a 5/16-inch-thick flat plate. The base of the tank sits on a concrete granular fill supported foundation to which the tank is attached at 60 lug points. The reinforced concrete foundation is described in Section 3.8.5.1.2. The tops of the cylindrical section of the tank is sealed at the side-wall/roof intersection using conical-shaped roofs whose apexes coincide with the tank’s longitudinal axis. An internal inspection of the RWST will be performed on a periodic basis for structural integrity and degradation.

The tank is equipped with an atmospheric vent located at the peak or cone apex of the roof. The vent is designed to pass a volume flow rate of air that is at least equal to the maximum

withdrawal rate from the tank. Necessary precautions have been taken in the design of the vent to assure birds, animals, and/or other foreign objects including rain cannot enter the tank. The foundation is shown in Figures 3.8.4-3 and 3.8.4-4.

Pipe Tunnels

The pipe tunnels housing the piping extending from the primary and refueling water tanks to the Auxiliary Building are concrete box-type structures which vary in width and height. The layout and configuration of the tunnels are shown in Figure 3.8.4-3.

3.8.4.1.5 Class IE Electrical Systems Manholes and Handholes

The location of category I electrical manholes and handholes is shown in Figure 3.8.4.5. The manholes and handholes shown in Figures 3.8.4-6 and 3.8.4-8 are typical of those that house the electrical cables that must remain in operation when flood levels rise above the plant grade. The manholes and handholes are rectangular box-type structures of reinforced concrete built essentially below plant grade with their top slab projecting above the surrounding soil.

3.8.4.1.6 East Steam Valve Room

The structure, shown in Figures 1.2.3-1 through 1.2.3-4, is designed to protect the isolation valves of the main steam and feedwater lines from the effects of tornadoes and earthquakes, as well as provide support for the valves and main steam pipes and feedwater pipes that exit from the Shield Building. The structure consists principally of three reinforced concrete walls anchored into a 7-foot-thick base slab. The structure is supported by eight concrete caissons 4 feet in diameter anchored in rock. A 1-inch expansion joint separates the Valve Room from the Shield Building.

Structural steel framing is used to support roof decking of the Valve Room. To protect the east steam valve room from over-pressurization due to postulated large high energy pipe breaks, the roof of the east steam valve room at Elevation 759 is designed to initiate pressure relief at a maximum of .5 psi (72 psf) differential pressure.

Additionally, to maintain the Environmental Qualification of the components located inside the valve room, the roof is designed to blow away and provide and maintain the necessary flow areas after pipe breaks required by the Superheat Analysis.

3.8.4.1.7 ERCW Pumping Station and Access Cells

The ERCW pumping station which supplies water to Units 1 and 2 is a waterfront concrete structure founded on bedrock. The base is tremie concrete contained by sheet pile cells; atop the base is a reinforced concrete box-type structure which houses the pumps, electrical and mechanical equipment. The structural outline of the pumping station is shown in Figures 1.2.3-14 through 1.2.3-16.

Six access cells house the ERCW piping and electrical conduit banks. They are filled with tremie concrete contained by sheet piling and are founded on bedrock. They also serve as access to the ERCW pumping station. Refer to Figure 3.8.4-9.

A rockfill dike (Figure 3.8.4.9) is located just upstream from the pumping station. This dike protects the pumping station from runaway barges. The dike is seismically qualified to prevent blockage of the intake to the ERCW Pumping Station.

Pile-Supported ERCW Piping Support Slab

The ERCW piping support slab is a segmented, reinforced concrete structure which passes through the ERCW access dike. The slab terminates at the first of the ERCW access roadway cells. The slab is supported by steel H-piles driven through the access dike to refusal. The slab is provided to prevent the imposition of excess deformations from settlement of the access dike on the ERCW piping. Typical cross sections of the ERCW access dike showing the location of the piping support slab and pile supports are shown in Section C5-C5 of Figure 3.8.4-9. The orientation of the slab along the longitudinal axis of the access dike and the spacing of the pile support is shown in Section A5-A5 of Figure 3.8.4-9.

ERCW Electrical Conduit Bank

The ERCW electrical conduit bank passes through the ERCW access dike parallel to and above the pile-supported piping slab discussed above. The bank is supported from the piping slab by concrete bents at intervals along the slab. Near the access dike-shoreline interface, the piping slab terminates. Beyond that point, the conduit bank is supported by pile-supported bents until the shoreline is reached. Cross sections of the access dike showing the relationship of the conduit banks and the piping slab are shown in Section C5-C5 of Figure 3.8.4-9. The location of the conduit bank along the longitudinal centerline of the access dike is shown on Section A5-A5 of Figure 3.8.4-9.

3.8.4.1.8 ERCW Discharge Box

The box is a soil supported, rectangular reinforced concrete box. The location and configuration of the structure is shown in Figure 3.8.4-10.

3.8.4.2 Applicable Codes, Standards, and Specifications

Unless otherwise indicated, the design and construction of the Category I structures other than the primary containment and interior structures are based upon appropriate sections of the following codes, standards, and specifications listed in Section 3.8.1.2, with the following additions. Modifications to these codes, standards, and specifications are made where necessary to meet the specific requirements of the structures. These modifications are noted in Sections 3.8.4.3, 3.8.4.4, and 3.8.4.6. Where date of edition, copyright, or addendum is specified, earlier versions of the listed documents were not used. In some instances, later revisions of the listed documents were used where design safety was not compromised.

3.8.4.3 Loads and Loading Combinations

3.8.4.3.1 Description of Loads

See Tables 3.8.4-1 through 3.8.4-17 for the loads of other Category I structures. Other Category I structures are in general subject to the same natural phenomena and basic dead, live, and earth pressure loading as described for the Shield Building in Section 3.8.1.3.

Construction loads differed for the Auxiliary Building because of the multistory effect of shoring from one floor to the next and the construction crane loading on the Control Building portion. The maximum temperature gradient for walls above grade with exterior exposure is the same as

the normal operating temperature gradient of the Shield Building. The design stresses induced by this temperature gradient are insignificant. The spent fuel pit and fuel transfer canal require additional temperature considerations. Under accident conditions the water is assumed to reach 212°F in 8 hours with the inside building temperature initially at 60°F. The normal temperature of the water in the fuel pit and canal is 120°F.

Hydrostatic pressure loads in the fuel pit and canal vary with water levels, either of which may be full or empty. A hydrostatic pressure load from either the fuel pool or cask loading area being drained is not included in the design of the interior wall of the spent fuel pool. The wind and tornado loading are described in Section 3.3. Blowout panels are necessary to restrict the tornado generated pressure differential to 100 lbs/ft^2 above the 734 floor in the Auxiliary Building and 72 lbs/ft^2 in the east valve room.

For initial design, the live load associated with supports and restraint anchorages for cable trays, piping systems, and other fastenings to interior masonry walls was restricted to a maximum of 20 lbs/ft^2 over the face of the wall.

A 1730-lbs/ft^2 surcharge loading was applied to the A1 and A15 line walls as a construction loading in the Auxiliary Building.

3.8.4.3.2 Load Combinations and Allowable Stresses

See Tables 3.8.4-1 through 3.8.4-17 for the loading combinations and allowable stresses.

Except for the Refueling Water Storage Tank foundation, Condensate Demineralizer Waste Evaporator building, additional equipment buildings, and ERCW Pumping Station, which were originally designed by the strength method per ACI 318-71, and two walls in the west steam valve room which have been reevaluated as specified in Section 3.8.4.4.1, the normal allowable stresses of ACI 318-63 were used in the original design for the basic loading combination of dead, live, earth pressure, hydrostatic ground water to Elevation 687 (or full pool water levels in the spent fuel pit) and effects of normal temperature gradients.

For additional loads such as induced moments or shears resulting from 1/2 SSE, accident pressure loading caused by a LOCA or steam pipe rupture and thermal effects corresponding to the accident conditions, a 25 percent increase in steel stress was allowed with concrete stresses restricted to normal allowables.

For construction loading instead of normal live loading or for flood water to Elevation 700 a 35 percent increase in both steel and concrete stresses was allowed.

For the combination of the basic loads with SSE effects, or tornado wind loads and associated missiles, or PMF loads, or impact loadings from jet impingement or jet loading on pipe restraints in conjunction with accident pressures a 67 percent increase in normal concrete stresses was allowed with steel stresses allowed to reach 0.9 of yield.

The maximum lateral forces generated by the SSE are transmitted to the base through shear walls which are designed in accordance with Section 2631 (c) of the "Recommended Lateral Force Requirements and Commentary" of the Seismology Committee, Structural Engineers Association of California, 1968.

As loading requirements and regulations change during the life of the plant, structures may be evaluated using later revisions of ACI 318. These evaluations shall use either the working stress design method (WSD) or the ultimate strength design method that was used in the original design of the structure. However, the live load verification program shall be completed using the load combinations and concrete design code specified in SQN-DC-V-1.3.3.1. In addition, SQN-DC-V-1.3.3.1 shall be used for the design of new building structures that are added.

3.8.4.4 <u>Design and Analysis Procedures</u>

The masonry walls are designed according to Sequoyah Nuclear Plant Design Criteria for Reinforced Concrete Block Walls, SQN-DC-V-1.1.1, which is outlined in Appendix 3.8E.

As a result of Integrated Design Inspection (IDI) item D4.3-9, representative "worst case" reinforced masonry walls were determined by a comparison of all such walls in Category I structures (height, thickness, restraint, boundary conditions, etc.) using the wall drawings and then evaluated. This evaluation consisted of analyzing the walls for the governing load combinations of TVA design criteria SQN-DC-V-1.1.1 using the allowable stresses of NUREG 0800, Section 3.8.4, Appendix A. The analysis included the effects of openings in the walls. The evaluation found the walls to be acceptable for restart. Upon completion of post-restart work (CCTS #NC0870361086), all reinforced block walls in all Category I structures, are in full compliance with NUREG 0800 allowables.

3.8.4.4.1 <u>Auxiliary Control Building</u>

<u>Control Bay Portion</u>

This concrete structure was originally designed in two stages in accordance with the ACI Building Code 318-63 using the elastic working stress theory. The loads, loading combinations, and allowable stresses used are given in Section 3.8.4.3.2.

Each stage of the two stage construction of the control bay was investigated for the controlling design conditions. The principal steel requirements for the Stage I construction was controlled by Stage I loading conditions. Only the dowel steel tying the Stage I and II construction together was controlled by Stage II loading conditions even though Stage I loading conditions do not include earthquake or tornado loads. The structure is founded on a 2-foot-thick-minimum concrete subpour. During Stage I construction the roof slab acted as a membrane stiffener for the top longitudinal sprandrel beams. These spandrel beams together with the roof slab formed a horizontal I-beam which spans between the end walls of the building. The beams were the flanges and the roof slab was the web of this long beam.

The support columns were thereby prevented from significant deflection in the transverse direction under wind load or crane sluing load. Before the roof slab was placed, columns were

held by temporary cross bracing during construction. The Stage I structure was designed as a freestanding reinforced concrete frame.

Stage II construction consisted of interior slabs, columns, and section of walls between main columns. Adequate dowels are provided for these sections. With Stage II construction, the control bay structure is an integral part of the Auxiliary Control Building. Floors and walls of the Auxiliary Building are continuous with the control bay east wall. Dowels and shear keys are provided in the Stage I and II control bay structure to provide for this structural continuity. The main portions of the building are designed by ICES STRUDL-II.

Procedures used to design the structural steel framing were based on simple beam and column construction as covered in AISC "Specification for the Design, Fabrication, and Erection of Structural Steel for Buildings," Part 1 with Type 2 framing connections. The beam-to-beam and beam-to-column connections were typical AISC double angle connections as required by the beam reactions, using either rivets or high strength bolts. Transfer of loads into the concrete structure was through bearing plates.

Control Room Shield Doors

The doors were designed assuming that the entire dead load is carried by the two vertical members in the door directly under the trolleys and the vertical load from the lead shot was acting horizontally on the side and skinplate panels.

The end panels were designed as a fixed beam with uniform load while the skinplate was designed as a square flat plate stayed at the four corners. The top and bottom members of the door were considered as simple beams.

Earthquakes are the only natural environmental condition which applies to the doors. Being inside the control room, the doors are protected from outside elements.

For design the earthquake loads for the various parts consisted of the loads produced by a SSE. Accelerations due to a SSE are greater than those due to 1/2 SSE by a factor of 2. Since the comparable allowable stress levels have a ratio of 1.75, it is obvious that the SSE controls the design.

Earthquake loads used in design of door and dogs were the loads produced by SSE having peak accelerations at floor Elevation 732.0 in the Control Building as follows:

Lateral (north-south)	- 0.60 g
Lateral (east-west)	- 0.64 g
Vertical	- 0.13 g

The accelerations were used as static loads for determining component and member sizes. After establishing the component and member sizes, a dynamic analysis, using appropriate response spectra, was made of the door and dogs to determine that the allowable stresses had not been exceeded.

In addition, the monorail located above the shield doors is designed to provide seismic support for the shield doors in the undogged (unbolted) configuration.

Auxiliary Building Portion

This concrete structure was originally designed according to the ACI Building Code 318-63 and the stresses are determined by the working stress method for the principal design cases as shown in Section 3.8.4.3.2. Stresses resulting from the static analysis are combined by the method of superposition with stresses resulting from moments, shears, deflections, and accelerations determined by the dynamic earthquake analysis described in Section 3.7.2. The exterior concrete walls above grade are designed to resist the tornado generated missiles as described in Section 3.5.

The condition of rapid depressurization during a tornado is provided for in the following manner. The exterior part of the building is designed for an internal positive pressure of 3 lb/in^2 occurring in 3 seconds with the following exceptions:

1. The area above the refueling floor at Elevation 734.0, as shown by Figure 1.2.3-1, is designed with blowout panels which open at 36 lbs/ft^2. The purpose of these blowout panels is to limit the tornado generated pressure differential on the roof of the refueling room to 100 lbs/ft^2.

2. The area below the 763 roof elevation is vented from openings in the roof. The roof and walls housing this area are nevertheless designed for 3 lb/in^2. The floor at Elevation 749 below this roof is also designed for an uplift of 3 lb/in^2 recognizing the venting of the area above this floor.

3. The heating and ventilating rooms at Elevation 714.0 (see Figure 1.2.3-4) are vented by the air intakes on the exterior walls. This results in the floor, roof, and interior walls of these rooms being designed as exterior members for 3 lb/in^2 pressure.

The exterior walls below grade Elevation 705 $\pm$ are designed for earth pressures. The exterior walls on the north and south ends of the Auxiliary Building are designed as cantilevered retaining walls from Elevation 665 to Elevation 688 $\pm$. These walls were built early before any adjacent walls and slabs to allow the construction field force to backfill and have early access to the area at Elevation 688 $\pm$. The lateral earth pressures are calculated using Coulomb theory and values as given in Section 3.8.1.3.6.

The exterior wall at the east end of the building, with five buttress walls framing into it, is designed for earth backfill from Elevation 665 to Elevation 704 $\pm$ to allow for placement of the 706 slab on grade.

Horizontal seismic forces are resisted by shear walls with the floor slabs and roof acting as diaphragms. Only those walls parallel to the seismic motion are assumed to resist that motion.

The total shear at any level is proportioned among the shear walls in accordance with the method in Portland Cement Association Publication T18-4, "Analysis of Small Reinforced Concrete Buildings for Earthquake Forces," Pages 30-32.

For the SSE, an allowable ultimate shear stress of 5.4 ϕ f'_c was used. This is the value specified in the SEAOC Code in Section 2631 (c) for walls with a height to width ratio less than one, as is the case for this structure. For the 1/2 SSE, an allowable value of one-half of the above is used. As can be seen in Section 3.8.4.5.1, the calculated shearing stresses do not exceed these values.

Main steam and feedwater pipes penetrate the exterior walls of the west steam valve room. These penetrations furnish pipe restraints through flued heads embedded in the walls. The flued head separate the pipe from the concrete which reduces the heat transfer to the concrete.

The Primary Structural Support System was designed as a Flat Slab Floor System with concrete columns. Large openings that required separate design are framed with beams. The thickness for many slab sections throughout the building is determined by shielding requirements. The general thickness and live load requirements for the original design of the different slab areas are shown on Figure 3.8.4-1.

The major portion of the building slabs are designed using the ICES STRUDL-II computer program. Moments and shears for small frames, beams, and one-way slabs were obtained by the moment distribution method. Where slabs act as two-way slabs due to walls or beams below, moments and shears were determined by use of method 2 of Appendix A in ACI Code 318-63.

The minimum percentage of reinforcing in the slabs is 0.15 percent in the top face of 0.18 percent in bottom face.

The roof slab at Elevation 763.0 is designed for 3 lb/in^2 uplift pressure as a flat slab using the ICES STRUDL-II computer program.

The roof at Elevation 778 is also designed for 3 lb/in^2 uplift pressure using the ICES STRUDL-II, Finite Element Method.

In the interior of the building there are many areas around equipment that require shielding which is provided by poured-in-place concrete walls. To permit equipment installation the construction of the shielding walls was delayed until the building frame and floor construction was completed and equipment was installed. Where possible, some walls were utilized as structural members and constructed with the building frame. These walls contain minimum steel percentages in the horizontal and vertical directions as specified by the TVA Temperature and Shrinkage Standards and the ACI Code 318-63, Section 2202 (f). These walls were checked for stresses resulting from seismic loading; however, seismic stresses did not control.

The thick concrete walls of the spent fuel pit and transfer canal are required for shielding. They are shown in Figure 1.2.3-8. The base slab is approximately 20 feet thick resting on a 2-foot-minimum concrete subpour placed on sound rock. The walls and base slab are built integrally with the slabs and walls of the Auxiliary Building. A structural wall separates the cask loading area from the spent fuel storage area. The design of the pool walls take into account hydrodynamic effects of the water and temperature stresses caused by a postulated failure of the Spent Fuel Cooling System. This structure was designed by moment distribution methods. The stresses in the

walls between the spent fuel pit and fuel transfer canal and those between the spent fuel pit and cask loading area were checked by the ICES STRUDL-II, computer program to determine the effect of the slot in the walls.

Railroad Access Hatch Covers

Structural members for the covers were designed as simple beams. Members of the embedded frame were considered as being rigidly supported by concrete. Loads from the embedded frame are transferred to the concrete by embedded anchors.

The earthquake forces, specified as follows, for design were determined by dynamic analysis including amplification through the supporting structure.

Accelerations at Elevation 734.0 for the SSE were as follows:

Lateral (north-south)	0.32 g
Lateral (east-west)	0.38 g
Vertical	0.54 g

These accelerations were used as static loads for determining component and member sizes. After establishing the component and member sizes, a dynamic analysis, using appropriate response spectrum was made of the covers to determine that allowable stresses had not been exceeded.

Railroad Access Door

The horizontal structural members of the door were designed as simple beams with uniformly distributed loads. The end reactions from these members were then transferred to the door end posts as concentrated loads located between rollers. As a conservative design, it was assumed that one roller was not in contact with the track and that the loading from the two horizontal members with the highest reactions was carried by the two adjacent rollers.

The skin plate for the door was designed, without regard to support of the plate from diagonal stiffeners, for the largest open rectangle within the structure. The plate was assumed to be a rectangular diaphragm with fixed edges.

The embedded door frame is rigidly supported by concrete. The portions of the frame which form the door track were designed as cantilever members with loading as applied by the door rollers.

The structural members of the steel enclosure above the door were designed as simple beams and the hoist supports as cantilevers from the Auxiliary Building wall.

Earthquake loads used in design of the door, frame, and track were the loads produced by a SSE having peak accelerations at ground level Elevation 706.0, which is the bottom of the door, as follows:

Lateral (north-south)	0.26 g
Lateral (east-west)	0.28 g
Vertical	0.12 g

Earthquake loads used in design of the hoist supports and enclosure were the loads due to accelerations at the hoist platform, Elevation 750.0, produced by a SSE. These accelerations were determined by dynamic analysis of the Auxiliary Building structure and were as follows:

Lateral (north-south)	0.38 g
Lateral (east-west)	0.44 g
Vertical	0.16 g

These accelerations were used as static loads for determining component and member sizes. After establishing the component and member sizes, a dynamic analysis, using appropriate response spectra, was made of the door, embedded frame, door track, and hoisting unit enclosure to determine that allowable stresses had not been exceeded.

Manways in the RHR Sump Valve Room

In the closed position, each door was considered as a structure supported around the periphery. In the open position, each door was considered as a cantilevered structure with the hinges and hinge anchorages being designed for their loading from the door in the open position. Each embedded frame was considered as being rigidly supported by concrete. Loads from the embedded frame are transferred to the concrete by embedded anchors.

Earthquake loads used in designing the manways were the forces due to accelerations determined for the sump valve room walls at the center of the manways by dynamic analysis of the Auxiliary Building for a SSE. These forces were used as static loads since the manways are rigid and firmly secured to the walls when closed.

Accelerations for a SSE are as follows:

Lateral (north-south)	0.18 g
Lateral (east-west)	0.18 g
Vertical	0.12 g

Pressure Confining Personnel Doors

Structural members for the doors, in the closed position, were designed as simple beams with end reactions carried by the outside members to the frames which were considered as being rigidly supported by concrete. Loads are transferred to the concrete through embedded anchors or bolt anchors.

In the open position, the doors were designed as cantilever structures with resultant concentrated loads being used for design of the hinge members.

For design, the earthquake loads for the various doors consisted of the loads produced by a SSE.

Earthquake forces due to building accelerations at the elevation of the center of gravity of the various doors were used as static loads for determining door component and member sizes. The building accelerations were determined by dynamic analysis including amplification through the

supporting structures. After establishing the component and member sizes, a dynamic analysis, using appropriate response spectra, was made of the doors to determine that allowable stresses had not been exceeded.

Spent Fuel Pool Gates

The gates are designed for a waterhead load of 25.42 feet imposed from the spent fuel pool side as measured from the centerline of the horizontal bottom seal to the normal pool level at elevation 726 feet 1-1/2 inches. The gates are constructed of welded corrosion resistant steel. When dewatering the fuel transfer canal, inflatable elastomer seals provide a watertight seal between the skin plate and the pool wall liner face. The fuel cask gate is to be in its stored position (open for use).

The gates have been analyzed for the effects of the OBE and SSE for both the operating and stored position. The gates are designed to maintain their sealing and structural integrity during and after an SSE. Earthquake loading considers simultaneous vertical and horizontal dynamic forces that act on the gates when there is water on both sides or for the fuel canal gate when there is water on the fuel pool side only. The gates are restrained by guides at the top, mid-height, and bottom. When in the storage position, the gates are horizontally restrained by top and bottom guides and vertically supported by hanger brackets.

Accelerations for an SSE are as follows:

North-south	0.32 g
East-west	0.36 g
Vertical	0.12 g

West Steam Valve Room

Two walls in the West Steam Valve Room have been reevaluated using an elasto-plastic dynamic analysis and yield line theory to determine the ultimate capacity of the walls. The walls have been reevaluated for the load combinations specified in Table 3.8.4-1 and are in conformance with the requirements of Appendix C of ACI 349-76 and NRC Regulatory Guide 1.142.

Waste Packaging Area

The base slab is designed to be supported by a bearing pile foundation as discussed in Section 2.5. The walls are designed to cantilever during construction and to be hinged at the joint on top after the top slab has been placed. The reinforcing steel in the top face of the roof slab was designed for temperature and shrinkage.

Condensate Demineralizer Waste Evaporator Building Portion

This two story structure was designed using the loads, loading combinations, and allowable stresses as given in Tables 3.8.4-1 and 3.8.4-2. The concrete portion was designed in accordance with the ACI 318-71 Building Code and the structural steel portion in accordance with AISC "Manual of Steel Construction," Seventh Edition. The building is designed to be

supported by a bearing pile foundation, with the piles founded on sound rock as discussed in Section 2.5. The intermediate floor and roof are supported by interior bearing walls and metal decking spanning between steel beams.

Additional Equipment Building Portion

These concrete structures were designed in accordance with ACI Building Code 318-71 using the loads and loading combinations as given in Table 3.8.4-1. The Unit 2 Building was designed for four stories above the base slab and Unit 1 for two stories above the base slab. The buildings consist of reinforced concrete exterior walls, slabs, and interior columns. For each building, all horizontal forces are transmitted through the floors and roof slab as diaphragms to the exterior shear walls and thence to the foundation base slab. The columns and exterior walls transmit the vertical loads to the base slab.

The building foundations are reinforced concrete wall grid systems which start beneath the base slab and extend down to reinforced concrete foundation slabs placed on sound rock. Weep holes are provided in the foundation walls to relieve possible buildup of hydrostatic pressure. Earthfill was placed within the Foundation Wall System to equalize external soil pressures and to support the base slab at Elevation 706 during placement.

The major walls and slabs of these structures were analyzed by STRUDL computer programs using plate-bending finite elements and grid members.

3.8.4.4.2 Condenser Water Supply Pumping Station, and Retaining Walls

Pumping Station

The box-type structure is analyzed by parts using moment distribution and PCA Structural Bulletin ST 63 for Design of Rectangular Concrete Tanks. The working stress method of design is used for all parts other than the missile barrier walls which are designed for ultimate strength.

The top slab is analyzed as a continuous two-way slab supported monolithically on the walls of the structure. A 164-kip mobile crane outrigger load placed any point upstream of the centerline of the condenser circulating water pumps is considered in the analysis.

The back wall of the pumping structure is analyzed as a one-way slab spanning horizontally between the pilasters of the back wall. The pilasters are analyzed as T-beams spanning between the base and the top slab.

The side walls are analyzed as continuous two-way slabs supported at the base, the top deck and at the front and back walls of the structure.

The front wall or stoplog is designed as a slab restrained on three edges and free on the other edge. This wall is designed to resist tornado loadings.

The base slab is analyzed as a two-way slab founded on rock.

The thick interior pump bay walls are analyzed in two parts. The thin 2-foot-thick portion of each pump bay wall is designed as a beam spanning horizontally between the massive, thick portion of the wall and the front wall of the pump well and valve room. The massive portion of each interior pump bay wall is designed as a beam spanning between the base slab and the top slab of the structure.

The front wall of the pump well and valve room is analyzed as a two-way slab.

The missile barrier walls anchored to the top slab of the structure are analyzed as cantilevers and designed using ultimate strength design.

The structure was investigated as a whole to ensure continuity of design. Reinforcement is proportioned to restrict crack widths in the top slab over the electrical equipment room to approximately 0.005 inch. In the remainder of the structure reinforcement is proportioned for service conditions to restrict crack width to approximately 0.010 inch. The structure was also investigated for stability against overturning, floating, and sliding.

In addition, the structure is designed to resist the pressure differential during a tornado and to maintain its stability under all conditions. Factors of safety for overturning, flotation, and sliding are listed in Table 3.8.4-3.

Retaining Walls

The structures were analyzed as cantilever walls founded on rock and originally designed in accordance with the ACI 318-63 Building Code. The factors of safety against overturning and sliding are listed in Table 3.8.4-4.

3.8.4.4.3 Diesel Generator Building

The structure was analyzed as a box-type structure assuming all walls fixed at the base slab, Elevation 722.0. The frame was analyzed by the moment distribution method. The 740.5 elevation floor and the Elevation 753.5 roof are one-way slabs continuous across interior walls and restrained at exterior walls. All horizontal forces are transmitted through the floor and roof slabs as diaphragms to parallel shear walls and thence to the foundation base slab as discussed in Section 3.8.4.4.1 for the Auxiliary Building.

The base slab distributes superstructure loads uniformly to the supporting soil and was analyzed as a flat slab.

Diesel Generator Building Doors and Bulkheads

Structural members for the doors and bulkheads were designed as simple beams. The skin plates were designed as square or rectangular diaphragms with all edges fixed. The crushable strips for energy absorptions were considered as being collapsible.

The design of the doors and bulkheads was by TVA without the use of a computer program. Design of members in crushing strips was based on tests made by Oak Ridge National

Laboratory. Results of these tests are recorded in their publication titled "Structural Analysis of Shipping Casks, Volume 9, Energy Adsorption Capabilities of Plastically Deformed Struts Under Specified Impact Loading Conditions."

Earthquake loads used in designing the doors and bulkheads were the accelerations determined for ground level Elevation 722.0, which is the bottom of the doors, for a SSE as follows:

Lateral (north-south)	0.74 g
Lateral (east-west)	0.74 g
Vertical	0.28 g

These accelerations were used as static loads for determining component and member sizes. After establishing the component and member sizes, a dynamic analysis was made of the doors and bulkheads.

The precast concrete bulkheads covering the doors were analyzed for missile impact loads. In establishing the required thickness of the precast concrete bulkheads, consideration was not given for the structural doors and the concrete bulkheads were designed to absorb full missile impact. Sections 3.5 and 3.8.4.1.3 discuss the missile requirements of precast bulkheads in more detail.

3.8.4.4.4 Category I Water Tanks and Pipe Tunnels

Water Tanks

See Section 3.8.4.1.4 for a description of the Refueling Water Storage Tanks. See Section 3.8.5.1.2 for a description of the foundations and Section 3.8.5.4.6 for a description of the design and analysis procedures for the tank foundations. Chapter 6 discusses the functionality requirements for the tanks.

Pipe Tunnels

The pipe tunnels were analyzed using a standard frame analysis and designed in accordance with the provisions of the ACI 318-63 Building Code.

3.8.4.4.5 Class 1E Electrical Systems Manholes and Handholes

The structures were designed using the provisions of the ACI 318-63 Building Code and the working stress design method.

3.8.4.4.6 East Steam Valve Room

The concrete structure is analyzed as an open box structure. The main steam and feed water lines exit from the 4-foot-thick north wall where restraints for these lines are anchored. Pipe restraints are also located in the 5-foot-thick interior wall in the south end as well as in the 6.5 foot by 10-foot-deep beam portion of the east wall. The 5-foot interior wall at the south end

stiffens the 1.5-foot-thick south exterior wall. The 1.5-foot-thick east wall spans horizontally between the stiff complex of end walls and vertically from the base slab to the 6.5-foot- thick portion. The walls were investigated using STRUDL flat plate and grid computer programs.

Stability of the structure was also investigated in the analysis. The base slab was backfitted with caissons into rock after experiencing some settlement problems.

Design procedures for the roof steel were based on simple beam construction as covered in AISC "Specifications for the Design, Fabrication, and Erection of Structural Steel for Buildings," Part 1 with Type 2 framing connections. The metal decking was attached to structural steel with four screws per sheet and designed to fail and blow off when the internal pressure at the roof reaches 72 lb/ft^2.

3.8.4.4.7 ERCW Pumping Station and Access Cells

The ERCW pumping station and access cells were analyzed using conventional structural analysis method. In accordance with ACI 318-71 Code and subsequent addenda, the ultimate strength method of design was used in the design of the structures.

The top two floors of the ERCW pumping station were analyzed as continuous slabs supported monolithically on the walls of the structure. The bottom floor was analyzed as a continuous slab supported in the middle by the concrete foundation and cantilevered at the corners. The side walls were analyzed as continuous slabs supported at the base, the top, and at the front and back walls of the structure. The missile barrier walls anchored to the top floor of the structure were analyzed as cantilevers. McDonnell - Douglas Strudl and General Electric Structural Engineering solver computer programs were used for analytical purposes.

The structures were investigated to ensure continuity of design. The structures were also investigated for stability against overturning, floating, and sliding. The pile supported ERCW support slab was analyzed horizontally as a series of segmented slabs and was designed for the maximum moment induced in any one segment. The electrical conduit bank was analyzed as a continuous slab. Vertically, both the slab and conduit bank were designed for seismic response plus deadweight.

3.8.4.5 Structural Acceptance Criteria

3.8.4.5.1 Concrete

The Category I structures were proportioned to maintain elastic behavior and stresses within stress allowables when subject to the loading combinations of Section 3.8.4.3. Two walls in the west steam valve room have been reevaluated as specified in Section 3.8.4.4.1 and utilized a ductility ratio of 3.3.

In the condenser cooling water pumping station the maximum shear stress for earthquake forces based upon the original design was 52 lb/in^2.

A maximum shear stress from the SSE of 178 lb/in^2 occurs at the base of the west wall of the Diesel Generator Building. Considering only those wall portions with height to depth ratios of less than one this is less than 71 percent of the allowable.

The stresses in shear walls parallel to the direction of the lateral earthquake forces in the Auxiliary Building are as follows (see Note):

Elevation	Maximum Calculated Stress Safe Shutdown Earthquake		Allowable Stresses (lbs/in^2)
	North-South	East-West	
669-690	146	112	250
690-714	104	120	250
714-734	98	90	250
734-749	90	96	250
749-763	92	62	250
763-778	176	114	250
Above 778	234	60	250

Note: This table is based upon original design calculations and does not reflect later evaluations. These evaluations were due to changes in loading, concrete evaluations, or modifications, and were documented in calculation packages.

Stresses for 1/2 SSE are one-half of those tabulated. Earthquake shear stresses were insignificant in all other structures.

All Category I structures are essentially low profile box structures with height to base ratios less than 1.0 and a high factor of safety against sliding or overturning under the most severe loading conditions. In addition, all structures are sufficiently heavy that there is no flotation problem under maximum flood conditions.

3.8.4.5.2 Structural Steel

Structural steel and welds are designed in accordance with AISC "Manual of Steel Construction," Seventh Edition, for Case I loading condition so that the stress in the members and connections do not exceed the allowable stress criteria as set forth in the February 1969, AISC "Specification for Design, Fabrication, and Erection of Structural Steel for Buildings." For the factor of safety of these allowable stresses with respect to specified minimum yield point of the material used, see Section 1.5 of "Commentary on the Specification for the Design, Fabrication, and Erection of Structural Steel for Buildings." Both specification and commentary are included in the AISC "Manual of Steel Construction."

For Case II loading condition the actual stresses do not exceed the allowable stresses as set forth in Table 3.8.4-2. The allowable stresses for Case II loading have a minimum factor of safety of 1.11 based on the specified minimum yield point of the material used.

3.8.4.5.3 Miscellaneous Components of the Auxiliary Building

Control Room Shield Doors

Allowable stresses for all load combinations used for the various parts of the door and dogs are given in Table 3.8.4-5. For normal load conditions the allowable stresses provide a safety factor of 2 to 1 on yield for structural parts and 5 to 1 on ultimate for mechanical parts. For the limiting condition of SSE, stresses do not exceed 0.9 yield.

Railway Access Hatch Covers

Allowable stresses for all load combinations used for the various parts are given in Table 3.8.4-6. For normal load conditions, the allowable stresses provide safety factors of 2 to 1 on yield for structural parts and 5 to 1 on ultimate for mechanical parts. For limiting conditions such as a SSE, stresses do not exceed 0.9 yield.

Railroad Access Door

Allowable stresses for all load combinations used for the various parts of the door, embedded frame, and hoist enclosure are given in Table 3.8.4-7. For normal load conditions the allowable stresses provide a safety factor of 2 to 1 on yield for structural parts and 5 to 1 on ultimate for mechanical parts. For limiting conditions, such as SSE and hoist stall, stresses do not exceed 0.9 yield.

Manways in RHR Sump Valve Room

Allowable stresses for all load combinations used for the various parts are given in Table 3.8.4-8. For normal load conditions, the allowable stresses provide safety factors of 2 to 1 on yield for structural parts and 5 to 1 on ultimate for mechanical parts. For limiting conditions such as a SSE, stresses do not exceed 0.9 yield.

Pressure Confining Personnel Doors

Allowable stresses for all load combinations used for the various parts are given in Table 3.8.4-9. For normal load conditions, the allowable stresses provide safety factors of 2 to 1 on yield for structural parts and 5 to 1 on ultimate for mechanical parts. For limiting conditions such as SSE, flood, and tornado loadings, stresses do not exceed 0.9 yield.

Spent Fuel Pool Gates

Allowable stresses for all load combinations used for the gates are given in Table 3.8.4-18. For normal load conditions the allowable stresses do not exceed 0.6 of yield. For limiting conditions such as the safe shutdown earthquake the stresses do not exceed 0.96 of yield since load case 4 is the governing condition.

3.8.4.5.4 Diesel Generator Building Doors and Bulkheads

Load combinations and allowable stresses for all combinations are given in Table 3.8.4-10. For normal load condition, the allowable stresses provide safety factors of 2 to 1 on yield for

structural parts and 5 to 1 on ultimate for mechanical parts. For limiting conditions stresses do not exceed 0.9 yield.

In the original design, missile protection was to be provided by the steel doors and bulkheads. The following paragraph describes the basis for that design and is provided for historical purposes.

For impact from missiles, the doors and bulkheads may deform but will stop missiles D1, D2, and D3 of spectrum D (Table 3.5.5-5) and remain in position. For missiles larger than those listed, it was assumed that these missiles would be dispersed so only one of the four doors or bulkheads would be struck severely enough for its diesel generator to become inoperable. Redundancy of the diesel generating units allows this loss.

Sections 3.8.4.1.3 and 3.5.5 discuss the upgrading of the missile spectrum for the equipment access openings to include missiles D4, D5, and D6 of spectrum D. Additional protection has been provided in the form of precast concrete bulkheads placed in front of the existing doors. The existing doors as will function as barriers to prevent scabbed particles from the concrete bulkheads entering the diesel generator compartments.

3.8.4.6 Materials, Quality Control, and Special Construction Techniques

3.8.4.6.1 Materials

General

The following materials were used in the construction of other Category I structures:

1. Concrete.
2. Reinforcing steel.
3. Miscellaneous structural steel.
4. Wood.

Concrete

Concrete work was the same for other Category I structures as performed for the interior concrete structures and described in Section 3.8.3.6.1, except that concrete strength requirements were generally less. In general the following concrete strength requirements were used:

Fill Concrete - 2000 lbs/in^2 at 90 days. This concrete class was used to replace overexcavated rock and to protect excavated areas from possible contamination or decomposition from weathering during construction.

Structural Mass Concrete - 3000 lbs/in^2 at 90 days. This class of concrete was principally used in massive wall and base slab pours where reinforcing steel requirements for flexure were less than 0.6 percent and where it was generally desirable to restrict the hydration heat rise of the concrete.

Normal Structural Concrete - 3000 lbs/in^2 at 28 days. This class of concrete was used in superstructure floors and in thin walls generally less than 18 inches thick.

Reinforcing Steel

See Section 3.8.1.6.

Structural Steel

See Section 3.8.1.6.

3.8.4.6.2 Special Construction Techniques

The structures were built in accordance with standard construction techniques.

3.8.4.6.3 Quality Control

The concrete quality requirements applied to other Category I structures were the same as provided in section 3.8.1.6.2 for the concrete shield building.

Some concrete mixes did not meet the TVA General Construction Specification No. G-2 requirement for strength during some time periods. The percent of tests less than the specified strength exceeded the G-2 requirement of 10 percent. All concrete pours placed during "low strength" time periods were evaluated.

The "low strength" periods for the mixes with specified strengths of 3000, 4000, and 5000 psi at 28 days were evaluated by determining estimated inplace design strengths based on the size of the member and the long-term strength gain based on a site testing program. The structure was evaluated for a reduced design strength if the inplace strength was less than required by the calculations or less than specified on the design drawings. The estimated inplace strengths were also verified by the results of 90 day strength tests on standard cured cylinders made at the time of the concrete placement.

A concrete mix with a specified strength of 8000 psi at 90 days was used for some walls in the valve rooms. This mix did not generally achieve the required strength. An evaluation of the strength results was performed and the structures evaluated for reduced equivalent specified strengths (6800 psi to 7600 psi depending on the time period).

The Control Room shield doors, railway access hatch covers, railroad access doors, manways in the RHR Sump Valve Room, and the pressure confining personnel doors were designed and erected by TVA in accordance with TVA's Quality Assurance Program. Design and fabrication by the Contractor were in accordance with the Contractor's Quality Assurance Program which was reviewed and approved by TVA's Design Engineers. The Contractor's Quality Assurance Program covers the criteria in Appendix B of 10 CFR 50.

Fabrication procedures such as welding and nondestructive testing were included in appendices to the Contractor's Quality Assurance Program.

ASTM standards were used for all material specifications and certified mill test reports were provided by the Contractor for materials used for all load carrying members.

Although the fuel pool gates were not procured under a formal QA program, TVA has determined that minimum QA standards were followed in the construction of these gates.

3.8.4.7 Testing and Inservice Surveillance Requirements

3.8.4.7.1 Concrete and Structural Steel Portions of Structures

A program to monitor the settlement of the Diesel Generator Building was instigated. See Section 2.5 for information concerning settlement readings.

3.8.4.7.2 Miscellaneous Components of the Auxiliary/Control Building

Control Room Shield Doors

After erection and adjustment the doors were inspected for proper operation of the dogs and free movement on the trolleys.

After the initial inspection, periodic visual inspections of the doors are to be made. Parts inspected during these visual inspections are to include all bolted connections, structural members for paint deterioration, connections to trolleys, and dogs.

Railway Access Door

Prior to shipment of the door from the Contractor's plant, the splice welds in the skin plate of the door and welds among the periphery of the skin plate and structural members were magnetic particle tested.

After completion of the initial tests and inspections, periodic visual inspections of the door and its parts are to be made. Parts inspected are to include all bolted connections, limit switches, door tracks, and rollers. Painting is to be inspected for evidence of deterioration, and the seals are to be carefully inspected for cracks, blemishes, or any other indications of deterioration of the rubber.

Manways in RHR Sump Valve Room

After completion of erection and adjustments, the manways were checked for leakage by pressurizing the space between the sealing rings on each door to 30 lbs/in^{2}g (125 percent design pressure). The test pressure was applied to the seals for 30 minutes with no detectable leakage. Individual compartments of the sump valve rooms were also pressure tested.

Pressure Confining Personnel Doors

After the initial inspection, periodic visual inspections of the doors are to be made. Parts inspected during these visual inspections are to include all bolted connections, structural members for paint deterioration, latching or dogging mechanisms and limit switches for physical condition, and the seals. The seals are to be carefully inspected for cracks, blemishes, or any other indications of deterioration and for proper seating at the sealing surfaces.

Spent Fuel Pool Gates

After initial inspection, periodic visual inspection of the gates are to be made. The seals are to be carefully inspected for cracks, blemishes, or any other indications of deterioration.

3.8.4.7.3 Diesel Generator Building Doors and Bulkheads

All parts of the doors and bulkheads are to be inspected at periodic intervals for free operation, paint deterioration, and weld condition.

3.8.4.7.4 ERCW Pumping Station and Access Cells

The initial program to monitor settlement of the ERCW Pumping Station and access cells is discussed in Section 2.5.5.3.2.

3.8.5 Foundations and Concrete Supports

3.8.5.1 Description of Foundation and Supports

3.8.5.1.1 Primary Containment

The primary containment foundation consists of a 9-foot-thick-circular reinforced concrete structural slab 131 feet 7 inches in diameter anchored to bedrock by a concentric pattern of 155 No. 11 reinforcing bars grouted 15 feet into rock near the outer periphery of the slab. The slab is further keyed and anchored into rock in the central portion by the 8-foot-thick walls of the reactor cavity extending a total of 27 feet into rock. A 2-foot-minimum-thick concrete subpour underlies the structural concrete and caps the top of the irregular rock surface. The base rock consists of alternating layers of hard limestone and softer shale whose bedding planes are inclined which accounts for the irregularity of all excavated surfaces. This rock was pressure grouted on 10-foot centers in two stages to a depth of 45 feet to assure a solid unyielding base for support of the reactor. See Section 2.5.1.7, 2.5.1.8, and 2.5.1.10 for additional discussion of the rock base and foundation treatment.

The interior concrete structures described in Section 3.8.3 constitute the Primary Support System for all equipment in the containment structures. For steel containment vessel anchorage refer to Appendix 3.8C. All major equipment such as steam generators, reactor coolant pumps, and pressurizers are anchored through the steel liner plate into the 9-foot-thick concrete base slab. Typical anchorage details are shown on Figure 3.8.2-7.

The base liner plate is anchored to the foundation through the use of embedded "T" sections which have provisions for leveling before concrete was placed. The embedded anchors were used as screed guides during the placement of the concrete to ensure that a flat surface was obtained coincident with the top of the anchors. See Figure 3.8.2-7 for a typical detail of a base liner plate anchor. All welded joints in the base liner plate were made at anchors. All joints in the base liner plate are equipped with leak chases to facilitate testing for leak tightness. All major tensile loads are anchored through the base liner plate in such a manner as to prevent the liner from becoming a stress carrying member.

3.8.5.1.2 Foundations of Other Category I Structures

Auxiliary Control Building

All of the Auxiliary Control Building, except the waste packaging area and the Condensate Demineralizer Waste Evaporator Building portion, is supported on rock with foundation treatment as described below.

Rock excavation varied from 15 feet to 40 feet in depth in various parts of the structure. The base slab over the 2-foot-minimum-thick subpour topping the rock surface was generally 2 feet thick. It was anchored into rock to resist hydrostatic uplift pressures under flood conditions by approximately 1836 No. 11 bars and 102 No. 14 bars grouted to various depths into rock. The depth is dependent on the elevation of the slab.

The waste packaging area is separated from the rest of the Auxiliary Building by 2 inches of fiberglass expansion joint material. The 45-inch-thick base slab at grade Elevation 705 is supported on H-bearing piles.

The base slab of the Condensate Demineralizer Waste Evaporator Building is 2-foot and 6-inches thick, except for the pipe tunnel part of the building which is 2-foot and 3-inches thick. The building is supported on H-bearing piles and is separated from the rest of the Auxiliary Building by 2 inches of fiberglass expansion joint material.

The base slabs of the Additional Equipment Building portion are 18-inches thick and 24-inches thick for Units 1 and 2, respectively. These slabs are at grade Elevation 705 and rest on a grillage of reinforced concrete foundation walls and slabs supported to sound rock. These structures are separated from the Reactor Building and the rest of the Auxiliary Building by two inches of fiberglass expansion joint material.

Condenser Cooling Water Pumping Station and Retaining Walls

The setting of the intake structure required rock excavation to Elevation 645. Because of the nature of the rock neat line excavation was impossible. As a result the end piers and back wall were cast directly against the irregular sloping rock surface up to Elevation 669. The base slab varied in thickness from 2 feet to 3 feet but under normal conditions merely served as a footing to transfer loads from the configuration of walls and piers to the base rock. Foundation stresses did not warrant grouting of the base rock.

The wing walls of the intake structure are designed to protect the forebay of the intake against earth slides during an earthquake. The base slab of these cantilevered walls rests on sound rock or a leveling pour of fill concrete to sound rock. The rock walls of the forebay were covered with a 12-inch-minimum thickness of concrete to prevent possible erosion of material from joints in the rock due to washing action of water in the intake channel.

East Steam Valve Room

The East Steam Valve Room is separated from the Shield Building by 1 inch of fiberglass joint material. The base slab at grade elevation is supported by eight concrete caissons 4 foot in diameter anchored into sound rock.

ERCW Pumping Station and Access Roadway

The interlocked tremie concrete cells supporting the ERCW pumping station and the access roadway cells are founded on bedrock. The tremie concrete is contained by sheet piles. The cells are shown in Figures 3.8.4-7, 3.8.4-8, and 3.8.4-9.

The ERCW piping support slab is a pile supported structure as shown on Figure 3.8.4-9.

Diesel Generator Building

The base slab of the Diesel Generator Building is discussed in Section 3.8.5.5.2. The depth of soil above bedrock varies from approximately 65 feet to 85 feet. A thorough investigation of soil properties under this building was made to determine the sensitivity of the soil properties under dynamic loading in order to assure stability of the slopes above and below the building under earthquake loading. For settlement analysis and record, see Section 2.5.5.3 and Figure 2.5.5-1, respectively.

Refueling Water Storage Tank Foundation

The refueling water storage tank (RWST) foundation provides support for the RWST and also provides a reservoir for storage of borated water after a postulated rupture of the RWST. The foundation is of reinforced concrete construction. The foundation is 53 feet 6 inches in diameter and is approximately 2.75 feet thick. Shear keys are provided to assure no sliding displacement. The allowable settlement for the foundation is limited by the deflection allowed in the Category I piping that connects to the tank. To limit settlement, the foundation is constructed on a uniform depth of engineered granular fill. Approximately 1500 cubic yards of granular fill has been placed below each foundation. The minimum base elevation for the granular fill is at Elevation 690, or if the soil below Elevation 690 had been disturbed by previous excavation, then the uniform base elevation for the granular fill was increased to allow for removal of the disturbed soil. The minimum diameter of the granular fill below the tank foundation is 54 feet.

3.8.5.2 Applicable Codes, Standards, and Specifications

See Sections 3.8.1.2, 3.8.3.2, and 3.8.4.2.

3.8.5.3 Loads and Loading Combinations

The loads and loading combinations are described in Sections 3.8.1.3, 3.8.3.3, and 3.8.4.3.

3.8.5.4 Design and Analysis Procedure

3.8.5.4.1 Primary Containment Foundation

The foundation was analyzed as a slab on an elastic foundation (considering the properties of the rock). The slab was divided into wedge-shaped radial strips.

One wedge was analyzed with normal operating loads and an adjacent wedge was analyzed with maximum uplift load from a steam generator support. The deflections of these two adjacent wedges were imposed upon a circumferential section. The wedge sections were used to determine radial moments and shears, and the circumferential section was used to determine circumferential moments and shears. The analysis was made using computer code, "Finite Element Stress Analysis (AMG033)" described in Appendix 3.8D.

Rock properties were considered to a depth of 22 feet below the slab and 13 feet beyond the outer radius of the slab. These dimensions are of sufficient magnitude to show the effects of slab loading on the rock. Beyond these dimensions, the in situ stresses are greater than those caused by the foundation loading. End conditions for the rock are: (1) zero horizontal deflection along the vertical face and (2) zero vertical deflection along the horizontal face.

3.8.5.4.2 Auxiliary-Control Building

The Auxiliary-Control Building is designed for maximum flood conditions with water at grade Elevation 705. Under these conditions the hydrostatic uplift is greater than the dead load of the slab and anchorage into rock is required. Only the buoyant weight of rock was considered in determining the minimum depth of rock which must be engaged by anchor rods to resist uplift. Various depth anchor rods were used; however, the spacing of rods was restricted in such a manner that the buoyant weight of the rock for the full depth of the pattern of anchors was considered effective. The minimum depth of anchor was based on the maximum uplift load on the bar divided by an 80 lb/in^2 allowable bond strength on the 3-inch hole. The 2-foot base slab was designed as a flat plate to resist the maximum uplift loads between rock anchors.

The slabs of the Condensate Demineralizer Waste Evaporator Building and the waste packaging area were designed as pile supported foundations. Walls were thicker than necessary because of shielding requirements.

The slabs for the Additional Equipment Building portion are supported to rock by a grillage of reinforced concrete foundation walls and slabs extending down to rock. Weep holes are provided in the foundation walls to relieve possible buildup of hydrostatic pressure. Earthfill is placed within the Foundation Wall System to equalize external soil pressures and to support the

base slab at Elevation 706 during placement. The foundation slab was designed to resist the maximum overturning effect on the building. The walls were considered to span between bedrock, the bottom of the base slab, and other foundation walls framing into them.

3.8.5.4.3 Condenser Cooling Water Pumping Station and Retaining Walls

The design of the base slab was controlled by uplift considerations under assumed unwatered conditions with one or two bays dry and full uplift over 100 percent of the area between the slab and the base rock. The slab was designed as a flat plate to span between piers.

3.8.5.4.4 ERCW Pumping Station and Access Roadway

As shown in Figures 3.8.4-7, 3.8.4-8, and 3.8.4-9, the cofferdam cells of the pumping station and access roadway cells were originally analyzed as a single unit due to their configuration. The pumping station cells were also analyzed as a single unit. A more recent calculation was made which proved that the roadway cells were acceptable when analyzed individually. All cells were investigated for stability and analyzed seismically. The ERCW support slab was designed as a pile supported foundation.

3.8.5.4.5 Soil Supported Structures

A uniform or linear distribution of base pressure was assumed in the design of all soil supported structures and all base slabs were essentially designed as flat plates.

Pile supported structures were designed using conventional frame analysis or through the use of ICES STRUDL-II finite element computer program.

3.8.5.4.6 Refueling Water Storage Tank Foundation

The foundation was analyzed as a slab on an elastic foundation (considering the properties of the engineered granular fill and the in situ soil beneath).

3.8.5.5 Structural Acceptance Criteria

3.8.5.5.1 Primary Containment Foundation

The base slab design contained the following conservative features:

1. Reinforcement in the radial direction was designed to carry all the loads.

2. Reinforcement in the circumferential direction was designed for the maximum deflection differentials of the radial strips as if they were free to deflect.

   Considering two-way plate action the slab has almost double the load carrying capacity of the design.

3. The worst combination of steam generator, and reactor coolant pump supports were combined in the radial strip design without consideration for the counteracting jet load which must impinge upon the slab for the support uplift loads to occur.

4. The anchorage into base rock at the outer periphery was not utilized to reduce flexural stresses in the base slab.

3.8.5.5.2 Foundations of Other Category I Structures

Auxiliary-Control Building

All flexural stresses in the base slab other than those induced by restraining moments at the exterior walls are the result of hydrostatic uplift loads at the base of the slab. The close spacing of anchor rods of 4 feet to 5 feet on centers greatly reduced reinforcement requirements for flexure in the 2-foot-thick structural slab. Pullout tests were performed on eight No. 11 bars stressed to 37,500 lbs/in^2 to verify the 80 lbs/in^2 allowable bond at the contact surface of grout and rock. The depth of embedment ranged from 35 inches to 45 inches with bond stresses at the rock contact surface ranging from 144 lbs/in^2 to 160 lbs/in^2 without a failure at the contact surface. In one instance the bar did pull out of the grout at a bond stress along the bar of 356 lbs/in^2 and in another instance the stress in the bar was increased to 53,000 lbs/in^2 and bond failure along the bar occurred at a bond stress of 512 lbs/in^2.

Since the minimum depth of anchorage into rock was more than twice the tested depth the factor of safety against bond failure in the anchorage in all cases was greater than 4.

The stability of the Additional Equipment Building foundations was investigated for the controlling seismic event. The maximum actual compression on rock is 29.5 k/ft^2 (205 lbs/in ^{2}) as compared to the maximum allowable value of 500 lb/in^2. The safety factor against overturning is 1.65.

Condenser Cooling Water Pumping Station and Retaining Walls

In the Intake Pumping Station the base slab serves no real purpose as a foundation since the stress under the piers is very low and the piers could easily have rested directly on rock. The principal design feature of the base slab is to serve as a water barrier under maintenance conditions with one or two bays dewatered.

ERCW Pumping Station and Access Roadway

The ERCW pumping station cells and access roadway cells as described in Section 3.8.5.1.2 are founded on bedrock. The stresses in the concrete cells are low since the primary function of the concrete is to provide mass for stability against overturning.

East Steam Valve Room

The base slab of the East Steam Valve Room is supported by eight concrete caissons anchored into sound rock. The depth of anchorage is such that it resists any uplift or overturning forces on the structure.

Diesel Generator Building and Emergency Cooling Water Structures

These structures are situated as described in Section 3.8.5.1.2. The Diesel Generator Building consists of a 9-foot 9-inch thick base slab which distributes superstructure loads to the supporting soil medium. A concrete apron extending 13 feet from the edge of the base slab is used to decrease the bearing on the subgrade to less than the allowable capacity.

3.8.5.6 Materials, Quality Control, and Special Construction Techniques

3.8.5.6.1 Materials

Concrete and Reinforcing Steel

See Section 3.8.1.6.1 and 3.8.4.6.1.

Backfill Materials

Backfill material was taken only from areas designated by the soils investigation program (see Section 2.5) as suitable for backfill material.

3.8.5.6.2 Quality Control

See Section 3.8.4.6.3 and 3.8.1.6.2.

Base Rock

The base area of all rock supported structures was inspected by the principal Civil Design Engineer in conjunction with an experienced TVA Geologist during final cleanup of rock surfaces to determine its suitability as a foundation.

Backfill

Quality control requirements for backfill material were as specified in Section 2.5.1.11.1.

3.8.5.6.3 Special Construction Techniques

Normal construction procedures were used in the construction of all other Category I structures.

3.8.6 Category I (L) Cranes

3.8.6.1 Polar Cranes

3.8.6.1.1 Description

See Figures 3.8.6-1 through 3.8.6-5.

There are two polar cranes, one in each of the reactor buildings. Each crane is a single trolley, overhead, electric traveling type; operating on an 86-foot diameter rail at the top of the crane wall and above the reactor. Each crane has a main hoist capacity of 175 tons and an auxiliary hoist capacity of 33 tons.

The main and auxiliary hoist motions are driven by AC Variable Frequency Motor drives with eddy current brakes for emergency lowering and stepless (infinite) speed control. The bridge and trolley travel motions are driven by AC variable frequency drives and stepless (infinite) control.

Structural portions of the crane bridges consist of welded box-type girders and welded, haunched, box-type end ties. Structural portions of the trolleys consist of welded box-type trucks and welded cross girts which are bolted to the trucks.

Control of each crane is from a cab located below the bridge walkway at one end of a girder.

3.8.6.1.2 Applicable Codes, Standards, and Specifications

The following codes, standards, and specifications were used in the design of the cranes:

National Electric Code, 1970 edition

National Electrical Manufacturers Association, Motor and Generator Standards, Standard MG-1, 1970 edition.

Electric Overhead Crane Institute Specification 61, "Specifications for Electric Overhead Traveling Cranes."

Federal Specification RR-W-410a, class 3.

American Society for Testing and Materials, "Material Standards," 1970 edition.

American Welding Society, D1.0, Code for Welding in Building Construction.

Section 1.23, Part I, "Specification for the Design, Fabrication, and Erection of Structural Steel for Buildings," Manual of Steel Construction, Part 5, American Institute for Steel Construction , 6th edition, 1963. Where date of edition, copyright, or addendum is specified, earlier versions of the listed documents were not used. In some instances, later revisions of the listed documents were used where safety was not compromised.

American Gear Manufacturers Association Standards for Spur, Helical, Herringbone, and Bevel Gears.

The cranes meet applicable requirements of the listed codes, standards, and specifications.

3.8.6.1.3 Loads, Loading Combinations, and Allowable Stresses

Loads, loading combinations, and allowable stresses are shown in Table 3.8.6-1.

3.8.6.1.4 Design and Analysis Procedure

The bridge girders and end ties for each crane were designed as simple beams in the vertical plane and as a continuous frame in the horizontal plane. Stresses in the girders and end ties were computed with the trolley positioned to produce maximum stresses.

Trolley positions used were the maximum end position, one-third point, and the point near the center which produces maximum bending moments.

All trolley members were designed as simple beams.

Design of the bridge girders and end ties was by TVA and utilized a computer program written by TVA. The contractor was required to check the size of all members designed by TVA. All mechanical parts and all structural members except the bridge girders and end ties were designed by the contractor. All calculations and designs made by the contractor were reviewed by TVA design engineers.

In designing for earthquake conditions, forces due to accelerations at the crane bridge rails were used as static loads for determining component and member sizes. After establishing component and member sizes, a dynamic analysis, using appropriate response spectra, was made of the total crane to determine that allowable stresses had not been exceeded.

Earthquake accelerations at the bridge rails were determined by dynamic analysis of the structures supporting the crane rails. These accelerations are as follows:

1/2 Safe Shutdown Earthquake (1/2 SSE)

Lateral (north-south)	0.35 g
Lateral (east-west)	0.33 g
Vertical	0.085 g

Safety Shutdown Earthquake (SSE)

Lateral (north-south)	0.50 g
Lateral (east-west)	0.45 g
Vertical	0.17 g

3.8.6.1.5 Structural Acceptance Criteria

Allowable stresses for all load combinations used for the various crane parts are given in Table 3.8.6-1. For normal load conditions, the allowable stresses provide safety factors of 2 to 1 on yield for structural parts and 5 to 1 on ultimate for mechanical parts except for wire ropes which

have a safety factor of 6 to 1 on ultimate. For limiting conditions such as a safe shutdown earthquake and stall, stresses do not exceed 0.9 yield. Factors of safety for a 1/2 safe shutdown condition are the same as for a normal condition.

3.8.6.1.6 Materials, Quality Controls, and Special Construction Techniques

A36 steel was used for the major structural portions of the crane. Design by TVA and erection by TVA were in accordance with TVA's quality assurance program. Design and fabrication by the contractor were in accordance with the contractor's quality assurance program which was reviewed and approved by TVA's design engineers. The contractor's quality assurance program covers the criteria in Appendix B of 10 CFR 50. Fabrication procedures such as welding, stress relieving, and nondestructive testing were included in appendices to the contractor's quality assurance program.

ASTM standards were used for all material specifications and certified mill test reports were provided by the contractor for materials used for all load carrying members.

3.8.6.1.7 Testing and Inservice Surveillance Requirements

Upon completion of erection and adjustments on each crane, all crane motions and operating parts were thoroughly tested with the crane handling 125 percent of rated capacity. Tests were made to prove the ability of each crane to handle its rated capacity and smaller loads smoothly at any speed within the specified speed range. Each brake was tested to demonstrate its ability to hold the required load.

After the initial test, periodic visual inspections of each crane are to be made. Parts inspected during the visual inspection are to include all bolted parts, couplings, brakes, hoist ropes, hoist blocks, limit switches, and equalizer systems.

3.8.6.1.8 Safety Features

The cranes were designed to withstand a 1/2 Safe Shutdown Earthquake and a Safe Shutdown Earthquake and to maintain any load up to rated capacity during and after the earthquake period.

The bridges are equipped with double flange wheels, spring set, electrically released brakes which set and firmly lock the wheels when the bridge drive machinery is not operating or when power is lost for any reason, and hold down lugs which run under the rail heads. During an earthquake the cranes may be displaced, but will not leave the crane rail supporting structure because of a seismically qualified girder to crane wall bumper on the ends of each girder. Guide rollers, mounted on each extreme corner truck travel against the outer surface of the bridge rail to assure bridge-truck alignment.

The trolleys are each equipped with double flange wheels, two spring set, electrically released brakes which set and firmly lock the driving wheels when the trolley drive machinery is not operating or when power is lost for any reason, and hold down lugs which run under the rail

heads. Positive wheel and bumper stops are provided at both ends of the bridges. During an earthquake, the trolleys could be displaced, but they will not leave their rails which are firmly attached to the bridge structures.

Safety features provided for each hoist include two independent gearing systems, two brakes with each of the brakes operating through one of the independent gearing systems, two upper travel limit switches, one lower travel limit switch, overspeed switches set to trip at 120 percent of maximum rated speed, and emergency eddy current braking for controlled lowering in case of simultaneous failure of AC power source and holding brakes. In addition the hoists are provided with a hydraulic equalizing cylinder in place of a conventional equalizing sheave in order to prevent dropping of the load in case of a single rope failure. Holding brakes for the hoists are the spring-set, electrically released type with provisions for manual release of the brakes. The capacity of each main hoist brake is 150% of the rated capacity of the main hoist motor.

Safety control features provided for all motions consist of torque limitation, overcurrent protection, undervoltage protection, control actuators which return to the stop position when released, and an emergency-stop pushbutton.

3.8.6.2 Auxiliary Building Crane

3.8.6.2.1 Description

See Figures 3.8.6-6 through 3.8.6-9.

The crane in the auxiliary building is a single trolley, overhead, electric traveling type with a span of 77 feet. The crane has a main hoist capacity of 125 tons and an auxiliary hoist capacity of 10 tons. The main hoist has been upgraded to single failure proof. The main hoist must meet NUREG-0554 single failure proof criteria for compliance with 10CFR72.124(a), “Design for Criticality Safety,” for handling spent fuel casks.

The main hoist, auxiliary hoists, bridge and trolley travel motions are AC operated with static-stepless regulated speed control.

Structural portions of the crane bridge consist of welded, box-type girders and welded, haunched box-type end ties. Structural portions of the trolley consist of welded, box-type trucks and welded cross girts.

Control of the crane is from a control console in the operators cab which is located at mid-span of the crane beneath the west girder.

The one crane serves the needs of two reactor units. It handles the fuel casks, new fuel shipments to the new fuel storage, shield plugs at the equipment access doors, and any large pieces of equipment going into or out of the reactor buildings via the auxiliary building.

3.8.6.2.2 Applicable Codes, Standards, and Specifications

The following codes, standards, and specifications listed in Section 3.8.6.1.2 were used in the design of the crane with the following additions:

> Institute of Electrical and Electronic Engineers, Criteria for Protection Systems for Nuclear Power Generating Stations, Standard No.279, 1971 edition.

AWS, D2.0, Code for Welded Highway and Railway Bridges.

The following codes, standards and specifications were used in the qualification of the crane for the upgrade to single failure proof:

CMAA-70-1975 (version 2000 used for controls and main hoist upgrade, except for speeds, which were 1975 version)

NUREG-0612
NUREG-0554
EDR1-(P)-A Rev. 3 (Ederer Topical Report)
AWS D1.1 & D14.1
AISC 9^{th} Edition (girder web buckling check only)

The cranes meet applicable requirements of the listed codes, standards, and specifications.

3.8.6.2.3 Loads, Loading Combinations, and Allowable Stresses

Loads, loading combinations, and allowable stresses conform to the acceptance criteria in Section 3.8.6.2.5.

3.8.6.2.4 Design and Analysis Procedure

See Section 3.8.6.1.4 except for the following exceptions:

A new dynamic seismic analysis was performed for the upgrade to single failure proof. Earthquake accelerations were determined by this analysis using the appropriate building response spectra at the crane rails.

Trolley positions used were the maximum end position, one-quarter point, and the point near the center which produces maximum bending moments.

3.8.6.2.5 Structural Acceptance Criteria

Allowable stresses for all load combinations used for the various crane parts conform to the codes, standards, specification, etc., in Section 3.8.6.2.2.

For the crane structure OBE and SSE stresses do not exceed .9 yield.

3.8.6.2.6 Materials, Quality Controls, and Special Construction Techniques

See Section 3.8.6.1.6. In addition, documentation reviews and some visual weld inspections of critical welds were conducted during the upgrade to single failure proof as part of the evaluation to qualify the crane to single failure proof.

3.8.6.2.7 Testing and Inservice Surveillance Requirements

See Section 3.8.6.1.7. In addition, testing and surveillance requirements to meet the requirements of NUREG-0554 single failure proof and NUREG-0612 will be performed.

3.8.6.2.8 Safety Features

The crane was designed to withstand a safe shutdown earthquake (SSE) and to maintain any load up to rated capacity during and after the earthquake period.

The bridge is equipped with double flange wheels, spring-set, electrically released brakes which set and firmly lock the wheels when the bridge drive machinery is not operating or when power is lost for any reason. During an earthquake the crane may be displaced, but it will not leave the crane rails supports. The crane end ties contact the building wall if displacement exceeds three inches. Positive wheel and bumper stops are provided at each end of the bridge travel.

The trolley is equipped with double flange wheels, two spring-set, electrically released brakes which set and firmly lock the driving wheels when the trolley drive machinery is not operating or when power is lost for any reason, and hold down lugs which run under the rail heads. Positive wheel and bumper stops are provided at both ends of the bridge. During an earthquake, the trolley could be displaced, but it will not leave the rails which are firmly attached to the bridge structure.

Safety features provided for the main hoist is in accordance with Ederer's Generic Licensing Topical Report EDR-1. Ederer's Generic Topical Report EDR-1 meets NUREG-0554 and NUREG-0612 requirements for single failure proof cranes. Ederer's eXtra Safety And Monitoring (X-SAM) system include the Hoists' Integrated Protective System (HIPS) that is comprised of a energy absorbing torque limiter, emergency drum brake system, failure detection system, drum safety structure, wire rope protection, and emergency stop button. The auxiliary hoist include two independent gearing systems, and two brakes with each of the brakes operating through one of the independent gearing systems. Each hoist include two upper traveling limit switches, one lower travel limit switch, overspeed switches set to trip at 120 and 125 percent of maximum rated speed for the auxiliary and main hoist, respectively, and emergency dynamic braking for controlled lowering in case of simultaneous failure of AC power source and holding brakes. In addition the main hoist is provided with a hydraulic equalizing cylinder in place of the conventional equalizing sheave in order to prevent dropping of the load in case of a single rope failure. The auxiliary hoist has a two-part whip-style reeving so that a single rope failure will not drop the load. Holding brakes for the hoists are the spring-set, electrically released type with provisions for manual release of the brakes. The capacity of the main hoist high speed holding brake is 150% of the rated capacity of the main hoist motor. The minimum capacity of the main hoist wire rope is 115% of the Maximum Critical Load (MCL).

Movements of the bridge and trolley in the vicinity of the spent fuel pool are restricted by limit switches (Figure 3.8.6-10) designed to the requirements of IEEE Standard No. 279-1971, in order to prevent the crane from transporting a load over the irradiated fuel in the pool as well as preventing interference between the cask handling system (125-ton crane) and the fuel hoist system. Trolley movement is also restricted by mechanical stops (Figure 3.8.6-11). The design collision between trolley bumpers and stops, including mechanical stops, was taken as the force produced by the trolley traveling with 125-ton load at maximum rated speed with power off. The design collision between bridge bumpers and stops was taken as the force produced by the crane traveling with 125-ton load at maximum rated speed with power off and trolley centered on bridge. Figure 3.8.6-12 is a sectional elevation view through the spent fuel pit showing the relationship of the fuel pit and crane while handling the fuel cask.

The electrical interlocks and mechanical stops will be administratively bypassed to allow use of the crane for handling the fuel transfer canal gate or any other administratively approved load

under 2100 lbs. The bypass is accomplished by means of a keyed switch, which when activated, bypasses all interlocks controlling crane movements and illuminates a green indicating light located beneath the operator's cab. The indicating light is visible from any point on the operating floor.

A key operated bypass, along with three pushbutton stations for opening the main line power disconnect, ensure that all bypass operations are controlled. The three pushbutton stations are located along the north wall of the auxiliary building about 4 feet above the 734.0 operating floor. These stations are readily accessible to personnel on the operating floor.

For testing of the interlocks after a bypass operation, each limit switch will be manually operated to ascertain proper function. With each of the limit switches in the operated position, the affected crane control will be operated to verify that the interlock is functioning properly.

Safety control features provided for all motions consist of torque limiting devices, overcurrent protection, undervoltage protection, control actuators which return to the stop position when released, and an emergency-stop pushbutton.

1. Includes all temporary construction loading during and after construction of containment.

2. V_c is lower for tension members and is essentially the same as given by (ACI 318-71).

LOADS NOMENCLATURE:

D	Dead loads, or their related internal moments and forces
F_{eqo}	Operating basis earthquake
F_{eqs}	Design basis earthquake
L	Live load, or their related internal moments and forces
P_a	Accident/incident maximum pressure
R_o	Piping loads during operating conditions
R_a	Piping loads due to increased temperature resulting from the design accident
T_a	Thermal loads under the thermal conditions generated by the postulated break and including T_o.
T_o	Operational temperature
Y_r	Reaction load on broken pipe due to fluid discharge

* The term “design basis earthquake” has the same meaning as the term “safe shutdown earthquake.”

Table 3.8.3-2A

Abnormal/ Severe Environ-mental	1.0	1.0	1.0	1.25	---	1.25	---	---	1.0	---	ϕ = 0.85
Abnormal/ Extreme Environ-mental	1.0	1.0	1.0	1.0	---	---	1.0	---	1.0	1.0	

1. Includes all temporary construction loading during and after construction of containment.
2. V_c is lower for tension members and is given by $V_c = 2\sqrt{f_c'}\,(1 + 0.002N_u/A_g)$, with N_u negative for tension.
3. The allowable stress is increased by 33-1/3% when temperature effects are combined with other loads.
4. The tensile strain may exceed yield when the effects of thermal gradients are included in the load combination, i.e., f_s can be <=f_y, and ε_s can be >ε_y when thermal effects are included.
5. The load combinations, load factors and allowable stresses in this table are based on the adopted ASME Section III Division 2, 1975 which are, in general, consistent with the proposed ACI 359 - ASME Section III Division 2, 1973 with the exception of load factors associated with the Y_r load.
6. Structural steel components of the through-bolted connection frames and tapered steel shims were designed in accordance with TVA Design Criteria SQN-DC-V-1.3.2, Miscellaneous Steel Components for Class I Structures.

LOADS NOMENCLATURE:

D	Dead loads, or their related internal moments and forces
F_{eqo}	Operating basis earthquake
F_{eqs}	Design basis earthquake
L	Live load, or their related internal moments and forces
P_a	Accident/incident maximum pressure
R_o	Piping loads during operating conditions
R_a	Piping loads due to increased temperature resulting from the design accident
T_a	Thermal loads under the thermal conditions generated by the postulated break and including T_o.
T_o	Operational temperature
Y_r	Reaction load on broken pipe due to fluid discharge (corresponds to R_r in ASME Section III Div. 2, 1975

* The term "design basis earthquake" has the same meaning as the term "safe shutdown earthquake."

Table 3.8.3-3

SEALS BETWEEN UPPER AND LOWER COMPARTMENTS

Loads, Loading Combinations, and Allowable Stresses

The seals were designed to withstand loads and environments resulting from the following conditions:

Normal

Differential pressure on seal	-	Negligible
Temperature	-	60° to 120° F
Radiation	-	2.0 x 10^7 rads for 40-year life
Relative movement of vessel to concrete structure	-	Less than combined accident and earthquake condition

Accident

Differential pressure on seals	-	12 psi
Temperature	-	327° F in air and steam for first 1-1/2 hours and 200°F in air and steam for next 10-1/2 hours
Radiation	-	4 x 10^7 rads (gamma) total integrated dose
Relative movement of vessel	-	Less than combined accident and earthquake condition

Earthquake

Earthquakes may occur under accident or normal conditions with pressure, temperature, and radiation as listed above. Maximum relative movement of vessel to concrete structure for combined accident and earthquake are as follows:

2.16 inches ± horizontal radially
1.00 inch ± horizontal tangential
0.60 inch vertical up; 0.30 inch vertical down

Table 3.8.3-4 (Sheet 1)

PERSONNEL ACCESS DOORS IN CRANE WALL

Loads, Loading Combinations, and Allowable Stresses

Normal operating conditions are as follows:

Pressure	-	Negligible
Temperature	-	60° to 120° F
Radiation	-	2 x 10^7 rads for 40-year life

The effect of pipe rupture accidents on the doors varied with the location and intensity of the accidents. The three types of pipe accidents producing maximum effect on the doors and conditions accompanying these accidents are as follows:

a. Accidents Without Jets or Missles Hitting the Doors

Temperature	327° F for first 1-1/2 hours 200° F for next 10-1/2 hours
Radiation	4 x 10^7 rads (gamma) total integrated dose
Pressure	12 psig acting from inside crane wall for 12 hours

b. Accidents With Jet Hitting a Door

Temperature	700° F maximum
Force and impact	As produced by maximum jet
Radiation	4 x 10^7 rads (gamma) total integrated dose

Duration of maximum temperature and maximum force from jet is for not more than 10 seconds and then gradually decreases. Pressure and temperature after maximum temperature and force are as outlined in (a) above.

c. Accidents With Missile and Jet from the Same Source Striking a Door

Temperature	700° F maximum
Force and impact	As produced by jet and missile
Radiation	4 x 10^7 rads (gamma) total integrated dose

Duration of maximum temperature and maximum force from jet is for not more than 10 seconds and then gradually decreases. Pressure and temperature after maximum temperature and force are as outlined in (a) above.

Table 3.8.3-4 (Sheet 2)

PERSONNEL ACCESS DOORS IN CRANE WALL

Loads, Loading Combinations, and Allowable Stresses

Structural Door and Frame Assembly

No.	Load Combinations	Allowable Stresses (psi) Tension	Compression	Shear
I	With door closed or open: Dead load plus *SSE	0.9 F_y	0.9 F_y	0.6 F_y
II	With door closed: Dead load plus *SSE plus 12 psig from inside of crane wall	0.9 F_y	0.9 F_y	0.6 F_y
III	With door closed: Dead load plus *SSE plus Load from maximum jet hitting doors at 615 psi	0.9 F_y	0.9 F_y	0.6 F_y
IV	With door closed: Dead load plus *SSE plus Load from missile with maximum energy (6900 lb/ft) hitting door plus jet from that missile source at 295 psi	0.9 F_y	0.9 F_y	0.6 F_y

Mechanical Parts

No.	Load Combinations	Allowable Stresses (psi) Tension and Compression	Shear
I	With door closed or open: Dead load plus Operator force of 75 pounds	$\frac{Ult}{5}$	$\frac{2 \times Ult}{15}$
II	With door closed or open: Dead load plus *SSE	0.9 F_y	0.6 F_y

Listed allowable stresses are for non-collapsible members only. Collapsible members are plastically deformed.

*Acts in one horizontal direction only at any given time and acts in vertical and horizontal directions simultaneously.

Table 3.8.3-4 (Sheet 3)

PERSONNEL ACCESS DOORS IN CRANE WALL

Loads, Loading Combinations, and Allowable Stresses

Potential missiles which the doors were designed to withstand are as follows:

Temperature element A, without well, boss, and pipe

Temperature element B, with well, boss, and pipe

Temperature element C, without well

Temperature element D, with well

Reactor coolant pump temperature element

Pressurizer temperature detector

Pressurizer heater

2-inch check valve (boron injection)

3/4 inch globe valve(sampling system)
(flow transmitters)
(pressure transmitters)

3/4-inch air-operated valve (head gasket monitoring)

1-inch manually-operated globe valve (excess letdown)

EQUIPMENT ACCESS HATCH
SUMMARY OF STRESSES FOR CONTROLLING DESIGN CONDITION
140 PERCENT DB LOCA - DL $\pm$ 1/2 SSE

	Calculated	ALLOWABLE
Bending stress in structural shapes and plates (f_y = 36,000 lb/in^2)	20,400 lb/in^2	26,600 lb/in^2 (0.60 f_y)
Shear stress in structural shapes and plates (f_y = 36,000 lb/in^2)	8,870 lb/in^2	14,400 lb/in^2 (0.40 f_y)
Tensile stress in anchor bolts (f_y = 36,000 lb/in^2)	15,750 lb/in^2	21,600 lb/in^2 (0.60 f_y)
Bearing stress under anchor bolt end plate (f'_c = 5,000 lb/in^2)	717 lb/in^2	1,250 lb/in^2 (0.25 f'_c Note 1)

Note 1 - See Table 1002(a), ACI 318-63 Code.

During the construction stage, the maximum calculated differential compartment pressures were increased by 40 percent in accordance with NRC requirements to account for uncertainties. At the Operating License stage, the design pressures equaled or exceeded the peak calculated differential pressures. The stresses calculated herein are for the original design and do not reflect the evaluations documented in Exhibit F of report CEB 86-19-C.

SELECTION OF STEELS IN RELATION TO PREVENTION OF NON-DUCTILE FRACTRUE OF ICE CONDENSER CONDESER COMPONENTS

Properties	Section Thickness: 5/8-inch thick and under		Section Thickness: over 5/8-inch thickness
Energy Absorption Level	None required		i) 20 ft-lb CVN at - 20° F for steel over 36,000 psi yield strength ii) 15 ft-lb CVN at - 20° F for steel under 36,000 psi yield strength
Heat Treatment	None required Steel can be used in the hot rolled condition		i) Normalizing ii) Quench and Temper
Type of Steel	i) Rimmed	(a)	i) Killed
	ii) Semi-killed	(b)	ii) Killed-fine grain practice
	iii) Killed	(b,c)	
	iv) Killed - fine grain practice		

GENERAL NOTES:

1) Hot rolled, normalized or quenched and tempered steels are used where applicable.

2) Charpy v-notch (CVN) impact testing shall be performed in accordance with the requirements of ASTM A370.

a) Rimmed steel shall be used only for carbon steel sheet products.
b) These type steels shall be applied for components which remain within AISC Code stress limits for all load conditions.
c) Killed steels for above AISC Code stress limits shall be upgraded by heat treatment, e.g., bolting.

TABLE 3.8.4-1 (Sheet 1)

AUXILIARY CONTROL BUILDING
CONCRETE STRUCTURE LOADS, LOADING COMBINATIONS,
AND ALLOWABLE STRESSES

I. Loads

The following terms are used in the load combination equation for the Category I structures.

C = Construction condition.

C' = Crane load, including wind on crane.

D = Dead load of structure and equipment plus any other permanent loads contributing stresses, such as soil pressure. Hydrostatic pressure with water surface Elevation 687.

D' = D + hydrostatic pressure from water surface Elevation 700, MPF.

E = 1/2 SSE.

E' = SSE.

H = Spent fuel pit hydrostatic pressure. Worst condition of:

1. Normal water level in pit, cask loading area and canal.
2. Canal empty of water. Normal water level in other areas.

L = Live load. For live load of slabs see Figure 3.8.4-1.

L' = Live load. 20 lb/ft^2 on one side of wall or 10 lb/ft^2 on each side of wall.

L_c = Construction live loads (greater than normal operating live loads) or loads of a temporary or unusual nature.

P_A = The pressure that occurs inside a compartment due to pipe rupture.

P' = The jet force from a pipe rupture or the pipe anchorage force resulting from a jet.

T = Loads caused by change in length of top deck and beams due to 50°F temperature change.

T_A = Accidental increase in temperature of water in pit to 212°F in 8 hours. Temperature inside building 60°F.

T_N = Normal temperature of water in fuel pit and canal 120°F. Temperature inside building 60°F.

W = Wind load. See Section 3.3.

W_T = Tornado loads. See Section 3.3.

TABLE 3.8.4-1 (Sheet 2)

AUXILIARY CONTROL BUILDING
CONCRETE STRUCTURE LOADS, LOADING COMBINATIONS,
AND ALLOWABLE STRESSES

Y_r = Pipe anchor force due to postulated pipe break.

Y_j = Jet force due to postulated pipe break.

Y_m = Missile impact due to postulated pipe break.

Auxiliary Building Concrete Structure Earth Values

Angle of internal friction	θ = 32°
Angle of friction between fill and structure	= 16°
Unit weight of fill	
Dry	w = 120 lb/ft^2
Saturated (buoyant unit weight)	w = 65 lb/ft^2
Surcharge	
A1 and A15 line walls (for construction condition only)	1730 lb/ft^2
Others	200 lb/ft^2

TABLE 3.8.4-2 (Sheet 1)

AUXILIARY CONTROL BUILDING
STRUCTURAL STEEL LOADS, LOADING CONDITIONS,
AND ALLOWABLE STRESSES

Control Building Portion

1. Live Loads (LL)

   a. Elevation 732.0 - 400 lb/ft^2 (to include cable trays, ducts, walls and electrical boards)

   b. Elevation 706.0 - 100 lb/ft^2

2. Dead Loads (DL)

   a. 8-Inch concrete brick wall - 100 lb/ft^2

   b. 1-1/2-Inch steel grating - 12 lb/ft^2

   c. Concrete - 12.5 lb/ft^2 per inch thickness

   d. Steel framing - 15 lb/ft^2

   e. Piping - varies

Auxiliary Building Portion

1. Live Loads (LL)

   a. Construction load - 20 lb/ft^2

   b. Miscellaneous live load - 30 lb/ft^2

2. Dead Loads (DL)

   a. Concrete - 12.5 lb/ft^2 per inch thickness

   b. Steel roof decking - 3.5 lb/ft^2

   c. Steel roof framing - 25 lb/ft^2

Vertical 0.12 g

Loading Condition	Tension on Net Section	Shear on Gross Section	Compression on Gross Section	Bending	Concrete Bearing
Case I DL + LL ± 1/2 SSE	$0.60F_y$	$0.40F_y$	See Note 1	$0.66F_y$ to $0.60F_y$	$0.25f'_c$
Case II DL + LL ± SSE	$0.90F_y$	$\frac{0.9F_y}{\sqrt{3}}$	See Note 2	$0.90F_y$	$1.9(0.25f'_c)$

Note 1 - Varies with slenderness ratio, see AISC "Manual of Steel Construction" Seventh Edition, Table 1-36, Page 5-84.

Note 2 - Varies with slenderness ratio:

Main and secondary members where

$$KL/r \leq C_c : F_a = 0.9F_y \left[1 - \frac{(KL/r)^2}{2C_c^2}\right] \qquad \text{(A)}$$

Main members where

$$C_c < KL/r \leq 200 : F_a = \frac{0.9\pi^2 E}{(KL/r^2)} \qquad \text{(B)}$$

Secondary members where

$$120 < L/r \leq 200 : F_{as} = \frac{F_a(\text{By Formula (A)or(B)})}{1.6 - L/200r}$$

TABLE 3.8.4-2 (Sheet 3)

AUXILIARY CONTROL BUILDING
STRUCTURAL STEEL LOADS, LOADING CONDITIONS,
AND ALLOWABLE STRESSES

Where:

$$C_c = \sqrt{\frac{2\,\pi^2\,E}{F_Y}}$$

E = Modulus of elasticity of steel (29,000 k/in^2)

F_a = Axial compressive stress permitted in the absence of bending moment

F_{as} = Axial compressive stress, permitted in the absence of bending moment, for bracing and other secondary members

F_Y = Specified minimum yield stress of material (kips per square inch)

f'_c = Compressive strength of concrete

K = Effective length factor

L = Actual unbraced length (inches)

r = Governing radius of gyration

<u>Material Properties</u>

Steel Properties

Cc = 126.1

E = 29,000,000 lb/in^2

F_Y = 36,000 lb/in^2

	Manway Open		
IV	Dead load plus *SSE	0.9 F_y	0.6 F_y

*Acts in one horizontal direction only at any given time and acts in vertical and horizontal directions simultaneously.

TABLE 3.8.4-8 (Sheet 2)

Normal, accident, and flood conditions used for design of the manways are as follows:

Normal

Pressure - Negligible
Temperature - -30° F to 120° F
Radiation - Negligible

Accident

0 To 12 hours after accident:

Air pressure - 12 lb/in^2 from inside
Hydraulic pressure - 10 lb/in^2 from inside (water to 696 feet-3 inches from melted ice, RWST contents, and reactor coolant)

Temperature - 170°F
Radiation dose - 1.5×10^6 rads

12 To 550 hours after accident:

Air pressure - Negligible
Hydraulic pressure - 24.0 lb/in^2 from inside (water to 727 feet-0 inches as required to remove fuel after certain primary system ruptures)

Temperature - 120°F
Radiation dose - 1.0×10^7 rads

Flood

Hydraulic pressure - 22 lb/in^2 from outside (water to 724.0)
Temperature - 0°F to 120°F
Radiation - Negligible

IV	Dead load plus 360-mph windload plus missiles at **100 mph	Parts may deform but must stop design missile and door or bulkhead remain in position	

* Acts in one horizontal direction only at any given time and acts in vertical and horizontal directions simultaneously.

** Doors and steel bulkheads are designed for the first three missiles of Spectrum D in Table 3.5.5-6. Precast concrete bulkheads placed in front of these doors and steel bulkheads will stop the full missile spectrum.

TABLE 3.8.4-11

DIESEL GENERATOR BUILDING
LOADS, LOADING COMBINATIONS, ALLOWABLE STRESSES AND MATERIAL PROPERTIES

Loads

D = Dead load of structure including the weight of the diesel generators

L = Live load - 200 lb/ft^2 or equipment load, whichever is greater on floor areas, and 20 lb/ft^2 on roof

L_c = Construction live load (50 lb/ft^2 on roof)

E = 1/2 SSE

E' = SSE

W_T = Tornado loadings (includes missiles)

Load Combinations

Case	Description	Allowable Stresses
I	D+L	Normal stresses*
II	$D+L_c$	Normal stresses*+ 33%
III	D+L+E	$f_c = 0.45\ f'_c$ $f_s = 0.50\ f_y$
IV	D+L+E'	$f_c = 0.75\ f'_c$ $f_s = 0.90\ f_y$
V	$D+L+W_T$	$f_c = 0.75\ f'_c$ $f_s = 0.90\ f_y$

*Normal stresses are as given for working stress design in ACI Code 318-63.

Material Properties

Concrete	f'_c	=	3000 lb/in^2 (4000 lb/in^2 for vent hoods)
	w	=	145 lb/ft^3
Reinforcing steel	f_y	=	60,000 lb/in^2 (ASTM A 615, Grade 60)

Table 3.8.4-12

PRIMARY AND REFUELING WATER PIPE TUNNELS LOAD, LOADING COMBINATIONS, ALLOWABLE STRESSES, AND MATERIAL PROPERTIES

Loads

D = Dead load of structure plus any permanent load contributing stress.

L = Live load which includes temporary earth weights and pressures, and pipe loads.

S = Surcharge from equivalent H-20 loading.

S' = H-20 truck wheel at center of roof span.

E = 1/2 SSE.

E' = SSE

P = Hydrostatic pressure with water surface at Elevation 687.0.

P' = Hydrostatic pressure with water surface at Elevation 705.0.

Case	Load Combination	Allowable Stresses
I	D+L+S+S'	1.25 x Normal (ACI 318-63)
II	D+L+E+P	Normal (ACI 318-63)
III	D+L+E'+P	*f_c = .75 f'_c f_s = .9 f_y
IV	D+L+P'	*f_c = .75 f'_c f_s = .9 f_y

*Concrete stresses other than flexure = 1.67 x Normal (ACI 318-63)

Normal stresses are as given for working stress in ACI 318-63.

Material Properties

Concrete	f'_c	= 3000 lb/in^2
	w	= 145 lb/ft^3
Reinforcing steel	f_y	= 60,000 lb/in^2 (ASTM A 615, Grade 60)

Reinforcing steel	f_y	= 60,000 lb/in^2 (ASTM A 615, Grade 60)

TABLE 3.8.4-14 (Sheet 1)

EAST STEAM VALVE ROOM
LOADS, LOAD COMBINATIONS, ALLOWABLE STRESSES, FACTORS OF SAFETY
AND MATERIAL PROPERTIES

Loads

D	=	Dead load of structure and equipment plus any other permanent load contributing stress.
L	=	Live loads which are uniform design loadings on the roof and floor slab that are used in lieu of moveable loads such as those due to equipment and snow. 200 lb/ft^2 is used in the design of the floor slab and 20 lb/ft^2 is used for the roof.
W_T	=	Tornado loadings described in Section 3.3.
E	=	1/2 SSE.
E'	=	SSE.
P_a	=	Pressure from postulated main steam pipe break.
Y_r	=	Pipe anchor force due to postulated pipe break.
Y_j	=	Jet force due to postulated pipe break.
Ym	=	Missile impact force due to postulated pipe break.
T_A	=	Thermal loads under thermal conditions generated by the postulated break and including T_o.
R_A	=	Pipe reactions under thermal conditions generated by the postulated break and including R_o.
T_o	=	Thermal effects and loads during normal operating or shutdown conditions, based on the most critical transient or steady-state condition.
R_o	=	Pipe reactions during normal operating or shutdown conditions, based on the most critical transient or steady-state condition.

Note 1 - Varies with slenderness ratio, see AISC "Manual of Steel Construction," Seventh Edition, Table 1-36, Page 5-84.

Note 2 - Varies with slenderness ratio:

Main and secondary members where $KL/r \leq C_c$:

$$F_a = 0.9 F_y \left[1 - \frac{(KL/r)^2}{2 C_c^2} \right] \qquad \text{(A)}$$

Main members where $C_c < KL/r < 200$:

$$F_a = \frac{0.9 \pi^2 E}{(KL/r)^2} \qquad \text{(B)}$$

Secondary members where $120 < L/r \leq 200$:

$$F_{as} = \frac{F_a (\text{by Formula (A) or (B)})}{1.6 - L/200r}$$

Where:

$$C_c = \sqrt{\frac{2 \pi^2 E}{F_y}}$$

E = Modulus of elasticity of steel (29,000 k/in^2)

F_a = Axial compressive stress permitted in the absence of bending moment

F_{as} = Axial compressive stress, permitted in the absence of bending moment, for bracing and other secondary members

F_y = Specified minimum yield stress of material (K/in^2)

Table 3.8.4-15 (Sheet 2)

EAST STEAM VALVE ROOM
STRUCTURAL STEEL
LOADING COMBINATIONS AND ALLOWABLE STRESSES FOR STRUCTURAL STEEL

K = Effective length factor

L = Actual unbraced length (inches)

r = Governing radius of gyration

Material Properties

Steel

C_c = 126.1

E = 29,000,000 lb/in^2

F_y = 36,000 lb/in^2

Table 3.8.4-16

ERCW PUMPING STATION LOADS AND LOADING COMBINATIONS

Loads

D = Dead load

L = Uniform live load of 400 lb/ft^2, or equipment load, whichever is greater

F_1 = Normal hydrostatic loading (Normal maximum pool, Elevation 683, normal minimum pool, Elevation 675) (with one bay unwatered)

F_2 = MPF, Still water at El. 723.5 with wave runup outside structure of 6.1 ft (El. 729.5) and surge inside structure of 0.5 ft (El. 724.0)

F_3 = 1/2 MPF, Still water at El. 698.1 with wave runup outside structure of 5.9 ft (El. 704.0) and surge inside structure of 0.5 ft (El. 698.6)

F_4 = Normal groundwater at El. 683 (Reservoir El. at 635.8, loss of downstream dam)

W = Normal wind load (95 mph)

W' = Wind loading (45 mph)

W_T = Tornado - Includes wind pressures with missiles internal pressure as defined in FSAR Sect. 3.3.2.

E = Earthquake load from 1/2 SSE with horizontal rock acceleration of 0.09 g

E' = Earthquake load from SSE with horizontal rock acceleration of 0.18 g

Loading Combinations (ACI 318-71)

Case Determination	Required Strength
Normal operating	$U = 1.4D + 1.7L + 1.4F_1$
Seismic operating	$U = 1.4D + 1.7L + 1.4F_1 + 1.9E$
Dead and seismic	$U = 1.2D + 1.9E$
Normal wind	$U = 1.4D + 1.7L + 1.7W + 1.4F_1$
Dead and wind	$U = 1.2D + 1.7W$
Extreme seismic	$U = D + L + F_4 + E'$
Extreme wind	$U = D + L + F_1 + W_T$
Construction condition	$U = 1.4D + 1.4L + 1.4F_1$
Probable maximum flood	$U = D + L + F_2 + W'$
Seismic condition	$U = D + L + F_3 + 1.25E$

Table 3.8.4-17 (Sheet 1)

REFUELING WATER STORAGE TANK
FOUNDATION

LOADS AND LOAD COMBINATIONS

Loads

Normal loads, which are those loads to be encountered during normal plant operation and shutdown, include:

D -- Dead loads or their related internal moments and forces including any permanent equipment loads and hydrostatic loads.

L -- Live loads or their related internal moments and forces including any moveable equipment loads and other loads which vary with intensity and occurrence, such as soil pressure.

Severe environmental loads include:

E -- Loads generated by the operating basis earthquake.

W -- Loads generated by the design wind specified for the plant.

Extreme environmental loads include:

E' -- Loads generated by the SSE.

W_T -- Loads generated by the design tornado specified for the plant.

Abnormal loads, which are those loads generated by a postulated high-energy pipe break accident, include:

Y_j -- Jet impingement equivalent static load on a structure generated by the postulated break, and including an appropriate dynamic load factor to account for the dynamic nature of the load.

Y_m -- Missile impact equivalent static load on a structure generated by or during the postulated break, as from pipe whipping, and including an appropriate dynamic load.

Load Combinations

The following cases of loading combinations apply to both concrete structure and foundation designs. Strength design method described in ACI 318-71 should be used.

a. For factored load conditions which include normal and severe environmental, the following load combinations should be considered:

(1) U = 1.4 D + 1.7 L
(2) U = 1.4 D + 1.7 L + 1.9 E
(3) U = 1.4 D + 1.7 L + 1.7 W
(4) U = 1.2 D + 1.9 E
(5) U = 1.2 D + 1.7 W

where U is the section strength required to resist design loads based on the strength design methods described in ACI 318-71.

Table 3.8.4-17 (Sheet 2)

REFUELING WATER STORAGE TANK
FOUNDATION

b. For factored load conditions, which represent extreme environmental, abnormal, abnormal/severe environmental and abnormal/extreme environmental conditions, the following load combinations should be considered:

(1) U = D + L + E'
(2) $U = D + L + W_t$
(3) U = D + L
(4) $U = D + L + Y_j + Y_m + 1.25\ E$
(5) $U = D + L + Y_j + Y_m + E'$

Stability

The stability shall be checked for the principal design cases with minimum safety factors as shown below:

	For Combination	Factor of Safety Against Overturning or Sliding
(1)	D + L + E	1.50
(2)	$D + L + W_T$	1.10
(3)	D + L + E	1.10
(4)	$D + L + Y_j + Y_m + E'$	1.10

Temperature and Shrinkage

For temperature variation consult the Lead Civil Engineer. The coefficient of thermal expansion shall be 0.000005 in. per in. per degree Fahrenheit. The modulus of elasticity of concrete for use in shrinkage computations shall be 3×10^6 psi.

Shrinkage reinforcement shall be proportioned in accordance with TVA standards. Where needed, the placing temperature of the concrete in walls more than 24 in. thick and slabs more than 30 in. thick shall be limited to 65°F by the addition of ice if required. All drawings shall so specify. A minimum of two conditions shall be investigated:

I	Construction condition -	Minimum temperature (T) = 30°F; limiting crack width (Wc) = 0.015 in.
II	Final condition -	Minimum temperature (T) is that of final condition; limiting crack width (Wc) = 0.010 in.

NOTE: T_o, R_o, T_a, R_a, P_a, Y_j, Y_r, Y_m = 0

D - Dead loads or their related internal moments and forces including any permanent equipment loads and hydrostatic loads.

L - Live loads or their related internal moments and forces including any movable equipment loads and other loads which vary with intensity and occurrence, such as soil pressure.

T_o - Thermal effects and loads during normal operating or shutdown conditions, based on the most critical transient or steady-state condition.

R_o - Piping reactions during normal operating or shutdown conditions, based on the most critical transient or steady-state condition.

E - Loads generated by the operating basis earthquake.

W - Loads generated by the design wind specified for the plant.

E' - Loads generated by the Safe Shutdown Earthquake.

W_T - Loads generated by the tornado specified for the plant.

NOTE: THE FOLLOWING CRITERIA SHALL BE USED TO DETERMINE WHEN DREDGING OF THE ERCW CHANNEL IS REQUIRED.

1. THE TRENCH IN FRONT OF THE PUMPING STATION INTAKES (SEE SECTION A1-A1) SHALL BE DREDGED WHEN THE SEDIMENT ACCUMULATES TO ELEVATION 627.5.
2. THE CHANNEL AS SHOWN IN PLAN-EL 633.5 SHALL BE DREDGED WHEN SEDIMENT ACCUMULATES TO ELEVATION 635.0.
3. THE DREDGING OPERATION SHOULD RETURN THE BOTTOM ELEVATION TO THE ORIGINAL DESIGN REQUIREMENTS OF ELEVATION 621.0 PLUS OR MINUS 0.5 FEET IN THE TRENCH AT THE PUMPING STATION INTAKES AND ELEVATION 634.0 PLUS OR MINUS 0.5 FEET IN THE CHANNEL. THE SIDE SLOPES IN THE CHANNEL SHALL BE 4 ON 1 OR FLATTER.
4. ISOLATED RUBBLE, INCLUDING THE RIP-RAP FROM SKIMMER WALL CELL #13 MAYBE LEFT IN PLACE.
5. PRIOR TO INITIATING THE DREDGING OPERATION A SAFETY ASSESSMENT/EVALUATION (SA/SE) SHALL BE WRITTEN ADDRESSING THE TYPE OF DREDGING TO BE USED AS WELL AS PRECAUTIONS TO BE TAKEN DURING THE DREDGING TO ENSURE PLANT OPERATION IS NOT ADVERSELY AFFECTED.

NOTES:

GENERAL

THE PURPOSE OF THE LIMIT SWITCH ARRANGEMENT AND THE MECHANICAL STOPS IS TO PREVENT THE CRANE HOOKS PASSING OVER ANY PORTION OF THE SPENT FUEL PIT, EXCEPT THE SPENT FUEL CASK STORAGE AREA. IN ORDER TO RAISE THE SPENT FUEL POOL GATES, ALL LIMIT SWITCHES CAN BE BYPASSED UNDER ADMINISTRATIVE CONTROL. THIS CONTROL IS ACCOMPLISHED ONLY THROUGH THE USE OF A KEYED SWITCH.

OPERATION OF LIMIT SWITCHES

CONDITION I

BRIDGE IS LOCATED EAST OF LIMIT SWITCH A TRIP BAR OR WEST OF LIMIT SWITCH B TRIP BAR.
1. POWER FOR ALL MOTIONS IS AVAILABLE AND TROLLEY CAN TRANSVERSE ENTIRE BRIDGE.

CONDITION II

TROLLEY IS LOCATED NORTH OF LIMIT SWITCH C (THIS CONDITION IS NECESSARY FOR THE BRIDGE TO PASS OVER THE POOL UNDER NORMAL CONDITIONS).
1. POWER FOR ALL MOTIONS IS AVAILABLE AND THE BRIDGE CAN TRANSVERSE ITS ENTIRE RUN.

CONDITION III

BRIDGE LOCATED EAST OF LIMIT SWITCH A TRIP BAR OR WEST OF LIMIT SWITCH B TRIP BAR AND THE TROLLEY IS SOUTH OF LIMIT SWITCH C.
1. WHEN LIMIT SWITCH A OR A' IS TRIPPED, POWER FOR FURTHER WESTWARD TRAVEL OF THE BRIDGE IS INTERRUPTED.
2. WHEN LIMIT SWITCH B OR B' IS TRIPPED, POWER FOR FURTHER EASTWARD TRAVEL OF THE BRIDGE IS INTERRUPTED.
3. IF SWITCH A OR A' OR B OR B' HAVE BEEN TRIPPED, THE BRIDGE CAN BE TRAVELED IN THE REVERSE DIRECTION TO ESTABLISH CONDITION I.

CONDITION IV

BRIDGE LOCATED BETWEEN LIMIT SWITCH A TRIP BAR AND LIMIT SWITCH B TRIP BAR AND TROLLEY IS LOCATED NORTH OF LIMIT SWITCH C AND TRAVELING SOUTH.
1. WHEN LIMIT SWITCH C OR C' IS TRIPPED, POWER FOR FURTHER SOUTHWARD TRAVEL OF THE TROLLEY IS INTERRUPTED.
2. TROLLEY CAN BE MOVED IN THE REVERSE DIRECTION (NORTH) TO ESTABLISH CONDITION II.

CONDITION V

ADMINISTRATIVE CONTROL KEYED SWITCH IS ACTUATED (ALL LIMIT SWITCHES ARE BYPASSED AND POWER TO MECHANICAL STOP IS INTERRUPTED). THIS CONDITION IS NECESSARY ONLY FOR THE USE OF THE CRANE IN HANDLING OF THE SPENT FUEL POOL GATE ON THE WEST SIDE OF THE POOL.
1. POWER FOR ALL MOTIONS IS AVAILABLE. THE BRIDGE CAN TRANSVERSE ITS ENTIRE RUN AND THE TROLLEY CAN TRAVEL THE ENTIRE LENGTH OF THE BRIDGE.

APPENDIX 38A

SHELL TEMPERATURE TRANSIENTS

LIST OF FIGURES

SHELL TEMPERATURE TRANSIENTS

Figure 3.8A-1 presents average shell temperatures adjacent to the three compartments as a function of time after the design basis accident. The design basis accident is a double-end rupture of the reactor coolant pipe with the reactor decay heat released into the lower compartment as steam. Initially the steam is condensed in the ice compartment. After the ice melts the steam is condensed in the upper compartment by a water spray.

The lower compartment temperature rises to 240°F essentially instantaneously, then is reduced to 220°F very shortly after the blowdown is completed. The blowdown is completed before the shell adjacent to the lower compartment reaches 220°F, thus the smooth curve presented in Figure 3.8A-1.

The upper compartment temperature rises essentially instantaneously due to compression of the noncondensable gases into the upper compartment. The sharp rise at 7000 seconds simulates the disappearance of the ice from the ice compartment. The shell temperature will rise at a maximum of 0.11 degree per second during the rise from 140° to 170°F. The subsequent temperature decrease of the shell adjacent to the upper compartment is due to the reduction in decay heat.

The curve labeled shell adjacent to the ice compartment indicates the temperature of the shell adjacent to the ice compartment. The shell is separated from the ice compartment with a thick layer of insulation, hence, the rather slow response for the temperature of the shell adjacent to the ice compartment. After the ice is all melted, the temperature inside the ice compartment will be the same as the temperature in the lower compartment; however, the shell temperature adjacent to the ice compartment will be less than the temperature in the ice compartment because of the insulation. The temperature of the shell adjacent to the ice compartment will peak at less than 200°F.

The curves in Figure 3.8A-1 are an average shell temperature representative for the bulk of the shell. Some areas near boundaries between compartments and near the base will differ significantly from the bulk. The lower portion of the lower compartment shell will be insulated for the purpose of minimizing the transient effects. Figure 3.8A-2 is a plot of shell temperature versus distance above elevation 679 feet, 9-3/8 inches for various times after a Loss-of-Coolant Accident (LOCA). In establishing these curves it was assumed that top of the concrete slab is at elevation 679 feet, 9-3/8 inches, that the top of the insulation is at elevation 684 feet, 1-3/8 inch, and the top 8 inches of insulation is tapered from 2-inches thick to 1/4-inch thick.

APPENDIX 3.8B

CONTAINMENT VESSEL PENETRATIONS

CONTAINMENT VESSEL PENETRATIONS

The penetrations are summarized under three categories: penetrations requiring bellows (hot fluid carrying and certain engineering safeguard system lines), penetrations that do not require bellows (cold fluid carrying lines), and nonprocess penetrations (heating, vent, electrical, and spare penetrations).

Axial loads are assumed to act along the longitudinal axis of the penetration while radial loads are assumed to act in a plane that is transverse to the penetration longitudinal axis. A torsional moment is assumed to act about the penetration longitudinal axis while the bending movement may be assumed to bend the penetration longitudinal axis in any direction that would produce the greatest loading effects on the containment liner.

Seismic loads from piping systems are included in the forces considered for the penetrations that do not require bellows. Seismic loads for penetrations requiring bellows and nonprocess penetrations are calculated from the dead loads supplied and the vessel's response.

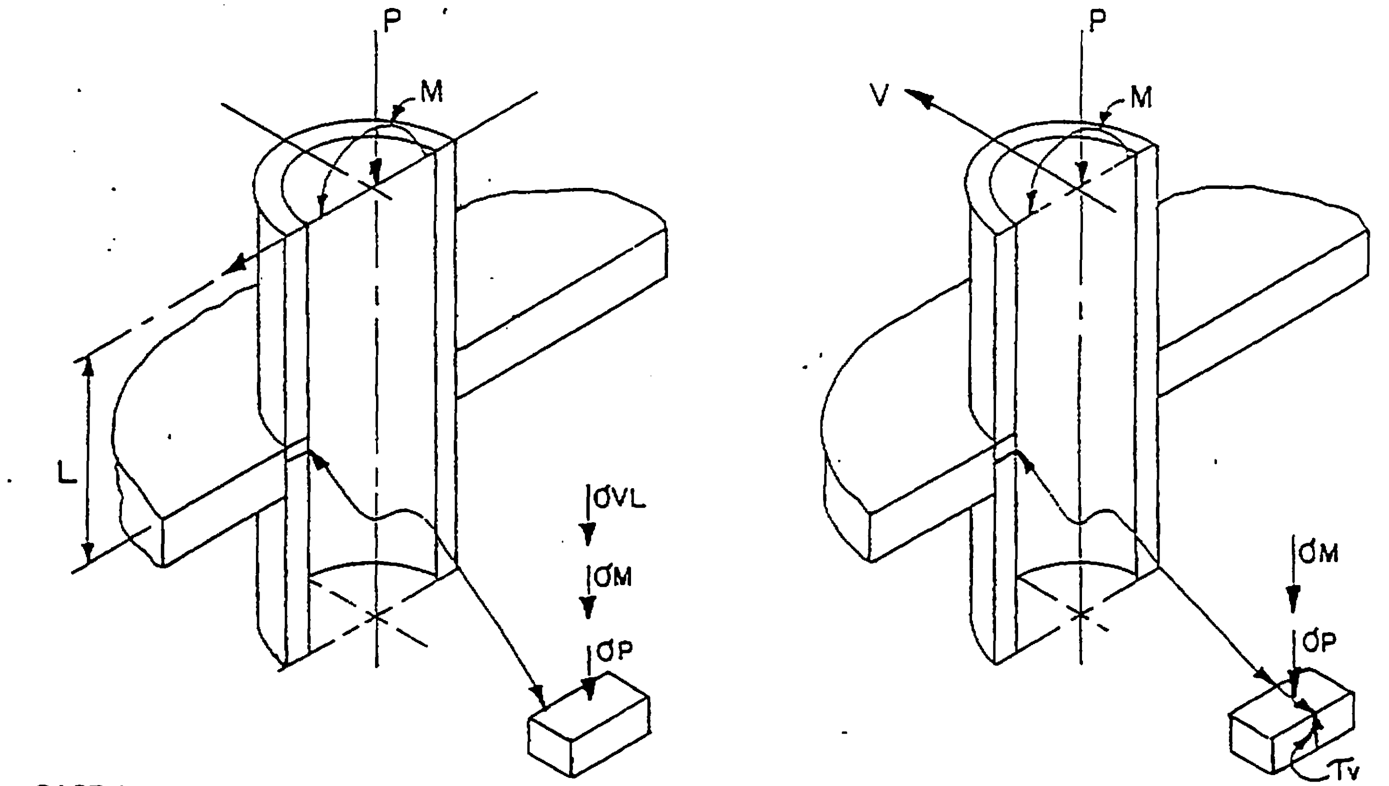
Each nozzle and adjacent vessel shell was analyzed for the specified loads acting simultaneously with other nozzles concurrent with the design internal pressure. The design internal pressure used in the analysis (10.8 psig) is based on maximum containment pressure of 12 psig reduced by 10 percent as allowed by the ASME Code.

The critical stress location is at the junction of the nozzle sleeve and the shell. Stresses in the nozzle sleeve at this point due to the applied loads were found by assuming the sleeve to be a rigid pipe subject to only primary axial, bending, and shear stresses.

Pressure produces a complex state of stress in both the shell and nozzle at their intersection. Paragraph N-451 (b) of the ASME Code, Section III, was used as a guide for the analysis of these stresses. This paragraph assumes that in the vicinity of a nozzle reinforced in accordance with ASME rules, maximum membrane pressure stress will not exceed 1.0 Sm and the maximum surface stress will not exceed 1.5 Sm. For the purpose of this analysis it was assumed that these stresses exist within the limits of reinforcement for both the nozzle and the shell.

Stresses and stress intensities were found, summarized, and compared to allowables for applied loads, pressure, and a combination of both, in accordance with Table 3.8.2-1.

Nozzle Stresses Due to Applied Loads



CASE 1

Maximum Stress Intensity =

$$S_1 = \sigma_p + \sigma_m \sigma_{VL}$$

CASE 2

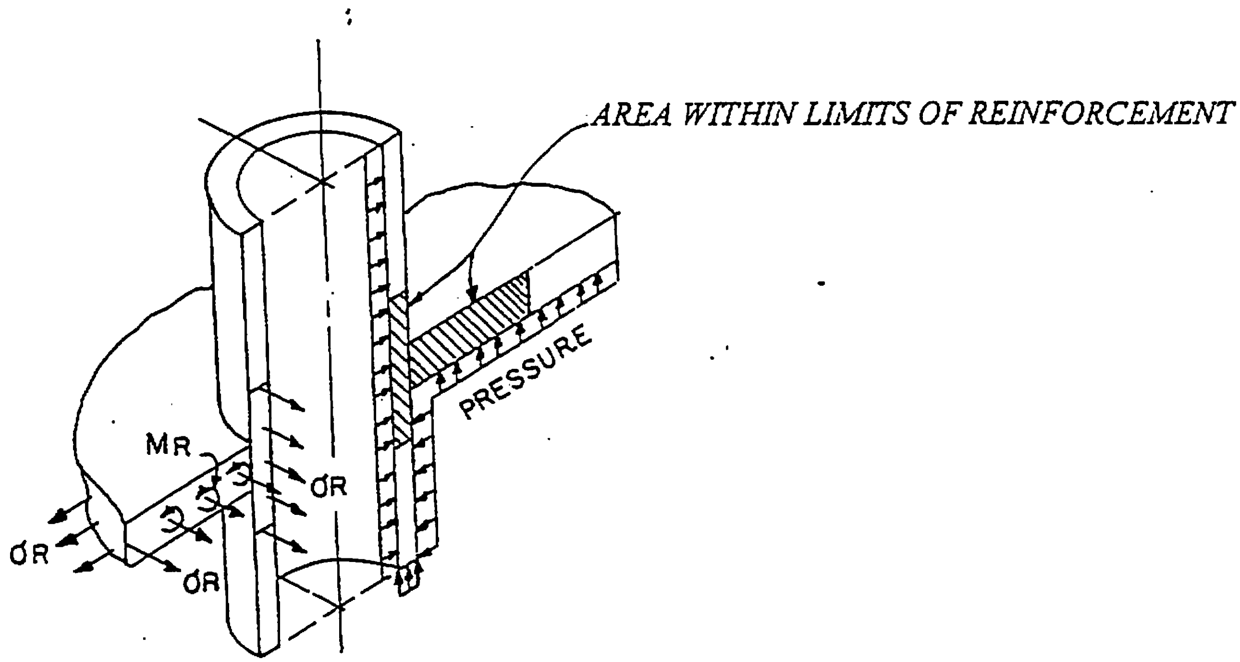
Maximum Stress Intensity =

$$S_2 = \sqrt{(\sigma_p + \sigma_m)^2 + 4\tau_v^2}$$

Where: $\sigma_p = P / A,\ \sigma_m = M / Z,\ \sigma_{VL} = VL / Z$

and: P = Specified Radial Load
V = Specified Lateral Load
M = Specified Moment
L = Maximum Specified Nozzle Projection
A = Metal Area of Nozzle Cross Section
Z = Section Modulas of Nozzle Cross Section
I = Moment of Inertia of Nozzle Cross Section
r_m = Mean Radius of Nozzle
t = Nozzle Wall Thickness

Nozzle and Shell Stresses Due to Pressure



$\sigma_R = \frac{\text{Area Replacement Required}}{\text{Area Replacement Available}}$ X Sm of Shell

$P = T\,\sigma_R$

Membrane Stresses Within Limits of Reinforcement

Shell: $\sigma_O = \sigma_X + \sigma_R$

Nozzle: $\sigma_O = \sigma_R$

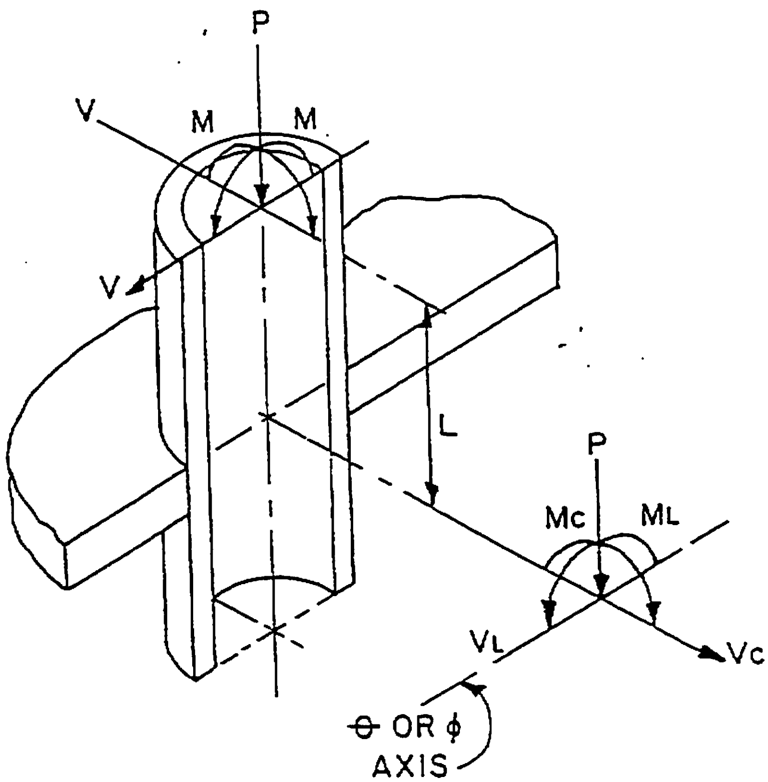
$\sigma_X = \sigma$ (Meridional Stresses are assumed externally balanced)

Surface Stresses Within Limits of Reinforcement

Shell: $\sigma_O = \sigma_X = 1.5\ \sigma_R$ (Bending due to M_R plus membrane)

Nozzle: Surface stress same as membrane

Shell Stresses Due to Applied Loads



LOADS APPLIED AT SHELL

$V_C = V_L = V$

$M_C = M_L = M + VL$

Loads were applied as shown above and analyzed by computer program. Note that maximum resulting stresses on computer print-out sheets are negative (compressive). This is due to assuming the radial load acting inward towards vessel. If the radial load had been assumed to act outward the maximum stresses would have the same value but would be positive (tensile). Since pressure stresses are tensile, the maximum stresses due to applied loads will be considered tensile and added directly to pressure stresses to derive combined stress intensities.

Nozzle Stress Due to Pressure and Applied Loads

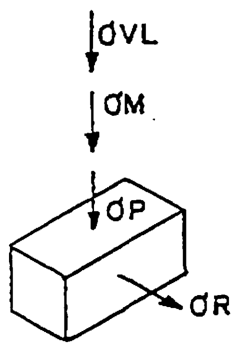
CASE 1

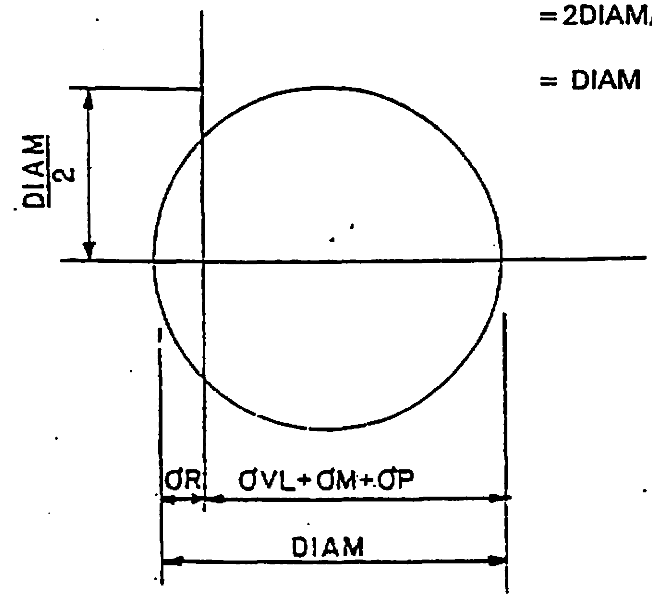
$$\textit{Maximum Stress Intensity} = \sigma_P + \sigma_m \sigma_{VL} + \sigma_R$$ 13

Stress FNT = 2MAX

= 2DIAM/2

= DIAM



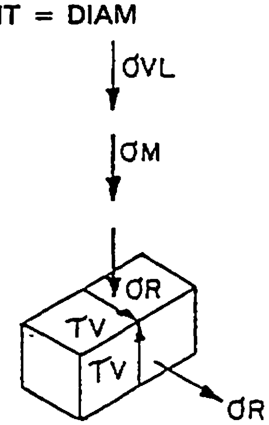


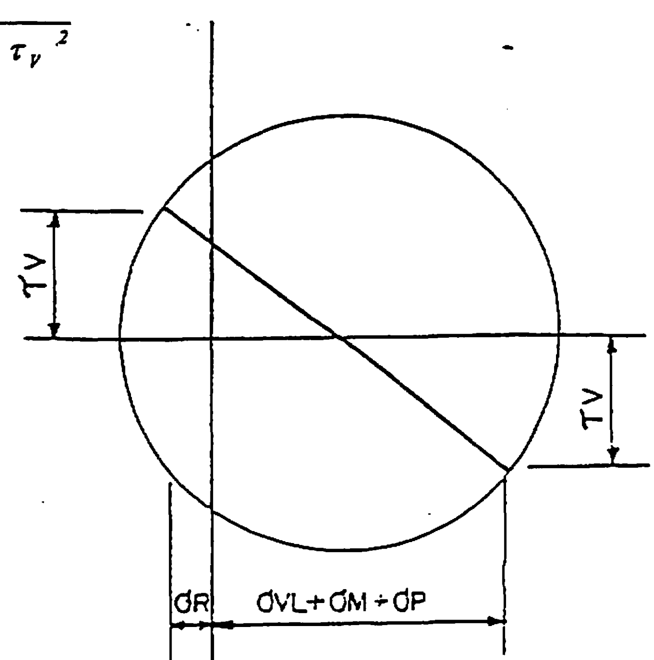
CASE 2

$$\textit{Maximum Stress Intensity} = \sqrt{(\sigma_P + \sigma_m + \sigma_R)^2 + 4\tau_v^2}$$ 13

$$DIAM = \sqrt{(\sigma_R + \sigma_{VL} + \sigma_M)^2 + 4\tau_V^{\ 2}}$$ 13

DSTRESS FNT = DIAM





APPENDIX 3.8C

CONTAINMENT ANCHORAGE

LIST OF FIGURES

Containment Anchorage

The anchorage for the containment vessel is subject to static, seismic, and nonaxisymmetric-pressure transient loads as shown for the specified loading combinations of Table 3.8.2-2.

Static and Seismic Loads

The anchorage for static and seismic loads was designed in accordance with ASME requirements for pressure parts and AISC requirements for nonpressure parts. Anchor bolts were preloaded to give the shell a circumferential load of 5.4 kips per inch. This preload was anchored to 3000-pound, 90-day mass concrete below elevation 676 feet, 0 inch and exceeded the applied over-pressure tensile load. Generally the analysis assumes no aid from the fact that the anchorage is totally encased in concrete.

The individual loading conditions are shown in Figure 3.8C-1.

The induced twisting moment was analyzed by assuming the anchorage divided into an upper ring section and a lower ring section as shown in Figures 3.8C-3 and 3.8C-4. Each ring was assumed loaded with a horizontal couple reaction resulting from the twisting moment.

For static and seismic conditions stresses for the anchor bolt, bridge plate and anchor plate were determined only for the bolt preload as they are unaffected by the applied loads. Stresses in the upper and lower ring sections were determined for each significant loading condition.

Pressure Transient Loads

Meridional loads on the shell at the base are shown in Figure 3.8C-2. These loads include the nonaxisymmetric-pressure transient loads. Tensile shell loads which exceed the preload are resisted by plate "A". This force is resisted by the 3-foot, 7-7/8-inch base slab above the rough concrete in bearing. Only four-5/16 inch on each side of the centerline of shell plate was assumed to resist these tensile loads. This symmetrical loading of plate "A" will not cause any additional twisting moment on the anchorage. See Figure 3.8C-3 for this loading condition.

Compressive shell loads are resisted by 3000-pound, 90-day, rough, mass concrete. This induces twisting moment, but this is less than the twisting moment for tensile shell loads. See Figure 3.8C-4 for this loading condition. Note that for an applied compressive load it was assumed that the concrete will not compress sufficiently to significantly reduce the bolt preload. For all loading combinations, the computed stresses were less than allowable stress intensities.

COMPUTER PROGRAMS USED IN STRUCTURAL ANALYSIS

LIST OF TABLES

LIST OF FIGURES

Computer programs used for structural analysis and design of Category I Structures have been validated by one of the following criteria or procedures:

a. The following computer programs are recognized programs in the public domain:

Program Name	Start Date	Hardware	Source
AMG032	1965	IBM	R&H
AMG033	1965	IBM	R&H
AMG034	1965	IBM	R&H
ANSYS	1972	CDC	CDC
ASHSD	1969	IBM	UCB
GENDEK 3	1969	IBM	UCB
GENSHL 2	1969	IBM	FIRL
GENSHL 5	1968	IBM	FIRL
GTSTRUDL	1979	CDC	CDC
NASTRAN	1974	CDC	CDC
SAP IV	1973	CDC	UCB
SDRC FRAME PACKAGE - SAGS/DAGS	1977	CDC	CDC
STARDYNE	1977	CDC	CDC
STRESS	1970	GE	GE
STRUDL	1972	IBM	ICES
STRUPAK	1971	CDC	CDC
SUPERB	1977	CDC	CDC
STRUDL	1975	IBM	McAUTO
WERCO	1979	CDC	AAA

Currently, all programs on IBM compatible hardware are run under the MVS-SP3 operating system on either an IBM 308ID or an AMDAHL 470 Y8. All programs on CDC hardware run under the NOS version 1.4 operating system on either Model 175 or 176 hardware.

The following abbreviations are used for program sources:

AAA - AAA Technology, Houston, TX
CDC - Control Data Corporation, Minneapolis, MN
FIRL - Franklin Institute Research Labs, Philadelphia, PA
GE - General Electric Co., Rockville, MD
ICES - Integrated Civil Engineering System, Worchester, MA
R&H - Rohm & Haas Company, Huntsville, AL
UCB - University of California, Berkeley, CA

b. The following programs have been validated by comparison with a program in the public domain:

RESPONSE FOR EARTHQUAKE AVERAGING SPECTRAL RESPONSE
Summary comparisons of results for these computer programs are provided in Figures 3.8D-1 and 3.8D-2.

c. The following programs have been validated by comparison with hand calculations:

BAP222
BIAXIAL BENDING - USD
CONCRETE STRESS ANALYSIS

THERMCYL
TORSIONAL DYNANAL
PNA100*

The following programs have been validated by comparison with analytical results published in the technical literature:

DYNANAL
ROCKING DYNANAL

Summary comparisons of results for these computer programs are provided in Tables 3.8D-1 through 3.8D-8.

* This information is provided for historical purposes. Computer program PNA100 is not currently used. Instead, hand calculations are performed on as needed basis.

APPENDIX 3.8E

DESIGN PROCEDURE FOR REINFORCED CONCRETE BLOCK WALLS

LIST OF FIGURES

APPENDIX 3.8E
DESIGN PROCEDURE FOR REINFORCED CONCRETE BLOCK WALLS

1.0 Purpose

The purpose of this design procedure is to establish a guide for the designer and checker to assure design uniformity and to assure that a safe and complete design of reinforced concrete block walls is achieved.

As a result of Integrated Design Inspection (IDI) item D4.3-9, representative "worst case" reinforced masonry walls were determined by a comparison of all walls (height, thickness, restraint, boundary conditions, etc.) using the wall drawings and evaluated. This evaluation consisted of analyzing the walls for the governing load combinations of Part 3.2 of this appendix using the allowable stresses of NUREG 0800, Section 3.8.4, Appendix A. The analysis included the effects of openings in the walls. The evaluation found the walls to be acceptable for restart, and upon completion of post- restart work, all walls are in full compliance with NUREG 0800 allowables. This IDI item D4.3 was closed per Inspection Report numbers 50-327/88-13 and 50-328/88-13--Integrated Design Inspection Followup.

2.0 General Description

This procedure is provided for use in the design and structural evaluation of reinforced concrete block walls for all Category I structures of this project. In addition, it may be used for Non-Category I structures.

Standard concrete blocks with closed ends and two cores will be used to permit the placement of one or two layers of vertical reinforcement at 8 inches on center or 16 inches on center. Only the cores that have reinforcement in them will be filled with concrete unless the wall is required for security or shielding. In this case, every core will be filled with concrete. The wall will be designed to withstand horizontal and vertical forces due to earthquake and equipment loads. The wall shall also be evaluated for its structural ability to withstand these additional loading conditions (identified in NRC IE Bulletin 80-11); impact or pressurization loads such as missile, pipe whip, pipe break, jet impingement, flooding, or tornado depressurization. If, in any of the load combinations listed in Section 3.2, the evaluation proves that the wall can withstand these additional design loads, no further action will be required for that wall. However, if the evaluation indicates that the wall cannot withstand any one of the load combinations, corrective action shall be taken to prevent failure of the wall. This may be accomplished in one of two ways:

(1) by designing a restraint system which would prevent the wall from failing, or (2) by reducing the loadings on the walls, where possible, to a safe limit through more refined theoretical analysis or physical modification of the walls or wall areas.

All openings in the walls at floor level will have to be sized so dowels in the structural slabs can be designed and located before the structural slabs are constructed. After structural slabs have been constructed, grouted-in dowels will be required to reinforce the concrete block walls. Other openings in the walls, including spare openings and sleeves by the mechanical and electrical disciplines will have to be sized, located, and designed before the block walls are installed. The spare openings and sleeves are to be filled in with concrete by the Field if they are not required.

The lintels will be designed for load distribution for short loose lintels. Only the portion of the lintel that is cast in place will be used for design. For wall spans in the vertical direction only the net area of block and the cores filled with concrete will be used for design.

Concrete block wire reinforcement shall be used in the bed joints of alternate courses of all concrete block walls. Corner and tee partition lock fittings shall be used at all wall intersections. Walls that extend to the ceiling above will either be doweled into the slab or restrained by continuous angles on both sides of the wall.

Concrete in the cores shall be placed in lift intervals or layers not to exceed 24 inches. Each layer shall be thoroughly consolidated and tied into the layer below by either rodding or internal vibration.

3.0 DESIGN CONSIDERATIONS

3.1 Materials

Materials	Specifications
Concrete block	Full length lightweight two core closed end. ASTM Designation C90, Grade N, Type I. Compressive strength = 1000 psi on gross area.
Sand	ASTM Designation C144
Portland cement	ASTM Specification C150, Type I or II.
Coarse aggregate	ASTM Specification C33, maximum size aggregate 3/4-inch; slag is not acceptable.
Mortar	ASTM Designation C270, Type S
Concrete	One part cement, 2-1/2 part sand, 2-3/4 part coarse aggregate, by weight, 6 gallons of water per bag of cement for lintels (maximum), 7 gallons of water per bag of cement for core fill (maximum). Minimum compressive strength at 28 days shall be 3,000 psi.
Reinforcement	(Vertical) ASTM Specification A615, Grade 60. Additional testing shall be carried out in accordance with Construction Specification G-2. (Horizontal) Block wire reinforcement standard grade with No. 9 side rods and No. 9 crossties, ASTM A82.

3.2 Load Combination and Allowable Stresses

Loads:

D	=	Dead Load.	Weight of wall with every other core filled with concrete. 8-inch wall = 62#/sq ft, 12-inch wall = 94#/sq ft Weight of wall with every other core filled with concrete. 8-inch wall = 86#/sq ft, 12-inch wall = 133#/sq ft
L	=	Live Load. (Vertical)	20#/sq ft on one side of wall or 10#/sq ft on each side of wall. Spacing of equipment and piping supports, restraints, and anchors shall be controlled so that these live loads are not exceeded.

E = Loads generated by Operational Basis Earthquake (OBE).

E' = Loads generated by Design Basis Earthquake (DBE).

P_a = Pressure equivalent static load within or across a compartment generated by the postulated break and including an appropriate dynamic load factor to account for the dynamic nature of the load.

Y_j = Jet impingement equivalent static load on structure generated by the postulated break and including an appropriate dynamic load factor to account for the dynamic nature of the load.

Y_m = Missile impact equivalent static load on a structure generated by or during the postulated break, as from pipe whip, and including an appropriate dynamic load factor to account for the dynamic nature of the load.

Y_r = Equivalent static load on the structure generated by the reaction on the broken high-energy pipe during the postulated break, and including an appropriate dynamic load factor to account for the dynamic nature of the load.

W_t = Loads generated by the design tornado specified for the plant. Tornado loads on interior block walls are due to tornado created differential pressure.

F = Hydrostatic equivalent static load in a structure generated by the Design Basis Flood or from a pipe break.

Load Combinations		Allowable WSD Stresses	
		Flexure	Shear
For service load conditions:			
Case I	= D+L	Block with alternate cores filled--810 psi on net area	47 psi
		Block with every core filled--900 psi	55 psi
		Concrete--1350 psi (lintel)	60 psi
		Reinforcing steel-- 24,000 psi	--
**Case II	= D+L+E	(Same as above except reinforcing steel = 30,000 psi)	

Load Combinations		Allowable WSD Stresses	
		Flexure	Shear
For extreme environmental and abnormal loads:			
Case III	= $D+L+W_t$	Block with alternate cores filled--1350 psi on net area	78 psi
		Block with every core filled--1500 psi	92 psi

Load Combinations		Allowable WSD Stresses Flexure	Shear
		Concrete--2250 psi (lintel) 100 psi Reinforcing steel --54,000 psi	--
Case IV	$= D+L+1.5P_a$		(Same as Case III)
**Case V	$= D+L+1.25P_a+1.0 (Y_j+Y_m+Y_r) +1.25E$		(Same as Case III)
**Case VI	$= D+L+1.0P_a+1.0 (Y_j+Y_m+Y_r) +1.0E'$		(Same as Case III)
Case VII	$= D+L+F$		(Same as Case III)

In load cases IV, V, and VI the maximum values of P_a, Y_r, Y_j and Y_m including an appropriate dynamic load factor should be used unless a time history analysis is performed to justify otherwise.

3.3 Design of External Wall Restraints

If restraints are required on any of the walls, their design including anchorage shall conform to "Sequoyah Nuclear Plant Design Criteria for Miscellaneous Steel Components for Class I Structures" SQN-DC-V-1.3.2.

**The natural period of vibration for concrete walls will be considered. Periods to be used in conjunction with appropriate response spectra (4 percent curve for E and 7 percent curve for E') are given in Figure 3.8E-1. (These periods are based upon one-way action, more refined analysis is acceptable.)

3.9 MECHANICAL SYSTEMS AND COMPONENTS

3.9.1 Dynamic System Analysis And Testing

Numerous analytical and experimental programs have been performed to evaluate mechanical systems and components of pressurized water reactors under various loading conditions. The most significant dynamic analysis techniques, methods and test results are highlighted in the following paragraphs. Detailed information of the dynamic system analysis and testing is presented in the reports listed in References 1 and 2.

3.9.1.1 Vibration Operational Test Program

The flow modes and transients to which the system components were subjected at Sequoyah are generally defined in the preoperational test program as outlined in Chapter 14 of the Sequoyah FSAR. In particular, the following Westinghouse (W) and TVA tests are flow-vibration - temperature related:

TVA-40	Main Steam System (TVA test NCS-3 "Extraction Steam System" includes vibration testing of the Main Steam System)
TVA-22	Auxiliary Feedwater System
TVA-29	Steam Generator Blowdown System
TVA-14	Diesel Generators and Supporting Auxiliaries
TVA-25	High Pressure Fire Protection System (pumps only)
TVA-27	Control Air System (auxiliary control air compressors)
W-12.1	Ice Condenser System (glycol equipment and piping)
W-3.1 W-3.2 W-3.3	Chemical & Volume Control System
W-6.1	Safety Injection System
TVA-18 TVA-19	Essential Raw Cooling Water System
W-1.2 W-1.3 W-1.4 W-1.5 W-1.8	Reactor Cooling System

TVA-20 Component Cooling System

TVA-21 Containment Spray System

W-2.2 Residual Heat Removal System

W-5.1 Waste Disposal System
W-5.2
W-5.3
W-5.4

W-2.1B Spent Fuel Pit Cooling System

TVA-51 Flood Mode Boration System

W-6.2 Upper Head Injection System (System has been deleted)

Acceptance criteria include those stipulated in the ASME B&PV Code Section III, Subparagraph NB3622.3, "Vibration." This code states that vibration effects in piping systems shall be visually observed, and where questionable shall be measured and corrected as necessary. Measurements of vibration amplitudes are made according to amplitudes and spans of families of pipe made from the same material.

The preoperational piping dynamic effects test program at this plant consisted of the following:

1. The dynamic behavior of all piping systems was observed during preoperational tests. Bench marks were used to check expansion, restraint, and return position of the RCS, Main Steam, and Feedwater Piping following the tests.

2. The preoperational tests conducted at this plant generally follow those described in Regulatory Guide 1.68 Preoperational and Initial Startup Test Programs for Water-Cooled Power Reactors.

3. The point of maximum deflection within any pipe support span of any piping system was visually inspected and measurements taken where required during those tests.

4. The maximum half-amplitude displacement which was allowed during this program below the endurance limit stress as defined in the ASME B&PV Code, Section III, 1974.

5. A graph was constructed using the endurance limit criterion. This graph, with the pipe span for the ordinate and deflection on the abscissa, included all the pipe sizes and weights used at this plant. Also considered were the various piping materials used at this plant.

6. In those cases where the deflection exceeded these allowable deflections, corrective restraints were designed and installed in the piping system. These new restraints were incorporated into the piping system analysis.

7. The flow mode or transient condition which produced the excessive displacement was repeated to assure that vibrations had been reduced to an acceptable level.

Vibration measurements were also taken on the upper head internals, all vital pumps and rotating machinery at baseline and on a periodic basis so that excessive vibration could be corrected early in the program and/or detected if it gradually became a problem. For heat exchangers, differential pressure measurements were taken and compared with design parameters. Although not conclusive, matching of pressure drops provides a favorable indication that fluid velocities are unlikely to create resonant responses.

The preoperational tests thoroughly checked critical systems under steady state flow conditions. Additionally, transient response observations were made for the following equipment and valves:

1. Rotating Equipment

   a. Motor-driven auxiliary feedwater pumps
   b. Turbine-driven auxiliary feedwater pumps
   c. Chemical and volume control centrifugal charging pumps
   d. RHR pumps
   e. Containment spray pumps
   f. Safety injection system pumps
   g. Reactor coolant system pumps
   h. ERCW pumps
   i. Component cooling water pumps
   j. Spent Fuel pool cooling pumps

2. Check Valves in Parallel Pump Configurations

   a. RHR system 74-514 and 74-515
   b. Safety injection system 63-524 and 63-526
   c. Auxiliary feedwater system 3-830, 3-871, 3-831, 3-872, 3-832, 3-873, 3-833, 3-874

3. Vibration Measurements During Qperation of the Prototype UHI System and RCS Flow Tests

For prototype experience, we cite the Indian Point No. 2 and Trojan Pressurized Water Reactors. Trojan is an 1130 MWe Westinghouse plant, is of the same generic family as Sequoyah, has 17 x 17 fuel, and lacks only the UHI (where Sequoyah is the prototype, since deleted).

3.9.1.2 Dynamic Testing Procedures

Design of Category I mechanical equipment to withstand seismic and accident loadings is provided either by analysis or dynamic testing. Design of Category I mechanical equipment to withstand operational vibratory loadings is provided by analysis and verified by dynamic testing as described in Section 3.9.1.1.

Generally, tests are run with either of the following two objectives:

1. To obtain information on parts or systems necessary to perform the required analysis, or

2. To prove the design adequacy of a given equipment or structure without performing any analysis of this particular equipment or structure.

The need for the first type of test is dictated by lack of information on some of the inputs vital to the performance of an analysis. The available information could be completely deficient or too conservative. These tests can be either static (to obtain spring constants) or dynamic (to obtain impedance characteristics). No general descriptions can be given for this type of test because of the strong dependence on the specific needs of the analyst.

The need for the second type of test is mainly dictated by the complexity of the structure or equipment under design. This vibration testing is usually performed in a laboratory or shop on a prototype basis, using various sources of energy.

Laboratory vibration testing can be conducted by employing various forms of shakers, the variation depending on the source of the driving force. Generally, the primary source of motion may be electro-magnetic, mechanical, or hydraulic-pneumatic. Each is subject to inherent limitations which usually dictate the choice. To properly simulate the seismic disturbance, the waveform must be carefully defined. The waveform seen by a given piece of equipment depends on:

1. The earthquake motion specified for a given site.

2. The soil-structure interaction.

3. The building in which the component is housed.

4. The floor on which the equipment is located.

5. The support and attachments to the equipment.

Components located on rocks or on stiff lower floors of buildings founded on rock are subjected to random-type vibrations. Components located on the upper floors of flexible buildings or buildings on soft foundations are roughly subjected to sine beats with a frequency close to fundamental frequency of the building.

If a random vibration system is available, extreme care is paid to the selection of random driving functions having frequency content and energy conservatively approaching those of the ground or building motion caused by the specified earthquake(s).

The most common and readily available vibration testing facilities can only carry simple harmonic motion. By analytical comparison with time history response obtained with a number of real earthquake motions, it has been found that these time histories can be approximately simulated with wave forms having the shape of sine beats with 5 or 10 cycles per beat, a frequency equal to the component natural frequencies, and maximum amplitude equal to the maximum seismic acceleration to which the component needs to be qualified. For equipment located on building

floors, the maximum seismic input acceleration is the maximum floor acceleration. This is obtained from the dynamic analysis of the building or from the appropriate floor response spectrum at the zero period of the equipment.

Where sine beat testing is performed to verify the design of seismic Category I equipment, sine beat inputs are applied to each of three perpendicular axes independently. The sine beat inputs are applied not only at the equipment natural frequencies but also at many frequencies (spaced at about 1/2 octave) below 33 Hz to ensure that the equipment would function normally regardless of uncertainties of building or equipment, thereby producing the most damaging effect to the components. This test excites the component to motion greater than the input and also produces fatigue damage well above that produced by seismic disturbances. This method is conservative in that it assumes that building natural frequency coincides with that of the equipment. Any possible coupling effect loses importance when compared to the excitation of components at sensitive frequencies as is done by the sine beat test. This test therefore provides more positive proof of equipment capability that the simultaneous random input test which, because of phase relationships, could result in less severe application of the seismic input. Justification of the use of single axis sine beat tests, as implemented by Westinghouse to seismically qualify equipment, is presented in Reference 3.

Detailed testing criteria have been specified by Westinghouse. These include, briefly:

1. A continuous sweep frequency search is performed to determine the natural frequencies of the equipment.

2. Sine beat tests are performed at test frequencies chosen to adequately and completely qualify the equipment. The natural frequencies found by the search of item 1 shall be included in these test frequencies, and serve as a starting point in the determination of other test frequencies.

3. A test at any frequency consists of five beats with a pause between beats such that there is no significant superposition of motion. The number of cycles per beat shall be either 5 or 10, depending on the percentage of critical damping of the building and equipment (References 3 and 4).

4. The peak horizontal SSE acceleration as a function of the test frequency is applied to the equipment, 2/3 of the horizontal value shall be used for input in the vertical direction.

5. A frequency search and sine beat test shall be performed independently for the two horizontal directions and the vertical direction.

Equipment is evaluated in its operating mode either during the testing program as defined above, or by analysis. These procedures assure that the equipment will function when subjected to seismic loadings.

3.9.1.3 Dynamic System Analysis Methods for Reactor Internals

3.9.1.3.1 Analysis Methods

The reactor internals are modeled dynamically for a) loads produced by a double-ended pipe rupture of the reactor coolant loop (the Design Basis Accident, DBA), for both cold and hot leg breaks, b) response due to a Safe Shutdown Earthquake [SSE], and c) for the most unfavorable combination of DBA and SSE. Seismic analysis of the reactor vessel and its internals are described in Subsections 3.7.2 and 3.7.3.

Figure 3.9.1-1 shows a sandwich type upper internals support structure made of two plates. The upper support plate is reinforced by a grid of beams, and the upper core plate is connected by hollow columns bolted to the plates, with the guide tubes pinned to the core plate. This structure compresses the fuel assemblies and the annular hold-down spring during assembly and is subjected to vertical upward forces from these springs. During operation, normal and abnormal transverse flow drag forces are applied to the columns and guide tubes and differential pressure exists across the horizontal plates. The forces on the columns and guide tubes vary with the distance from the outlet nozzles. Because of the complexity of the upper package geometry and loading conditions, the modeling of the reactor internals was performed by using the method of analysis based on the finite element idealization of the structure and matrix displacement for each finite element. This finite-element structural analysis computer program permits static elastic and plastic analysis, steady state and transient heat transfer, dynamic mode shape analysis, linear and non-linear dynamic analysis, and plastic dynamic analysis. Descriptions of the techniques used to model the various parts of the internals follow. The top structure, deep beam, and upper core plate have been modeled with flat shell elements, the support columns with "three-dimensional" beam elements and the fuel assemblies and hold-down springs with "three-dimensional" spring elements. Because of symmetry, a one-eighth slice of the upper package has been modeled. Figure 3.9.1-2 shows the geometry of the model with the various components separated. The core plate is perforated and is modeled as a geometrically equivalent solid plate which has elastic constants modified according to the theory of perforated plates.

Columns of two different lengths are modeled, the long columns connecting the plates and the short columns connecting the beam grid with the upper core plate.

Under the loads used for design, according to the operating condition under study, the previously described computer program provides stresses and deflections at all model points.

The study of the lower internals structure which supports the core is another application of the system code to determine the behavior of a complex structure subjected to a given load. This is a sandwich-type structure and consists essentially of the perforated support casting, support columns, and lower perforated core plate. To obtain a realistic representation of the interaction of the components, the lower support structure was also modeled using the finite-element structural analysis computer programs. Two geometry plots (views from different angles) of the analytical model, which is built of finite shell and pipe elements, are given in Figure 3.9.1-3. The core plate, diffuser plate, and support casting, as well as the lower part of the core barrel, are represented by flat triangular shell elements. Reduced plate strength, due to the perforations, is accounted for by using an equivalent elastic modulus and Poison ratio in the calculations. This

structure is loaded with various vertical forces, due to normal and abnormal operations, and the deflections and stresses are obtained for each case. The experimental values have been converted according to basic scaling laws and applied to the prototype structure. The comparison of experimental and theoretical vertical deflections, presented in Figure 3.9.1-4 shows good agreement. The test values are larger, as expected, since they are obtained in the absence of the core plate, diffuser plate, and support columns structures, making the casting more flexible. Using the same model, this type of system code is also used to compute stresses and deformation due to non-uniform temperature distributions. With temperature at the component surfaces and the gradient generated by the heat generation as input for the system code, the deflected shape of the structure is obtained. Stresses in components such as the perforated upper and lower core plates, core support plate and top support plate are then computed using the stress intensification factor provided by the standard theory of perforated plates.

3.9.1.3.2 Preoperational Tests

The program used to establish the integrity of reactor internals has involved extensive design analysis, model testing and post hot functional inspection. Additionally, a full size reactor has been instrumented (Reference 1) to measure the Dynamic behavior of a Sequoyah-size plant and has compared measurements with predicted values.

This program was instituted as part of a basic philosophy of instrumenting the internals of the first-of-a-kind current Nuclear Steam Supply System designs for power plants. The magnitude of this test program was much greater than the intent of the philosophy, and was established as part of an extensive plan to develop theories and basic concepts related to internals vibration under various operating conditions. Thus, not only is added assurance obtained that all of the hardware will operate in the manner for which it was designed, but these data also assist in the development of increased capability for the prediction of the dynamic behavior of pressurized water reactor (PWR) internals. The previous "first-of-a-kind" plants that were instrumented are R. E. Ginna (two loops), H. B. Robinson (three loops) and Indian Point Unit 2 (four loops).

The Indian Point II reactor has been established as the prototype for a four-loop plant internals verification program. Subsequent four-loop plants are similar in design. Past experience with other reactors indicates that plants of similar designs behave in a similar manner. For these reasons a comprehensive instrumentation program was conducted on the Indian Point Plant to confirm the behavior of the reactor components. The main objectives of this test were to increase confidence in the adequacy of the internals by determining stress or deflection levels at key locations and to obtain data that can be used to develop improved analytical tools for prediction of internals vibration.

In the final analysis, the proof that the internals are adequate, free from harmful vibrations and have performed as intended is through component observations and examinations during service. With this thought, Indian Point II, the four-loop prototype, was subjected to a thorough visual and dye-penetrant examination by qualified Quality Assurance engineers before and after the hot functional test. This inspection was in addition to the normal inspection of the internals in the shop and before and after shipment.

The only significant differences between Indian Point 2 and the Sequoyah plants are in the geometry.

The bore size of the lower instrumentation guides is larger on Sequoyah to accommodate larger instrument thimbles. Another example of geometric difference is in the upper core plan. Since Sequoyah has fewer head penetrations and, therefore, fewer possible rod cluster locations, Sequoyah has fewer rod cluster control positions in the upper core plan. These differences are not considered to be of any structural significance.

For a discussion of the verification and pre-operational testing for Sequoyah see References 5 and 6.

This modification and the resulting benefits are all in the direction of reducing the vibration amplitude of the internals, as was confirmed with a 1/24th-scale model. The flow test was conducted on a model with a thermal shield. The results indicated that the vibration levels of the internals were low and levels on the thermal shield were negligible. This set of core support structures will receive the normal pre-and post-hot functional examination for integrity per Paragraph D, "Regulations for Reactor Internals Similar to the Prototype Design," of Regulatory Guide 1.20, for units subsequent to a prototype.

Regulatory Guide 1.20, "Vibration Measurements on Reactor Internals," is satisfied for this four-loop plant as described in the balance of this section.

The internals were subject to a thorough examination prior to preoperational flow tests. This examination included the 35 points shown in Figure 3.9.1-5. These 35 points are characterized as the following:

1. All major load-bearing elements of the reactor internals relied upon to retain the core structure in place.

2. The lateral, vertical and torsional restraints provided within the vessel.

3. Those locking and bolting devices whose failure could adversely affect the structural integrity of the internals.

4. Those other locations on the reactor internal components which were examined on the prototype Indian Point II design.

The inside of the reactor vessel was inspected before and after the hot-functional test, with all the internals removed, to verify that no loose parts or foreign material were in evidence.

1. <u>Lower Internals</u>. A particularly close inspection was made on the following items or areas using a 5X or 10X magnifying glass or penetrant testing where applicable. The locations of these areas are shown in Figure 3.9.1-5.

    a. Upper barrel flange and girth weld.

b. Upper barrel to lower barrel girth weld.

c. Upper core plate aligning pin. Examine for any shadow marks, burnishing, buffing, or scoring. Check for the soundness of lockwelds.

d. Irradiation specimen basket bolt and locking devices.

e. Baffle assembly locking devices. Check for lockweld integrity.

f. Lower barrel to core support girth weld.

g. Thermal shield bolt and locking devices. Examine the connections for evidence of change in tightness of lockweld integrity.

h. Radial support key welds to barrel.

i. Insert locking devices. Examine soundness of lockwelds.

j. Core support columns and instrumentation guide tubes. Check all the joints for tightness and soundness of the locking devices.

k. Secondary core support assembly welds.

l. Insert locking devices. Examine soundness of lockwelds.

m. Lower radial support lugs and inserts. Examine for any shadow marks, burnishing, buffing or scoring. Check the integrity of the lock-welds. These members supply the radial and torsional constraint of the internals at the bottom relative to the reactor vessel while permitting axial growth between the two. One would expect to see, on the bearing surfaces of the key and keyway, burnishing, buffing or shadow marks which would indicate pressure loading and relative motion between the two parts. Some scoring of engaging surfaces is also possible and acceptable.

n. Bearing surfaces of upper core plate radial support key.

o. Gaps and baffle joints. Check for gaps between baffle and top former and at baffle to baffle joints.

2. Upper Internals. A particularly close inspection was made on the following items or areas using a magnifying glass of 5X or 10X magnification, where necessary. The locations of these areas are shown in Figure 3.9.1-5.

a. Thermocouple conduits, clamps and couplings.

b. Guide tube, support column and thermocouple assembly locking devices.

c. Support column and conduit assembly clamp welds.

d Radial support keys and insert between the upper core plate and upper core barrel. Examine for any shadow marks, burnishing, buffing, or scoring. Check the integrity of lockwelds.

e. Connections of the support columns and guide tubes to the upper core plate. Check for tightness.

f. Thermocouple conduit gusset and clamp welds.

g. Thermocouple end-plugs. Check for tightness.

h. Guide tube closure welds, tube-transition plate welds and card welds.

Acceptance standards are the same as required in the shop by the original design drawings and specifications.

During the hot functional test, the internals were subjected to a total operating time, at greater than normal full-flow conditions (four pumps operating), for at least 240 hours. This provides a cyclic loading of approximately 10^7 cycles on the main structural elements of the internals. In addition, there was some operating time with only one, two and three pumps operating.

Therefore, when no signs of abnormal wear are found or of harmful vibration being present in the core support structures, and with no apparent structural changes taking place, the four-loop core support structures are considered adequate.

3.9.1.3.3 Flow-Induced Vibration

The dynamic behavior of reactor components has been studied using experimental data obtained from operating reactors along with results of model tests and static and dynamic tests in the fabricators' shops and at plant sites. Extensive instrumentation programs to measure vibration of reactor internals (including prototype units of various reactors) have been carried out during preoperational flow tests and reactor operation.

From scale model tests, information on stresses, displacements, flow distribution and fluctuating differential pressures is obtained. Studies have been performed to verify the validity and determine the prediction accuracy of models for determining reactor internals vibration due to flow excitation. Similarity laws need to be satisfied to assure that the model response can be correlated to the real prototype behavior.

Vibration of structural parts during preoperational tests is measured using displacement gauges, accelerometers and strain transducers. The signals are recorded with magnetic tape records. Onsite and offsite signal analysis is done using both hybrid real-time and digital techniques to determine the approximate frequency and phase content. In some structural components the spectral content of the signals include a nearly discrete frequency or very narrow band, usually

due to excitation by the main coolant pumps and other components that reflect the response of the structure at a natural frequency to broad-band, mechanically or flow-induced, excitation. Damping factors are also obtained from wave analyses.

It is known from the theory of shells that the normal modes of a cylindrical shell can be expressed as sine and cosine combinations with indices m and n indicating the number of axial half waves and circumferential waves, respectively. The shape of each mode and the corresponding natural frequencies are functions of the numbers m and n. The general expression for the radial displacement of a simply supported shell is:

$$w(x,\Psi,t) = \sum_{n=0}^{\infty} \sum_{m=1}^{\infty} \left[A_{nm}(t)\cos n\Psi + B_{nm}(t)\sin n\Psi \right] \sin\frac{m\pi x}{L}$$

The shell vibration at a natural frequency depends on the boundary conditions at the ends. The effect of the ends is negligible for long shells or for higher-order m modes, and long shells will have the lowest frequency for n = 2 (elliptical mode). For short shells, the effects of the ends are more important, and the shell will tend to vibrate in modes corresponding to values of $n \geq 2$.

With these previous considerations as a basis, the following procedures have been performed in the study of thermal shield vibration:

1. During a test program performed with a 1/7th-scale model of the thermal shield in water the natural frequencies and the maximum vibration amplitude were measured.

2. Shaker test programs performed on a prototype thermal shield with the actual boundary conditions, provided full scale natural frequencies and mode shapes in air. These modes were established by measuring accelerations at the center, top (support elevation) and bottom of the shield. In Figure 3.9.1-6 the results obtained are plotted for n = 4 and correspond to a thermal shield with eight supports which are indicated in the same figure. The amplitudes of vibration are fitted with a curve $y = A \sin 4\Theta$.

3. Maximum displacements were measured during the preoperational reactor test and were correlated with the information obtained in the 1/7-scale model and shaker test.

4. In Figure 3.9.1-7 the maximum amplitudes of vibration are plotted as measured on a thermal shield with six supports. The experimental points have been least square fitted with a curve $y = A \sin 3\Theta$.

In general, the study follows two parallel procedures: obtain frequencies and spring constants analytically, and confirm these values from the results of the tests. Damping coefficients are established experimentally, and forcing functions are estimated from pressure fluctuations measured during operation and in models. Once these factors are established, the response can be computed analytically. In parallel, the responses of important reactor structures are measured during preoperational reactor tests and the frequencies and mode shapes of the structures are obtained. Once all the dynamic parameters are obtained as explained above, the forcing functions can be estimated. These two procedures are not independent; both are performed

simultaneously and when combined they provide indications of the internals behavior during reactor operation. Finally it should be mentioned that internals behavior during reactor operation has been measured using mechanical devices and nuclear noise methods. The last method involves the frequency spectral analysis of signals from out-of-core ion chambers. Information is obtained on the frequency, amplitude, and damping of the vertical and lateral vibrations of the core because relative motions of the core causes reactivity perturbations and fluctuations in the neutron flux signal level.

Some components, such as control rod guide tubes, fuel rods and incore instrumentation tubes, are subjected to cross flow and parallel flow with respect to the axis of the structure. In these cases there are numerous theoretical and experimental studies directed toward establishing the response of the structure (Reference 2). These studies also provide information on the added apparent mass of the water, which has the effect of decreasing the natural frequency of the component. For both cases, cross and parallel, the response is obtained after the forcing function and the damping of the system are determined.

Cross flow may excite the structure with periodic vortex shedding, which gives rise to a lateral oscillatory lift force perpendicular to the flow direction and a drag force in the flow direction. The dimensionless vortex shedding frequency, or Strouhal number S = fD/V, is a function of the Reynolds number and known for different cross sections. The structure is usually designed in such a manner that its natural frequency in water is considerably higher than the vortex shedding frequency so as to avoid coincidence. The lateral force per unit length is given by:

$$F(x,\ t) = C_L\ [1/2\rho_f\ \ V(x)^2]\ D\ \cos\ \omega t \qquad (3.9\text{-}1)$$

where

C_L = the oscillatory lift coefficient including correlation length effects (depending on the Reynolds number)

ρ_f = fluid density

V = cross flow velocity

D = the characteristic diameter

ω = the vortex shedding circular frequency

Data obtained from preoperational and shop tests are used to confirm the coefficients used.

3.9.1.3.4 Vibration Monitoring

Since reactor internals of a given type (i.e., two, three or four loop) are designed and manufactured to essentially the same procedures, processes and similar drawings, the response of these structures within a pressurized water reactor environment is similar.

Performance data from the instrumentation of actual reactors as well as mechanical and flow scale models are available (References 1, 2, 5, 6, 7, and 8).

For example, the preoperational flow test on the Indian Point 2 Plant, a four-loop prototype plant, has been completed. The pre-and post-pre-operational flow test examination of the internals has been completed indicating that all the components performed as predicted. No evidence of damage or incipient failure has been found.

The testing programs consisted of measurements of the stresses, deflections and responses of select key points in the internals structures during hot functional and low power physics tests. The main purpose of this testing program was to assure that no unexpected large amplitudes of vibration existed in the internals structure during operation.

These tests, however, were by no means designed or intended to be capable of detecting possible incipient failures of all the various components within the core support structures. They were designed with the purpose of giving data and results on what were assumed to be indicators of overall core support structure performance and to verify particular stress and deflection quantities.

3.9.1.3.5 Dynamic Analysis of Safety-Related Mechanical Equipment

A description of the analyses used in the design of safety-related mechanical equipment such as pumps and heat exchangers to withstand seismic loading is given in Paragraphs 3.7.2.1 and 3.7.3.1.

3.9.1.3.6 Dynamic Analysis of the Ice Condenser

This information is presented in Chapter 6.

3.9.1.3.7 Inelastic Stress Analysis

No plastic instability allowable limits are used when dynamic analysis is performed. The limit analysis methods have the limits established by the ASME Section III for Normal, Upset and Emergency Conditions. (Summer 1968 Addenda to the ASME Boiler and Pressure Code, Section III.) For these cases, the limits are sufficiently low to assure that the elastic system analysis is not invalidated. For faulted conditions, the limits are specified in Paragraph 5.2.1.3. These limits are established in such a manner that there is an equivalence with the adopted elastic limits and consequently will not invalidate the elastic system analysis. Particular cases of concern are checked by readjusting the elastic system analysis.

3.9.1.3.8 Core Components

Stainless steel clad silver-indium-cadmium alloy absorber rods are resistant to radiation and thermal damage thereby ensuring their effectiveness under all operating conditions. Rods of similar design have been successfully used in the original and reload cores of San Onofre, Connecticut-Yankee, and others.

Two burnable poison rods of smaller length but similar in design to those planned in this reactor have been exposed to inpile test conditions in the Saxton Test Reactor in October 1967. A visual examination of the rods was made in early June, 1968 and a visual and profilometer examination was made on July 30, 1968 after an exposure of 1900 effective full power hours (approximately 25 percent B^{10} depletion). The rods were found to be in excellent condition and profilometry results showed no dimensional variation from the initial condition.

An experimental verification of the reactivity worth calculations for borosilicate glass tubing has been accomplished. Similar rods have been successfully operated in the Ginna reactor with no evidence of deficiency.

Manufacturing defects will not appear during the hot functional tests; any manufacturing defect will be detected in the shop or during the assembly period. The basic program that is currently being used to insure adequacy of manufacturing practices consists of:

1. Extremely thorough nil ductility temperature and Quality Assurance Program at the internals vendors.

2. Extensive visual examination at the plant site prior to hot functional testing of the primary system.

3. Running the hot functional test with full flow for 240 hours which accumulate approximately 10^7 cycles on the majority of the core structure components.

4. Re-examining all areas of the internals after the 240 hour hot functional test.

3.9.1.4 Correlation of Tests and Analytical Results for Reactor Internals

The program to establish internals integrity has been to utilize extensive design analysis, model testing, and pre- and post-hot functional inspection. Additionally, Westinghouse has instrumented full size reactors to measure the dynamic behavior of the first-of-a-kind of each size plant and has compared measurement with predicted values. This program was instituted as part of the basic philosophy of Westinghouse to instrument the internals of a first-of-a-kind of the current nuclear steam supply system designs for power plants. The previous "first-of-a-kind" plants that were instrumented were Jose Cabrera, 1-loop, R. E. Ginna, 2-loop, H. B. Robinson, 3-loop and Indian Point 2, 4-loop. The Indian Point No. 2 plant has been the most thoroughly instrumented plant to date. The magnitude of that test program was much greater than the intent of the philosophy, and was established as part of an extensive plan to develop theories and basic concepts related to internals vibration under various operating conditions. Thus, not only is added assurance obtained that all of the hardware will operate in the manner for which it was designed, but these data also assist in the development of increased capability for the prediction of the dynamic behavior of PWR internals.

The data collected from the 4-loop Indian Point 2 plant compared very well with similar data taken on other plants. Further, the predictions of the dynamic response that were made prior to the test program for highly stressed components were closely substantiated by the results of this testing, showing clearly that the structural dynamic response of the internals is both understood and well behaved.

The flow condition to which the vessel and internals are subjected is fairly uniform over a wide range of frequencies, and, therefore, the internals will be excited at the natural frequencies of the components. The equipment motion at these frequencies will be amplified. The dynamic beam and shell mode shapes that are associated with these frequencies can be identified. The amount of amplification at any point in the structure will depend on the the relationship of that point to the vibratory mode shapes of the resonant frequencies.

Complete identification of the resonant frequencies and the associated modes from pre-operational tests allows correlation with the associated resonant frequencies and modes from a mathematical model of the internals. This model can then be used for the dynamic analysis of the reactor internals under LOCA loadings. This correlation provides verification that the modeling techniques used are accurate and that the analytical dynamic LOCA response of the reactor internals will be determined from a valid model.

3.9.1.5 <u>Analysis Methods Under LOCA Loadings</u>

Parts 1, 2, and 4 of FSAR Section 3.9.1.5 as described in Regulatory Guide 1.70 Revision 1 are provided in Subsection 3.9.3 (Part 3 is listed below).

3. The scope of the different dynamic analysis techniques and methods used to evaluate mechanical systems and components of the Westinghouse Pressurized Water Reactor for loads produced by a auxiliary line branch nozzle pipe rupture on the main coolant loop (DBA), is very extensive.

<u>Reactor Internals Analysis</u>

Analysis of the reactor internals for blowdown loads resulting from a loss of coolant accident is based on the time history response of the internals to simultaneously applied blowdown forcing functions. The forcing functions are defined at points in the system where changes in cross section or direction of flow occur such that differential loads are generated during the blowdown transient. The dynamic analysis can employ the displacement method, lumped parameters, stiffness matrix formulations and assumes that all components behave in a linearly elastic manner.

In addition, because of the complexity of the system and the components, it is necessary to use finite element stress analysis codes to provide more detailed information at various points.

A comprehensive explanation of all the techniques and analytical methods used cannot be included in the scope of this FSAR. The more important and relevant methods are presented as an overview in Section 3.9.3.5.

<u>Reactor Coolant Loop (RCL) Analysis</u>

A flow diagram representing the procedure for the complex time-history dynamic solution is shown in Figure 3.9.1-8. The time-history nonlinear dynamic structural analysis was performed in the following manner:

The natural frequencies and normal modes of the loop were determined using the WESTDYN computer program. The natural frequencies, normal modes, and time-history forcing functions were used in the Westinghouse proprietary computer program, WESTDYN, to determine the time-history dynamic deflection response of the lumped-mass representation of the RCL.

Where a support was considered as a nonlinear (single direction of action) member, the support forces were a time-history calculation of the program WESTDYN. In those cases where a support (for instance, a column) had different stiffness values in tension and compression, the smaller value was input as a linear spring, and the difference was input as a nonlinear element in the appropriate direction.

The computer program WESTDYN applied the time-history dynamic forces at mass points on the loop RCL model along with RPV LOCA motion and computed a response of internal forces, deflections, and stresses at each end of the members of the RCL piping system.

3.9.1.6 Analytical Methods for ASME Code Class 1 NSSS Components

No plastic instability allowable limits given in ASME Section III are used when dynamic analysis is performed. The limit analysis methods have the limits established by ASME Section III for Normal, Upset and Emergency Conditions. For these cases, the limits are sufficiently low to assure that the elastic system analysis is not invalidated. For ASME Code Class 1 NSSS components, the stress limits for faulted loading conditions are specified in Section 5.2. These faulted condition limits are established in such a manner that there is equivalence with the adopted elastic limits and consequently will not invalidate the elastic system analysis. Particular cases of concern are checked by readjusting the elastic system analysis.

For components other than Class 1 NSSS components, the stress limits for all loading conditions are specified in Sections 3.9.2 and 3.9.3.

3.9.2 Safety Class B, C, and D Fluid Components (Includes Class A piping (Reactor Coolant Loop Branch Lines) analyzed by TVA.)

3.9.2.1 Plant Conditions and Design Loading Combinations

Design pressures, temperatures, and other information that provide the basis for the design of safety-related systems and components are presented in the corresponding sections that describe the system functional requirements. Codes that govern the analysis of vessels, tanks, valves, pumps, and piping are defined in Table 3.9.2-1. Environmental equipment such as ventilation and air treatment components and other equipment which is safety related but which have no applicable code for design are qualified for the loading combinations specified in Table 3.9.2-2 by analysis and/or test in accordance with guidelines established by IEEE 344-71.

The seismic qualification of safety-related electrical and mechanical equipment (including fluid system components such as pumps, valves, and tanks) at SQN has been evaluated against current criteria, IEEE 344-1975 and Regulatory Guide 1.100 (Reference 14). The NRC's Seismic Qualification Review Team (SQRT) conducted the evaluation during the licensing phase. The SQRT concluded that the SQN equipment, originally qualified in accordance with IEEE 344-1971, satisfies the requirements of current criteria (Reference 15). The results of the NRC SQRT audit provide justification for making IEEE 344-1975 the design basis acceptance criteria for the seismic qualification of safety-related electrical mechanical equipment at Sequoyah. In accordance with the SQRT audit commitments, to the fullest extent reasonably possible, this acceptance criteria has been used for procurement of new equipment and evaluation of existing equipment for the Sequoyah design basis seismic events since September 1, 1974 (Reference 16).

Subsection 3.9.3 describes the analytical methods used for NSSS components not covered by the ASME code of record.

3.9.2.2 Design Loading Combinations

Design loading combinations and allowable stress levels for classes B, C, and D components (excluding piping) are shown in Tables 3.9.2-2 and 3.9.2-3.

Design loading combinations and allowable stress levels for classes B, C, and D piping are shown in Table 3.9.2-4.

Design loading combinations and allowable stress levels for piping supports are shown in Table 3.9.2-5.

Design loading combinations are categorized with respect to normal, upset, and faulted conditions. The categories are defined as follows:

1. Normal Conditions. Any condition in the course of system startup, operation in the design power range, and system shutdown, in the absence of upset, faulted, and test conditions.

2. Upset Conditions. Any deviations from normal conditions anticipated to occur often enough that design should include a capability to withstand the conditions without operational impairment. The upset conditions include those transients which result from any single operator error or control malfunction, transients caused by a fault in a system component requiring its isolation from the system, transients due to loss of load or power, and any system upset not resulting in a forced outage. The upset condition includes the effects of a one-half safe shutdown earthquake for which the system must remain operational or must regain its operational status.

3. Faulted Conditions. Those combinations of conditions associated with extremely low probability, postulated events whose consequences are such that the integrity and functionality of the nuclear energy system may be impaired to the extent that considerations of public health and safety are involved. The faulted condition includes the effects of the safe shutdown earthquake and the dynamic effects of postulated pipe rupture considered as separate events (see Table 3.9.2-2). It also includes the combined effects of a SSE event and the containment motion from DBA LOCA event.

3.9.2.3 Inelastic Deformation

The stress limits for the faulted condition for groups B, C, and D components are within the code allowable for primary loads. Other safety related equipment which has no applicable code for design is qualified as described in Sections 3.9.2.1 and 3.9.3. Consequently, functional and structural integrity are assured for the faulted condition.

3.9.2.4 Design and Installation Criteria, Pressure Relieving Devices

The design and installation of pressure relieving devices are consistent with the requirements established by Regulatory Guide 1.67, "Installation of Overpressure Protective Devices."

The safety valves are mounted on a header and introduce torsion, bending, and thrust loads in the header during valve operation. The header has been designed to accommodate both dynamic and static loading effects of all valves blowing down simultaneously.

The safety valves and power-operated atmospheric relief valves are Seismic Category I components. They have been seismically qualified by analyses and/or test per criteria presented in Section 3.7.3 and Table 3.9.2-3.

Pressure relief valves in auxiliary safety-related systems have been installed considering loads carried in the support members produced by:

1. deadweight of valve and appurtenances,

2. thermal effects,

3. seismic effects,

4. maximum valve thrust, moment, and torsional loading effects, and

5. internal pressure

Relief valves that discharge to the atmosphere are either rigidly supported by their own individual support or the nozzle and component to which the valve is attached (vessel, tank, or pipe) have been designed to carry the valve static and dynamic loads. Individual supports have been designed to stress levels defined in Table 3.9.2-5. Stresses in nozzles and components produced by the valve loads considered above are determined per the method delineated in Welding Research Council Bulletin No. 107, or other appropriate analytical techniques, and are combined with concurrent loads for the component. Relief valves blowing down is considered as an upset loading condition for the plant. Therefore, the load cases and allowable stress intensities for the component supporting the valve loads are in accordance with those given in Tables 3.9.2-2 and 3.9.2-3.

Loading associated with relief valves discharging through piping components to a collector tank are analyzed considering the surge effects of the initial discharge through the pipe. This condition is considered as an upset loading condition for the piping components connecting to the valve and the allowable stress intensity is in accordance with those for piping components tabulated in Table 3.9.2-4.

3.9.2.5 Stress Levels for Category I Components

3.9.2.5.1 Scope of System Analysis

TVA Class A Piping (Excluding the Reactor Coolant Loops)

The scope consists of TVA Class A piping within the reactor coolant pressure boundary, but excluding the reactor coolant loops, as shown in the following simplified figures:

1. Reactor Coolant System Flow Diagram (Figure 5.1-1)

2. Safety injection System Flow Diagram (Figure 6.3.2-1)

3. Chemical Volume and Control Flow Diagram (Figures 9.3.4-1,-2,-3)

4. Residual Heat Removal Flow Diagram (Figure 5.5.7-1)

The following is a listing of Class A piping analyzed by TVA:

1. Charging line and alternate charging line from the designated isolation or check valve up to the branch connections on the reactor coolant loop.

2. Letdown line and excess letdown line from the branch connections on the reactor coolant loop to the designated isolation or check valve.

3. Pressurizer spray lines from the reactor coolant cold legs to the spray nozzle on the pressurizer vessel.

4. Residual heat removal lines to/from the reactor coolant loops up to designated isolation or check valve.

5. Safety injection lines from the designated isolation or check valve to the reactor coolant loops.

6. Accumulator lines from the designated isolation or check valve to the reactor coolant loops.

7. Loop fill, loop drain, sample, and instrument lines to/from the designated isolation valve to/from the reactor coolant loops.

8. Pressurizer surge line from one reactor coolant loop hot leg to the pressurizer vessel inlet nozzle.(Westinghouse performed the fatigue evaluation of the surge line to demonstrate compliance with NRC Bulletin 88-11)

9. Pressure relief lines from nozzles on top of the pressurizer vessel up to and through the power-operated pressurizer relief valves and pressurizer safety valves.

10. Seal injection water and labyrinth differential pressure lines to/from the reactor coolant pump inside reactor containment.

11. Auxiliary spray line from the designated isolation valve to the pressurizer spray line header.

12. Sample lines from pressurizer or loop to the designated isolation valve.

13. Any other lines of TVA Class A as indicated on Engineering Flow Diagrams.

TVA Class B, C, D, and Non-Nuclear Safety Piping

TVA has evaluated the necessity of performing a rigorous analysis on all piping systems and identified the limits of the analysis using the following guidelines:

1. Analyze most TVA Class B, C, and D lines 6-inch diameter and larger. Note: Where practical, Alternate Analysis may be performed on small sections of moderate energy 6 inches and larger Class B, C, or D piping. For a description of the Alternate Analysis methodology, see Section 3.7.3.9.

2. Analyze all piping in Category I structures larger than 1-inch diameter that has a maximum operating temperature of 200°F or greater and a maximum operating pressure of 275 psig or greater, unless it can be determined that there is not a potential for unacceptable pipe rupture interactions.

3. Analyze piping which, due to high temperature or other extraordinary loading conditions, cannot be economically or practically supported using alternate analysis procedures.

4. All systems requiring seismic qualification, but not requiring complete analysis as outlined above, will be evaluated according to the procedures outlined in Section 3.9.2.6.

The following systems are within the scope outlined above, and are being completely analyzed for thermal, seismic, transient, design basis accident, seismic anchor movement, and deadweight conditions:

1. Main steam system
2. Main steam blowdown system
3. Feedwater system
4. Auxiliary feedwater system
5. Chemical and volume control system
6. Safety injection system
7. Containment spray system
8. Residual heat removal system
9. Component cooling system
10. Essential raw cooling water
11. Auxiliary boiler piping
12. Spent fuel pool cooling and cleaning
13. Parts of other systems which require rigorous analysis

3.9.2.5.2 Analytical Methods

Loading Conditions and Stress Limits

The design loading combinations and the allowable stress limits considered in the design of TVA piping systems within the scope of Section 3.9.2.5.1 are shown in Table 3.9.2-4. Design loading combinations are categorized with respect to normal, upset, and faulted conditions.

Piping components have been designed to the ANSI B31.1-1967 power piping code utilizing the equations and rules from ASME Section III, Winter 1972 ADDENDA for loading combinations not defined in ANSI B31.1, and the allowable stress and material property values from Appendix I of the ASME Section III Winter 1972 ADDENDA.

While the ANSI B31.1 1967 code did not define allowable stress limits for some of the loading combinations considered in Table 3.9.2-4, the allowable stress levels are in basic agreement with Appendix I of the ASME Section III, Winter 1972 ADDENDA.

The rules and criteria of ANSI B31.1 1967 are considered to be equivalent to those of Section NC3000 of the ASME Section III, Winter 1972 ADDENDA with the appropriate additional consideration of the equation 9 requirements of the ASME Code.

Analyses

1. Stress evaluations due to loadings such as deadweight, thermal expansion, and anchor movements are performed using static analysis techniques, while stress evaluations due to earthquake loadings and other dynamic loads are performed using dynamic analysis techniques. The computer programming for application of both techniques is described in Section 3.9.2.5.3.

2. Loads on equipment nozzles are combined and evaluated against allowables established by the equipment vendor and/or TVA.

3. Seismic valve accelerations are generally maintained below 2 g vertical, and 3 g horizontal. Cases exist such that valve accelerations may exceed these standard limits. Such cases are evaluated and approved individually; this process is controlled by the Rigorous Analysis Handbook.

4. In general, safety-related valves at SQN were procured to reflect a minimum extended structure fundamental frequency of 25 Hz and, as such, are considered rigid. Under this approach, valve extended structures are modeled as rigid cantilevers in the piping dynamic simulation. A few cases exist such that valve extended structures do not satisfy the 25 Hz criteria. For these cases, extended structures are modeled as flexible cantilevers with appropriate consideration for inertial loading. Modifications to existing valves which affect fundamental frequency and dynamic response are evaluated on a case-by-case basis.

5. Pump casings are inherently rigid with regard to predominant structural frequency and, as such, provide a piping analysis boundary condition which closely approximates an anchor at the pump nozzles. Typically, this approach results in a conservative prediction of thermal expansion induced nozzle loads which are considered in combination with nozzle loads from seismic response. Calculated nozzle loads are evaluated against conservative allowables for all design basis loading conditions to ensure adequate pump qualification. This process is controlled by the Rigorous Analysis Handbook.

   In those few cases where pump assemblies have been found to be nonrigid (f <25 Hz), appropriate considerations were made with regard to piping and/or pump qualification. The only case which required a special analytical approach to achieve seismic qualification was documented by Nonconforming Condition Report 69D, dated September 16, 1977.

   The safety and reliability of pump and attached piping system designs are enhanced by TVA's preoperational testing and in-service surveillance/maintenance programs described in Sections 3.9.1.1, 6.8, and 14.1. These programs are intended to ensure that mechanical and fluid induced vibration levels are kept within acceptable limits for all system operating modes and that degradation mechanisms are appropriately addressed throughout the lifetime of the system.

6. Buried piping is analyzed as described in Section 3.7.3.12.

7. The analysis of the Unit 2 Feedwater (FW) piping due to the rapid FW check valve closure following a pipe break near the main feedwater header was performed utilizing linear elastic and non-linear plastic analyses based on Appendix F of Section III of the 1986 ASME Code. R. L. Gridley's letter to NRC dated February 18, 1988 provided notification of TVA's plan to qualify the FW piping according to Appendix F for faulted loads.

   The following is a summary of the Unit 2 analyses performed to demonstrate the structural integrity of the safety-related portion of the FW system during and following this postulated event:

   Thermohydraulic analyses using RELAP5 were performed to establish forcing functions for all four FW lines.

   Rigorous piping analyses were performed on two representative FW lines to calculate piping stresses and support loads due to the waterhammer event. The remaining two FW lines were qualified by similarity.

   Component qualification was performed for the steam generator nozzles, the steel containment vessel penetrations, the feedwater bellows, and the feedwater check valve.

   Structural analyses were performed to evaluate the loadings on the concrete walls, structural steel, and embedded plates.

   Some of the pipe supports were evaluated to ensure that their failure would not damage other safety-related components.

   These analyses show that some piping supports may fail, but that the piping itself would remain intact, with its deflection limited by the presence of the pipe whip restraints.

   Since the design of the Unit 1 FW lines are opposite hand to the Unit 2 FW lines, the Unit 1 FW lines are qualified on the basis of similarity between the two units.

8. For cases where TVA may have installed safety Class B small bore (two-inches and less) pipe and fittings in safety Class A applications, a 40 percent stress reduction was used in lieu of NDE (non-destructive examination) to assure plant safety. ANSI

B31.7c-1971, paragraph 1-724, provides for a reduction in allowable stress in lieu of NDE. The conditions described in B31.7, for which the 40 percent stress reduction is imposed, are identical to the conditions TVA is addressing. The 40 percent reduction is applied to the stress limits defined in Table 3.9.2-4.

3.9.2.5.3 Programs Used for Category I Piping Analyses

The following is a list of computer programs used for dynamic and/or static analysis of Category I, Class A, B, and C piping. Each program's scope, background, applicability, and method of validation is discussed in the program descriptions below:

Program Name	Application	Owner
PISOL1A	Dynamic	EDS/IMPELL
PISOL3A	Static	EDS/IMPELL
TPIPE	Static and Dynamic	TVA/PMB
PFA	Static	TVA
SUPERPIPE	Static and Dynamic	EDS/IMPELL
NUPIPE-SW	Static and Dynamic	Stone & Webster
ME101	Static and Dynamic	BECHTEL
ANSYS	Static, Dynamic, and Non-linear	Stone & Webster

1. PISOL1A--for the dynamic elastic analysis of piping systems subject to seismic excitation.

   EDS Program (IMPELL) PISOL1A analyzes arbitrary, three-dimensional piping systems for seismic excitation using the dynamic analysis technique known as the response spectrum mode superposition method. In this technique, the earthquake excitation is characterized by acceleration response spectra, and the total response of the system is evaluated as a square root of the sum of the squares combination of the response of the significant natural modes of vibration of the system. Closely spaced modes can be combined using either the modified NRC 10 percent method or the modified NRC 10 percent grouping method. The results for earthquakes acting in both horizontal directions separately, each combined with vertical motion are computed, or alternatively, earthquakes acting in all three directions simultaneously may be computed.

   A piping system is idealized as a mathematical model consisting of lumped masses connected by massless elastic members. The locations of the lumped masses are chosen to adequately represent the dynamic characteristics of the system. The direct stiffness method of structural analysis is used to form the system stiffness matrix, including stiffness modifications for curved components, and diagonal mass and damping matrices are assumed. The dynamic properties of the system (periods of vibration and normal mode shapes) are determined using the Householder-QA method, and the system response is then computed by the modal superposition procedure.

PISOL1A has been used for dynamic seismic piping analysis for more than 15 nuclear power plants and has been verified by independent analysis by the Bechtel Power Corporation of San Francisco for several of these plants. In addition, the program has been benchmarked by EDS (IMPELL) against the ASME Sample Problem No. 1 contained in ASME publication, "Pressure Vessel and Piping 1972, Computer Programs Verification," and the benchmark data has been submitted to the ASME. Typical plants for which the program has been used for dynamic seismic piping analysis include Donald C. Cook, Rancho Seco, Trojan, and Calvert Cliffs Unit 1.

2. PISOL3A--for the static elastic analysis of piping systems subject to static loading.

EDS Program (IMPELL) PISOL3A analyzes arbitrary, three-dimensional piping systems subject to applied static loadings and displacements. The program is based on the direct stiffness method of structural analysis. A piping system is idealized as a mathematical model consisting of lumped weights connected by weightless elastic members. The location of the lumped weights is chosen to adequately represent the weight distribution of the system for dead load analysis. The direct stiffness method of structural analysis is used to form the stiffness matrix including stiffness modifications for curved components. The equations of equilibrium are solved to determine the system displacements, and hence member forces and moments for the applied loading and/or displacements, using a Gaussian reduction procedure.

PISOL3A has been used for static piping analysis for more than 30 nuclear power plants. The program has been used for independent verification of the programs of the Bechtel Power Corporation of San Francisco for several plants, and was included on the Monticello docket. In addition, the program has been benchmarked by EDS (IMPELL) against other programs such as EDSGAP and MEL-40. Typical plants for which the program has been used for static piping analysis include Monticello, Donald C. Cook, Rancho Seco, Trojan, and Calvert Cliffs Unit 1.

3. TPIPE--for the linear elastic structural analysis of arbitrary, 3-dimensional piping systems subject to static and dynamic loadings. Analyses are performed to ASME requirements for Classes 1, 2, or 3 systems.

A piping system is idealized as a mathematical model consisting of lumped weights connected by weightless elastic members. The locations of the lumped weights are chosen to adequately represent the dynamic characteristics of the system for dynamic considerations.

The direct stiffness method of structural analysis is used to form the stiffness matrix, including stiffness modifications for curved components. Diagonal mass and damping matrices are assumed. The equations of equilibrium are solved to determine the system displacements, and hence member forces and moments for the applied loading and/or displacements, using a Gaussian elimination procedure.

TPIPE analyzes piping systems subject to applied static loading conditions using the method discussed in the preceding paragraph, however, the piping dead load analysis considers both distributed weight properties of the piping and any concentrated weights.

TPIPE analyzes piping systems for dynamic excitation using the analysis technique known as the response spectrum modal super- position method. A direct integration or modal super-position time history capability is also available. Seismic options include a multiple support zone capability. The dynamic properties of the system (periods of vibration and normal mode shapes) are determined using a modified subspace iteration technique, and the system response is then computed by the modal superposition procedure.

TPIPE has been benchmarked by TVA against the NRC program EPIPE in accordance with the Standard Review Plans, NUREG-0800, Section 3.9.1.II and NUREG/CR-1677. TPIPE is verified and maintained by TVA using formal software QA procedures.

4. PFA--for the elastic static analysis of piping systems subject to thermal and applied displacement loadings.

Piping Flexibility Analysis Program, PFA, was bought from the Service Bureau Corporation by TVA. PFA analyzes arbitrary, 3-dimensional piping systems subject to thermal and displacement loadings. The program is based on the direct stiffness method of structural analysis. The results are modified by a postprocessor at points requiring "tee" stress intensification by multiplying the indicated stress by the stress intensification factor ratio.

The usefulness of PFA is restricted by the program problem size limitation which is determined as follows:

$$6 (A + L - 1) + R < 95$$

A = Number of anchors

L = Number of loops

R = Number of restrained directions

PFA is verified and maintained by TVA using formal software QA procedures.

5. SUPERPIPE - For linear elastic structural analyses of piping systems for static and dynamic loadings. Analyses are performed to ASME requirements for Classes 1, 2, and 3 systems.

The program has various features for user ease in defining the piping system. Various plotting capabilities and extensive diagnostic error and warning messages aid in checking the model.

In addition to the basic capabilities, SUPERPIPE offers the following specialized piping analysis specifications.

Analysis with response spectra for piping supported at multiple zones.

Modal superposition or direct integration techniques of time history analysis.

Analysis with multiple earthquake records for situations in which a piping system is subjected to independent motions at each support and the effect of phase relationships between these motions is important.

Static or dynamic equilibrium equations are formulated using the direct stiffness method, in which element stiffness matrixes are formed according to virtual work principles and assembled to form a global stiffness matrix for the system, relating external forces and moments to joint displacements and rotations. Six degrees of freedom may be specified at each joint of the global system for both static and dynamic analyses.

Static equilibrium equations are solved using Gaussian reduction techniques on the compacted stiffness matrix. For dynamic problems, the equilibrium equations may be solved using either step-by-step direct integration of the coupled equations of motion, or by first calculating natural frequencies and mode shapes and transforming the system into a set of uncoupled equations of motion. Natural frequencies and mode shapes are calculated using the determinant search technique.

The program has been thoroughly tested and verified for a comprehensive set of sample problems, including extensive comparison with several publicly-available programs and ASME benchmark problems. This has included benchmarking by EDS (IMPELL) against the ASME sample problems 1 and 6 contained in ASME publication, "Pressure Vessel and Piping 1972, Computer Program Verification." All verification analyses have been documented in accordance with established EDS (IMPELL) quality assurance procedures.

6. NUPIPE-SW - The NUPIPE-SW (SWEC 1982) piping program performs a linear elastic analysis of three-dimensional piping systems subjected to thermal, static, and dynamic loads. It utilizes the finite element method of analysis.

NUPIPE-SW handles all loading conditions required for complete nuclear piping analyses. A given piping configuration may be analyzed successively for a number of static and dynamic load conditions in a single computer run. Separate load cases, such as thermal expansion and anchor displacements, may be combined to form additional analysis cases. The piping deadload analysis considers both distributed weight properties of the piping and any added concentrated weights.

A lumped mass model of the system is used for all dynamic analysis, and both translational and rotational degrees of freedom may be considered. Location of lumped masses and degrees of freedom at each mass point are preselected by the analyst. The program automatically computes values of translational lumped masses.

Program input consists basically of program control, piping configuration description, and load specification information. Output includes certain computed system information and a listing of calculated forces, moments, deflections, and stresses for each individual load case. Output from seismic analyses includes system normal mode information. NUPIPE-SW output data also contains pipe stress and pipe support summaries and piping isometric plots. Output data of NUPIPE-SW can be saved on a separate tape for further analysis, if required.

The NUPIPE-SW program is designed to perform analysis in accordance with ASME Section III, Nuclear Power Plant Components (Code). Features ensuring code conformance include use of accepted analysis methods, incorporation of specified stress indices and flexibility factors, proper combination of moment resultants, and provision to generate (automatically) results of combined loading cases. A program option is available to specify among:

1. Class 1 analysis per Article NB-3600 of the Code,

2. Class 2 analysis per Article NB-3600 of the Code,

3. Analysis per ANSI B31.1.0 power piping code, and

4. Combined Class 1 and Class 2 analysis per Articles NB-3600 and NC-3600 of the Code.

NUPIPE-SW program has been verified with ADLPIPE (ADL 1972) for thermal, weight, and response spectrum seismic analysis.

Comparisons were also made with the ASME (1972) Benchmark solution for force time-history dynamic response.

The Class 1 pipe stresses computed by NUPIPE-SW agree with those calculated by hand.

NUPIPE-SW is verified and maintained by SWEC using formal software QA procedures.

7. ME101- (BECHTEL) is a finite element computer program to perform linear elastic response of piping systems. The input is simple and user friendly. It provides extensive data checking and automatic re-numbering of internal data points to optimize computer costs. The program includes all traditional piping stress options, such as static, thermal, weight, uniformly distributed loads, external loads, effective weight,

SAM analysis, dynamic and static seismic analysis with enveloped spectrum methodology. ME101 also includes the latest "state of the art" type analyses which are ISM (Independent Support Motion) or MRS (Multiple Response Spectrum) spectrum analysis, closely-spaced modes and modal coupling analysis using CQC and double sum methodologies, ISM time history analysis in the form of arbitrary support displacements or accelerations, force or pressure transient time-history analysis, ZPA analysis using static or missing mass correction, Bechtel's non-linear energy absorber analysis, direct integration time-history method considering non-linear kinematic hardening supports, harmonic and steady-state vibration analysis. The program can analyze and evaluate piping systems in accordance to the latest NRC Regulatory requirement of 1.61, 1.92, 1.48, and ASME code cases N-411 and N-420. The program provides a great flexibility in load combination, support/hanger guidance, stress check, and stress summary based on the ANSI B31.1 Power Piping Code and ASME Section III Nuclear Class 2 and 3 (including the latest 1983 code criteria). ME101 is verified and maintained by BECHTEL using formal software QA procedures.

8. ANSYS - The ANSYS computer program is a large-scale general purpose computer program (developed by Swanson Analysis Systems, Incorporated) for the solution of several classes of engineering analysis problems. ANSYS is capable of analyzing structures with static and dynamic loadings, elastic and plastic member properties, creep and swelling, buckling, and small and large deflections.

   The matrix displacement method of analysis based upon finite element idealization is employed throughout the program. This ANSYS version is verified and maintained by SWEC using formal software QA procedures.

3.9.2.5.4 Results of Piping Analyses

The analytical results of the piping system analyses performed in accordance with Section 3.9.2.5.2 are controlled by the Rigorous Analysis Handbook.

Figure 3.9.2-1 is representative of the mathematical models for the analyses of all TVA Class A piping systems defined in Section 3.9.2.5.1.

3.9.2.6 Field Run Piping

Field engineering personnel field route and support category I, TVA Class B, C, D, G, K, and M process piping and instrument lines that do not require complete analysis as defined in Section 3.9.2.5. These activities are based on input/direction from Engineering Design.

The field run piping design criteria is limited to piping components which meet the following conditions:

1. Materials

   a. Stainless steel equivalent to A312/358/376, Type 304/316.

b. Carbon steel equivalent to A106, Grade B or seamless A53, Grade B.

c. Aluminum equivalent to 6061T4 or 6061T6.

d. Copper tubing for water, air, or refrigerant service.

2. Stress intensity

Material allowable stress intensity at design temperature must be equal to or greater than 14,000 psi for steel and 5,700 psi for aluminum piping.

Copper tubing allowable stress intensity at design temperature must be equal to or greater than 6,000 psi for water or air service and 4,800 psi for refrigerant service.

3. Temperature Range Limits Considered For Steel Only

a. Sizes 3/8 through 1 inch - maximum of 650°F.

b. Sizes 1-1/4 through 4 inches - maximum of 200°F.

c. Sizes greater than 4 inches - require independent analysis.

4. Specific Exclusions

a. Piping requiring analysis under Section 3.9.2.5.

b. TVA Class A piping.

c. Piping classified as "High Energy."

d. Piping systems requiring analysis consideration of external or DBA loads.

e. Piping supporting large concentrated loads which are not independently supported.

3.9.2.7 Interim Acceptance Criteria

An interim acceptance criteria was used for temporary resolution of several critical engineering issues for the 1988 restart of Sequoyah Nuclear Plant (Phase I). The criteria involved minor deviations to the FSAR licensing commitments for alternate analysis.

Piping Criteria Exception: Secondary stresses resulting from seismic anchor movements (SAM) and thermal plus thermal anchor movements (TAM) were evaluated for piping systems greater than 200°F. For piping systems 200°F or less, secondary stresses resulting from SAM plus TAM were evaluated.

Pipe Support Criteria Exceptions:

1. Only safe-shutdown earthquake (SSE) seismic loads were evaluated; operating-basis earthquake (OBE) loads were not.

2. The effects of friction loads resulting from thermal growth were not considered in the reevaluation of existing supports.

3. The allowable loads for expansion anchor bolts were based on a minimum safety factor of 2.5 for wedge bolts and 2.8 for self- drilling anchors.

In addition, TVA has evaluated supports using Section 3.8.4 of the NRC Standard Review Plan 6 and Subsection NF of Section III of the ASME Code.

For rigorous analysis, additional restart criteria were developed to establish priorities for implementation of pipe support modifications. These restart criteria were presented in criteria document CEB-CI-21.89 (see TVA letters of August 31 and November 17, 1987(a)). The NRC staff approved the criteria with certain restrictions in a letter to TVA dated February 23, 1988. All supports satisfied the restart criteria before restart of Sequoyah.

3.9.3 NSSS Components Not Covered By ASME Code

3.9.3.1 Core and Internals Integrity Analysis (Mechanical Analysis)

The response of the reactor core and vessel internals under excitation produced by a simultaneous complete severance of a reactor coolant pipe and seismic excitation for a typical Westinghouse Pressurized Water Reactor (PWR) plant internals has been determined. The following mechanical functional performance requirements apply:

1. Following the design basis accident, the basic operational or functional requirement to be met for the reactor internals is that the plant will be shutdown and cooled in an orderly fashion so that fuel cladding temperature is kept within specified limits. This implies that the deformation of certain critical reactor internals must be kept sufficiently small to allow core cooling.

2. For large breaks, the reduction in water density greatly reduces the reactivity of the core, thereby shutting down the core whether the control rods are inserted or not. The subsequent refilling of the core by the Emergency Core Cooling System (ECCS) uses borated water to maintain the core in a subcritical state. Therefore, the main requirement is to assure effectiveness of the ECCS. Insertion of the control rods, although not needed, gives further assurance of ability to shut the plant down and maintain it in a safe shutdown condition.

3. The functional requirements for the Core Structures during the design basis accident are shown in Table 3.9.3-1. The inward upper barrel deflections are controlled to insure no contacting of the nearest rod cluster control guide tube. The outward upper barrel deflections are controlled in order to maintain an adequate annulus for the coolant between the vessel inner diameter and core barrel outer diameter.

4. The rod cluster control guide tube deflections are limited to insure operability of the control rods.

5. To insure no column loading of rod cluster control guide tubes, the upper core plate deflection is limited to the value shown in Table 3.9.3-1.

6. The reactor has mechanical provisions which are sufficient to maintain the design core and internals and to assure that the core is intact with acceptable heat transfer geometry following transients arising from the design basis accident operating conditions (References 1, 8, 13, and 17).

7. The core internals are designed to withstand mechanical loads arising from operating basis earthquake, safe shutdown earthquake and pipe ruptures (Reference 1, 2, 8, 9, 10, 13, and 17).

The following events are considered in the faulted conditions category:

1. Loads produced by a double ended pipe rupture of the main coolant loop design basis accident, for both cases: cold and hot leg break. The methods of analysis adopted are related to the type of accident assumed (cold leg break or hot leg break).

2. Response due to a safe shutdown earthquake.

3. Most unfavorable combination of safe shutdown earthquake and design basis accident. Maximum stresses obtained in each case are added in the most conservative manner.

Maximum stress intensities are compared to allowable stresses for each of the above conditions. When fatigue is of concern, the applicable stress concentration factors are utilized and peak stresses are used to establish the usage factor. Elastic analysis is utilized to obtain the response of the structure and the stress analysis on each component is performed on an elastic basis. For faulted conditions stresses are above yield in a few locations. For these cases only, when deformation requirements exist, a plastic analysis is independently performed to ensure that functional requirements are maintained (guide tubes deflections and core barrel expansion). The elastic limit allowable stresses are used to compare with the result of the analysis. No inelastic stress limits are used.

The above described analyses show that the stresses and deflections which would result following a faulted condition are less than those which would adversely affect the integrity of the structures. Also, the natural and applied frequencies are such that resonance problems will not occur.

3.9.3.2 Reactor Internals Response Under Blowdown and Seismic Excitation

A loss of coolant accident would result from a rupture of reactor coolant piping. During the blowdown of the coolant, critical components of the core are subjected to vertical and horizontal excitation as a result of rarefaction waves propagating inside the reactor vessel.

For these large breaks, the reduction in water density greatly reduces the reactivity of the core, thereby shutting down the core whether the control rods are inserted or not. The subsequent refilling of the core by the ECCS uses borated water to maintain the core in a subcritical state. Therefore, the main requirement is to assure effectiveness of the ECCS. Insertion of rod cluster control assemblies, although not needed, gives further assurance of ability to shut the plant down and maintain it in a safe shutdown condition.

The pressure waves generated within the reactor are highly dependent on the location and nature of the postulated pipe failure. In general, the more rapid the severance of the pipe, the more severe the imposed loadings on the components. A one millisecond severance time is taken as the limiting case.

In the case of the hot leg break, the vertical hydraulic forces produce an initial upward lift of the core. A rarefaction wave propagates through the reactor hot leg nozzle into the interior of the upper core barrel. Since the wave has not reached the flow annulus on the outside of the barrel, the upper barrel is subjected to an impulsive compressive wave. Thus, dynamic instability (buckling) or large deflections of the upper core barrel or both is the possible response of the barrel during hot leg blowdown. In addition to the above effects, the hot leg break results in transverse loading on the upper core components as the fluid exits the hot leg nozzle.

In the case of the cold leg break, a rarefaction wave propagates along a reactor inlet pipe arriving first at the core barrel at the inlet nozzle of the broken loop. The upper barrel is then subjected to a non-axisymmetric expansion radial impulse which changes as the rarefaction wave propagates both around the barrel and down the outer flow annulus between vessel and barrel. After the cold leg break, the initial steady state hydraulic lift forces (upward) decrease rapidly (within a few milliseconds) and then increase in the downward direction. These cause the reactor core and lower support structure to move initially downward.

If a simultaneous seismic event with the intensity of the safe shutdown earthquake is postulated with the loss of coolant accident, the imposed loading on the internals component may be additive in certain cases and therefore the combined loading must be considered.

In general, however, the loading imposed by the earthquake is small compared to the blowdown loading.

3.9.3.3 Acceptance Criteria

The criteria for acceptability in regard to mechanical integrity analyses is that adequate core cooling and core shutdown must be assured. This implies that the deformation of the reactor internals must be sufficiently small so that the geometry remains substantially intact. Consequently, the limitations established on the internals are concerned principally with the maximum allowable deflections and stability of the parts in addition to a stress criterion to assure integrity of the components.

Allowable Deflection and Stability Criteria

For the loss of coolant plus the safe shutdown earthquake condition, deflections of critical internal structures are limited to the values given in Table 3.9.3-1. In a hypothesized downward vertical displacement of the internals, energy absorbing devices limit the displacement to 1.25 inches by contacting the vessel bottom head.

Upper Barrel

The upper barrel deformation has the following limits:

1. To insure a shutdown and cooldown of the core during blowdown, the basic requirement is a limitation on the outward deflection of the barrel at the locations of the inlet nozzles connected to the unbroken lines. A large outward deflection of the barrel in front of the inlet nozzles, accompanied with permanent strains, could close the inlet area and stop the cooling water coming from the accumulators. Consequently a permanent barrel deflection in front of the unbroken inlet nozzles larger than a certain limit, called the "no loss of function" limit, could impair the efficiency of the Emergency Core Cooling System.

2. To assure rod insertion and to avoid disturbing the control rod cluster guide structure, the barrel should not interfere with the guide tubes. This condition also requires a stability check to assure that the barrel will not buckle under the accident loads.

Control Rod Cluster Guide Tubes

The guide tubes in the upper core support package house the control rods. The deflection limits were established from tests and are provided in Table 3.9.3-1.

Fuel Assembly

The limitations for this case are related to the stability of the thimbles in the upper end. The upper end of the thimbles must not experience stresses above the allowable dynamic compressive stresses. Any buckling of the upper end of the thimbles must not experience stresses above the allowable dynamic compressive stresses. Any buckling of the upper end of the thimbles due to axial compression could distort the guide line and thereby affect the free fall of the control rod.

Upper Package

The local vertical deformation of the upper core plate, where a guide tube is located, will be below 0.100 inch. This deformation will not cause the plate to contact the guide tube since the clearance between plate and guide tube is 0.100 inch. This limit will prevent the guide tubes from undergoing compression. For a plate local deformation of 0.150 inches, the guide tube will be compressed and deformed transversely to the upper limit previously established; consequently, the value of 0.150 inch is adopted as the no loss of function local deformation, with an allowable limit of 0.100 inch. These limits are given in Table 3.9.3-1.

Allowable Stress Criteria

The allowable stress limits during the design basis accident used for the core support structures are based on the limits specified in Section 4.2.2.5. This section defines various criteria based upon their corresponding method of analysis. To account for multi-axial stresses, the von Mises theory is also considered.

3.9.3.4 Methods of Analysis

The internals structures are analyzed for loads corresponding to normal, upset, emergency and faulted conditions. The analysis performed depends on the mode of operation under consideration.

The scope of the stress analysis problem is very large requiring many different techniques and methods, both static and dynamic. The more important and relevant methods are presented as an overview in Subsection 3.9.1 and summarized in the following.

3.9.3.5 Blowdown Forces Due to Cold and Hot Leg Break

A blowdown digital computer program (Reference 11) which is developed for the purpose of calculating local fluid pressure, flow, and density transients that occur in Pressurized Water Reactor coolant systems during a loss of coolant accident, is applied to the subcooled, transition, and saturated two-phase blowdown regimes. This is in contrast to programs such as WHAM (Reference 9) which are applicable only to the subcooled region and which, due to their method of solution, could not be extended into the region in which large changes in the sonic velocities and fluid densities take place. This blowdown code is based on the method of characteristics wherein the resulting set of ordinary differential equations, obtained from the laws of conservation of mass, momentum, and energy, are solved numerically using a fixed mesh in both space and time.

Although spatially one dimensional conservation laws are employed, the code can be applied to describe three dimensional system geometries by use of the equivalent piping networks. Such piping networks may contain any number of pipes or channels of various diameters, dead ends, branches (with up to six pipes connected to each branch), contractions, expansions, orifices, pumps, and free surfaces (such as in the pressurizer). System losses such as friction, contraction, expansion, etc. are considered.

Predictions from this code have been connected with numerous test data (Reference 12) and the results show good agreement in both the subcooled and the saturated blowdown regimes.

FORCE Model for Blowdown

The blowdown code evaluates the pressure and velocity transients for a maximum of 2400 locations throughout the system. These pressure and velocity transients are stored as a permanent tape file and are made available to the program FORCE (Reference 1) which utilizes a detailed geometric description in evaluating the loadings on the reactor internals.

Each reactor component for which FORCE calculations are required is designated as an element and assigned on element number. Forces acting upon each of the elements are calculated summing the effects of:

1. The pressure differential across the element.

2. Flow stagnation on, and unrecovered orifice losses across the element.

3. Friction losses along the element.

Input to the code, in addition to the blowdown pressure and velocity transients, includes the effective area of each element on which the force acts due to the pressure differential across the element, a coefficient to account for flow stagnation and unrecovered orifice losses, and the total area of the element along which the shear forces act.

The mechanical analysis has been performed using conservative assumptions in order to obtain results with extra margin. Some of the most significant are:

1. The mechanical and hydraulic analysis has been performed separately without including the effect of the water-solid interaction. Peak pressures obtained from the hydraulic analysis will be attentuated by the deformation of the structures.

2. When applying the hydraulic forces, no credit is taken for the stiffening effect of the fluid environment which will reduce the deflections and stresses in the structure.

3. The multi-mass model described below is considered to have a sufficient number of degrees of freedom to represent the most important modes of vibration in the vertical direction. This model is conservative in the sense that further mass-spring resolution of the system would lead to further attentuation of the shock effects obtained with the present model.

Vertical Excitation Model for Blowdown

For the vertical excitation, the reactor internals are represented by a multi-mass system connected with springs and dashpots simulating the elastic response and the viscous damping of the components. Also incorporated in the multi-mass system is a representative of the motion of the fuel elements relative to the fuel assembly grids. The fuel elements in the fuel assemblies are kept in position by friction forces originating from the preloaded fuel assembly grid fingers. Coulomb type friction is assumed in the event that sliding between the rods and the grid fingers occurs. A spring-mass system is used to represent the internals. In order to obtain an accurate simulation of the reactor internals response, the effects of internal damping, clearances between various internals, snubbing action caused by solid impact, Coulomb friction induced by fuel rods motion relative to the grids, and preloads in hold down springs have been incorporated in the analytical model. The modeling is conducted in such a way that uniform masses are lumped into easily identifiable discrete masses while elastic elements are represented by springs.

The appropriate dynamic differential equations for the multi-mass model describing the aforementioned phenomena are formulated and the results obtained using a digital computer program (Reference 13) which computes the response of the multi-mass model when excited by a set of time dependent forcing functions. The appropriate forcing functions are applied simultaneously and independently to each of the masses in the system. The results from the program give the forces, displacements and deflections as functions of time for all the reactor internals components (lumped masses). Reactor internals response to both hot and cold leg pipe ruptures is analyzed. The forcing functions used in the study are obtained from hydraulic analyses of the pressure and flow distribution around the entire Reactor Coolant System as caused by double ended severance of a Reactor Coolant System pipe.

Transverse Excitation Model for Blowdown

Various reactor internal components are subjected to transverse excitation during blowdown. Specifically, the barrel, guide tubes, and upper support columns are analyzed to determine their response to this excitation.

Core Barrel

For the hydraulic analysis of the pressure transients during hot leg blowdown, the maximum pressure drop across the barrel is a uniform radial compressive impulse. The barrel is then analyzed for dynamic buckling using these conditions and the following conservative assumptions:

1. The effect of the fluid environment is neglected (water stiffening is not considered);

2. The shell is treated as simply supported.

During cold leg blowdown, the upper barrel is subjected to a non-axisymmetric expansion radial impulse which changes as the rarefaction wave propagates both around the barrel and down the outer flow annulus between vessel and barrel.

The analysis of transverse barrel response to cold leg blowdown is performed as follows:

1. The upper core barrel is treated as a simply supported cylindrical shell of constant thickness between the upper flange weldment and the lower core barrel weldment without taking credit for the supports at the barrel midspan offered by the outlet nozzles. This assumption leads to conservative deflection estimates of the upper core barrel.

2. The upper core barrel is analyzed as a shell with four variable sections to model the support flange, upper barrel, reduced weld section, and a portion of the lower core barrel.

3. The barrel with the core and thermal shielding pads, is analyzed as a beam fixed at the top and elastically supported at the lower radial support and the dynamic response is obtained.

Guide Tubes

The dynamic loads on rod cluster control guide tubes are more severe for a loss of coolant accident caused by hot leg rupture than for an accident by cold leg rupture since the cold leg break leads to much smaller changes in the transverse coolant flow over the rod cluster control guide tubes. Thus, the analysis is performed only for a hot leg blowdown.

The guide tubes in closest proximity to the ruptured outlet nozzle are the most severely loaded. The transverse guide tube forces during the hot leg blowdown decrease with increased distance from the ruptured nozzle location.

A detailed structural analysis of the rod cluster control guide tubes was performed to establish the equivalent cross section properties and elastic end support conditions. An analytical model was verified both dynamically and statically by subjecting the control (Reference 13) rod cluster guide tube to a concentrated force applied at the transition plate. In addition, the guide tube was loaded experimentally using a triangular distribution to conservatively approximate the hydraulic loading. The experimental results consisted of a load deflection curve for the rod cluster control guide tube plus verification of the deflection criteria to assure rod cluster control insertion.

The response of the guide tubes to the transient loading due to blowdown may be found by utilizing the equivalent single degree freedom system for the guide tube using experimental results for equivalent stiffness and natural frequency.

The time dependence of the hydraulic transient loading has the form of a step function with constant slope front with a rise time to peak force of the same order of the guide tube fundamental period in water. The dynamic amplification factor in determining the response is a function of the ramp impulse rise time divided by the period of the structure.

Upper Support Columns

Upper support columns located close to the broken nozzle during hot leg break will be subjected to transverse loads due to cross flow.

The loads applied to the columns were computed with a similar method to the one used for the guide tubes; i.e., taking into consideration the increase in flow across the column during the accident. The columns were studied as beams with variable section and the resulting stresses were obtained using the reduced section modulus at the slotted portions.

3.9.3.6 Methods and Results of Blowdown Analysis (Mechanical)

The results obtained from the linear analysis indicate that during blowdown, the relative displacement between the components will close the gaps and consequently the structures will impinge on each other, making the linear analysis unrealistic and forcing the application of non-linear methods to study the problem. Although linear analysis will not provide information

about the impact forces generated when components impinge each other, it can, and is, applied prior to gap closure. The effects of the gaps that could exist between vessel and barrel, between fuel assemblies, between fuel assemblies and baffle plates, and between the control rods and their guide paths are considered in the analysis. References 1, 13, and 17 provide further details of the blowdown method used in the analysis of the reactor internals.

Results of these analyses indicate that both static and dynamic stress intensities are within acceptable limits. In addition, the cumulative fatigue usage factor is also within the allowable usage factor of unity.

The stresses due to the safe shutdown earthquake (vertical and horizontal components) are combined in the most unfavorable manner with the blowdown stresses in order to obtain the largest principal stress and deflection.

These results indicate that the maximum deflections and stress in the critical structures are below the established allowable limits. For the transverse excitation, it is shown that the upper barrel does not buckle during a hot leg break and that it has an allowable stress distribution during a cold leg break.

Even though control rod insertion is not required for plant shutdown, this analysis shows that most of the guide tubes will deform within the limits established experimentally to assure control rod insertion. These limits are shown in Table 3.9.3-1. For the guide tubes deflected above the no loss of function limit, it must be assumed that the rods will not drop. However, the core will still shutdown due to the negative reactivity insertion in the form of core voiding. Shutdown will be aided by the great majority of rods that do drop. Seismic deflections of the guide tubes are generally negligible by comparison with the no loss of function limit of Table 3.9.3-1.

3.9.3.7 Control Rod Drive Mechanisms

The control rod drive mechanisms are Class A components designed to meet the stresses of the ASME Boiler and Pressure Vessel Code and are presented in Section 4.2.

3.9.3.8 Evaluation of Reactor Internals for Limited Displacement RPV Inlet and Outlet Nozzle Breaks

This section contains an evaluation of the effects of a limited displacement 144 in^2 RPV inlet nozzle safe end break and a limited displacement 144 in^2 RPV outlet nozzle safe end break on the reactor internals. Both breaks are assumed to have a break opening time of one millisecond.

The main operational requirement to be met is that the plant be shutdown and cooled down in an orderly fashion so that the fuel cladding temperature is kept within the specified limits. This implies that the deformation of the reactor internals must be kept sufficiently small to allow core cooling and assure effectiveness of the ECCS. As a further criterion, the allowable stress criteria used for the core support structures are presented in Section 3.9.3.3.

The evaluation of the reactor internals for the RPV inlet break is composed of two parts. The first part is the in-plane response of the core barrel occurring in the vertical plane passing through the broken inlet nozzle. This is taken from the DARI-WOSTAS response similar to the RPV support analysis as described in Section 5.2.1.7. The second part of this evaluation is the core-barrel shell response which consists of the various n = 0, 2, 3 etc., ring mode responses occurring in the horizontal plane. These ring mode responses are generated as the inlet break rarefaction wave propagates to the core barrel at the inlet nozzle, which subjects the upper barrel to a non-axisymmetric expansion radial impulse which changes as the rarefaction wave propagates both around the barrel and down the outer flow annulus between the barrel and the vessel. This second part, or ring mode evaluation is described in Reference 9 and is independent of the loop forces and cavity pressure.

From the moment and shear force time histories resulting from the DARI-WOSTAS response, the core barrel beam bending stresses and shear stresses are obtained. The barrel beam stresses (the first part of the evaluation) are evaluated at the mid-barrel girth weld where the highest stresses in the barrel occur.

For the second part or shell mode analysis of the core barrel, the differential pressures across the core barrel wall distributed around the circumference must be determined. These differential pressures are directly obtained from the blowdown analysis. The application of the differential pressures around the barrel circumference (i.e., resolving into Fourier components, etc.) is further described in Reference 7. It is important to note, that unlike the beam analysis, the shell response of the barrel (the various horizontal ring modes 0, 2, 3, 4, etc.) is independent of the response of the vessel on its supports, the response of the fuel, or any combination of these beam mode responses. Even though there are various phenomena which may affect vessel beam behavior, there is only one set of barrel shell results to be included in the stress combination. Also included in the stress results for the barrel is the vertical response from the DARI-WOSTAS analysis. The vertical response of the barrel is considered uniform around the circumference. However, since the DARI-WOSTAS model couples the horizontal beam and the vertical response of the reactor at the vessel supports, variation in horizontal response may be seen in the vertical behavior.

To properly evaluate the total stress results in the core barrel, the combination of the horizontal beam, vertical, and shell modes is performed on a time-history basis. This combination is performed at the girth weld, which is the most highly stressed region of the core barrel.

The evaluation of the reactor internals for the RPV outlet nozzle break involves primarily three internal components: core barrel, control rod guide tubes, and upper support columns. The rarefaction wave, which is independent of the loop loads and cavity pressure, propagates into the upper plenum from the outlet nozzle break, which subjects the upper core barrel to a uniform radial compressive impulse resulting from the pressure drop across the core barrel. The stability of the barrel is checked to ensure that buckling due to the compressive impulse does not occur. The beam response (including the vertical response of the barrel) and shell mode response are considered in the analysis. The maximum deflections calculated for the core barrel are within the allowable limits established in Section 3.9.3.3.

Also included in the outlet nozzle break analysis is an evaluation of the control rod guide tubes and upper support columns. The guide tubes and support columns (primarily those close to the broken hot leg nozzle) are subjected to transverse loads due to increased cross flow in the upper plenum. These loads are independent of the loop loads and cavity pressure loads. The analysis results indicate that the deflections are within the allowable limits presented in Section 3.9.3.3 and therefore, the internals geometry is maintained and significant control rod insertion is not impaired.

3.9.4 Additional Support Requirements

3.9.4.1 Support Welds

Supplemental steel and supports not governed by B31.1 were welded in accordance with the American Welding Society, "Structural Welding Code," AWS D1.1-72 as implemented by TVA General Construction Specification G-29C. NCIG-01, Revision 2, may be used after June 26, 1985, to evaluate weldments that were designed and fabricated to the requirements of AISC/AWS. When invoked, NCIG provisions will be implemented as indicated in section 3.6.8.

3.9.4.2 Allowable Loads for U-bolts and Unistrut Type Clamps

The basic allowables for U-bolts and Unistrut type clamps have been established by tests with the results evaluated in accordance with ASME section III 1974, Subsection NF, including 1974 winter addenda. The load ratings envelope low bound test results and were further limited by a 1/8" deflection criteria.

FAULTED (Pipe Rupture)	See Section 3.6 for Pipe Rupture Criteria					

(1) Suitable tests subject to review may be substituted for analysis, however, the applicable ASME Code stress allowables must be satisfied. The applicable code edition for a component is generally defined by the date of procurement as described in Section 3.2, Table 3.2.2-1. With this consideration, qualification for seismic and DBA inertial loads may be accomplished by analysis or test in accordance with the guidelines of IEEE 344-71 or IEEE 344-75. IEEE 344-75 is used to the extent practical for procurements after September 1, 1974.

(2) Functional design requirements apply only to active components whose functionality is relied upon to perform a safety function (as well as reactor shutdown function) during the transients or events considered in the respective operating categories.

(3) Governs the analysis of Class A, B, C, and D piping analyzed by TVA.

(4) Exceptions to the natural frequency requirements may be approved on a case-by-case basis.

DESIGN LOADING COMBINATIONS
FOR GROUP CLASSES B, C, AND D COMPONENTS

Loading Cases	Operating Condition
a. Pressure + deadweight + thermal + other sustained loads	Normal
b. Pressure + deadweight + thermal + other sustained loads + valve thrust + fluid transients + OBE	Upset
c. Pressure + deadweight + thermal + other sustained loads + valve thrust + fluid transients + SSE + DBA SCV inertia and displacement	Faulted
d. Pressure + deadweight + other sustained loads + valve thrust + fluid transients + pipe rupture	Faulted

NOTES:

1. Loads which are not concurrent need not be combined.

2. Other sustained loads include mechanical loads, the weight of contained fluids, pressure blowoff loads due to untied bellows, and similar sustained effects.

3. Pipe rupture evaluations are conducted separately as described in Section 3.6.

4. The DBA steel containment vessel (SCV) loads consist of dynamic movements at the initiation of the DBA event and later thermal expansion displacements of the SCV in the post DBA event phase.

5. Many component loads result from component/piping and component/ mounting interfaces. The corresponding load combinations and allowable stresses for interfacing piping and supports (including component supports) are defined in Tables 3.9.2-4 and 3.9.2-5, respectively. Component qualification codes, interface limits, and allowable stresses are defined in Tables 3.9.2-1 and 3.9.2-3.

COMPONENT LOADING CONDITIONS AND STRESS LIMITS[1,3]

Plant Loading Condition	Pressure Vessels and Storage Tanks	Pumps	Valves	Containment Penetrations (Nozzles)
Normal	Primary General Membrane Stress Intensity[2] $\leq S_m$ Primary + Secondary Stress Intensity[2] $\leq 3\ S_m$	ASME III Draft for Pumps and Valves. Performance testing in accordance with standards of the Hydraulic institute Procedures	ASME III, 1968/ ANSI B16.5 and B16.34 Ratings	ASME, Section III, 1971 Edition, Subsection NE
Upset	Primary General Membrane Stress Intensity[2] $\leq 1.1\ S_m$ Primary + Secondary Stress Intensity[2] $\leq 3\ S_m$	Structural and functional integrity is ensured by satisfaction of limits identified in Table 3.9.2-1. Pumps and valves are supported to assure each component is not seismically loaded in excess of the "g" loading specified in the design specification. Pumps and valves have been demonstrated to be rigid ($f_n \geq 25$ Hz). Higher accelerations and lower natural frequencies may be approved on a case-by-case basis.		ASME, Section III, 1971 Edition, Subsection NE
Emergency	N/A			ASME, Section III, 1971 Edition, Subsection NE
Faulted	Primary General Membrane Stress Intensity[2] $\leq 1.2\ S_m$ or S_y Buckling check required Secondary stresses need not be evaluated			N/A

S_m = ASME Section III, 1968, or later, Edition Code allowable stress intensity at design or operating temperature.

NA = No loading condition assigned.

S_y = Yield stress at design or operating temperature.

1 Allowable stress limits from the 1968 or later editions of the ASME Section III code subsections, which are applicable to the type of component and approved by the NRC in accordance with 10 CFR 50.55a, may be used provided that all associated provisions of that code edition are satisfied.

2 Primary local membrane plus bending allowables are 1.5 times the primary general membrane allowables.

3. Stress limits used for new design, modification, and evaluation after September 1, 1974 are identified by Table 3.9.2-3A.

Table 3.9.2-3a
SAFETY CLASS B, C, AND D COMPONENT LOADING CONDITIONS AND STRESS LIMITS
FOR NEW DESIGN, MODIFICATION, AND EVALUATION AFTER SEPTEMBER 1, 1974

Plant Loading Condition	Tanks and Vessels [1, 2, 3, 5, 6]	Pumps [1, 2, 4, 5]	Valves [1, 2, 4, 5]
Normal (Service Level A)	Design Stress Limits from applicable ASME Section III Subsections NC/ND-3200, -3300, -3800, or -3900. Vendor-designed support stresses limited to normal AISC allowable.	Design Stress Limits from ASME Section III Subsections NC/ND-3400. Vendor-designed support stresses limited to normal AISC allowable.	Design Stress Limits from ASME Section III Subsections NC/ND-3500. Extended structure stresses limited to normal AISC allowable.
Upset and Faulted (Service Levels B and D)	Stress Limits from applicable ASME Section III Subsections NC/ND-3200, -3300, -3800, or -3900, and ASME Code Cases 1607-1 and 1657-1. Vendor-designed support stresses limited to 1.33 times normal AISC allowable. Additional shell buckling stress limits for low pressure, thin-wall tanks and vessels.	Stress Limits from ASME Section III Subsections NC/ND-3400 and ASME Code Case 1636-1. Vendor-designed support stresses limited to 1.33 times normal AISC allowable. Additional stress and functionality/operability limits for Active Pumps.	Stress Limits from ASME Section III Subsections NC/ND-3500 and ASME Code Case 1635-1. Extended structure stresses limited to 1.33 times normal AISC allowable. Additional stress and functionality/operability limits for Active Valves.

Notes:

1. ASME Code Cases 1607-1, 1635-1, 1636-1, and 1657-1 were issued in 1974 and incorporated in ASME Section III 1977 Edition.
2. Basic pressure boundary stress limits are consistent with the ASME Section III Code 1971 Edition with Addenda through Summer 1973 or the applicable code edition identified in the component design/procurement specification. Any conflict identified between these two alternatives is resolved in a conservative manner. Stress limits from later ASME Section III codes approved by the NRC according to 10CFR 50.55e may be utilized provided all of the provisions of that code are satisfied for the component.
3. An alternate approach is permitted for existing ASME Section III and Section VIII Code Tanks and Vessels that were designed and fabricated to the 1968 or 1971 Code Edition. By this alternate approach, design stress limits are met and pressure boundary stresses for faulted loading conditions are limited to 1.2 times the design primary stress limits.
4. An alternate approach is also permitted for existing Pumps and Valves that were procured prior to September 1, 1974. By this alternate approach, design stress limits are met and pressure boundary stresses for faulted conditions are limited to 1.2 times the design primary stress limits.
5. AISC stress limits are consistent with the AISC Manual of Steel Construction Edition identified in the component design/procurement specification or used by the vendor for design and fabrication.
6. Steel Containment Vessel loading conditions and allowable stresses are described in Section 3.8.2.3.2, Table 3.8.2-1, and Table 3.8.2-2.

NOTES

1. Loads which are not concurrent need not be combined.

2. The requirements of either equation 10 or equation 11 must be met.

3. The effects of OBE Seismic Anchor Movements may be excluded from equations 10 and 11 if they are included in equation 9U.

4. Pipe rupture (i.e., jet impingement, etc.) is not considered in equation 9F unless required by the evaluation methods given in Section 3.6.

5. The DBA Steel Containment Vessel (SCV) inertia movements are dynamic movements of SCV during the DBA. The post DBA SCV movements are the containment pressure and temperature anchor movements of the SCV following a DBA. Effective 03-06-90, piping analysis containing the DBA event will utilize SCV inertia and displacement data which has incorporated the effects of LBB technology.

6. This table is also applicable for Class A piping (reactor coolant loop branch lines) analyzed by TVA.

7. Dynamic loads may be combined by the square root of the sum of the squares (SRSS) method if the time-phase relationship between the dynamic loading events is such that the maximum stresses resulting from the events are not postulated to occur at the same time. The guidelines provided in NUREG-0484 will be used to determine when the SRSS combination method is applicable.

LOADING COMBINATIONS AND STRESS/LOADING LIMITS FOR SAFETY CLASS B, C, AND D SUPPORTS

Plant Condition	Load Combination	Linear Support*	Standard Support Components	Snubber Pre-NF Hydraulic	Snubber Pre-NF Mechanical	Snubber NF Mechanical	Notes
Normal	Deadweight + Other Sustained Loads + Thermal	$1.0S_{AISC}$	$1.0S_{58}$				1, 2, 3
Upset	Deadweight + Other Sustained Loads + Thermal + OBE SAM + OBE Inertia + Valve Thrust + Fluid Transients	$1.33S_{AISC}$	$1.2S_{58}$	$1.0S_{58}$	$1.0S_{58}$	LCDS	1,2,3,5
Faulted (Case 1)	Deadweight + Other Sustained Loads + Thermal + SSE SAM + SSE Inertia + Valve Thrust + Fluid Transients + DBA	$1.5S_{AISC}$	$2.0S_{58}$	$1.2S_{58}$	$1.33S_{58}$	LCDS	1,2,3,5
Faulted (Case 2)	Deadweight + Other Sustained Loads + Thermal + Valve Thrust + Fluid Transients + DBA + Pipe Rupture	$1.5S_{AISC}$	$2.0S_{58}$	$1.2S_{58}$	$1.33S_{58}$	LCDS	1,2,3 4,5,7

Table 3.9.2-5 (Sheet 2)

LOADING COMBINATIONS AND STRESS/LOADING LIMITS FOR SAFETY CLASS B, C, AND D SUPPORTS

Plant Condition	Load Combination	Linear Support*	Standard Support Components	Snubber Pre-NF Hydraulic	Snubber Pre-NF Mechanical	Snubber NF Mechanical	Notes
Faulted** (Case 3)	Deadweight + Other Sustained Loads + Thermal + SSE SAM + SSE Inertia + Valve Thrust + Fluid Transients	$1.33S_{AISC}$	$2.0S_{58}$	$1.2S_{58}$	$1.33S_{58}$	LCDS	1,2,3,6
Faulted** (Case 4)	Deadweight + Other Sustained Loads + Thermal + Valve Thrust + Fluid Transients + Pipe Rupture	$1.33S_{AISC}$	$2.0S_{58}$	$1.2S_{58}$	$1.33S_{58}$	LCDS	1,2,3,4 6,7

*Resulting allowables shall not exceed $0.9S_Y$ for tension and $0.52S_y$ for shear. For U-bolt and unistrut type allowables, see section 3.9.4.2.

NOTES

1. S_{AISC} = Allowable Stress Defined in Part 1 of the AISC Specification
   S_Y = Minimum Yield Stress
   S_{58} = Load Rating Defined Per MSS SP-58
   LCDS = Load Capacity Data Sheets
2. This also includes supports on Class A piping (Reactor Coolant Loop Branch Lines) analyzed by TVA
3. Loads which are not concurrent need not be combined. See Design Criteria SQN-DC-V-24.2 (Reference 18) for additional information associated with load combinations and stress limits.
4. Pipe rupture (i.e., jet impingement, etc.) is not considered unless required by the evaluation methods given in Section 3.6.
5. Dynamic loads may be combined by the square root of the sum of the squares (SRSS) method if the time - phase relationship between the dynamic loading events is such that the maximum support loads resulting from the events are not postulated to occur at the same time. The guidelines provided in NUREG-0484 will be used to determine when the SRSS combination method is applicable.
6. This additional faulted loading combination applies only to containment spray and RHR supports attached to the steel containment vessel.
7. This additional faulted loading combination applies only when the seismic pipe support is utilized as a pipe rupture restraint.

3.10 SEISMIC DESIGN OF CATEGORY I INSTRUMENTATION AND ELECTRICAL EQUIPMENT

3.10.1 Seismic Design Criteria

3.10.1.1 Instrumentation

TVA supplied instruments are classified as Seismic Category I in accordance with the system served and instrument function. Seismic Category I systems are identified in Subsection 3.2.1. TVA instruments and instrument supporting structures are qualified per TVA Quality Assurance documents inserted as appendices to specifications for the equipment. Procurement specifications prior to September 1, 1974 reflected the guidance of IEEE 344-1971. Subsequent specifications reflect the recommended practices of IEEE 344-1975 to the fullest extent reasonably possible.

The seismic qualification of safety-related electrical and mechanical equipment (including fluid system components such as pumps, valves, and tanks) at SQN has been evaluated against current criteria, IEEE 344-1975 and Regulatory Guide 1.100 (Reference 16). The NRC's Seismic Qualification Review Team (SQRT) conducted the evaluation during the licensing phase. The SQRT concluded that the SQN equipment, originally qualified in accordance with IEEE 344-1971, satisfies the requirements of IEEE 344-1975 and Regulatory Guide 1.100 (Reference 17). The results of the NRC SQRT audit provide justification for making IEEE 344-1975 the design basis acceptance criteria for the seismic qualification of safety-related electrical and mechanical equipment at Sequoyah. In accordance with the SQRT audit commitments, to the fullest extent reasonably possible, this acceptance criteria has been used for procurement of new equipment and evaluation of existing equipment for the Sequoyah design basis seismic events since September 1, 1974 (Reference 18).

Type testing for seismic qualification has been performed on the Seismic Category I instruments. The instruments are capable of performing their function during and following a Safe Shutdown Earthquake. For the purpose of ensuring compatibility between the instruments and instrument supporting structures, the seismic qualification of instruments is sufficiently high to envelop its installation requirements, including any applicable support structure amplification.

The reactor trip system, and engineered safety features actuation system are designed so that they are capable of providing the necessary protective actions during and after a Safe Shutdown Earthquake (SSE); therefore, the reactor protection system will be capable of tripping the reactor during and after a Safe Shutdown Earthquake. The engineered safety features actuation system and the safety features systems are designed to initiate their protective functions during and after an SSE.

The following list identifies typical instrumentation and electrical equipment requiring seismic qualification by the supplier of the Nuclear Steam Supply System.

1. Foxboro Model E-11 pressure transmitter and Model E-13 differential pressure transmitter.

2. Foxboro Process Control Equipment cabinets.

3. Westinghouse Solid-State Protection System cabinets.

4. Nuclear Instrumentation System cabinets.

5. Safeguards Test Racks.

6. Resistance Temperature Detectors.

7. Power range Neutron Detectors.

8. Reactor trip breakers.

9. Barton Models 332 and 386 differential pressure transmitters.

10. Main Control Room Panels.

References 1 through 5 provide the typical seismic evaluation of Seismic Category I instrumentation and electrical equipment supplied by Westinghouse. These documents satisfy the requirements of IEEE 344-1971. The results show that there were no electrical irregularities that would leave the plant in an unsafe condition even though some trips were initiated.

Resistance temperature detectors used to sense the temperature in the main coolant loops are rigid, ruggedly built devices designed to withstand the high temperature, high pressure, and flow vibration induced acceleration forces which they are subjected to when installed in the coolant loops. The natural frequency of these devices is designed to be higher than the frequencies associated with the seismic disturbance. Since these resistance temperature detectors are designed and built to operate in a rugged environment and are considered a rigid body at seismic disturbance frequencies, no seismic testing is necessary.

The Nuclear Instrumentation System power range neutron detector has been vibration tested in both the transverse (horizontal) direction and the longitudinal (vertical) direction at acceleration levels greater than those expected during a seismic disturbance at the Sequoyah Nuclear Plant site. Detector current measurements were made during the tests and neutron sensitivity, resistance, and capacitance checks were made after the tests. No significant changes were seen. There was no mechanical damage to the detector.

Typical switches, which could defeat automatic operation of a required safety function, and indicators have been tested to determine their ability to withstand seismic excitation without malfunction. The control boards are stiff and past experience indicates that the amplification due to the board structure is sufficiently low so that the acceleration seen by the device is considerably less than that used in testing.

All critical instruments of the reactor protection system and the engineered safety feature circuits are mounted on Seismic Category I supporting structures. They are designed to withstand horizontal and vertical accelerations at each floor level for the safe shutdown earthquake. See Paragraph 3.7.2.2 for a discussion on the development of the response spectra at critical plant elevations. The instrument supporting structures located throughout the plant (local panels) have

been standardized in design and have been analyzed and seismically qualified by testing. The local panels were tested using response spectra for the highest elevation (El 763) on which any of these panels are mounted. The test criteria was developed per the applicable QA program documents and IEEE 344-1971.

Where space requirements preclude the use of the standard local panels, a small wall-mounted panel designed for only two instruments is used. This panel is qualified, to the same criteria as the local panels, by analysis. The analysis is very conservative and shows that the wall- mounted panels are adequate for supporting Seismic Category I instrumentation.

In addition, any instrumentation used for plant upgrade, such as Post-TMI Instrumentation, which is purchased after the May 23, 1980 issuance of Commission Memorandum and Order 80-CLI-21, is to be qualified to the requirements of IEEE 344-1975.

3.10.1.2 Electrical Equipment

Category I electrical equipment is identified in Subsection 3.2.1, Seismic Qualifications. That list also indicates the degree of compliance with IEEE 344-1971, for each Seismic Category I component.

The capability of ESF circuits and the standby power system to withstand seismic disturbances during post accident operation is established by seismic analysis and/or testing of each system component. The occurrence of a LOCA will not affect the seismic integrity of these components. The design criteria used in the design of Seismic Category I electrical equipment are given below.

1. Equipment designated Seismic Category I, when subjected to the vertical and horizontal acceleration of the safe shutdown earthquake, shall perform as follows:

   a. Equipment shall retain its structural integrity during and after the maximum peak accelerations obtained from the floor response spectrum for the equipment location and the natural frequency of the equipment.

   b. Equipment shall be capable of performing its design function during and after the maximum peak accelerations obtained from the floor response spectrum for the equipment location and the natural frequency of the equipment. No device whose incorrect operation could jeopardize the capability of performing the required reactor protective action immediately after the earthquake shall be caused to misoperate by the maximum peak accelerations.

   c. Maximum displacement of the equipment during the earthquake shall not cause loss of integrity with any externally connected parts, such as conduit, cable, or bus connections.

   d. The equipment shall be designed for anchoring firmly to the floor. The weight and center of gravity location, recommended location, and strength of anchors, shall be documented.

3.10.2 Seismic Analyses, Testing Procedures, and Restraint Measures

3.10.2.1 Instrumentation

The seismic type testing performed by the Nuclear Steam Supply System supplier (Westinghouse) is described in References 1 through 5. The test method used was the sine beat procedure described in IEEE Standard 344-1971.

The seismic type testing using the sine beat procedure described in IEEE 344-1971 has been evaluated against IEEE 344-1975 and Regulatory Guide 1.100 (Reference 16). The NRC's Seismic Qualification Review Team (SQRT) conducted a generic review of Westinghouse supplied equipment as described in WCAP-8833 and related documents. The SQRT concluded that the equipment, originally qualified in accordance with IEEE 344-1971, satisfies the requirements of IEEE 344-1975 and Regulatory Guide 1.100 (Reference 17). The results of the NRC SQRT audit provide the justification for making IEEE 344-1975 the design basis acceptance criteria for the seismic qualification of safety-related electrical and mechanical equipment at Sequoyah.

3.10.2.2 Supporting Structures

Panels

The qualification of the supports for Seismic Category I instruments has been accomplished by either analysis or testing. The method commonly used is testing under simulated conditions. Basically, all tests by TVA on supporting structures were similar and were qualified under similar specifications. The support structure was mounted on a vibration generator in a manner that simulated the intended service mounting. The vibratory forces were applied to each of the three major perpendicular axes independently. Maximum service dead loads were simulated. Selected points were monitored to establish amplification of loads. Testing was done at the structure's resonant frequencies. The resonant frequencies were determined by an exploratory test using a sinusoidal steady-state input of low amplitude, (two continuous sweeps from 1 to 35 and back to 1 Hz at a rate of 1 to 10 Hz per minute). The qualification test was conducted using the sine beat method at the resonant frequencies using the appropriate acceleration input as determined from the building response acceleration spectra.

The local panel tests conformed to the "Design Qualification of Seismic Class I and Seismic Class II Mechanical and Electrical equipment" given in the applicable QA program documents. The test specimen consisted of an instrumented panel with worst case instruments mounted. The panel was bolted to the floor as it will be bolted in service. The test acceleration input was .42 g horizontal and .28 g vertical with a frequency range of 1 to 35 Hertz. The test was run using the sine beat method at resonant frequencies determined by sweeping at a low amplitude of 0.1 g. Each axis was tested independently. The panels are so designed that no detrimental amplification of loads occurred that would cause the instruments to fail to perform their function. This was verified by monitoring the induced accelerations of the worst case instruments during testing. See Reference 13 for results.

Additional similar modular-type panels that are prewired are used at El 690 and are also qualified at the Safe Shutdown Earthquake. The seismic testing for these particular panels was performed per Appendix C of Contract 73C-92784.

Electric Equipment Supports

1. Restraint Measures

   Typically, category I electric equipment such as battery racks, instrument racks, and control consoles, located in Category I structures, are attached to anchor plates by bolting or welding. These anchor plates are of ASTM A36 steel embedded in the concrete slab using headed concrete anchor studs welded to the plate.

2. Analyses

   For dead loads combined with live loads and for dead loads combined with 1/2 safe shutdown earthquake, the designs are based on allowable stress levels of the AISC Specification of Structural Steel for Buildings. For dead loads combined with safe shutdown earthquake loads the stresses are limited to 90 percent of yield stresses for the material involved. Information on equipment weights, centers of gravity, and response frequencies is obtained from the vendor. Unless the vendor has certified a natural response frequency in the rigid range for the item of equipment, the design is for the floor resonant response frequency using the seismic amplification factors covered in Section 3.7.

Cable Tray and Supports

1. Cable Trays

Cable trays located in Category I structures except those in the CCW Intake Pumping Structure and the communications and secondary alarm station (SAS) rooms (el. 669, control bldg.) are considered safety related and are designed to resist gravity and Safe Shutdown Earthquake (SSE) forces. There are no safety related cables routed on the trays in the intake structure or the communications and SAS rooms, and it has been determined that should these trays fall, no Category I equipment would be damaged.

Cable tray acceptance criteria are derived from testing. A factor of safety of 1.25 against the tested capacity, is maintained for the vertical load for normal horizontal tray configurations. A maximum ductility factor of 3 (based on test data) is used to define an elastic-perfectly plastic curve that is used in the transverse direction (parallel to the rungs). These limits are used in an interaction equation to evaluate tray sections for the SSE loading condition. The trays are evaluated to ensure a minimum factor of safety of 1.25 against test capacity for actual dead loads.

Cable tray X and T fittings are evaluated to ensure a minimum factor of safety of 1.25 against formation of a first hinge in the direction for normal vertical loadings. These fittings are not evaluated in the horizontal direction since intersecting trays provide axial support in this direction.

Other cable tray components (i.e., bolts and connectors) are evaluated using American Iron and Steel Institute or American Institute of Steel Construction allowables with a .9 Fy limit. Where test data is used to establish capacities, a factor of safety of 1.5 is maintained against the ultimate test load for the SSE loading condition.

The cable trays are designed to carry a design load of 30 pounds per square foot (45 pounds per linear foot for 18 inch trays). In cases where weights exceed these values (because of cable overfill and application of flame-retardant coating), the actual dead loads are used. The trays are qualified for dead load, construction load, design basis accident loads, and SSE loads.

2. Supports

Cable tray supports for the above trays are designed to resist seismic forces applied to the dead weight of trays and cables. Each support is designed independently to support its appropriate length of tray and cable weights. Consideration is given to the relative stiffness of adjacent supports in the longitudinal direction of a tray run for determination of the appropriate length of tray. Additional load in the longitudinal direction of the tray is conservatively included for long straight tray runs, if the support is rigidly braced in the longitudinal direction and all other supports are flexible cantilevers. Seismic load inputs are based on dynamic analysis applied to either axis of the support using methods described in Section 3.7. Seismic loads are based on 5% SSE and 2% OBE damping.

In addition to the 30 pounds per square foot tray load and the actual tray loads when they exceed this value, the supports are designed to carry an additional construction load of 30 pounds per linear foot on the top tray. Load combinations and allowable stresses are as contained in Table 3.10.2-1. For evaluation of tube to tube interfaces, the methodology provided in AWS D1.1-81 is used.

Conduit and Supports

1. Conduit

   Conduit containing Class 1E cables located in Category I structures are considered safety related and designed to resist gravity and SSE forces. The conduit stresses and support loads are determined based on SSE design response spectra generated at 5 percent damping. The seismic qualification utilizes the same analysis methods as seismic Category I subsystems described in Section 3.7.3 and limits allowable stress to 90 percent of the yield stress of the conduit material.

2. Supports

   All conduit supports in Category I structures are designed to resist gravity and SSE forces applied to the conduit and cables. Supports for conduit containing Class 1E cables are designated Category I and stresses are limited to 90 percent of the yield stress of the support material. Seismic load inputs are based on SSE design response

spectra generated at 5 percent damping. Supports for conduit containing only non-Class 1E cables are designated Category I(L) and designed to preclude a failure which would reduce the ability of Category I structures, systems, and components to perform their intended safety-related function.

3. Conduit Banks

The Category I underground electrical conduit banks which run from the Auxiliary Building to the Diesel-Generator Building, to the auxiliary cooling towers, and to the pumping stations were analyzed by one of the following two methods.

1. The conduit banks were analyzed as a beam with unconstrained ends, on an elastic foundation.

2. The conduit banks were assumed to have the same motion as the soil deposits in which they are buried. The soil deposit was then assumed to be an infinitely long uniform soil deposit resting on a rigid foundation which responds to earthquake motion by moving a continuous sinusoidal plane wave. The soil displacement and bending moments for the conduit banks were determined using the following equations.

The displacement (D) of the soil is

$$D = a_{\max}\left(\frac{T}{2\pi}\right)^2$$

Where a_{max} = Maximum soil acceleration considering the effects of soil amplification on the peak rock acceleration

T = Fundamental period of soil deposit

The fundamental period and the effect of amplification of the input motion by the soil deposit were found by modeling the soil deposit as an elastic medium and making a dynamic analysis of a slice of unit thickness using only the horizontal shearing resistance of the soil.

The wave length (L) is

$$L = T V_{ST}$$

where V_{ST} = Average shear wave velocity of the soil deposit

Using the results from the above equations, the bending moment due to the earthquake is

$$M = EID\left(\frac{2\pi}{L}\right)^2$$

where E = Young modulus of conduit bank
I = Moment of inertia of conduit bank
L = One-half of the wave length

Welds

Welding for structural supports was in accordance with the American Welding Society, "Structural Welding Code," AWS D1.1-72 as implemented by TVA General Construction Specification G-29C. Nuclear Construction Issues Group documents NCIG-01, Revision 2, may be used after June 26, 1985, to evaluate weldments that were designed and fabricated to the requirements of AISC/AWS. When invoked, NCIG provisions will be implemented as indicated in section 3.6.8.

Table 3.10.2-1

Load Combinations and Allowables for Cable Tray Supports

Load Combination	Allowable
D + E	S
D + To + E	S
D + To + E'	.9FY
D + To + E' + DBA	.9FY
D + Ta + E'	.9FY

D - Dead Load (includes construction load on top tray)

To - Thermal effects and loads during normal operating or shutdown conditions based on the most critical transient or steady-state condition.

E - Operating Basis Earthquake (1/2 Safe Shutdown Earthquake)

E' - Safe Shutdown Earthquake

DBA - Loads generated by the design basis accident

Ta - Thermal loads under thermal conditions generated by the postulated break and including To.

S - The required section strength based on elastic design methods and the allowable stresses defined in Part 1 of the AISC "Specification for the Design, Fabrication, and Erection of Structural Steel for Buildings"

.9FY - Stresses are limited to 90 percent of yield stress for the material involved, except for shear which is limited to .52 times the yield stress, and axial compression which is limited to .9 times the critical buckling load.

3.11 ENVIRONMENTAL DESIGN OF MECHANICAL AND ELECTRICAL EQUIPMENT

Information showing that safety-related mechanical and electrical equipment is designed to function properly in normal and postulated post-DBE local environments at the Sequoyah Nuclear Plant is presented. A listing of the safety-related equipment that must function to properly mitigate accidents is provided first. Following this is a summary of the normal and worst-case post DBE local environmental conditions that are postulated at plant locations containing Reactor Protection System (RPS) and engineered safety feature (ESF) equipment. Accompanying this summary of worst-case local environments are references to the analyses that defined these circumstances. Environmental design criteria utilized for the RPS and ESF equipment are then given. Policies employed for assuring that properly qualified equipment was installed to perform these safety-related functions are next defined. Following this is an evaluation of the environmental effects that would follow a loss of a plant ventilation system when it is being used for cooling RPS or ESF equipment.

SQN Environmental Design Criteria SQN-DC-V-21.0 (see FSAR 15.5.8, Reference 17) will identify and specify all environmental parameters associated with normal/abnormal and DBA plant conditions necessary for design, procurement, and qualification of equipment. Each reload fuel evaluation will verify that the consequences of an accident previously evaluated has not increased.

3.11.1 Equipment Identification

Safety-related mechanical and electrical equipment that must function to properly mitigate accident effects is listed in Table 3.11.1-1.

3.11.2 Environmental Design and Analyses

Environmental design and analyses ensure that engineered safety feature equipment capabilities are compatible with their particular operating environments. Initially, environmental design criteria were obtained from analyses of specific situations that could occur at specific plant locations containing RPS or ESF equipment. These findings then became a basis for ESF system design and component selection. Additionally, electric equipment in the scope of 10CFR50.49 is included in the SQN 10CFR50.49 Environmental Qualification Program.

3.11.2.1 Environmental Design Criteria

Two different approaches were followed in establishing environmental design criteria for RPS and ESF equipment. One of these included a survey of the environmental qualifications of available components suitable for use in such systems, the selection of appropriate environmental design limits and the sizing of environmental control equipment to maintain acceptable conditions for the RPS and ESF equipment during the worst possible set of circumstances. The other approach utilized to establish environmental design criteria began with a series of analyses of various plant operations, accident condition and naturally occurring outside environment extremes and concluded with a review of the analytical results and adoption of the worst case situation as the environmental design criteria for ESF equipment installed at that particular plant location.

Environmental parameters postulated for normal/abnormal and post-DBE conditions are presented in detail in the SQN Environmental Design Criteria SQN-DC-V-21.0 and provide the basis for procurement, design, and qualification of ESF and RPS equipment at SQN.

3.11.2.2 Environmental Design Criteria for ESF Equipment

Safety-related equipment were designed for the worst case postulated environment. Such environments are given as a function of plant location in the SQN Environmental Design Criteria SQN-DC-V-21.0. All environmental parameters necessary for procurement, design, and qualification of equipment in accordance with 10CFR50.49 are specified on this design criteria.

3.11.2.3 Environmental Design of ESF Components

ESF Systems and RPS components have established industrial ratings equal to or in excess of the required environmental capabilities. These environmental capabilities are demonstrated by testing or by appropriate analyses. 10 CFR50.49 scope equipment is addressed under the harsh environment qualification program (see Section 3.11.2.4).

Qualification of other equipment important to safety is addressed by design/purchase specifications, functional requirements, and associated environmental conditions. Periodic maintenance and surveillance adequately demonstrates qualification of equipment in mild environments.

Additional information on the qualification of 10CFR50.49 scope equipment is provided in Section 3.11.2.4.

3.11.2.4 Environmental Design of 10CFR50.49 Scope Equipment

Electric equipment determined to be in the scope of 10CFR50.49 is included in the SQN 10CFR50.49 Environmental Qualification (EQ) Program. This program ensures that a listing of equipment is maintained and that there exists an auditable documentation package demonstrating harsh environment qualification in accordance with 10CFR50.49 criteria.

3.11.3 Loss of Ventilation

All plant locations containing ESF equipment that need a controlled environment to perform the required accident mitigation operations are served by fully redundant environmental control facilities. Such redundancy assures that no loss of ESF function will occur from a single failure or equipment provided for controlling the local environment for ESF equipment. Data provided in the SQN Environmental Design Criteria SQN-DC-V-21.0 (See FSAR 15.5.8, Reference 17) for controlled local environmental conditions during accidents is valid for situations in which a single loss of ventilation has occurred.

Table 3.11.1-1 (Sheet 1)

ELECTRICAL AND MECHANICAL EQUIPMENT REQUIRED TO FUNCTION DURING AND/OR AFTER AN ACCIDENT

ESF System	Equipment Required to Function
Reactor Protection System	Pressurizer Level and Pressure Transmitters, Steam Line Flow Transmitters, Narrow and Wide Range RTDs for Reactor Coolant System, Narrow Range Steam Generator Level, Reactor Coolant System Flow Transmitters, Wide Range Reactor Coolant System Pressure Transmitters,.
Ice Condenser	Ice compartment doors and door jambs, ice bed, and ice bed structural supports.
Containment Air Return Fan	Air return motor and fan, hydrogen collector ducting backflow damper, power and control circuitry
Containment Spray System	Piping, heat exchanger valves, spray header and nozzles, pump, and motor
Containment Isolation System	Accident sensors and monitors, electrical cables, electrical penetrations, mechanical penetrations, airlocks, hatches, blind flanges
Emergency Power System	Diesel generators, batteries, transformers, relay boards, electrical cables
Emergency Core Cooling System	Accumulators, isolation valves, pump and motor assemblies, tanks, pipes, heat exchangers, motor operated valves, other valves, cabling for equipemnt power control and instrumentation.
Essential Raw Cooling Water	Pumps, valves, pipes, heat exchangers, strainers, lower compartment coolers
Component Cooling Water System	Pump and motor assemblies, valves, heat exchangers, surge tank, pipe
Emergency Gas Treatment System	Air cleanup units, ducts, fans, damper assemblies, valves, filters and adsorbers, instrumentation and controls, heaters
Containment Air Cooling System	Lower compartment coolers (fans)

Table 3.11.1-1 (Sheet 2)

ELECTRICAL AND MECHANICAL EQUIPMENT REQUIRED TO FUNCTION DURING AND/OR AFTER AN ACCIDENT

ESF System	Equipment Required to Function
Auxiliary Building Gas Treatment System	Air cleanup units, ducts, fans and motors, dampers, valves, filters, adsorbers, instrumentation and controls, heaters
Auxiliary Building Isolation Equipment	Isolation dampers, airlocks, secondary containment electrical and mechanical penetration seals, instrumentation
Auxiliary Building Shutdown Board Rm Air Cond. System	Fans, motors, ducts, dampers, air-handling units, water chillers, pumps, valves
Control Building Air Conditioning and Air Cleanup System	Fans, motors, ducts, dampers, condensing units, air-handling units, filters, valves and adsorbers
Auxiliary Building 480-V Board Rm Air Cond. System	Fans, motors, ducts, dampers, air-handling units, condensers, valves, and compressors.
Auxiliary Building Safety Feature Equipment Coolers	Fans, motors, ducts, valves and dampers
Diesel Generator Building Diesel Room Ventilation System	Fans, motors, ducts, and dampers
Auxiliary Feedwater System	Pumps, motors, turbine, valves, instrumentation & controls
Main Steam System	Valves

3.12 Control of Heavy Loads

3.12.1 Introduction/Licensing Background

The Control of Heavy Loads program at SQN was established through a number of letters submitted to the NRC. These submittals include:

- Letter from L.M. Mills (TVA) to E. Adensam (NRC) dated March 1, 1982 (A27 820301 034)
- Letter from L.M. Mills (TVA) to E. Adensam (NRC) dated February 25, 1983 (A27 830225 024)
- Letter from L.M. Mills (TVA) to E. Adensam (NRC) dated February 28, 1984 (A27 840228 012)
- Letter from L.M. Mills (TVA) to E. Adensam (NRC) dated July 27, 1984 (A27 840727 010)
- Letter from L.M. Mills (TVA) to E. Adensam (NRC) dated December 7, 1984 (L44 841207 807)

In response to these submittals, the NRC issued a Safety Evaluation Report (SER) on the Control of Heavy Loads at SQN. This SER was transmitted to TVA by a letter from T. M. Novak (NRC) to H.G. Parris (NRC) dated March 26, 1985 (L44 850403 263).

Subsequent to the SER, the following letters contained amendments to the original SER affecting the Control of Heavy Loads:

- Letter from Suzanne Black (NRC) to Oliver D. Kingsley (TVA) dated December 5, 1988 (A02 881212 001)

- Letter from Suzanne Black (NRC) to Oliver D. Kingsley (TVA) dated May 26, 1989 (A02 890601 006)

- Letter from David E. LaBarge (NRC) to Oliver D. Kingsley (TVA) dated June 14, 1995 (L44 950622 001)

3.12.2 Safety Basis

The safety basis for the Control of Heavy Loads is provided by assuring the risks associated with load-handling failures is acceptably low. This assurance is provided by meeting the requirements of NUREG 0612, Section 5.1.1, the use of an equivalent single-failure-proof crane for the reactor head lift, and the use of a single-failure-proof crane for dry cask lifts in the auxiliary building.

3.12.3 Scope of Heavy Load Handling Systems

A heavy load for SQN is defined as any load weighing in excess of 2,100 lbs that is lifted in an area designated as a critical lift zone. Critical lift zones are those where an overhead handling system exists and the potential exists for a dropped load to impact irradiated fuel, impact safe shutdown equipment, or damage equipment required for spent fuel cooling. Overhead handling systems that meet these criteria are:

- Polar Crane
- Auxiliary Building Crane
- ERCW Hydraulic Pedestal Crane

In addition, over one hundred overhead handling systems were reviewed and excluded from this list on the basis that a load drop would not result in damage to any system required for plant shutdown or decay heat removal for one of the following reasons:

1. There is sufficient physical separation of the overhead handling system from any system or component required for safe shutdown or decay heat removal.

2. The system or component over which the load is carried is out of service while the load handling system is used.

3. The load weighs less than 2,100 lbs and is not considered to be a heavy load.

3.12.4 Control of Heavy Loads Program

The Control of Heavy Loads Program consists of the following:

1. SQN commitments in response to NUREG-0612, Section 5.1.1 elements

2. For Reactor Pressure Vessel Head (RPVH) lifts, an equivalent single-failure-proof crane

3. For spent fuel cask lifts over the spent fuel pool, a single-failure-proof crane

3.12.4.1 SQN Commitments in Response to NUREG 0612, Section 5.1.1

The control of heavy loads is performed by compliance with the seven guidelines outlined in NUREG 0612, Section 5.1.1.

These guidelines are met through the following:

Guideline	Compliance Method
1	Safe load paths - Safe load paths are contained in maintenance instructions. Directions contained within these instructions provide requirements for control of any lift greater than 2,100 pounds, lifts in the auxiliary building, lifts in the upper compartments of the reactor buildings, and lifts at the ERCW pumping station in those areas designated as critical lifting zones (CLZ). The critical lifting zones are defined as follows: Reactor building critical lifting zone - the region inside the polar crane wall of the upper compartment when there is fuel in the reactor or cavity pool and at least one of the horizontal reactor cavity missile shields has been removed. Spent fuel pit critical lifting zone - the region whose boundaries are defined by the limit switches and mechanical stops on the 125 ton Auxiliary Building Crane. The Spent Fuel Pit CLZ is expanded when there is spent fuel being transferred in the Fuel Transfer Canal or when a cask is being loaded with spent fuel or when spent fuel assemblies are stored in the cask loading area. Dry cask lift critical lifting zone - encompasses areas in the Auxiliary Building from elevation 706' railroad bay to elevation 734' refueling floor. ERCW pumping station critical lifting zone - area over Quality and/or Safety Related equipment within the ERCW pumping station. Auxiliary building critical lifting zone - the region within 15 feet of the residual heat removal and containment spray heat exchanger hatches when the hatch plugs have been removed and the heat exchangers are in service. Any area in which temporary hoists and rigging must be used for lifts greater than 2100 pounds over operable quality and/or safety related equipment. To control load movement, maintenance instructions direct the crane operator to raise and transfer the load to its destination, following safe load paths which have been designated in the instructions. To ensure that the established load paths are followed, all lifts performed per these instructions are done under the supervision of a designated individual (person-in-charge) who will verify the load path is clear prior to load movement. Deviations from approved load paths require prior approval of the plant operations review committee (PORC).

2 Procedures - Load handling procedures for the reactor building crane and the auxiliary building crane are contained in maintenance instructions. These instructions contain sections covering scope of control, references, prerequisites, precautions and limitations, acceptance criteria, performance, inspections, tables of approved heavy load lifts, and drawings identifying safe load paths. Tables of the various approved heavy load lifts identify the crane to be used, approved rigging or lifting devices, component weights, and reference drawings and procedures.

3 Crane Operators - Programs for crane operator training, qualification, and conduct are contained in TVA Safety Procedures. The training programs include:
Operating Practices and Functional Characteristics
Rigging Fundamentals
Electrical Maintenance
Certification Skills for Overhead cab-operated Cranes
These training programs incorporate all of Chapter 2.2 of ANSI (ASME) B30.2.

4 Special lifting devices - SQN Special Lifting Devices are the reactor pressure vessel head lift rig and internals lift rig. Qualification of these devices is provided by WCAP 10346. Inspection of these lift rigs is performed on a 10 year interval using Acoustic Emission Testing (AET). Acceptance of Acoustic Emission Testing for the lift rigs in lieu of the requirements of ANSI N14.6 was accepted by the NRC in a letter dated October 1, 1991 (A02 911007 002).

5 Lifting devices that are not specially designed - All slings and other lifting devices not specially designed used with cranes subject to NUREG 0612, Section 5.1, are designed, inspected, and tested in accordance with ANSI (ASME) B30.9 or ANSI N14.6, respectively. Evaluation of dynamic loads imposed by handling systems has been performed to determine if specialized selection and markings are required. Only one crane (ERCW 20 ton hydraulic pedestal crane) was determined to generate dynamic loads in excess of 15% of rated load. The only below-the-hook lifting device used with this crane is the stoplog lifting beam, which has been evaluated and shown to comply with the necessary design requirements. No special markings or selection criteria are necessary for the slings.

6 The crane should be inspected, tested, and maintained in accordance with Chapter 2-2 of ANSI B30.2-1976 - Cranes and hoists at SQN are inspected, tested, and maintained in accordance with specific site maintenance (MI) and preventative maintenance (PM) instructions which implement the requirements of the applicable ANSI (ASME) standard. Each handling system as listed below has its own unique instruction or procedure to control inspection and testing. The load handling system and applicable standard are as follows:

Handling System	Procedure	Reference Standard
Polar Crane	MI	ANSI B30.2-1976
Auxiliary Building Crane	MI	ANSI B30.2-1976
ERCW Hydraulic Pedestal Crane	PM	ANSI B30.15-1973

7 The crane should be designed to meet the applicable criteria and guidelines of Chapter 2-1 of ANSI B30.2-1976 and CMAA-70 - The actual design data for the auxiliary building crane and the reactor building crane were compared with the guidelines of CMAA-70 and ANSI (ASME) B30.2. Where specific compliance was not evident by review, an evaluation was made by imposing these guidelines on the actual design. Principally, this was the approach used for evaluating the design of major structural components by using load combinations and allowable stresses given in CMAA-70. The results of this review and analysis indicate that both cranes meet or exceed the requirements of CMAA-70 and ANSI (ASME) B30.2.
The remaining overhead handling system subject to compliance with NUREG-0612, is the ERCW hydraulic pedestal crane, which has been verified to be compliant with applicable industry standards.

3.12.4.2 Reactor Pressure Vessel Head (RPVH) Lifting Procedures

SQN maintenance instructions are used to control the removal and replacement of the reactor pressure vessel head. These instructions and TVA Safety Procedures contain requirements to ensure the single-failure-proof equivalency of the reactor building crane is maintained. These requirements include:

- Upper containment temperature is at least 70°F
- Periodic (at start of refueling outage) inspection of the crane has been completed. This inspection includes a check of the drum bearings as required by NEI 08-05 for a crane not equipped with drum safety plates.
- All safety functions of the crane are verified to be operational prior to performing the lift (per NEI 08-05).

The SQN reactor building crane was evaluated against NUREG 0554 as part of the station response to NUREG 0612, Section 5.1.3 (1) (and thus Section 5.1.6) compliance. This evaluation indicated that the crane is equipped with numerous single-failure-proof features. These features, as also described in part in FSAR Section 3.8.6.1, include:

- Master Switches with Spring Return to Off Feature
- Cab Mounted Emergency Stop Button
- Floor Mounted Emergency Stop Buttons
- Overload Protection
- Overspeed Detection
- Dual Wire Ropes with a Factor of Safety Between 5:1 and 10:1
- Two independent Holding Brakes of at least 125% of head lift hoisting torque each. Brakes apply automatically when power is removed from the hoisting motor.
- Dual interconnected gear trains
- Two Upper Limits Switches (2nd upper limit switch is a power disconnect)
- Stress Limits meet CMAA 70-1975
- Designed for Safe Shutdown Earthquake with the Maximum Critical Load

The reactor building crane is not furnished with drum safety plates and the wire rope does not provide a 10:1 factor of safety against breaking strength for the rated load. Thus, the reactor building crane is not fully single-failure-proof.

NEI 08-05 defines the requirements for an equivalent single-failure-proof crane for the purposes of lifting the reactor head. In addition to having the required safety features, the following equivalency measures are provided for the reactor head lift -

- Crane is a Class C design with a design margin of between 8% and 15%
- Drum bearings are inspected as part of the annual (periodic) inspection
- Ambient air temperature is at least 70° F
- All safety functions of the crane are verified to be operational prior to performing the lift
- Direct communications are provided between the Crane Operator, Person-In-Charge and Signal Person via headsets
- Emergency stop buttons are manned during lift
- Backup Emergency Stop Signal is provided
- Pre-job brief performed that includes identification of supervisory oversight, establishment of lift management protocol, acceptable travel limits of crane, verification of emergency stop button locations, and manning of emergency stop buttons
- Maintenance rule (a)(4) measures addressed in outage safety plan

With the equivalency measures provided in NEI 08-05, the reactor building crane is equivalent to single-failure-proof based for lifting the reactor head.

3.12.5 Safety Evaluation

Heavy load lifts at SQN are done safely and in accordance with NUREG 0612. Basis is provided by:

- Controls implemented by NUREG 0612, Section 5.1.1, make the risk of a load drop very unlikely.
- The use of an equivalent single-failure-proof crane makes the risk of a reactor head load drop extremely unlikely and acceptably low.
- The risk associated with the movement of heavy loads is evaluated and controlled by station maintenance instructions and the outage safety plan.

3.13 Flex Response System

3.13.1 Flex Response System Mitigation of Beyond Design Basis External Events

TVA has developed and installed diverse and flexible mitigation strategies (FLEX) that will increase defense-in-depth for beyond design basis scenarios to address an extended loss of alternating current power and loss of normal access to the ultimate heat sink occurring simultaneously at Units 1 and 2. This development is in response to orders from the Nuclear Regulatory Commission regarding the Fukushima Daiichi, Japan nuclear accident and is further described in SQN-DC-V-48.0; Reference 3.13.2. The FLEX Response System components are designed to interface with existing safety related components. FLEX connections to plant systems are described in Reference 3.13.2.

4.0 REACTOR (WESTINGHOUSE FUEL)

4.1 SUMMARY DESCRIPTION

This section addresses Westinghouse Standard (STD) and Vantage 5H (V5H) fuels. See 4.5.0 for information regarding AREVA fuel. Information concerning the power level uprate associated with the implementation of the Leading Edge Flow Meter is also included in Section 4.5.

This chapter describes 1) the mechanical components of the reactor and reactor core including the fuel rods and fuel assemblies, reactor internals, and the control rod drive mechanisms, 2) the nuclear design, and 3) the thermal-hydraulic design.

The reactor core is comprised of an array of fuel assemblies which are similar in mechanical design, but different in fuel enrichment. Three enrichments were employed in the initial core. Reload cores employ multiple enrichments.

Three Westinghouse fuel designs may be used: (1) STD fuel; (2) V5H fuel; (3) V5H fuel with certain Standard features (V5H with STD inconel grids and the corresponding guide tube diameters). AREVA fuel is also applicable for use and is discussed in Section 4.5.

In the discussion in the remainder of this chapter, the STD and V5H designs are discussed explicitly. Where appropriate, the discussion should be understood to apply to V5H fuel with inconel grids.

The core is cooled and moderated by light water at a pressure of 2250 psia in the Reactor Coolant System. The moderator coolant contains boron as a neutron poison. The concentration of boron in the coolant is varied as required to control relatively slow reactivity changes including the effects of fuel burnup. Additional boron, in the form of Integral Fuel Burnable Absorbers (IFBA) or burnable absorber rods, is employed as needed to decrease the moderator temperature coefficient and to control the power distribution.

Two hundred and sixty-four fuel rods, twenty four guide thimble tubes and one instrumentation thimble tube are arranged within a supporting structure to form a fuel assembly. The instrumentation thimble is located in the center position and provides a channel for insertion of an incore neutron detector and thimble tube if the fuel assembly is located in an instrumented core position. The guide thimbles provide channels for insertion of either a rod cluster control assembly, a neutron source assembly, a burnable absorber assembly or a plugging device, depending on the position of the particular fuel assembly in the core. The fuel rods are supported in intervals along their length by grid assemblies which maintain the lateral spacing between the rods throughout the design life of the assembly. The grid assembly consists of an "egg-crate" arrangement of interlocked straps. The straps contain spring fingers and dimples for fuel rod support as well as coolant mixing vanes.

The fuel rods consist of slightly enriched uranium dioxide, ceramic cylindrical pellets contained in slightly cold worked Zircaloy-4 tubing which is plugged and seal welded at the ends to encapsulate the fuel. All fuel rods are pressurized with helium during fabrication to reduce stresses and strains which serves to increase fatigue life.

The center position in the assembly is reserved for the incore instrumentation, while the remaining 24 positions in the array are equipped with guide thimbles joined to the grids and the

top and bottom nozzles. Depending upon the position of the assembly in the core, the guide thimbles are used as core locations for rod cluster control assemblies, neutron source assemblies, and burnable absorber rods. Otherwise, the guide thimbles may be fitted with plugging devices to limit bypass flow.

The bottom nozzle is a box-like structure which serves as a bottom structural element of the fuel assembly and directs the coolant flow distribution through the assembly. The top nozzle assembly functions as the upper structural element of the fuel assembly in addition to providing a partial protective housing for the rod cluster control assembly or other components.

The rod cluster control assemblies each consist of a group of individual neutron absorber rods fastened at the top end to a common hub or spider assembly, and contain neutron absorber material to control the reactivity of the core under operating conditions.

The control rod drive mechanisms for the rod cluster control assemblies are of the magnetic latch type. The latches are controlled by three magnetic coils. They are so designed that upon a loss of power to the coils, the rod cluster control assembly is released and falls by gravity to shutdown the reactor.

The components of the reactor internals are divided into three parts consisting of the lower core support structure (including the entire core barrel and neutron shield and assembly), the upper core support structure and the incore instrumentation support structure. The reactor internals support the core, maintain fuel alignment, limit fuel assembly movement, maintain alignment between fuel assemblies and control rod drive mechanisms, direct coolant flow past the fuel elements and to the pressure vessel head, provide gamma and neutron shielding, and provide guides for the incore instrumentation.

The nuclear design analyses and evaluation establish physical locations for control rods and burnable absorbers and physical parameters such as fuel enrichments and boron concentration in the coolant. This is to ensure that the reactor core has inherent characteristics which together with corrective actions of the reactor control, protective and emergency cooling systems provide adequate reactivity control. This control is maintained even if the rod cluster control assembly of the highest negative reactivity worth is stuck in the fully withdrawn position (stuck rod criterion).

The thermal-hydraulic design analyses and evaluation establish coolant flow parameters which assure that adequate heat transfer is assured between the fuel cladding and the reactor coolant. The thermal design takes into account local variations in dimensions, power generation, flow distribution and mixing. The mixing vanes incorporated in the fuel assembly spacer grid design induce additional flow mixing between the various flow channels within a fuel assembly as well as between adjacent assemblies.

Core instrumentation is provided internally and externally to monitor the nuclear, thermal-hydraulic, and mechanical performance of the reactor and to provide inputs to automatic control functions.

The reactor core design together with corrective actions of the reactor control protection and emergency cooling systems can meet the reactor performance and safety criteria specified in Section 4.2.

To illustrate the effects of the change in fuel design, Table 4.1-1 "Reference Core Report 17 x 17" WCAP-8185 presents a comparison of the principal nuclear, thermal-hydraulic and mechanical design parameters between the reference 4-loop plant with 17 x 17 fuel assemblies including the effects of fuel densification, and the Trojan Nuclear Plant (Docket 50-344) with 17 x 17 fuel assemblies without fuel densification. Table 4.1-1 of this report presents the same comparisons between Sequoyah units 1 and 2 with the reference plant, both with 17 x 17 fuel assemblies including fuel densification effect.

The effects of fuel densification were evaluated with the methods described in Reference 1.

The analysis techniques employed in the core design are tabulated in Table 4.1-2. The loading conditions considered in general for the core internals and components are tabulated in Table 4.1-3. Specific or limiting loads considered for design purposes of the various components are listed as follows: fuel assemblies in Subparagraph 4.2.1.1.2; reactor internals in Paragraph 4.2.2.3 and Table 5.2-2; neutron absorber rods, burnable absorber rods, neutron source rods and thimble plug assemblies in Subparagraph 4.2.3.1.3; control rod drive mechanisms in Subparagraph 4.2.3.1.4. The dynamic analyses, input forcing functions, and response loadings are presented in Section 3.9.

4.2 MECHANICAL DESIGN

The plant conditions for design are divided into four categories in accordance with their anticipated frequency of occurrence and risk to the public: Condition I - Normal Operation; Condition II - Incidents of Moderate Frequency; Condition III - Infrequent Incidents; Condition IV - Limiting Faults.

The reactor is designed so that its components meet the following performance and safety criteria:

1. The mechanical design of the reactor core components and their physical arrangement, together with corrective actions of the reactor control, protection, and emergency cooling systems (when applicable) assure that:

    a. Fuel damage (fuel damage as used here is defined as penetration of the fission product barrier: i.e., the fuel rod clad) is not expected during Condition I and Condition II events. It is not possible, however, to preclude a very small number of rod failures. These are within the capability of the plant cleanup system and are consistent with the plant design bases.

    b. The reactor can be brought to a safe state following a Condition III event with only a small fraction of fuel rods damaged although sufficient fuel damage might occur to preclude resumption of operation without considerable outage time.

    c. The reactor can be brought to a safe state and the core can be kept subcritical with acceptable heat transfer geometry following transients arising from Condition IV events.

2. The fuel assemblies are designed to accommodate expected conditions for handling during assembly, inspection and refueling operations, and shipping loads.

3. The fuel assemblies are designed to accept control rod insertions in order to provide the required reactivity control for power operations and reactivity shutdown conditions.

4. All fuel assemblies have provisions for the insertion of incore instrumentation necessary for plant operation.

5. The reactor internals in conjunction with the fuel assemblies direct reactor coolant through the core to achieve acceptable flow distribution and to restrict bypass flow so that the heat transfer performance requirements can be met for all modes of operation. In addition, the internals provide core support and distribute coolant flow to the pressure vessel head so that the temperature differences between the vessel flange and head do not result in leakage from the flange during the Condition I and II modes of operation. Required in-service inspection can be carried out as the internals are removable and provide access to the inside of the pressure vessel.

4.2.1 Fuel

4.2.1.1 Design Bases

The fuel rod and fuel assembly design bases are established to satisfy the general performance and safety criteria presented in Section 4.2 and specific criteria noted below.

4.2.1.1.1 Fuel Rods

The integrity of the fuel rods is ensured by designing to prevent excessive fuel temperatures, excessive internal rod gas pressures due to fission gas releases, and excessive cladding stresses and strains. This is achieved by designing the fuel rods so that the following conservative design bases are satisfied during Condition I and Condition II events over the fuel lifetime:

1. Fuel Pellet Temperatures - The center temperature of the hottest pellet is to be below the melting temperature of the UO_2 (melting point of 5080°F (Reference 1) unirradiated and reducing by 58°F per 10,000 MWD/MTU). While a limited amount of center melting can be tolerated, the design conservatively precludes center melting. A calculated centerline fuel temperature of 4700°F has been selected as an overpower limit to assure no fuel melting. This provides sufficient margin for uncertainties, as described in Paragraph 4.4.1.2 and Subparagraph 4.4.2.10.1.

2. Internal Gas Pressure - The internal gas pressure of the lead rod in the reactor will be limited to a value below that which could cause the diametral gap to increase due to outward clad creep during steady-state operation, and which could cause extensive DNB propagation to occur. (The safety evaluation of the fuel rod internal pressure design basis is presented in Reference 14).

3. Clad Stress - The effective clad stresses are less than that which would cause general yield of the clad. While the clad has some capability for accommodating plastic strain, the yield strength has been accepted as a conservative design basis.

4. Clad Tensile Strain - The clad tangential strain range is less than one percent. The clad strain design basis addresses slow transient strain rate mechanisms where the clad effective stress never reaches the yield strength due to stress relaxation. The 1% strain limit has been established based upon tensile and burst test data from irradiated clad. Irradiated clad properties are appropriate due to irradiation effects on clad ductility occurring before strain limiting fuel clad interaction during a transient event can occur.

5. Strain Fatigue - The cumulative strain fatigue cycles are less than the design strain fatigue life. This basis is consistent with proven practice.

The effective clad stress is less than that which would cause general yield of the clad. While the clad has some capability for accommodating plastic strain, the yield strength has been accepted as a conservative design basis limit.

Radial, tangential, and axial stress components due to pressure differential and fuel clad contact pressure are combined into an effective stress using the maximum-distortion-energy theory. The Von Mises criterion is used to evaluate if the yield strength has been exceeded. Von Mises criterion states that an isotropic material under multiaxial stress will begin to yield plastically when the effective stress (i.e., combined stress using maximum-distortion-energy theory)

becomes equal to the material yield stress in simple tension as determined by a uniaxial tensile test. Since general yielding is to be prohibited, the volume average effective stress determined by integrating across the clad thickness is increased by an allowance for local non-uniformity effects before it is compared to the yield strength. The yield strength correlation is that appropriate for irradiated clad since the irradiated properties are attained at low exposure whereas the fuel/clad interaction conditions which can lead to minimum margin to the design basis limit always occurs at much higher exposure.

The fuel rods are designed for extended burnup operation using the NRC approved Westinghouse extended burnup design methods, models and criteria in References 5, 6, and 18. The detailed fuel rod design establishes such parameters as pellet size and density, clad-pellet diametral gap, gas plenum size, and helium pre-pressure. The design also considers effects such as fuel density changes, fission gas release, clad creep, and other physical properties which vary with burnup.

Irradiation testing and fuel operational experience has verified the adequacy of the fuel performance and design bases. This is discussed in Reference 2, 3, and 18. Fuel experience and testing results, as they become available, are used to improve fuel rod design and manufacturing processes and assure that the design bases and safety criteria are satisfied.

4.2.1.1.2 Fuel Assembly Structure

Structural integrity of the fuel assemblies is assured by setting limits on stresses and deformations due to various loads and by determining that the assemblies do not interfere with the functioning of other components. Three types of loads are considered.

1. Non-operational loads such as those due to shipping and handling,

2. Normal and abnormal loads which are defined for Conditions I and II,

3. Abnormal loads which are defined for Conditions III and IV.

These criteria are applied to the design and evaluation of the top and bottom nozzles, the guide thimbles, the grids and the thimble joints.

The design bases for evaluating the structural integrity of the fuel assemblies are:

1. Non-Operational - dimensional stability, under specified g loading

2. Normal Operation (Condition I) and Incidents of Moderate Frequency (Condition II),

   For the normal operating (Condition I) and upset conditions (Condition II), the fuel assembly component structural design criteria are classified into two material categories, namely, austenitic steels and zircaloy. The stress categories and strength theory presented in the ASME Boiler and Pressure Vessel Code, Section III, are used as a general guide. The maximum shear-theory (Tresca criterion) for combined stresses is used to determine the stress intensities for the austenitic steel components. The stress intensity is defined as the numerically largest difference between the various principal stresses in a three dimensional

field. The allowable stress intensity value for austenitic steels, such as, nickel-chromium-iron alloys, is given by the lowest of the following:

a. 1/3 of the specified minimum tensile strength or 2/3 of the specified minimum yield strength at room temperature;

b. 1/3 of the tensile strength or 90 percent of the yield strength at temperature but not to exceed 2/3 of the specified minimum yield strength at room temperature.

The stress intensity limits for the austenitic steel components are listed below. All stress nomenclature is per ASME Boiler and Pressure Vessel Code, Section III.

Categories	Limit
General Primary Membrane Stress Intensity	Sm
Local Primary Membrane Stress Intensity	1.5 Sm
Primary Membrane plus Bending Stress Intensity	1.5 Sm
Total Primary plus Secondary Stress Intensity	3.0 Sm

The zircaloy structural components which consist of guide thimble, inner six grids (for V5H fuel), and fuel tubes are in turn subdivided into two categories because of material differences and functional requirements. The fuel tube design criteria is covered separately in Subparagraph 4.2.1.1.1. The maximum stress theory is used to evaluate the guide thimble design. The maximum stress theory assumes that yielding due to combined stresses occur where one of the principal stresses are equal to the simple tensive or compressive yield stress. The zircaloy unirradiated properties are used to define the stress limits.

3. Abnormal loads during Conditions III or IV - worst cases represented by combined seismic and blowdown loads.

   a. Deflections of components cannot interfere with the reactor shutdown or emergency cooling of the fuel rods.

   b. The fuel assembly structural component stresses under faulted conditions are evaluated using primarily the methods outlined in Appendix F of the ASME Pressure Vessel Code Section 3. Since the current analytical methods utilize elastic analysis, the stress allowables are defined as the smaller value of 2.4 Sm or 0.70 Su for primary membrane and 3.6 Sm or 1.05 Su for primary membrane plus primary bending. For the austenitic steel fuel assembly components, the stress intensity is defined in accordance with the rules described in the previous section for normal operating conditions. For the zircaloy components the stress limits are set at two-thirds of the material yield strength, Sy, at reactor operating temperature. This results in zircaloy stress intensity limits being the smaller of 1.6 Sy or 0.70 Su for primary membrane and 2.4 Sy or 1.05 Su for primary membrane plus bending. For conservative purposes, the zircaloy unirradiated properties are used to define the stress limits.

The grid component strength criteria are based on experimental tests. The limit is established at Pc where Pc is the experimental collapse load determined at the 95% confidence level on the true mean, as taken from the distribution of grid crush test measurements.

4.2.1.2 Design Description

The standard fuel assembly and fuel rod design data are given in Table 4.1-1. NRC approval of the VANTAGE 5H design is given in Reference 19.

Two hundred and sixty-four fuel rods, twenty-four guide thimble tubes and one instrumentation thimble tube are arranged within a supporting structure to form a fuel assembly. The instrumentation thimble is located in the center position and provides a channel for insertion of an incore neutron detector and thimble tube if the fuel assembly is located in an instrumented core position. The guide thimbles provide channels for insertion of either a rod cluster control assembly, a neutron source assembly, a burnable absorber assembly or a plugging device, depending on the position of the particular fuel assembly in the core. Figure 4.2.1-1 shows a cross-section of the fuel assembly array, and Figure 4.2.1-2 and Figure 4.2.1-2a show fuel assembly full length outlines. The fuel rods are loaded into the fuel assembly structure so that there is clearance between the fuel rod ends and the top and bottom nozzles.

Shown in Figure 4.2.1-2a is a comparison of the two assembly designs noting respective overall height and grid elevation dimensions. The most significant design change associated with the VANTAGE 5H assembly, is the use of Zircaloy grids to replace the six intermediate STD Inconel grids. The guide thimbles and instrumentation tube diameters are reduced to accommodate this change. The VANTAGE 5H assembly incorporates the reconstitutable top nozzle (RTN) design and uses a slightly longer fuel rod with a redesigned reconstitutable bottom end plug. The debris filter bottom nozzle (DFBN) is also used and is similar to the STD assembly design except it is lower in height and has a new pattern of smaller flow holes in its thinner top plate. This design minimizes passage of debris particles which could cause fretting damage to fuel rod cladding.

The VANTAGE 5H fuel assembly has the same cross-sectional envelope as the STD assembly, however, it is 0.210 inches longer overall. The grid centerline elevations for the VANTAGE 5H are 0.270 inches lower than those of the STD assembly, except for the top and bottom grids. The VANTAGE 5H top and bottom grids, respectively, are 0.360 and 0.355 inches lower than the STD design. However, any integral contact between the two assemblies will be grid-to-grid. By matching grid elevation, any crossflow maldistribution between the STD and the VANTAGE 5H fuel assembly is minimized.

Each fuel assembly is installed vertically in the reactor vessel and stands upright on the lower core plate, which is fitted with alignment pins to locate and orient the assembly. After all fuel assemblies are set in place, the upper support structure is installed. Alignment pins, built into the upper core plate, engage and locate the upper ends of the fuel assemblies. The upper core plate then bears downward against the fuel assembly top nozzle via the holddown springs to hold the fuel assemblies in place.

4.2.1.2.1 Fuel Rods

The STD and Vantage 5H fuel rods consist of uranium dioxide ceramic pellets contained in slightly cold worked Zircaloy-4 tubing which is plugged and seal welded at the ends to

encapsulate the fuel. Schematics of the fuel rod are shown in Figure 4.2.1-3 and 4.2.1-3a. The fuel pellets are right circular cylinders consisting of uranium-dioxide powder which has been compacted by cold pressing and then sintered to the required density. The ends of each pellet are dished slightly to allow greater axial expansion at the center of the pellets and are chamfered to minimize pellet cracking during handling.

An older design of the STD fuel rod is also in use at SQN. A typical schematic of the fuel rod is shown in Figure 4.2.1-10 (labeled GROUP - 2). The older design of fuel pellets are dished, but may or may not be chamfered depending on the date that they were made. The older STD fuel rod has an external grip for rod loading. STD fuel rods are used in both STD skeletons (grids, guide and instrument tubes, and top and bottom nozzles) and in VANTAGE 5H skeletons.

The VANTAGE 5H and the STD fuel rods have the same clad wall thickness and outer diameters. Also, the bottom end plug has an internal grip feature to facilitate rod loading on both designs. The VANTAGE 5H fuel rod length is larger by 0.640 inches to provide a longer plenum and bottom end plug. The bottom end plug is longer to provide a longer lead-in for the removable top nozzle reconstitution feature. The VANTAGE 5H rods may have axial blankets and Integral Fuel Burnable Absorbers (IFBA) features.

The VANTAGE 5H rods contain standardized pellets which are a refinement of the pellets in the standard assembly design. The ends of each fuel pellet have a small chamfer at the cylindrical surface and a reduction in the dish diameter and depth compared to previous Westinghouse unchamfered pellets. Additionally, the pellet length is reduced (L/D = 1.2). The chamfer improves pellet chip resistance during manufacturing and handling. Also, compared to previous Westinghouse fuel designs, the VANTAGE 5H rods use a smaller fuel rod plenum spring which satisfies the 4g axial and 6g lateral load design bases. The lower spring force reduces the already low potential for chamfered pellet chipping in the fuel rod. The smaller fuel rod plenum spring also provides additional plenum volume for fission gas release.

The axial blankets, if present, are a nominal six inches of unenriched fuel pellets at each end of the fuel rod pellet stack. Axial blankets reduce neutron leakage and improve fuel utilization. The axial blankets utilize chamfered pellets which are physically different (length) than the enriched pellets to help prevent accidental mixing during manufacturing.

The IFBA coated fuel pellets are identical to the enriched uranium dioxide pellets except for the addition of a thin zirconium diboride (ZrB_2) coating less than 0.001 inch in thickness on the pellet cylindrical surface. Coated pellets occupy the central portion of the fuel column (up to 134 inches). The number and pattern of IFBA rods within an assembly may vary depending on specific application. The ends of the IFBA enriched coated pellets, like the enriched uncoated pellets, are also dished to allow for greater axial expansion at the pellet centerline and void volume for fission gas release. An evaluation and test program for the IFBA design features are given in Section 2.5 in Reference 20.

To avoid overstressing of the cladding or seal welds, void volume and clearances are provided within the rods to accommodate fission gases released from the fuel, differential thermal expansion between the cladding and the fuel, and fuel density changes during burnup. Shifting of the fuel within the cladding during handling or shipping prior to core loading is prevented by a stainless steel helical spring which bears on top of the fuel. During assembly the pellets are stacked in the cladding to the required fuel height, the spring is then inserted into the top end of

the fuel tube and the end plugs pressed into the ends of the tube and welded. All fuel rods are internally pressurized with helium during the welding process in order to minimize compressive clad stresses and creep due to coolant operating pressures. The helium pre-pressurization may be different for each fuel region. Fuel rod pressurization is dependent on the planned fuel burnup as well as other fuel design parameters and fuel characteristics (particularly densification potential). The fuel rods are designed such that (1) the internal gas pressure of the lead rod will not exceed the value which causes the fuel-clad diametral gap to increase due to outward cladding creep during steady state operation, (2) extensive DNB propagation will not occur, (3) the cladding stress-strain limits (Section 4.2.1.1.1) are not exceeded for condition I and II events, and (4) clad flattening will not occur during the fuel core life.

4.2.1.2.2 Fuel Assembly Structure

The fuel assembly structure consists of a bottom nozzle, top nozzle, guide thimbles and grids, as shown in Figures 4.2.1-2 and 4.2.1-2a.

Bottom Nozzle

The bottom nozzle is a box-like structure which serves as a bottom structural element of the fuel assembly and directs the coolant flow distribution to the assembly. The square nozzle is fabricated from type 304 stainless steel and consists of a perforated plate and four angle legs with bearing plates as shown in Figure 4.2.1-2 and 4.2.1-2a. The legs form a plenum for the inlet coolant flow to the fuel assembly. The plate itself acts to prevent a downward ejection of the fuel rods from their fuel assembly. The bottom nozzle is fastened to the fuel assembly guide tubes by weld-locked screws or integral deformable locking cap screws which penetrate through the nozzle and mate with an inside fitting in each guide tube, as shown in Figure 4.2.1-4.

The VANTAGE 5H design will include use of the DFBN to reduce the possibility of fuel rod damage due to debris-induced fretting. The relatively large flow holes in a conventional bottom nozzle are replaced with a new pattern of smaller holes. The holes are sized to minimize passage of debris particles large enough to cause damage while providing sufficient flow area, comparable pressure drop, and continued structural integrity of the nozzle. Tests to measure pressure drop and demonstrate structural integrity verified that the 304 stainless steel DFBN is totally compatible with the current design.

Changes in design compared to the 17x17 STD bottom nozzle design include: 1) a modified flow hole size and pattern as described above; 2) a decreased nozzle height and thinner top plate to accommodate the extended burnup fuel rod; and, 3) increased lead-in chamfers for the core pin interface to improve handling. The DFBN will be fabricated from 304 stainless steel as is the 17x17 STD design.

Coolant flow through the fuel assembly is directed from the plenum in the bottom nozzle upward through the penetrations in the plate to the channels between the fuel rods. The penetrations in the plate are positioned between the rows of the fuel rods.

Axial loads (holddown) imposed on the fuel assembly and the weight of the fuel assembly are transmitted through the bottom nozzle to the lower core plate. Indexing and positioning of the

fuel assembly is controlled by alignment holes in two diagonally opposite bearing plates which mate with locating pins in the lower core plate. Any lateral loads on the fuel assembly are transmitted to the lower core plate through the locating pins.

Top Nozzle

The top nozzle assembly functions as the upper structural element of the fuel assembly in addition to providing a partial protective housing for the rod cluster control assembly or other components. It consists of an adapter plate, enclosure, top plate, hold down springs, clamps, and pads as shown in Figure 4.2.1-2 and 4.2.1-2a. The springs and bolts are made of Inconel 718 and Inconel 600 respectively, whereas other components are made of type 304 stainless steel.

The square adapter plate is provided with round and obround penetrations to permit the flow of coolant upward through the top nozzle. For STD fuel other round holes are provided to accept sleeves which are welded to the adapter plate and mechanically attached to the thimble tubes. The ligaments in the plate cover the tops of the fuel rods and prevent their upward ejection from the fuel assembly. The enclosure is a sheet metal shroud which sets the distance between the adapter plate and the top plate. The top plate has a large square hole in the center to permit access for the control rods and the control rod spiders. Holddown springs are mounted on the top plate and are fastened in place by bolts and clamps located at two diagonally opposite corners. On the other two corners integral pads are positioned which contain alignment holes for locating the upper end of the fuel assembly.

The reconstitutable top nozzle (RTN) for the VANTAGE 5H fuel assembly differs from the conventional design in two ways: a groove is provided in each thimble thru-hole in the nozzle plate to facilitate attachment and removal, and the nozzle plate thickness is reduced to provide additional axial space for fuel rod growth.

In the VANTAGE 5H reconstitutable top nozzle design, a stainless steel nozzle insert is mechanically connected to the top nozzle adapter plate by means of a pre-formed circumferential bulge near the top of the insert. The insert engages a mating groove in the wall of the adapter plate thimble tube thru-hole. The insert has four (4) equally spaced axial slots which allow the insert to deflect inwardly at the elevation of the bulge, thus permitting the installation or removal of the nozzle. The insert bulge is positively held in the adapter plate mating groove by placing a lock tube with a uniform ID identical to that of the thimble tube into the insert.

To remove the top nozzle, a tool is first inserted through a lock tube and expanded radially to engage the bottom edge of the tube. An axial force is then exerted on the tool which overrides the local lock tube deformations and withdraws the lock tube from the insert. After the lock tubes have been withdrawn, the nozzle is removed by raising it off the upper slotted ends of the nozzle inserts which deflect inwardly under the axial lift load. With the top nozzle removed, direct access is provided for fuel rod examinations or replacement. Reconstitution is completed by the remounting of the nozzle and the insertion of lock tubes. The design bases and evaluation of the reconstitutable top nozzle are given in Section 2.3.2 in Reference 20.

Guide and Instrument Thimbles

The guide thimbles are structural members which also provide channels for the neutron absorber rods, burnable absorber rods or neutron source assemblies. Each one is fabricated from Zircaloy-4 tubing having two different diameters. The larger diameter at the top provides a relatively large annular area to permit rapid insertion of the control rods during a reactor trip as well as to accommodate the flow of coolant during normal operation. The lower portion of the guide thimbles has a reduced diameter to produce a dashpot action near the end of the control rod travel during a reactor trip. Four holes are provided on the thimble tube above the dashpot to reduce the rod drop time. The dashpot is closed at the bottom by means of an end plug which is provided with a small flow port to avoid fluid stagnation in the dashpot volume during normal operation and to accommodate the outflow of water from the dashpot during a reactor trip. The lower end of the guide thimble is fitted with an end plug which is then fastened into the bottom nozzle by a weld locked screw or integral locking cap screw. In the VANTAGE 5H design, the top end of the guide thimbles are fastened to a tubular nozzle insert sleeve by three expansion swages. The inserts engage into mating grooves in the top nozzle adapter plate as shown in Figure 4.2.1-6b. In the STD assembly design, the guide thimbles are similarly fastened to the top grid sleeves which are then welded to the top nozzle adapter plate as shown in Figure 4.2.1-6a.

Guide thimbles of the VANTAGE 5H design are identical to those of the STD design with the exception of a reduction in diameter and length above the dashpot. The diametral reduction is required to allow for the thicker straps of the mid Zircaloy grids; the length reduction is required by the RTN design. The VANTAGE 5H thimble tube ID provides an adequate nominal diametral clearance of 0.061 inches for the control rods. The VANTAGE 5H thimble tube ID also provides sufficient diametral clearance for burnable absorber rods, source rods, and thimble plugs. The thimble plugs used in the Sequoyah Units are the dually compatible type and can be inserted into the STD and VANTAGE 5H assembly guide thimbles.

For both the VANTAGE 5H and STD designs, each grid is fastened to the guide thimble assemblies to create an integrated structure. The fastening method depicted in Figures 4.2.1-7a and 4.2.1-7b is used for all but the top and bottom grids in the VANTAGE 5H assembly. Shown in Figure 4.2.1-5 and 4.2.1-7c is the fastening method for the mid grids of the STD assembly.

An expanding tool is inserted into the inner diameter of the Zircaloy thimble tube at the elevation of stainless steel sleeves that have been brazed into the Inconel grid assembly. In the VANTAGE 5H design, these mid grid sleeves are made of Zircaloy and are laser welded to the Zircaloy grid assemblies. The four-lobed tool forces the thimble and sleeve outward to a predetermined diameter, thus joining the two components.

The bottom grid assembly is joined to the assembly as shown in Figure 4.2.1-8. The stainless steel insert is spotwelded to the bottom grid and later captured between the guide thimble end plug and the bottom nozzle by means of a stainless steel thimble screw.

The described methods of grid fastening are standard and have been used successfully since the introduction of Zircaloy guide thimbles in 1969.

The central instrumentation tube of each fuel assembly is constrained by seating in counterbores in each nozzle. This tube is a constant diameter and guides the incore neutron detectors. The instrumentation tube of the VANTAGE 5H design has a reduced diameter as compared to that of the STD design. Sufficient diametral clearance exists for the flux thimble to traverse the tube without binding. Instrumentation tubes are expanded at the top and mid grids in the same manner for both assembly designs as the previously discussed expansion of the guide thimbles to the grids.

Grid Assemblies

The fuel rods, as shown in Figures 4.2.1-2 and 4.2.1-2a, are supported at intervals along their length by structural grid assemblies which maintain the lateral spacing between the rods. Each fuel rod is supported laterally within each grid cell by a combination of support dimples and springs (six support locations per cell: four dimples and two springs). The magnitude of grid spacing spring force on the fuel rods is set high enough to minimize possible fretting, without overstressing the cladding at the contact points. All grid assemblies allow axial thermal expansion of the fuel rods without imposing restraint sufficient to develop buckling or distortion.

The top and bottom grids are made of Inconel 718 strap materials, chosen for its strength and high corrosion resistance. These non-mixing vane grids are nearly identical in the STD and VANTAGE 5H designs. VANTAGE 5H differences are: 1) a snag resistant design minimizes assembly interactions during core loading/core unloading; 2) dimples are rotated 90 degrees to minimize fuel rod fretting and dimple cocking; 3) grid heights are increased to 1.522 inches to accommodate rotated dimples; 4) the top grid spring force has been reduced to minimize rod bow; and, 5) top grid sleeves are made of 304L stainless steel instead of 304 S/S as in the STD design.

The six intermediate (mixing vane) grids of the VANTAGE 5H design are made of Zircaloy straps (chosen for its low neutron absorption properties), whereas Inconel is used for the mid grids of the STD design. Inner straps of both designs include mixing vanes which project into the coolant stream and promote mixing of the coolant in the high heat flux region of the assemblies. Relative to STD Inconel mid grids, the VANTAGE 5H grid includes: 1) increased strap thickness and strap height for structural performance; 2) the anti-snag feature as noted above; 3) chamfered upstream strap edges; and 4) grid springs positioned diagonally to further improve pressure drop. The VANTAGE 5H Zircaloy mid grid is designed for approximately the same pressure drop as the STD Inconel mid grid and has superior structural performance relative to it as discussed in Reference 19.

All grid assemblies consist of individual slotted straps assembled in an interlocking "egg-crate" arrangement. Zircaloy grid strap joints and grid/sleeve joints are fabricated by laser welding, whereas all Inconel grid joints are brazed. The outside straps on all grids contain mixing vanes which, in addition to their mixing function, aid in guiding the grids and fuel assemblies past projecting surfaces during handling or during loading and unloading of the core.

4.2.1.3 Design Evaluation

4.2.1.3.1 <u>Fuel Rods</u>

The fuel rods are designed to assure the design bases are satisfied for Condition I and II events. This assures that the fuel performance and safety criteria (Section 4.2) are satisfied.

<u>Materials - Fuel Cladding</u>

The desired fuel rod cladding is a material which has a superior combination of neutron economy (low absorption cross section), high strength (to resist deformation due to differential pressures and mechanical interaction between fuel and clad), high corrosion resistance (to coolant, fuel and fission products), and high reliability. Zircaloy-4 has this desired combination of cladding properties. As shown in Reference 2, there is considerable PWR operating experience on the capability of Zircaloy as a cladding material. Clad hydriding has not been a significant cause of clad perforation since current controls on fuel contained moisture levels were instituted (Reference 2).

Metallographic examination of irradiated commercial fuel rods have shown occurrences of fuel/clad chemical interaction. Reaction layers of <1 mil in thickness have been observed between fuel and clad at limited points around the circumference. Westinghouse metallographic data indicates that this interface layer remains very thin even at high burnup. Thus, there is no indication of propagation of the layer and eventual clad penetration.

Stress corrosion cracking is another postulated phenomenon related to fuel/clad chemical interaction. Out-of-reactor tests have shown that in the presence of high clad tensile stress, relatively large concentrations of iodine, or cadmium in solution in liquid cesium can stress corrode zircaloy tubing and lead to eventual clad cracking. Extensive post irradiation examination has produced no conclusive evidence that this mechanism is operative in commercial fuel.

<u>Materials - Fuel Pellets</u>

Sintered, high density uranium dioxide fuel is chemically inert, with respect to the cladding, at core operating temperatures and pressures. In the event of cladding defects, the high resistance of uranium dioxide to attack by water protects against fuel deterioration although limited fuel erosion can occur. As has been shown by operating experience and extensive experimental work, the thermal design parameters conservatively account for changes in the thermal performance of the fuel elements due to pellet fracture which may occur during power operation. The consequences of defects in the cladding are greatly reduced by the ability of uranium dioxide to retain fission products including those which are gaseous or highly volatile.

Observations from several operating Westinghouse PWR's (Reference 4) have shown that fuel pellets can densify under irradiation to a density higher than the manufactured values. Fuel densification and subsequent incomplete settling of the fuel pellets results in local and distributed gaps in the fuel rods. Fuel densification has been minimized by improvements in the fuel manufacturing process and by specifying a nominal 95 percent initial fuel density.

The effects of fuel densification have been taken into account in the nuclear and thermal-hydraulic design of the reactor described herein in Section 4.3 and 4.4, respectively.

Materials - Strength Considerations

One of the most important limiting factors in fuel element duty is the mechanical interaction of fuel and cladding. This fuel cladding interaction produces cyclic stresses and strains in the cladding, and these in turn consume cladding fatigue life. The reduction of fuel cladding interaction is therefore a principal goal of design. In order to achieve this goal and to enhance the cyclic operational capability of the fuel rod, the technology for using pre-pressurized fuel rods in Westinghouse PWR's has been developed.

Steady State Performance Evaluation

In the calculation of the steady-state performance of a nuclear fuel rod, the following interacting factors must be considered:

1. Clad creep and elastic deflection,

2. Pellet density changes, thermal expansion, gas release, release of helium from IFBA, if present, and thermal properties as a function of temperature and fuel burnup,

3. Internal pressure as a function of fission gas release, rod geometry, and temperature distribution.

These effects are evaluated using overall fuel rod design models (References 5 and 6), which include appropriate models for time dependent fuel densification. With these interacting factors considered, the model determines the fuel rod performance characteristics for a given rod geometry, power history, and axial power shape. In particular, internal gas pressure, fuel and cladding temperatures, and cladding deflections are calculated. The fuel rod is divided lengthwise into several sections and radially into a number of annular zones. Fuel density changes, cladding stresses, strains and deformations, and fission gas releases are calculated separately for each segment. The effects are integrated to obtain the internal rod pressure.

The initial rod internal pressure is selected to delay fuel/clad mechanical interaction and to avoid the potential for flattened rod formation. It is limited, however, by the design criteria for the rod internal pressure. The plenum height of the fuel rod has been designed to ensure that the maximum internal pressure of the fuel rod will not exceed the value which would cause the fuel clad diametral gap to increase during steady state operation.

The gap conductance between the pellet surface and the cladding inner diameter is calculated as a function of the composition, temperature, and pressure of the gas mixture, and the gap size or contact pressure between clad and pellet. After computing the fuel temperature for each pellet annular zone, the fractional fission gas release is calculated based on local fuel temperature and burnup. The total amount of gas released is based on the average fractional release within each axial and radial zone and the gas generation rate which in turn is a function of burnup. Finally, the gas released is summed over all zones and the pressure is calculated.

The model shows good agreement in fit for a variety of published and proprietary data on fission gas release, release of helium from IFBA, if present, fuel temperatures and clad deflection

(References 5 and 6). Included in this spectrum are variations in power, time, fuel density, and geometry. The in-pile fuel temperature measurement comparisons used are referenced in Paragraph 4.4.2.2.

Initially, the gap between the fuel and cladding is sufficient to prevent hard contact between the two. However, during power operation a gradual compressive creep of the cladding onto the fuel pellet occurs due to the external pressure exerted on the rod by the coolant. Cladding compressive creep eventually results in fuel/clad contact. During this period of fuel/clad contact, changes in power level could result in changes in cladding stresses and strains. By using prepressurized fuel rods to partially offset the effect of the coolant external pressure, the rate of cladding creep toward the surface of the fuel is reduced. Fuel rod prepressurization delays the time at which fuel/clad contact occurs and hence, significantly reduces the number and extent of cyclic stresses and strains experienced by the cladding both before and after fuel/clad contact. These factors result in an increase in the fatigue life margin of the cladding and lead to greater cladding reliability. If gaps should form in the fuel stacks, cladding flattening will be prevented by the rod prepressurization so that the flattening time will be greater than the fuel core life.

The clad stresses at a constant local fuel rod power are low. Compressive stresses are created by the pressure differential between the coolant pressure and the rod internal gas pressure. Because of the pre-pressurization with helium the volume average effective stresses are always less than ~11,000 psi at the pressurization level used in this fuel rod design. Stresses due to the temperature gradient are not included in this average effective stress because thermal stresses are, in general, negative at the clad ID and positive at the clad OD and their contribution to the clad volume average stress is small. Furthermore, the thermal stress decreases with time during steady-state operation due to stress relaxation. The stress due to pressure differential is highest in the minimum power rod at the beginning of life (due to low internal gas pressure) and the thermal stress is highest in the maximum power rod (due to steep temperature gradient).

For rods designed for increased discharge burnup, the internal gas pressure at BOL ranges from ~650 psi to ~1050 psi. The total tangential stress at the clad ID at BOL is ~15,800 psi compressive (~14,600 psi due to -P and ~1,200 psi due to-T) for a low power rod, operating at 5 kw/ft and ~15,100 psi compressive (~11,900 psi due to-P and ~3200 psi due to-T) for a high power rod operating at 15 kw/ft. However, the volume average effective stress at BOL is between ~8,000 psi (high power rod) and ~11,000 psi (low power rod). These stresses are substantially below even the unirradiated clad strength ~55,500 psi) at a typical clad mean operating temperature of 700°F.

Tensile stresses could be created once the clad has come in contact with the pellet. These stresses would be induced by the fuel pellet swelling during irradiation. There is very limited clad pushout after pellet-clad contact. Fuel swelling can result in small clad strains (< 1%) for expected discharge burnups but the associated clad stresses are very low because of clad creep (thermal and irradiation-induced creep). Furthermore, the 1% strain criterion is extremely conservative for fuel-swelling driven clad strain because the strain rate associated with solid fission products swelling is very slow ($.5x10^{-7}$ hr^{-1}). In-pile experiments (Reference 7) have shown that Zircaloy tubing exhibits "super-plasticity" at slow strain rates during neutron irradiation. Uniform clad strains of >10% have been achieved under these conditions with no sign of plastic instability.

Pellet thermal expansion due to power increases is considered the only mechanism by which significant stresses and strains can be imposed on the clad. Power increases in commercial reactors can result from fuel shuffling (e.g., Region 3 positioned near the center of the core for Cycle 2 operation after operating near the periphery during Cycle 1), reactor power escalation following extended reduced power operation, and control rod movement. In the mechanical design model, lead rods are depleted using best estimate power histories as determined by core physics calculations. During the depletion, the amount of diametral gap closure is evaluated based upon the pellet expansion-cracking model, clad creep model, and fuel swelling model. At various times during the depletion the power is increased locally on the rod to the burnup dependent attainable power density as determined by core physics calculations. The radial, tangential, and axial clad stresses resulting from the power increase are combined into a volume average effective clad stress.

The von Mises criterion is used to evaluate if the clad yield stress has been exceeded. This criterion states that an isotropic material in multiaxial stress will begin to yield plastically when the effective stress exceeds the yield stress as determined by a uniaxial tensile test. The yield stress correlation is that for irradiated cladding since fuel/clad interaction occurs at high burnup. Furthermore, the effective stress is increased by an allowance, which accounts for stress concentrations in the clad adjacent to radial cracks in the pellet, prior to the comparison with the yield stress. This allowance was evaluated using a two-dimensional (γ,θ)1 finite element model.

Slow transient power increases can result in large clad strains without exceeding the clad yield stress because of clad creep and stress relaxation. Therefore, in addition to the yield stress criterion, a criterion on allowable clad positive strain is necessary. Based upon high strain rate burst and tensile test data on irradiated tubing, 1% strain was determined to be the lower limit on irradiated clad ductility and thus adopted as a design criterion.

In addition to the mechanical design models and design criteria, Westinghouse relies on performance data accumulated through transient power test programs in experimental and commercial reactors, and through normal operation in commercial reactors.

It is recognized that a possible limitation to the satisfactory behavior of the fuel rods in a reactor which is subjected to daily load follow is the failure of the cladding by low cycle strain fatigue. During their normal residence time in reactor, the fuel rods may be subjected to ~1000 cycles with typical changes in power level from 50 to 100% of their steady-state values.

The assessment of the fatigue life of the fuel rod cladding is subjected to a considerable uncertainty due to the difficulty of evaluating the strain range which results from the cyclic interaction of the fuel pellets and claddings. This difficulty arises for example from such highly unpredictable phenomena as pellet cracking, fragmentation, and relocation. Nevertheless, since early 1968, Westinghouse has been investigating this particular phenomenon both analytically and experimentally. Strain fatigue tests on irradiated and nonirradiated hydrided Zr-4 claddings were performed which permitted a definition of a conservative fatigue life limit and recommendation of a methodology to treat the strain fatigue evaluation of the Westinghouse reference fuel rod designs.

However, Westinghouse is convinced that the final proof of the adequacy of a given fuel rod design to meet the load follow requirements can only come from in-pile experiments performed on actual reactors. The Westinghouse experience in load follow operation dates back to early

1970 with the load follow operation of the Saxton reactor. More recently, successful load follow operation has been performed on Point Beach unit 1 (300 load follow cycles) and Point Beach unit 2 (150 load follow cycles). In both cases, there was no significant coolant activity increase that could be associated with the load follow mode of operation.

The following paragraphs present briefly the Westinghouse analytical approach to strain fatigue.

A comprehensive review of the available strain-fatigue models was conducted by Westinghouse as early as 1968.

This included the Langer-O'Donnel model, (Reference 8), the Yao-Munse model, and the Manson-Halford model. Upon completion of this review and using the results of the Westinghouse experimental programs discussed below, it was concluded that the approach defined by Langer-O'Donnel would be retained and the empirical factors of their correlation modified in order to conservatively bound the results of the Westinghouse testing program.

The Langer-O'Donnel empirical correlation has the following form:

$$S_a = \frac{E\ 1n}{4\sqrt{N_f}} \left(\frac{100}{100\ -\ RA}\right) + S_e$$

Where: $S_a = 1/2\ E\ \text{-}\varepsilon_t$ = pseudo - stress amplitude which causes failure in N_f cycles (lb/in^2)

$\text{-}\varepsilon_t$ = total strain range (in/in)

E = Young's Modulus (lb/in^2)

N_f = number of cycles to failure

RA = reduction in area at fracture in a uniaxial tensile test (%)

S_e = endurance limit (lb/in^2)

Both RA and Se are empirical constants which depend on the type of material, the temperature and the irradiation. The Westinghouse testing program was subdivided in the following sub-programs:

1. A rotating bend fatigue experiment on unirradiated Zr-4 specimens at room temperature and at 725°F. Both hydrided and non-hydrided Zr-4 cladding were tested.

2. A biaxial fatigue experiment in gas autoclave on unirradiated Zr-4 cladding both hydrided and non-hydrided.

3. A fatigue test program on irradiated cladding from the CVTR and Yankee Core V conducted at Battelle Memorial Institute.

The results of these test programs provided information on different cladding conditions including the effect of irradiation, of hydrogen level, and of temperature.

The Westinghouse design equations followed the concept for the fatigue design criterion according to Section 3 of the ASME Boiler and Pressure Vessel Code. Namely:

1. The calculated pseudo-stress amplitude (S_a) has to be multiplied by a factor of 2 in order to obtain the allowable number of cycles (N_f).

2. The allowable cycles for a given S_a is 5% of N_f, or a safety factor of 20 on cycles.

The lesser of the two allowable number of cycles is selected. The cumulative fatigue life fraction is then computed as:

$$\sum_{1}^{k} n_k / N_{fk} \leq 1$$

where: n_k = number of diurnal cycles of mode k.

The potential effects of operation with waterlogged fuel are discussed in Paragraph 4.4.3.6. Waterlogging is not considered to be a concern during operational transients.

4.2.1.3.2 Fuel Assembly Structure Stresses and Deflections

The potential sources of high stresses in the assembly are avoided by the design. For example, stresses in the fuel rod due to thermal expansion and Zircaloy irradiation growth are limited by the relative motion of the rod as it slips over the grid spring and dimple surfaces. Clearances between the fuel rod ends and nozzles are provided so that Zircaloy irradiation growth will not result in end interferences. As another example, stresses due to holddown springs in opposition to the hydraulic lift force are limited by the deflection characteristic of the springs. Stresses in the fuel assembly caused by tripping of the rod cluster control assembly have little influence on fatigue because of the small number of events during the life of an assembly. Welded joints in the fuel assembly structure are considered in the structural analysis of the assembly. Appropriate material properties of welds are used to insure the design bases are met. Assembly components and prototype fuel assemblies made from production parts have been subjected to structural tests to verify that the design bases requirements are met.

The fuel assembly design loads for shipping have been established. Probes are permanently placed into the shipping cask to monitor and detect fuel assembly displacements that would result from loads in excess of the criteria. Past history and experience has indicated that loads which exceeded the allowable limits rarely occur. Exceeding the limits requires reinspection of the fuel assembly for damage. Tests on various fuel assembly components such as the grid assembly, sleeves, inserts and structure joints have been performed to assure that the shipping design limits do not result in impairment of fuel assembly function.

The methodology for the seismic analysis of the fuel assemblies are presented in References 9, 13, and 19.

Dimensional Stability

A prototype fuel assembly has been subjected to column loads in excess of those expected in normal service and faulted conditions (see References 9 and 19).

The coolant flow channels are established and maintained by the structure composed of grids and guide thimbles. The lateral spacing between fuel rods is provided and controlled by the support dimples of adjacent grid cells. Contact of the fuel rods on the dimples is assured by the clamping force provided by the grid springs. Lateral motion of the fuel rods is opposed by the spring force and the internal moments generated between the spring and the support dimples. Grid testing is discussed in References 9 and 19.

No interference with control rod insertion into thimble tubes will occur during a postulated LOCA transient due to fuel rod swelling, thermal expansion, or bowing. In the early phase of the transient following the coolant break the high axial loads which potentially could be generated by the difference in thermal expansion between fuel clad and thimbles are relieved by slippage of the fuel rods through the grids. The relatively low drag force restraint on the fuel rods will only induce minor thermal bowing not sufficient to close the fuel rod-to-thimble tube gap. This rod-to-grid slip mechanism occurs simultaneously with control rod drop.

Vibration and Wear

The effect of a flow induced vibration on the fuel assembly and individual fuel rods is minimal. The cyclic stress range associated with deflections of such small magnitude is insignificant and has no effect on the structural integrity of the fuel rod.

The conclusion that the effect of flow induced vibrations on the fuel assembly and fuel rod is minimal is based on test results and analysis documented in the Hydraulic Flow Test of the 17 x 17 Fuel Assembly report (Reference 10) which takes into consideration the condition normally encountered in reactor operation. Hydraulic flow test results of the VANTAGE 5H assembly are discussed in Reference 19.

The reaction on the grid support due to vibration motions is also correspondingly small and definitely much less than the spring preload.

Firm contact is therefore maintained. No significant wear of the cladding or grid supports is expected during the life of the fuel assembly, based on out-of-pile flow tests, performance of similarly designed fuel in operating reactors, and design analyses. Clad fretting and fuel rod vibration has been experimentally investigated, as shown in Reference 10.

Evaluation of the Reactor Core for a Limited Displacement RPV Inlet Nozzle Break and a Double-Ended RCP Outlet Nozzle Break

The fuel assembly responses resulting from a limited displacement RPV inlet nozzle break and a double-ended Reactor Coolant Pump outlet nozzle break were analyzed using time history

techniques. The limited displacement RPV outlet nozzle break was not analyzed since previous analyses have indicated that the fuel assembly impact forces and deflections for this break size and location were substantially less than those obtained for the RPV inlet nozzle break. The vessel motion resulting from the various pipe breaks induce lateral loads on the reactor core which are analyzed using the seismic model described in Reference 9. The model which is used to assess fuel assembly interaction, specifically the displacements and impact forces, consists of a finite element representation of the fuel assemblies arranged in a planar array with inter assembly gaps. For the Sequoyah plant, fifteen fuel assemblies which corresponds to the maximum number of assemblies across the core diameter were used in the model.

Examination of the upper and lower horizontal core plate motions resulting from the reactor vessel translation and internal forces indicated significant differences. As a result, the symmetric assumption used in the seismic analysis was no longer valid and necessitated the use of the complete fuel assembly beam type finite element model with six nodal positions representing each active grid location (see Reference 13).

A series of fifteen fuel assembly elements as shown in Figure 4.2.1-9 was used to represent the core with the core baffle and support represented by a single beam element as indicated. The upper and lower core plate time history motions designated as $F^1(t)$ and $F^2(t)$ in Figure 4.2.1-9 were obtained from the analysis of the reactor vessel and piping. (See Section 5.2.1.7). The core plate motions were then simultaneously applied to the simulated core baffle and fuel assemblies.

The fuel assembly response, namely, displacements and grid impact forces, was obtained from the reactor core model using the core plate motions. Examination of the fuel assembly response curves for the inlet nozzle break indicate that the initial relative motion is in the opposite direction with respect to the excitation motion. The fuel assembly motion then reverses resulting in impacting at the baffle wall opposite the pipe break. The maximum fuel assembly deflection occurred in the peripheral fuel assembly. The fuel assembly stresses resulting from this deflection were evaluated and showed substantial margins compared to the allowable values.

The reactor core response resulting from the double ended break at the reactor coolant pump was similar to that obtained for the RPV inlet nozzle break. However, the fuel assembly maximum displacement was significantly lower.

The fuel assembly grid impact forces were also obtained from the reactor core time history response. A comparison of the grid impact forces for the two break locations indicated that the RPV inlet nozzle break produces slightly higher forces. The maximum impact forces occurred at the peripheral fuel assembly locations adjacent to the baffle wall. The grid impact forces were rapidly attenuated for fuel assembly positions away from the periphery. Consequently only a small portion of the core experiences substantial grid impact forces. The maximum grid impact forces are required to be less than the allowable grid crush strength. A calculation of the maximum LOCA and seismic grid impact forces, combined the square root sum of the squares method (in accordance with SRP 4.2, Appendix A), demonstrate that the maximum value is less than the allowable grid strength.

4.2.1.3.3 <u>Operational Experience</u>

Westinghouse has had considerable experience with Zircaloy-clad fuel since its introduction in the Jose Cabrera plant in June 1968. This experience is extensively described in Reference 2.

4.2.1.3.4 Test Rod and Test Assembly Experience

This experience is presented in Sections 8 and 23 of Reference 3, and in Reference 20, Addendum 1-A, Section D.

4.2.1.4 Testing and Inspection Plan

4.2.1.4.1 Quality Assurance Program

The quality assurance program plan of the Westinghouse Nuclear Fuel Division for the Nuclear Plant (SQN) Sequoyah is summarized in Reference 11.

The program provides for control over all activities affecting product quality, commencing with design and development and continuing through procurement, materials handling, fabrication, testing and inspection, storage, and transportation. The program also provides for the indoctrination and training of personnel and for the auditing of activities affecting product quality through a formal auditing program.

Westinghouse drawings and product, process, and material specifications identify the inspections to be performed.

4.2.1.4.2 Quality Control

Quality control (QC) philosophy is generally based on the following inspections being performed to a 95 percent confidence that at least 95 percent of the product meets specification, unless otherwise noted.

A. Fuel system components and parts.

   The characteristics inspected depend upon the component parts; the QC program includes dimensional and visual examinations, check audits of test reports, material certification, and nondestructive examination, such as X-ray and ultrasonic.

   All material used in this core is accepted and released by QC.

B. Pellets

   Inspection is performed for dimensional characteristics such as diameter, density, length, and squareness of ends. Additional visual inspections are performed for cracks, chips, and surface conditions according to approved standards.

   Density is determined in terms of weight per unit length and is plotted on zone charts used in controlling the process. Chemical analyses are taken on a specified sample basis throughout pellet production.

C. Rod inspection

The fuel rod inspection consists of the following nondestructive examination techniques and methods, as applicable:

1. Each rod is leak tested using a calibrated mass spectrometer, with helium being the detectable gas.

2. All weld enclosures are ultrasonic tested or X-rayed. X-rays are taken in accordance with Westinghouse specifications meeting the requirements of ASTM-E-142.

3. All rods are dimensionally inspected prior to final release. The requirements include such items as length, camber, and visual appearance.

4. All of the fuel rods are inspected by gamma scanning or other approved methods to ensure proper plenum dimensions.

5. All of the fuel rods are inspected by gamma scanning or other methods to ensure that no significant gaps exist between pellets.

6. All of the fuel rods are active gamma scanned to verify enrichment control prior to acceptance for assembly loading.

7. Traceability of rods and associated rod components is established by QC.

D. Assemblies

Each fuel assembly is inspected for compliance with drawing and/or specification requirements. Other incore control component inspection and specification requirements are given in Paragraph 4.2.3.4.

E. Other inspections

The following inspections are performed as part of the routine inspection operation:

1. Tool and gage inspection and control, including standardization to primary and/or secondary working standards. Tool inspection is performed at prescribed intervals on all serialized tools. Complete records are kept of calibration and condition of tools.

2. Audits are performed of inspection activities and records to ensure that prescribed methods are followed and that records are correct and properly maintained.

3. Surveillance inspection, where appropriate, and audits of outside contractors are performed to ensure conformance with specified requirements.

F. Process control

To prevent the possibility of mixing enrichments during fuel manufacture and assembly, strict enrichment segregation and other process controls are exercised.

The UO_2 powder is kept in sealed containers. The contents are fully identified both by descriptive tagging and preselected color coding. A Westinghouse identification tag completely describing the contents is affixed to the containers before transfer to powder storage. Isotopic content is confirmed by analysis.

Powder withdrawal from storage can be made by only one authorized group, which directs the powder to the correct pellet production line. All pellet production lines are physically separated from each other and pellets of only a single nominal enrichment are produced in a given production line at any given time.

Finished pellets are placed on trays identified with the same color code as the powder containers and transferred to segregated storage racks within the confines of the pelleting area. Samples from each pellet lot are tested for isotopic content and impurity levels prior to acceptance by QC. Physical barriers prevent mixing of pellets of different nominal densities and enrichments in this storage area. Unused powder and substandard pellets are returned to storage in the original color-coded containers.

Loading of pellets into the clad is performed in isolated production lines, and again only one enrichment is loaded on a line at a time.

A serialized traceability code is placed on each fuel tube to provide unique identification. The end plugs are inserted and then inert-welded to seal the tube.

At the time of installation into an assembly a matrix is generated to identify each rod in its position within a given assembly. The top nozzle is inscribed with a permanent identification number providing traceability to the fuel contained in the assembly.

Similar traceability is provided for burnable absorber rods, source rods, and control rodlets, as required.

4.2.1.4.3 Onsite Inspection

Surveillance of fuel and reactor performance is routinely conducted on Westinghouse reactors. Power distribution is monitored using the excore fixed and incore movable detectors. Coolant activity and chemistry is followed which permits early detection of any fuel clad defects.

Visual fuel inspection is routinely conducted during refueling. Additional fuel inspections are dependent on the results of the operational monitoring and the visual inspections.

4.2.1.4.4 Removable Fuel Rod Assembly

As part of a continuing Westinghouse fuel performance evaluation program, one surveillance fuel assembly containing 88 removable fuel rods is included in Region III of the initial Sequoyah core loading. The objective of this program is to facilitate interim and end-of-life fuel evaluation as a

function of exposure. The rods can be removed, nondestructively examined, and reinserted at the end of intermediate fuel cycles. At end-of-life the rods can be removed easily and subjected to a destructive examination.

The overall dimensions, rod pitch, number of rods and materials are the same as for other Region III assemblies. These fueled rods were fabricated in parallel with the regular Region III rods using selected Region III clad and pellets assembled, and released to the same manufacturing tolerance limits. Mechanically the special assemblies differ only slightly from other Region III assemblies. These differences are:

1. The end plugs on the removable rods are designed to facilitate removal and reinsertion.

2. The upper nozzle adapter plate on the assembly is modified to allow access to the removable rods.

3. The base plate on the thimble plug assembly is modified to provide axial restraint of the fuel rods normally provided by the upper nozzle adapter plate for standard assemblies. The distances between the top of the rods and the restraining plates, for both types of rods in the removable rod assembly, are identical to those of the standard assembly.

Figure 4.2.1-10 compares the mechanical design of a removable fuel rod to that of a standard rod; Figure 4.2.1-11 shows the removable rod fuel assembly, the modified upper nozzle adapter plate and thimble plug assembly, to compare to a standard assembly shown in Figure 4.2.1-2. The location of the removable rods within the fuel assembly is shown in Figure 4.2.1-12.

Previous experience with removable rods has been attained at Saxton, Yankee, San Onofre Zorita, Zion Units 1 and 2, Point Beach Unit 1, H. B. Robinson Unit 2, Trojan and Surry Units 1 and 2 reactors. Handling of removable rods have been done routinely and without difficulty.

The same fuel rod design limits indicated in Section 4.2.1 for standard fuel rods and assemblies are maintained for these removable rods. Over the active fuel length, the removable rod cladding and pellet dimensions and enrichment are identical to other rods in the same fuel region. Therefore, there is no reduction in margin to DNB or other thermal limits. Their inclusion in the initial Sequoyah Unit 1 core loading introduces no additional safety considerations and in no way changes the safeguard analyses and related engineering information presented in previously submitted material in support of the license application.

4.2.2 Reactor Vessel Internals

4.2.2.1 Design Bases

The design bases for the mechanical design of the reactor vessel internals components are as follows:

1. The reactor internals in conjunction with the fuel assemblies shall direct reactor coolant through the core to achieve acceptable flow distribution and to restrict bypass flow so that the heat transfer performance requirements are met for all modes of operation. In addition,

required cooling for the pressure vessel head shall be provided so that the temperature differences between the vessel flange and head to do not result in leakage from the flange during reactor operation.

2. In addition to neutron shielding provided by the reactor coolant, a separate thermal shield is provided to limit the exposure of the pressure vessel in order to maintain the required ductility of the material for all modes of operation for the life of the plant.

3. Provisions shall be made for installing incore instrumentation useful for the plant operation and vessel material test specimens required for a pressure vessel irradiation surveillance program.

4. The core internals are designed to withstand mechanical loads arising from the SSE and 1/2SSE and pipe ruptures and meet the requirement of Item 5 below.

5. The reactor shall have mechanical provisions which are sufficient to adequately support the core and internals and to assure that the core is intact with acceptable heat transfer geometry following transients arising from abnormal operating conditions.

6. Following the design basis accident, the plant shall be capable of being shutdown and cooled in an orderly fashion so that fuel cladding temperature is kept within specified limits. This implies that the deformation of certain critical reactor internals must be kept sufficiently small to allow core cooling.

7. UHI upper internals assembly were originally installed to provide passage for the core cooling water from the vessel head plenum directly to the top of the fuel assemblies during the postulated "loss-of-coolant accident." However, the UHI System has been removed. Some UHI-related components remain installed in the RCS.

The functional limitations for the core structures during the design basis accident are shown in Table 4.2.2-1. To insure no column loading of rod cluster control guide tubes, the upper core plate deflection is limited to not exceed the value shown in Table 4.2.2-1.

Details of the dynamic analyses, input forcing functions, and response loadings are presented in Section 3.9.

4.2.2.2 Description and Drawings

The reactor vessel internals are described as follows:

The components of the reactor internals consist of the lower core support structure (including the entire core barrel and thermal shield), the upper core support structure and the incore instrumentation support structure. The reactor internals support the core, maintain fuel alignment, limit fuel assembly movement, maintain alignment between fuel assemblies and control rod drive mechanisms, direct coolant flow past the fuel elements, direct coolant flow to the pressure vessel head, provide gamma and neutron shielding, and provide guides for the incore instrumentation. The coolant flows from the vessel inlet nozzles down the annulus

between the core barrel and the vessel wall and then into a plenum at the bottom of the vessel. It then reverses and flows up through the core support and through the lower core plate. The lower core plate is sized to provide the desired inlet flow distribution to the core. After passing through the core, the coolant enters the region of the upper support structure and then flows radially to the core barrel outlet nozzles and directly through the vessel outlet nozzles. A small portion of the coolant flows between the baffle plates and the core barrel to provide additional cooling of the barrel. Similarly, a small amount of the entering flow is directed into the vessel head plenum and exits through the vessel outlet nozzles.

All the major material for the reactor internals is Type 304 stainless steel. Parts not fabricated from Type 304 stainless steel include bolts and dowel pins which are fabricated from Type 316 stainless steel. The radial support clevis insert and bolts which are fabricated of inconel. The only stainless steel materials used in the reactor core support structures which have yield strengths greater than 90,000 pounds are the 403 series used for holddown springs. The use of these materials is compatible with the reactor coolant and is acceptable based on the 1971 ASME Boiler and Pressure Vessel Code, Case Number 1337.

All reactor internals are removable from the vessel for the purpose of their inspection as well as the inspection of the vessel internal surface.

<u>Lower Core Support Structure</u>

The major containment and support member of the reactor internals is the lower core support structure, shown in Figure 4.2.2-1. This support structure assembly consists of the core barrel, the core baffle, and the lower core plate and support columns, the thermal shield, and the core support which is welded to the core barrel. All the major material for this structure is Type 304 stainless steel. The lower core support structure is supported at its upper flange from a ledge in the reactor vessel and its lower end is restrained from transverse motion by a radial support system attached to the vessel wall. Within the core barrel are an axial baffle and a lower core plate, both of which are attached to the core barrel wall and form the enclosure periphery of the core. The lower core support structure and core barrel serve to provide passageways and direct the coolant flow. The lower core plate is positioned at the bottom level of the core below the baffle plates and provides support and orientation for the fuel assemblies.

The lower core plate is a member through which the necessary flow distribution holes for each fuel assembly are machined. Fuel assembly locating pins (two for each assembly) are also inserted into this plate. Columns are placed between the lower core plate and the core support of the core barrel to provide stiffness and to transmit the core load to the core support. Adequate coolant distribution is obtained through the use of the lower core plate and core support.

The one piece thermal shield is fixed to the core barrel at the top with rigid bolted connections. The bottom of the thermal shield is connected to the core barrel by means of axial flexures. This bottom support allows for differential axial growth of the shield/core barrel but restricts radial or horizontal movement of the bottom of the shield. Rectangular specimen guides in which material samples can be inserted and irradiated during reactor operation are welded to the thermal shield and extended to the top of the thermal shield. These samples are held in the rectangular specimen guides by a preloaded spring device at the top and bottom.

Vertically downward loads from weight, fuel assembly preload, control rod dynamic loading, hydraulic loads and earthquake acceleration are carried by the lower core plate into the lower core plate support flange on the core barrel shell and through the lower support columns to the core support and hence through the core barrel shell to the core barrel flange supported by the vessel flange. Transverse loads from earthquake acceleration, coolant cross flow, and vibration are carried by the core barrel shell and distributed between the lower radial support to the vessel wall, and to the vessel flange. Transverse loads of the fuel assemblies are transmitted to the core barrel shell by direct connection of the lower core plate to the barrel wall and by upper core plate alignment pins which are welded into the core barrel.

The radial support system of the core barrel is accomplished by "key" and "keyway" joints to the reactor vessel wall. At six equally spaced points around the circumference, an Inconel clevis block is welded to the vessel inner diameter. Another Inconel block is bolted to each of these blocks, and has a "keyway" geometry. Opposite each of these is a "key" which is welded to the lower core support. At assembly, as the internals are lowered into the vessel, the keys engage the keyways in the axial direction. With this design, the internals are provided with a support at the furthest extremity, and may be viewed as a beam fixed at the top and simply supported at the bottom.

Radial and axial expansions of the core barrel are accommodated, but transverse movement of the core barrel is restricted by this design. With this system, cyclic stresses in the internal structures are within the ASME Section III limits. In the event of an abnormal downward vertical displacement of the internals following a hypothetical failure, energy absorbing devices limit the displacement of the core after contacting the vessel bottom head. The load is then transferred through the energy absorbing devices of the lower internals to the vessel.

The energy absorbers are mounted on a base plate which is contoured on its bottom surface to the reactor vessel bottom internal geometry. Their number and design are determined so as to limit the stresses imposed on all components except the energy absorber to less than yield (ASME Code Section III valves). Assuming a downward vertical displacement, the potential energy of the system is absorbed mostly by the strain energy of the energy absorbing devices.

Upper Core Support Assembly

The upper core support structure, shown in Figures 4.2.2-2, 4.2.2-3, and 4.2.2-4 consists of the upper support assembly and the upper core plate between which are contained support columns and guide tube assemblies. The support columns establish the spacing between the top support plate assembly and the upper core plate and are fastened at top and bottom to these plates. The UHI support columns serve to transmit the fuel assembly holddown loads from the upper core plate to the upper support and thence to the vessel flange. They position the upper core plate and upper support which act as the boundaries for the flow plenum at the outlet of the core. Additionally each UHI column has a central axial flow passage full length. Water can enter the flow passage through a small hole on the side of the top of the UHI support column. A support column is provided at each fuel assembly position that does not contain accommodation for a control rod with the exception of the peripheral low power fuel assembly locations. The fuel assemblies which do not have a support column above them are located in front of the inlet and outlet nozzles of the vessel. The UHI support columns also contain thermocouple supports. Figure 4.2.2-3 illustrates a typical UHI support column.

The guide tube assemblies (see Figures 4.2.2-2 and 4.2.2-5) shield and guide the control rod drive rods and control rods. They are fastened to the upper support and are guided by pins in the upper core plate for proper orientation and support. Additional guidance for the control rod drive rods is provided by the upper guide tube extension which is attached to the upper support. All plants designed with UHI have the maximum number of guide tubes independent of other RCC requirements.

The upper core support assembly, which is removed as a unit during refueling operation, is positioned in its proper orientation with respect to the lower support structure by slots in the upper core plate which engage flat-sided upper core plate alignment pins which are welded into the core barrel. At an elevation in the core barrel where the upper core plate is positioned, the flat-sided pins are located at angular positions of 90° from each other. As the upper support structure is lowered into the lower internals, the slots in the plate engage the flat-sided pins axial direction. Lateral displacement of the plate and of the upper support assembly is restricted by this design. Fuel assembly locating pins protrude from the bottom of the upper core plate and engage the fuel assemblies as the upper assembly is lowered into place. Proper alignment of the lower core support structure, the upper core support assembly, the fuel assemblies and control rods are thereby assured by this system of locating pins and guidance arrangement. The upper core support assembly is restrained from any axial movements by a large circumferential spring which rests between the upper barrel flange and the upper core support assembly. The spring is compressed when the reactor vessel head is installed on the pressure vessel.

Vertical loads from weight, earthquake acceleration, hydraulic loads, and fuel assembly preload are transmitted through the upper core plate via the support columns to the upper support assembly and then into the reactor vessel head. Transverse loads from coolant cross flow, earthquake acceleration, and possible vibrations are distributed by the support columns to the upper support and upper core plate. The upper support plate is particularly stiff to minimize deflection.

Incore Instrumentation Support Structures

The incore instrumentation support structures consist of an upper system to convey and support thermocouples penetrating the vessel through the head and a lower system to convey and support flux thimbles penetrating the vessel through the bottom (Figure 7.7.1-5 shows the Basic Flux- Mapping System).

The upper system utilizes the reactor vessel head penetrations. Instrumentation port columns are slip-connected to in-line columns that are in turn fastened to the upper support plate. These port columns protrude through the head penetrations. The thermocouples are carried through these port columns and the upper support plate at positions above their readout locations. The thermocouple conduits are supported from the columns of the upper core support system. The thermocouple conduits are 304 stainless steel tubes.

In addition to the upper incore instrumentation, there are reactor vessel bottom port columns which carry the retractable, cold worked stainless steel flux thimbles that are pushed upward into the reactor core. Conduits extend from the bottom of the reactor vessel down through the concrete shield area and up to a thimble seal line. The minimum bend radii are about 144 inches and the trailing ends of the thimbles (at the seal line) are extracted at least 14 feet during

refueling of the reactor in order to avoid interference within the core. If the lower internals are to be removed, or potentially removed, then the thimbles are retracted approximately 23 feet. The thimbles are closed at the leading ends and serve as the pressure barrier between the reactor pressurized water and the containment atmosphere.

Mechanical seals between the retractable thimbles and conduits are provided at the seal table. During normal operation, the retractable thimbles are stationary and move only during refueling or for maintenance, at which time a space of at least 14 feet above the seal line is cleared for the retraction operation.

The incore instrumentation support structure is designed for adequate support of instrumentation and is rugged enough to resist damage or distortion under the conditions imposed by handling during the refueling sequence. These are the only conditions which affect the incore instrumentation support structure. Reactor vessel surveillance specimen capsules are covered in Paragraph 5.4.3.7. That section covers all the necessary details with regard to irradiation surveillance, including a cross-section of the reactor showing the capsule identity and location.

4.2.2.3 Design Loading Conditions

The design loading conditions that provide the basis for the design of the reactor internals are:

1. Fuel Assembly Weight
2. Fuel Assembly Spring Forces
3. Internals Weight
4. Control Rod Scram (equivalent static load)
5. Differential Pressure
6. Spring Preloads
7. Coolant Flow Forces (static)
8. Temperature Gradients
9. Differences in thermal expansion
    a. Due to temperature differences
    b. Due to expansion of different materials
10. Interference between components
11. Vibration (mechanically or hydraulically induced)
12. One or more loops out of service
13. All operational transients listed in Table 5.2-2
14. Pump overspeed
15. Seismic loads (operation basis earthquake and design basis earthquake)
16. Blowdown forces injection transients for the cold and hot leg break including UHI (UHI System has been removed and capped; however, all reactor vessel and loop blowdown forces are still considered)

Combined seismic and blowdown forces are included in the stress analysis as a design loading condition by assuming the maximum amplitude of each force to act concurrently.

The main objectives of the design analysis are to satisfy allowable stress limits, to assure and adequate design margin, and to establish deformation limits which are concerned primarily with the functioning of the components. The stress limits are established not only to assure that peak

stresses will not reach unacceptable values, but also limit the amplitude of the oscillatory stress component in consideration of fatigue characteristics of the materials. Both low and high cycle fatique stresses are considered when the allowable amplitude of oscillation is established. Dynamic analysis on the reactor internal is provided in Section 3.9.

As part of the evaluation of design loading conditions, extensive testing and inspections are performed from the initial selection of raw materials up to and including component installation and plant operation. Among these tests and inspections are those performed during component fabrication, plant construction, startup and checkout, and during plant operation.

4.2.2.4 Design Loading Categories

The combination of design loadings fits into either the normal, upset or faulted conditions as defined in the ASME Section III Code.

Loads and deflections imposed on components due to shock and vibration are determined analytically and experimentally in both scaled models and operating reactors. The cyclic stresses due to these dynamic loads and deflections are combined with the stresses imposed by loads from component weights, hydraulic forces, and thermal gradients for the determination of the total stresses of the internals.

The reactor internals are designed to withstand stresses originating from various operating conditions as summarized in Table 5.2-2.

The scope of the stress analysis problem is very large requiring many different techniques and methods, both static and dynamic. The analysis performed depends on the mode of operation under consideration.

Allowable Deflections

For normal operating conditions, downward vertical deflection of the lower core support plate is negligible.

For the loss of coolant accident plus the 1/2 safe shutdown earthquake condition, the deflection criteria of critical internal structures are the limiting values given in Table 4.2.2-1. The corresponding no loss of function limits are included in Table 4.2.2-1 for comparison purposes with the allowed criteria.

The criteria for the core drop accident are based upon analyses which have been performed to determine the total downward displacement of the internal structures following a hypothesized core drop resulting from loss of the normal core barrel supports. The initial clearance between the secondary core support structures and the reactor vessel lower head in the hot condition is approximately one-half inch. An additional displacement of approximately 3/4 inch would occur due to strain of the energy absorbing devices of the secondary core support; thus the total drop distance is about 1-1/4 inches which is insufficient to permit the grips of the rod cluster control assembly to come out of the guide thimble in the fuel assemblies.

Specifically, the secondary core support is a device which will never be used, except during a hypothetical accident of the core support (core barrel, flange, etc.). There are 4 supports in each reactor. This device limits the fall of the core and absorbs the energy of the fall is calculated assuming a complete and instantaneous failure of the primary core support and is absorbed during the plastic deformation of the controlled volume of stainless steel, loaded in tension. The maximum deformation of this austenitic stainless piece is limited to approximately 15 percent, after which a positive stop provided to insure support.

For additional information on design loading categories, see Section 3.9.

4.2.2.5 Design Criteria Basis

The basis for the design stress and deflection criteria is identified below:

Allowable Stress

For normal operating conditions, Section III of the ASME Nuclear Power Plant Components Code is used as a basis for evaluating acceptability of calculated stresses. Both static and alternating stress intensities are considered. Under code case 1618 bolt material type 316 Stainless Steel is now covered in ASME Section III and is so treated. It should be noted that the allowable stresses in Section III of the ASME Code are based on unirradiated material properties. In view of the fact that irradiation increases the strength of the 304 stainless steel used for the internals, although decreasing its elongation, it is considered that use of the allowable stresses in Section III is appropriate and conservative for irradiated internal structures.

The allowable stress limits during the design basis accident used for the core support structures are based on the January 1971 draft of the ASME Code for Core Support Structures, Subsection NG, and the Criteria for Faulted Conditions.

4.2.3 Reactivity Control System

4.2.3.1 Design bases

4.2.3.1.1 Design Stresses

A basis for temperature, stress on structural members, and material compatibility are imposed on the design of the reactivity control components. The reactivity control system is designed to withstand stresses originating from various operating conditions as summarized in Table 5.2-2.

Allowable Stresses: For normal operating conditions Section III of the ASME Boiler and Pressure Vessel Code is used as a general guide.

Dynamic Analysis: The cyclic stresses due to dynamic loads and deflections are combined with the stresses imposed by loads from component weights, hydraulic forces and thermal gradients for the determination of the total stresses of the reactivity control system.

4.2.3.1.2 Material Compatibility

Materials are selected for compatibility in Pressurized Water Reactor environment, for adequate mechanical properties at room and operating temperature, for resistance to adverse property changes in a radioactive environment, and for compatibility with interfacing components.

4.2.3.1.3 Reactivity Control Components

The reactivity control components are subdivided into two categories:

1. Permanent devices used to control or monitor the core and

2. Temporary devices used to control or monitor the core

The permanent type components are the rod cluster control assemblies, control rod drive mechanism assemblies, neutron source assemblies and thimble plug assemblies. Although the thimble plug assembly does not directly contribute to the reactivity control of the reactor, it is presented as a reactivity control system component in this document because it may be used to restrict bypass flow through those thimble not occupied by absorber, source of burnable absorber rods.

The temporary component is the burnable absorber assembly which is normally used only for one cycle. The design bases for each of the mentioned components are in the following paragraphs.

Absorber Rods

Absorber rods from Westinghouse (both standard and enhanced performance) and AREVA/Framatome are used at Sequoyah. Framatome absorber rods were purchased in 2001 and similar AREVA/Framatome absorber rods were purchased in 2016. Westinghouse absorber rods were purchased before the AREVA/Framatome rods. Significant differences between the two types of absorber rods are provided in Section 4.2.3.2.1.

The following are considered design conditions under subsections NG and NB of the ASME Boiler and Pressure Vessel Code Section III. The control rod which is cold rolled 304, stainless is the only non-code material use in the control rod assembly. The stress intensity limit S_m for this material is defined at 2/3 of the 0.2% offset yield stress. The absorber rods are designed to resist the following:

1. The external pressure equal to the Reactor Coolant System operating pressure

2. The wear allowance equivalent to 1,000 reactor trips

3. Bending of the rod due to a misalignment in the guide tube

4. Forces imposed on the rods during rod drop

5. Loads caused by accelerations imposed by the control rod drive mechanism

6. Radiation exposure for maximum core life

7. Temperature effects at operating conditions

The absorber material temperature shall not exceed its melting temperature (1470°F for Ag-In-Cd absorber material) (Reference 12).

The Westinghouse designed enhanced performance RCCA (EPRCCA) may be used in place of the standard RCCA in reload cores. Reference 21 verifies that the EPRCCA design meets rod cluster control assembly design criteria.

Burnable Absorber Rods

The burnable absorber rod clad is designed using subsections NB and NG of the ASME Boiler and Pressure Vessel Code Section III, 1973 as a general guide for Conditions I and II. For abnormal loads during Condition III and IV Code stresses are not considered limiting. Failures of the burnable rods during these conditions must not interfere with reactor shutdown or emergency cooling of the fuel rods.

The burnable absorber material is non-structural. The structural elements of the burnable absorber rod are designed to maintain the absorber geometry even if the absorber material is fractured. The rods are designed so that the absorber material is below its softening temperature (1492°F) for Reference 12. In addition, the structural elements are designed to prevent excessive slumping.

The Westinghouse designed wet annular burnable absorber (WABA) is used in reload cores. Reference 16 verifies that WABA design meets burnable absorber design criteria.

Neutron Source Rods

The neutron source rods are designed to withstand the following:

1. The external pressure equal to the Reactor Coolant System operating pressure and

2. An internal pressure equal to an initial prepressurization and the pressure generated by released gases over the source rod life.

Thimble Plug Assembly

The thimble plug assemblies satisfy the following:

1. Accommodate the differential thermal expansion between the fuel assembly and the core internals

2. Maintain positive contact with the fuel assembly and the core internals

3. Limit the flow through each occupied thimble

4.2.3.1.4 Control-Rod Drive Mechanisms

The Pressure Vessel Assembly consists of Class I components designed to meet the stress requirements for normal operating conditions of Section III of the ASME Boiler and Pressure

Vessel Code. Both static and alternating stress intensities are considered. The stresses originating from the required design transients are included in the analysis.

A dynamic seismic analysis is required on the control rod drive mechanism when a seismic disturbance has been postulated to confirm the ability of the mechanism to meet ASME Code, Section III allowable stresses and to confirm its ability to trip when subjected to the seismic disturbance.

The control rod drive mechanism (CRDM) design used for the 17 x 17 fuel assembly control rods is identical to the 15 x 15 control rod drive mechanism. The seismic analysis and response of the 17 x 17 control rod drive mechanism will be identical to those of the 15 x 15 mechanism.

Control Rod Drive Mechanism Operational Requirements

The basic operational requirements for the Control Rod Drive Mechanisms are:

1. 5/8 inch step

2. 144 inch nominal travel

3. 360 pound maximum load

4. Step in or out at 45 inches/min (72 steps/min), maximum

5. Power interruption shall initiate release of drive rod assembly

6. Trip delay of less than 150 ms - Free fall of drive rod assembly shall begin less than 150 ms after power interruption no matter what holding or stepping action is being executed with any load and coolant temperatures of 100°F to 550°F.

7. 40 year design life with normal refurbishment

8. 28,000 complete travel excursions which are 13 x 10^6 steps with normal refurbishment

4.2.3.2 Design Description

Reactivity control is provided by neutron absorbing rods and a soluble chemical neutron absorber (boric acid). The boric acid concentration is varied to control long-term reactivity changes such as:

1. Fuel depletion and fission product buildup

2. Cold to Hot, zero power reactivity change

3. Reactivity change produced by intermediate-term fission products such as xenon and samarium

4. Burnable poison depletion

Chemical and Volume Control is covered in Subsection 9.3.4.

The rod cluster control assemblies provide reactivity control for:

1. Shutdown

2. Reactivity changes due to coolant temperature changes in the power range

3. Reactivity changes associated with the power coefficient of reactivity

4. Reactivity changes due to void formation

If soluble boron were the sole means of control, the moderator temperature coefficient would be positive. It is desirable to have a negative moderator temperature coefficient throughout the entire cycle in order to reduce possible deleterious effects caused by a positive coefficient during loss of coolant or loss of flow accidents. This is accomplished by installation of burnable poison assemblies or IFBA rods.

The neutron sources assemblies provide a means of monitoring the core during periods of low neutron activity.

The most effective reactivity control components are the rod cluster control assemblies and their corresponding drive rod assemblies which are the only kinetic parts in the reactor. Figure 4.2.2-5 identifies the rod cluster control and drive rod assembly, in addition to the arrangement of these components in the reactor relative to the interfacing fuel assembly, guide tubes, and control rod drive mechanism. In the following paragraphs, each reactivity control component is described in detail except for IFBA rods which are discussed in section 4.2.1.2.1.

The guidance system for the rod cluster control assembly is provided by the guide tube as shown in Figure 4.2.2-5. The guide tube provides two regimes of guidance. 1) In the lower section a continuous guidance system provides support immediately above the core. This system protects the rod against excessive deformation and wear due to hydraulic loading. 2) The region above the continuous section provides support and guidance at uniformly spaced intervals.

The envelope of support is determined by the pattern of the rod cluster control assembly as shown in Figure 4.2.3-1. The guide tube ensures alignment and support of the control rods, spider body, and drive rod assembly while maintaining trip times at or below required limits.

4.2.3.2.1 Reactivity Control Components

Rod Cluster Control Assembly

The rod cluster control assemblies are divided into two categories: control and shutdown. The control groups compensate for reactivity changes due to variation in operating conditions of the reactor, i.e., power and temperature variations.

Two criteria have been employed for selection of the control groups. First the total reactivity worth must be adequate to meet the nuclear requirements of the reactor. Second, in view of the fact that some of these rods may be partially inserted at power operation, the total power peaking factor should be low enough to ensure that the power capability is met. The control and shutdown groups provide adequate shutdown margin which is defined as the instantaneous amount of reactivity by which the reactor is subcritical or would be subcritical from its present condition assuming all full length rod cluster assemblies (shutdown and control) are fully inserted except for the single rod cluster assembly of highest reactivity worth which is assumed to be fully withdrawn.

A rod cluster control assembly comprises a group of individual neutron absorber rods fastened at the top end to a common spider assembly, as illustrated in Figure 4.2.3-1.
